Keywords: Integrated water resources management (IWRM), Hydroeconomic modeling, Stochastic dynamic programming (SDP), Water quality management, Water value, River basin

Highlights

- We jointly optimize water resources and water quality management
- Treatment and scarcity costs are minimized under given water quality constraints
- The modeling framework was applied to the Ziya River basin on the North China Plain
- Water quality constraints significantly change the optimal management
- A proposed approach to operationalize the China 2011 No. 1 Central Policy Document

Abstract

A hydroeconomic optimization approach is used to guide water management in a Chinese river basin with the objectives of meeting water quantity and water quality constraints, in line with the China 2011 No. 1 Policy Document and 2015 Ten-point Water Plan. The proposed modeling framework couples water quantity and water quality management and minimizes the total costs over a planning period assuming stochastic future runoff. The outcome includes cost-optimal reservoir releases, groundwater pumping, water allocation, wastewater treatments and water curtailments. The optimization model uses a variant of stochastic dynamic programming known as the water value method. Nonlinearity arising from the water quality constraints is handled with an effective hybrid method combining genetic algorithms and linear programming. Untreated pollutant loads are represented by biochemical oxygen demand (BOD), and the resulting minimum dissolved oxygen (DO) concentration is computed with the Streeter-Phelps equation and constrained to match Chinese water quality targets. The baseline water scarcity and operational costs are estimated to 15.6 billion CNY/year. Compliance to water quality grade III causes a relatively low increase to 16.4 billion CNY/year. Dilution plays an important role and increases the share of surface water allocations to users situated furthest downstream in the system. The modeling framework generates decision rules that result in the economically efficient strategy for complying with both water quantity and water quality constraints.

1 Introduction

The North China Plain (NCP) has experienced severe water scarcity and water quality challenges over the past decades as a result of the economic development, population growth and regional climate change (Liu and Xia, 2004; Mo et al., 2013; Zheng et al., 2010). Consequently, the surface water resources are fully utilized, the groundwater aquifers are heavily overexploited to cover the annual deficit in the water budget and the rivers are used as waste water recipients (Brown, 2001; Liu et al., 2001; Xia et al., 2006; Zheng et al., 2010).

In 2011, the Government of P.R. China launched the China 2011 No. 1 Central Policy Document (No. 1 Document, CPC Central Committee and State Council, 2010) and the 2015 Ten-point Water Plan (State Council, 2015), which target the increasing challenges of sustainable management of the Chinese water resources. The implementation of the so-called Strictest Water Resource Management System (SWRMS) is divided into three focus areas known as the Three Red Lines (Ministry of Water Resources, 2012). The Three Red Lines set objectives for 1) reduction of overexploitation of the water resources, 2) efficient use and control of the growing water demands and 3) water quality and pollution control (Ministry of Water Resources, 2012). Similarly to the European Water Framework Directive in the European Union, the No. 1 Document is regarded as one of the most important water policy documents produced by China, and it is expected to significantly change water management in China (Griffiths et al., 2013). Introduction of water markets, water right trading schemes and scarcity-dependent water pricing are suggested as tools to meet the objectives set by the No. 1 Document, but no clear-cut guidelines are enforced so far (Griffiths et al., 2013; Yang et al., 2013). Yang et al. (2013) underlined the need for an integrated approach to solve the complex water issues, because focus on a single sector, technology or policy will be insufficient.

In integrated water resources management, the overall objective is to promote coordinated optimal management of the resources, while ensuring economic and ecological sustainability and social equity (Loucks and van Beek, 2005). In this context, hydroeconomic analysis provides a consistent framework for assessing conflicts among competing water uses, by representing the various interests using a common monetary unit (Harou et al., 2009). While hydroeconomic optimization models have been widely applied to water quantity management problems (e.g. Heinz et al., 2007; Pulido-Velázquez et al., 2006; Tilmant et al., 2012) and water quality management problems (e.g. Cools et al., 2011; Hasler et al., 2014), only few studies have addressed optimization of coupled water quantity-quality problems (Ahmadi et al., 2012; Karamouz et al., 2008).

