Motions of liquid metal inside the Earth's outer core are responsible for generating the geomagnetic field in a dynamo process. Prominent features in the observed core surface field are intense equatorial flux patches drifting westwards at a rate of 17km/yr. We investigate the formation and dynamics of such flux features in numerical dynamo models, varying the convection strength. We study a set of numerical dynamo models varying the convection strength by a factor of 30 and ratio of magnetic to viscous diffusivities by a factor of 20 at fixed rapid rotation rate ($E = \nu / (2\Omega d^2) = 10^{-6}$) using a heat flux outer BC. This regime has been little explored (aside from a pioneering study by Sakuraba & Roberts) due to the significant computing resources required. Our simulations are carried out using a discretisation of degree and order 256 in spherical harmonics, and 516 finite difference points in radius and parallelized on 516 processors. We present an analysis of the time-evolution and force balance associated with low-latitude magnetic flux concentrations. We also report a comparison of our results with the proposed rotating convection and dynamo scaling laws.