Ejaz and Peralta (1995) presented an optimization-simulation approach based on the response matrix approach. The model framework maximized allocations of surface water and groundwater and waste loads from a sewerage treatment plant to a river, while complying with water quality constraints, such as dissolved oxygen and nutrients. A coupled water allocation (MODSIM) and water quality routing (QUAL2E-UNCAS) simulation-based decision support tool was developed by de Azevedo et al. (2000). Performance measures for water allocation (e.g. reliability) and water quality (e.g. compliance to stream standard) was

used to assess performance planning alternatives. Cardwell and Ellis (1993) used stochastic dynamic programming (SDP) to minimize waste water treatment costs, while complying with dissolved oxygen (DO) water quality constraints, in a setup with river reaches as stages, water quality parameters as state variables and water treatment as decision variables. A few studies, such as Hayes et al. (1998) and Kerachian and Karamouz (2007) also include reservoirs, which leads to coupling of decisions in time. Hayes et al. (1998) assessed the impacts of upstream water management changes on river water quality downstream of reservoirs. In this study the hydropower revenue was maximized while the DO concentration, computed from the biochemical oxygen demand (BOD) with the Streeter-Phelps equation, was used as water quality constraint. Cai et al. (2003) applied a hydroeconomic optimization approach, based on a simple decomposition approach, to maximize the sum of irrigation, hydropower and ecological benefit subject to salinity control, for a complex multi-reservoir basin. Kerachian and Karamouz (2007) used a simplified SDP framework based on genetic algorithms (GA) to resolve water conflicts from water demands, water quality and waste load allocations, summarized in a Nash bargaining setup. Total dissolved solids (TDS) and temperature were selected as the most critical water quality parameters. Later, Ahmadi et al. (2012) used a fuzzy multi-objective GA approach to guide quality and quantity management, while determining the land uses that maximize agricultural production in an upstream region.

This study builds on previous efforts to solve complex water management problems in China on the basis of rational economic decisions (Davidsen et al., 2014, n.d.). In Davidsen et al. (2014) an integrated hydroeconomic optimization approach was used to solve a water allocation problem. A variant of SDP known as the water value method (Stedinger et al., 1984) was used to guide long term sustainable management of the water resources. The discrete sub-problems of the SDP framework were strictly linear, and the future cost function was convex and thus solvable with linear programming (LP). In Davidsen et al. (n.d.), a second state variable was introduced, which allowed inclusion of a more realistic representation of the groundwater aquifer. Non-convexity arising from head-dependent groundwater pumping costs required use of a nonlinear global solver. A hybrid GA-LP implementation developed by Cai et al. (2001) was applied. The overall objectives are i) to couple water quality decisions and water allocation decisions within the framework of the water value method, ii) to demonstrate how complex non-linear water quality constraints can be used to enforce good water quality in the rivers and iii) estimate the additional costs of meeting minimum water quality in the rivers.

2 Methods

2.1 Case study area

The Ziya River is a medium-sized river formed in the Taihang Mountains in the eastern Shanxi Province of China (see Figure 1). The natural river routes in the lower basin on the NCP in the Hebei Province have been modified extensively as part of flood control projects more than 50 years ago. Originally, the Hutuo and Fuyang rivers joined the Hai River but today New Ziya River, a large floodwater spillway, generally denoted the “Ziya River Basin” by the Hai River Commission, leads the remaining non-diverted water directly to the Bohai Gulf. The 52,000 km² basin has a population of 25 million people (2007) with the majority located on the NCP (Bright et al., 2008). Reservoirs on all the natural mountain tributaries allow almost full utilization of the surface water resources. Some of the NCP river channels are mostly carrying untreated wastewater, while others provide occasional irrigation water from the reservoirs. Farmers along the rivers without access to groundwater sometimes pump wastewater for irrigation directly to their fields.

Figure 1: The Ziya River basin modified from Davidsen et al. (2014). The boundary between the upper and lower pollution catchments is indicated with a dashed line. SNWTP is the South-to-North Water Transfer Project.

According to Chinese legislation (HRB WRPB, 2008), surface water quality is divided into 6 grades as shown in Table 1. Grade I represents natural water quality, while water that does not meet the requirements of Grade V is considered heavily polluted. The major pollutants

include chemical oxygen demand (COD), BOD and ammonia (Ministry of Environmental Protection, 2010). In 2009, 42% of the river sections in the Hai River Basin failed to meet the Grade V standard (Ministry of Environmental Protection, 2010), which is also supported by our field observations. In the northern part of the Ziya River Basin, significant natural attenuation of pollutants is observed as the river flows from Xinzhou city through the Taihang Mountains and into the reservoirs located close to Shijiazhuang city. The main water quality challenges are therefore in the lower part of the catchment, and water quality in the upstream catchment is not considered in this study.

Table 1: Surface water quality classification in China (GB3838-2002, HRB WRPB, 2008) with selected water quality indicators shown. DO = dissolved oxygen, COD = Chemical Oxygen Demand and BOD₅ = Biochemical Oxygen Demand over 5 days. All units are in g O₂/m³.

Quality	DO $\geq$	COD $\leq$	BOD ₅ $\leq$
Grade I	90% of DO_{sat}	15	3
Grade II	6	15	3
Grade III	5	20	4
Grade IV	3	30	6
Grade V	2	40	10

Simulation models can handle a high number of pollutants and are capable of simulating complex physical processes, whereas optimization models are, often computationally, limited to simpler representations of the real world problems (Harou et al., 2009). Davidsen et al. (2014) formalized the management problem as a simplified optimization as illustrated in Figure 2A with water users in three sectors irrigated agriculture, domestic and industries, upstream and downstream of a central reservoir. This central surface water reservoir is an aggregation of the five major reservoirs in the basin (see Davidsen et al., 2014) and it receives the combined runoff from the sub basins upstream these reservoirs. It is assumed that reservoir releases can be moved to any point downstream this central reservoir, an assumption which is realistic given high connectivity of the downstream rivers and channels. Runoff from both the Hutuo and Fuyang rivers is included in the aggregated reservoir model. The water values from the aggregated optimization model can be used with a much more detailed simulation model with multiple smaller reservoirs, within the suggested framework.

Figure 2: Conceptual sketch of the optimization problem. Runoff (Q) from the mountains can be diverted (x) to users upstream the reservoir in the Shanxi Province (represented by user 1 and 2) or enter the reservoir. From the reservoir, water is released to the users in the Hebei Province (represented by user 3-6). A) the allocation problem as applied by Davidsen et al. (2014) without any spatial disaggregation of users 3-6. B) the allocation problem added water quality, with pollution releases (y) to two nodes (n_1 and n_2). The white circles are pollution treatment points. Pollution can be removed before and after use at a marginal water treatment cost. Unused water is available to ecosystems (q_E).

The case study is based on the dataset by Davidsen et al. (2014) presented in Table 2. Each water user (in Figure 2 represented by user 1-6) is characterized by a fixed monthly water demand and fixed curtailment costs, i.e. the marginal cost of not meeting the users' water demand. In addition, the 12 users at node 1 and 2 have pollution characteristics shown in Table 3. In the Shanxi Province, domestic, industry and irrigated maize agriculture is represented. From the reservoir, water can be allocated to Beijing and to the two nodes, each with four users (domestic, industry and irrigated wheat and maize agriculture). The generation of pollution is divided into a variable generation linked to water allocation and a fixed generation independent of water allocations. BOD generation by agriculture and industries is assumed to be proportional to water allocation, i.e. no allocation will cause zero production. In contrast, the BOD generation by domestic users is constant and independent of water allocation, as changes in allocation are assumed to change wastewater concentration and not pollution load. Because of limited data availability, the industrial and domestic treatment costs per unit weight BOD in river water and wastewater are assumed to be the same. This assumption is realistic as both sources are often mixed before treatment in a combined wastewater treatment plant.

Table 2: Annual water demands and curtailment costs for the users in the Ziya River basin. Based on the dataset from Davidsen et al. (2014).

	Shanxi	Hebei Province		
		Node 1	Node 2	
Population (10 ⁶ people)	5.8	12.4	6.8	^a
Water demands (10 ⁶ m ³ /year)				
Industries	539	350	193	^b
Domestic	223	558	306	^c
Maize	569	982	540	^d
Wheat	-	3,930	2,159	^d
Beijing	-	645	355	^e
Ecosystems	-	65	35	^f
Total	1,331	6,532	3,587	
Curtailment costs (CNY/m ³)				
Industries	5.3	5.3	5.3	^g
Domestic	3.2	3.2	3.2	^g
Maize	1.8	2.8	2.8	^h
Wheat	-	2.1	2.1	^h
Beijing	-	5.5	5.5	ⁱ

^a2007 population extracted from Landscan (Bright et al., 2008). ^bDemands scaled with area, (Berkoff, 2003; Moiwo et al., 2010; World Bank, 2001). ^cBased on daily water demand (National Bureau of Statistics of China, 2011) scaled with the population. ^dBased on the land cover (USGS, 2013) and irrigation practices collected in the field. The wheat irrigation demand is evenly distributed in March, April, May and June. Maize is irrigated in July. ^eBased on plan by The People's Government of Hebei Province (2012), (Ivanova, 2011). ^fEstimated deficit in the Baiyangdian Lake (Honge, 2006). ^gEstimate by World Bank (2001). ^hBased on the water use efficiency (Deng et al., 2006) and producers' prices (USDA Foreign Agricultural Service, 2012). ⁱEstimate by Berkoff (2003).

Table 3: Pollution generation data for the water users where flexible BOD is the pollution generation dependent on water allocations and fixed BOD is generation independent from water allocations.

Water user	Node	Quality ^[1] mg BOD/l	Flexible BOD g/m ³	Fixed BOD 10 ⁶ kg	Treatment costs CNY/kg
Agriculture	$n_1 + n_2$	10 ^[2]	0.2 ^[3]	-	∞ ^[6]
Industry	$n_1 + n_2$	6 ^[2]	4.1 ^[4]	-	39 ^[7]
Domestic	n_1	0	-	22.5 ^[5]	39 ^[7]

^[1]Reference BOD concentration criteria before water treatment, ^[2](HRB WRPB, 2008), ^[3]based on COD from agricultural sector in Ziya (Li et al., 2014), converted to BOD with an average BOD/COD ratio of 0.52 (ADB, 2002) ^[4]based on annual COD statistics from Hebei Province (IPE Beijing, 2013), scaled with population to the Ziya River Basin, ^[5]based on average BOD generation 67 g/capita/day (McKinney, 2004), ^[6]treatment costs infinite large as the farmers cannot treat the diffuse pollution, ^[7]estimated from annual COD from industries in Hebei and scaled with population to Ziya River Basin. COD data is converted to BOD with an average BOD/COD ratio of 0.52 (ADB, 2002).

To evaluate water quality conflicts arising from users located in series, the basin downstream the reservoir is spatially disaggregated into two groups as illustrated in Figure 2B. The first user group has access to the clean water released from the reservoir and discharges any untreated pollutants to node 1. The second user group, located downstream node 1, has access to the remaining water, which contains the pollutants from node 1. The second user group discharges pollutants to node 2. Decision variables include surface water allocations, groundwater allocations, allocations of inter-basin transferred water from the South-to-North Water Transfer Project (SNWTP), water curtailments and reservoir release. The classical

water allocation problem is extended to include optimal pollution discharge and water treatment, while complying with water quality requirements in the river. In Figure 2B, the additional water quality decisions (removal of pollutants from the intake surface water before use, removal of generated pollutants and pollution concentration at the two nodes) are indicated. Unused water flows to the Bohai Gulf or is utilized for ecosystem services. In Figure 1, the assumed boundary between the upstream and downstream areas is indicated. To compute the industrial and domestic water demands, total demands are scaled with the share of total 2007 population (Bright et al., 2008), while the irrigation water demands are scaled by the share of total area.

2.2 Optimization model formulation

In our approach, we assume that the combined storage capacity of the surface water reservoirs can be operated fully flexibly and without consideration of existing regulations and policies. The natural runoff was estimated by Davidsen et al. (2014) with a rainfall-runoff model based on the Budyko framework (Budyko, 1958; Zhang et al., 2008). The hydrological model was set up for a close-to-natural sub-catchment in the mountains and calibrated to measured runoff at the Pingshan station (Number 30912428) (MWR. Bureau of Hydrology, 2011). The calibrated model was applied to all sub-catchments located upstream of the reservoirs. The resulting 51 years of daily runoff from 1958 to 2008 was aggregated to monthly time steps and normalized. A 3-state Markov Chain, which describes the runoff serial correlation between three flow classes defined as dry (0 – 20th percentile), normal (20th – 80th percentile), and wet (80th – 100th percentile) was established. The Markov Chain was validated to ensure second-order stationarity (Loucks and van Beek, 2005). A shift in the regional precipitation pattern previously reported in the literature is observed in the precipitation time series (Cao et al., 2013; Chen, 2010; Sun et al., 2010). The shift is assumed to occur in 1980 with stationary climate before and after this year.

The simplified management problem with water quality (see Figure 2B) is formalized as a stochastic dynamic program similar to the model by Davidsen et al. (2014), with stochastic unknown future runoff. We applied the water value method, a variant of SDP, to identify a long-term optimal water management strategy for the basin (Pereira and Pinto, 1991; Stage and Larsson, 1961; Stedinger et al., 1984). The SDP proceeds recursively backward in time in monthly time steps (stages) and, for each stage, loops through all possible combinations of states, here the Markov Chain flow classes and discrete surface water reservoir storage levels. Thereby, all possible management decisions are evaluated, as the SDP produces the decision rules, assuming stochastic runoff. For each combination of system states, a sub optimization problem, which minimizes the sum of the immediate and expected future costs, is solved. The optimal value function $F_t^*(V_{sw,t}, Q_{sw,t}^k)$ is based on the classical Bellman formulation:

$$F_t^*(V_{sw,t}, Q_{sw,t}^k) = \min \left(IC(V_{sw,t}, Q_{sw,t}^k) + \sum_{l=1}^L (p_{kl} F_{t+1}^*(V_{sw,t+1}, Q_{sw,t+1}^l)) \right) \quad (1)$$

where $V_{sw,t}$ is the surface water reservoir storage in month t (m^3), $Q_{sw,t}^k$ is the natural runoff upstream the reservoir ($m^3/month$) in the Markov Chain runoff class k , IC is the immediate cost arising from water allocation (CNY), water curtailment and pollution treatment, l indexes the L Markov Chain runoff flow classes in $t+1$, p_{kl} is the transition probability from runoff class k in month t to runoff class l in month $t+1$. The immediate costs are defined as:

$$IC(V_{sw,t}, Q_{sw,t}^k) = \sum_{m=1}^M (c_{sw}x_{sw} + c_{gw}x_{gw} + c_{SNWTP}x_{SNWTP} + c_{ct}x_{ct} + c_{pre-wwt} + c_{post-wwt})_m - rb_{hp} \quad (2)$$

where m indexes the M water users in the basin, c_{sw} is the cost (CNY/ m^3) of allocating a unit volume of surface water x_{sw} (m^3), c_{gw} is the cost (CNY/ m^3) of pumping groundwater x_{gw} (m^3), c_{SNWTP} is the cost (CNY/ m^3) of allocating SNWTP water x_{SNWTP} (m^3), c_{ct} is the curtailment cost (CNY/ m^3) if the user is curtailed (m^3), $c_{pre-wwt}$ is the cost of water treatment before use (CNY), $c_{post-wwt}$ is the wastewater treatment costs after use and before discharge to the river (CNY), r is the monthly reservoir releases (m^3) and b_{hp} is the marginal hydropower benefits (CNY/ m^3). The optimization is subject to the following constraints:

$$x_{sw,m} + x_{gw,m} + x_{SNWTP,m} + x_{ct,m} = dm_m \quad (3)$$

$$V_{sw,t} + Q_{sw,t} - \sum_{u=1}^U x_{sw,u,t} - r_t - s_t = V_{sw,t+1} \quad (4)$$

$$r + s = \sum_{n=1}^N x_{sw,n} + q_E \quad (5)$$

$$\sum_{u=1}^U x_{sw,u} \leq Q_{sw} \quad (6)$$

$$r \leq R, \quad x_{SNWTP} \leq Q_{SNWTP}, \quad q_E \geq Q_E, \quad V_{sw} \leq V_{max} \quad (7)$$

$$FC \geq \lambda_h (V_{end} - V_h) + FC_h \quad (8)$$

where dm is water demand (m^3), u indexes the U users located upstream the reservoir, s are reservoir releases (m^3) exceeding the hydropower turbine capacity R (m^3), n indexes the N users located on the NCP downstream of the reservoir, q_E is the unused water leaving the system and available to the ecosystems (m^3), Q_{SNWTP} is the share of the SNWTP available to the Ziya River Basin and Beijing (m^3), Q_E is the minimum in-stream water requirement for ecosystems ($m^3/month$) and V_{max} is the upper storage capacity of the surface water reservoir (m^3). The future cost function FC is included as a series of h linear segments (one for each discrete surface water reservoir storage level) with λ_h being the shadow prices (CNY/ m^3) determined in $t+1$ and FC_h the optimal value (CNY) determined in $t+1$. The groundwater

resource is available for unrestricted pumping at a given fixed use cost c_{gw} (CNY/m³), adopted from Davidsen et al. (n.d.).

Eq. 3 is the demand fulfillment constraint, i.e. the sum of allocations and water curtailment must equal the water demand. Eq. 4 is the water balance equation for the surface water reservoir, while Eq. 5 is the water balance for the reservoir releases. Water users upstream of the reservoir have no access to surface water storage and are therefore limited to the monthly runoff as shown in Eq. 6.

Each stage of the backward moving SDP is fully parallelized as the states within a single stage are independent. In the initial stage of the backward-in-time recursive loop, the future costs are set to zero. With no future costs, the optimal strategy is to empty the reservoir. As the SDP moves backward in time, the future costs become increasingly important and the benefits of emptying the reservoir in t are traded off against increased costs of low storage in $t+1$ and onwards. The yearly backward recursion is repeated until the immediate and future costs in t are no longer affected by the end conditions (zero future costs). At this point, the inter-annual difference in the shadow prices, becomes zero and the model has reached equilibrium.

The equilibrium water value tables are suitable for decision support in a water pricing scheme and application in real-time water management, assuming stochastic future runoff, as demonstrated in a simulation run. The simulation run finds the series of monthly water allocations, water curtailments and water treatment decisions, which minimizes the total costs (sum of water curtailment costs, water treatment costs, water allocation costs and hydropower benefits) over a given planning period. From a given starting point with known runoff, month and reservoir storage level, the present flow class is determined as dry, normal or wet. The corresponding equilibrium water values and future costs are used as the expected future cost function as presented in Eq. 8. These future costs are traded off against the immediate costs, which yields the expected present optimal reservoir release and allocation policy, similarly to the backward moving SDP algorithm. Moving to the next month, the reservoir storage level is known from the previous reservoir inflow and releases. This simulation model is run through the 51 years of simulated runoff. Additionally, a perfect foresight benchmark based on dynamic programming (DP) is run. In this setup, the inflows occurring over the entire planning period are assumed to be known a priori.

2.3 Water quality constraints

The optimization model is subject to water quality constraints. We use BOD to demonstrate the water quality capabilities of the method, but the model is able to handle a variety of other pollutants as explained in the discussion section. In contrast to other pollutants, the main problem of BOD is not the direct toxic effect but the oxygen depletion resulting from BOD load. The water quality constraints are therefore set as lower bounds on the dissolved oxygen concentration DO at any point in the river.

The objective function includes water treatment costs. The monthly total pollution reduction costs (tc_{wwt}) for each of the downstream users are defined as the sum of the pre-usage treatments ($c_{pre-wwt}$) for water exceeding user specific reference water quality and post-usage treatment costs ($c_{post-wwt}$):

$$tc_{wwt} = c_{pre-wwt} + c_{post-wwt} \quad (9)$$

with

$$c_{pre-wwt} = \begin{cases} x_{sw} (C - C_{ref}) c_{wt}, & C > C_{ref} \\ 0, & C \leq C_{ref} \end{cases} \quad (10)$$

$$c_{post-wwt} = \begin{cases} (\alpha x + \beta - y) c_{wwt}, & \alpha x + \beta > y \\ 0, & \alpha x + \beta \leq y \end{cases} \quad (11)$$

where C is the pollutant concentration at the intake point (g BOD/m³ in river), C_{ref} is the maximum concentration of pollutant given by the user-specific reference water quality target (see Table 3) at which pre-usage treatment is initiated (g BOD/m³ in the river), c_{wt} is the marginal water treatment costs of intake water (CNY/g BOD), α is the BOD generation dependent on water allocations (g BOD/m³ allocated) (see Table 3), x is the total allocated water to the user (m³/month), β is the fixed BOD generation independent of water allocations (g BOD/month), y is the non-treated pollution release to the river (g BOD/month) and c_{wwt} is the waste water treatment costs of reducing the pollution load of the return flow (CNY/g BOD).

The pollution pre-treatment is governed by the surface water allocation decision variable, the pollutant concentration in the river and two constants (C_{ref} and c_{wt}). For node 1, the pollutant concentration is a function of the reservoir release, the surface water allocations to and the pollution releases from the users located at node 1:

$$C_1 = C_0 + \frac{y_j + \dots + y_J}{r - (x_{sw,j} + \dots + x_{sw,J})} \quad (12)$$

where C_1 is the concentration at node 1 (g BOD/m³), C_0 is the pollutant concentration in the reservoir release (g BOD/m³) and j indexes the J users located at node 1. From this equation

it is evident that the pollutant concentration depends nonlinearly on multiple decision variables (y , x_{sw} , r).

The downstream management problem is spatially disaggregated as sketched in Figure 2B, with two groups of water users located in series with a distance dx (m) between them. If the flow velocity v (m/d) is assumed constant, the elapsed time between the two nodes is also constant ($t = dx / v$). The BOD removal is assumed to follow first order decay:

$$\frac{dBOD}{dt} = -k_1 BOD \quad (13)$$

with the solution:

$$BOD(t) = BOD_0 \exp(-k_1 t) \quad (14)$$

where k_1 is the deoxygenation rate (d^{-1}). The remaining BOD at node 2 is found from the travel time of the water between the two nodes:

$$C_2 = C_1 \exp(-k_1 t) + \frac{y_z + \dots + y_Z}{r - (x_{sw,j} + \dots + x_{sw,J}) - (x_{sw,z} + \dots + x_{sw,Z})} \quad (15)$$

where z indexes the Z users located at node 2. The concentration at node 2 is, just like node 1, a non-linear expression of multiple decision variables. The concentration depends both on the upstream decisions and the allocations and post-use treatments at node 2.

The post-usage treatment cost in Eq. 11 is a linear expression of the decision variables. The Streeter-Phelps equation estimates the DO concentration in the river, assuming perfect mixing in the river (Streeter and Phelps, 1958):

$$D = \frac{k_1 BOD_0}{k_2 - k_1} (e^{-k_1 t} - e^{-k_2 t}) + D_0 e^{-k_2 t} \quad (16)$$

where D is the oxygen saturation deficit (g/m^3) ($DO_{sat} - DO$), k_2 is the reaeration rate (d^{-1}), BOD_0 is the initial oxygen demand of the organic matter in the water (g/m^3), t is the elapsed time (d) and D_0 is the initial oxygen saturation deficit (g/m^3). The dissolved oxygen concentration DO (g/m^3) is derived from the saturated oxygen concentration DO_{sat} (g/m^3):

$$D = DO_{sat} - DO \quad (17)$$

The dissolved oxygen concentration is a function of the elapsed time and decreases until the critical time t_c (d) at which the deficit reaches its maximum (i.e. the dissolved oxygen is at minimum). In a river water quality perspective, location and value of this critical dissolved oxygen concentration are of interest. The water quality constraint should be expressed in terms of the critical concentration, i.e. at no point downstream in the river does the dissolved oxygen concentrations fall below a given constraint. The critical time is found by differentiating Eq. 16 with respect to time and setting this equal to zero:

$$t_c = \frac{1}{k_2 - k_1} \ln \left[\frac{k_2}{k_1} \left(1 - \frac{D_0(k_2 - k_1)}{BOD_0 k_1} \right) \right] \quad (18)$$

Insertion of the critical time in Eq. 16 yields an expression of the maximum dissolved oxygen deficit D_{crit} (g/m^3). The minimum dissolved oxygen concentration, DO_{min} (g/m^3) downstream node 1 is found by inserting D_{max} and the given initial conditions for DO_{sat} , D_0 , k_1 , k_2 and L_a in Eq. 17. Similarly, the Streeter-Phelps equation is used to compute DO_{min} downstream node 2. Here the remaining BOD and DO are found by inserting the elapsed time between the two nodes in Eq. 14 and 16 and D_0 and BOD_0 are the calculated values at the end of the upstream section. With the BOD concentrations at node 1 and 2 as the only inputs, the resulting DO_{min} downstream both nodes are found.

The saturated oxygen concentration along with the reaeration and deoxygenation processes is highly temperature dependent (Schnoor, 1996). The optimization runs in monthly time steps and the temperature in the basin varies greatly throughout the year. k_1 and k_2 were therefore temperature corrected (Schnoor, 1996):

$$k_i = k_{i,20} \theta^{(T-20)} \quad (19)$$

where $k_{i,20}$ is the reaeration or the BOD assimilation rate at 20°C, with $k_{1,20}$ estimated to 0.3 d^{-1} and $k_{2,20}$ estimated to 0.6 d^{-1} , T is the actual stream temperature, and θ is a constant. For k_1 , θ has the value 1.047, and for k_2 the value 1.024 (Schnoor, 1996). The saturated dissolved oxygen concentration is estimated with Weiss baseline DO concentration at zero salinity and one atmosphere (U.S. Geological Survey, 2013; Weiss, 1970).

The daily minimum and maximum air temperatures reported by the China Meteorological Administration (2009) is averaged to monthly levels. The average water temperature is assumed to be equal to the average air temperature. In Table 4 the average monthly air temperatures, the corresponding oxygen solubility and the temperature corrected deoxygenation and reaeration rates are presented.

Table 4: Mean air temperature, the oxygen solubility at saturation and the temperature corrected BOD assimilation and reaeration rates. *For January, a water temperature of zero degrees Celsius is used.

2.4 Solving the nonlinear sub problems

If the optimization problem is strictly linear and convex, linear programming is a highly efficient approach to solve the high number of optimization sub-problems arising within the SDP framework. In this study, the sub-problems are non-linear because of the water quality constraints and an alternative to LP is therefore needed. Efficient genetic algorithms (GA, see e.g. Goldberg, 1989; Reeves, 1997) have been used widely to find the global optimum in complex nonlinear optimization problems. In water resources management, GAs have been applied for a variety of nonlinear optimization problems such as, for example, coupled groundwater-surface water management problems, hydropower production and reservoir water quality problems (Cai et al., 2001; Davidsen et al., n.d.; Kerachian and Karamouz, 2007; Nicklow et al., 2010). A GA searches for the global optimal solution with a search approach inspired by natural evolution. Using a GA with in our case more than 70 decision variables is expected to be computationally infeasible within the SDP framework. Cai et al. (2001) developed a hybrid GA-LP implementation to solve a nonlinear surface water management problem. In this approach, the complicating decision variables, which cause the nonlinearity, are “outsourced” to the GA. With these complicating values fixed, the remaining optimization problem becomes strictly linear and solvable with LP. As demonstrated in Eq. 12 and 15, the BOD concentrations in node 1 and 2 both depend on multiple decision variables, and fixing C_1 and C_2 reduces the remaining decisions to an LP. The GA uses the fast LP as fitness measure, as it iteratively searches for the optimal solution in each discrete combination of system states.

The optimization model is developed in MATLAB and uses the standard GA function *ga* (MathWorks Inc., 2013). The options for *ga* are selected through multiple test runs and include, besides the default options, a population size of 30, constraint and function tolerances of 10^{-9} , elite count of 5 and a migration interval of 1. Finally, a random uniform population is generated within the feasible decision space and supplied as the initial population to *ga*. The

default MATLAB function *linprog* can be used to solve the LP, but in this study the computationally faster commercial solver *cplexlp* by IBM is used (IBM, 2013). Each stage is fully parallelized as all storage levels and the Markov Chain flow classes are fully independent. With 30 discrete reservoir storage levels and 3 flow classes, each optimization year requires 25 minutes on 18 2.8 GHz cores in a high performance computer (HPC) environment. With a need of estimated 10 optimization years to reach equilibrium, the total optimization time becomes around 4 hours per climate period per scenario.

The SDP model loops through flow classes and reservoir storage levels backward in time. A flow chart of the algorithm design is presented in Figure 3. Initially, the input data are assigned, including an initial population of feasible samples. Next, an LP with the BOD concentration at each node given as input variables is used to find the minimum summed costs of immediate management and future costs. In MATLAB the LP is supplied as a fitness function to the *GA*, with the node concentrations as the two decisions. As the *GA* iteratively approaches the optimal solution, new mutations and crossovers of parents are constrained by the minimum DO concentration, computed with the Streeter-Phelps equation. The Streeter-Phelps equation is supplied as a nonlinear constraint to the *GA*.

Figure 3: Flow chart of the SDP model and the simulation phase.

2.5 Scenario runs and local sensitivity analysis

Several scenarios were simulated to demonstrate the potential use of the model in decision support. By default, a monthly minimum in-stream flow to the ecosystem is set to 5% of the natural runoff. Davidsen et al. (n.d.) found that the long-term sustainable groundwater pumping costs in the Ziya River Basin can be assumed constant. At steady state, the groundwater cost is constant at approximately 2.2 CNY/m³. If the groundwater table is below equilibrium, the groundwater cost is higher. The groundwater cost is set at a constant value of 2.5 CNY/m³ in this study, to stimulate recovery of the currently over-pumped groundwater aquifer.

The first scenario is a baseline run that does not consider water quality constraints. Five additional scenarios require compliance with the five water quality grades presented in Table 1. In the No Treatment (NT) scenario, water cannot be treated, i.e. water quality constraints must be satisfied by dilution and curtailment only. A final scenario with water quality constraint set to grade III and a minimum in-stream flow constraint at 20% of the natural runoff is run to estimate the costs of obtaining close-to-natural conditions in the river.

Because of the high computational load, a Monte Carlo uncertainty analysis as applied by Davidsen et al. (2014) is infeasible. Instead, a local sensitivity analysis of the total cost was conducted. Five uncertain parameters were identified in the input data; water demands, water curtailment costs, wastewater treatment costs, BOD generation and river flow velocity. Each parameter was increased by 10%, and the resulting change in the total costs used as a measure of sensitivity.

3 Results and discussion

A sample of the equilibrium water value tables generated in the 7 scenario runs are presented in Figure 4. These water values show the value of storing a marginal volume of water in the reservoir for later use. The water values are lowest in the rainy season (June-August) when water values are comparable to hydropower benefits at 0.036 CNY/m³. In the dry winter and spring months water values are typically around 2.2 CNY/m³ for storage above 1/3 of the reservoir capacity (reflects curtailment of wheat agriculture) and 2.5 CNY/m³ below 1/3 storage (shift to groundwater pumping). As the water quality is improved, the marginal values of storing water increases particularly in the wet months.

Figure 4: Equilibrium water values for three of the water quality scenarios for the recent climate period (1980 to 2008). The equilibrium water values are the long-term value of storing the water for later use. These water values are linked to three discrete system states: the y-axis shows variation along the reservoir storage system state (from empty to full storage); the x-axis shows the temporal variation; the three rows (wet, normal and dry) show the variation related to the discrete reservoir inflow class states used in the three-state Markov Chain. The baseline scenario does not include water quality, class I to V are the Chinese water quality classes (Table 1). The equilibrium water values are used to represent the future costs in a forward simulation with uncertain future reservoir inflow. A figure with all water quality classes and both climate periods are included as supplementary information.

A summary of scenario results is presented in Table 5. As expected, the total costs increase as the water quality constraint is increased. Relative to the baseline scenario without water quality constraints, the increases in total costs are on the order of 4-8%, equivalent to 0.6 to 1.3 billion CNY/year (see Table 5). The NT scenario showed a 130 million CNY/year increase in the total costs when complying with Grade III. While these costs are highly uncertain, the relatively low increase indicates that the model by default avoids BOD removal and favors dilution.

Table 5: Total costs for all scenarios where TC is the average total costs over the 51 year planning period, DP is the simulation with perfect foresight (dynamic programming), E20 is minimum ecosystem releases set to 20% of natural runoff, NT is the simulation with water quality constraints but no wastewater treatment facilities. The last five rows are the sensitivity with 10% increased dm (water demands), ct (curtailment costs), cwt (marginal costs of wastewater treatment), pg (pollution generation) and v (flow velocity in the river).

Quality	Run	DO mg/l	TC SDP 10 ⁹ CNY/year	TC DP 10 ⁹ CNY/year	Sensitivity % change
Baseline	E ₅	-	15.6	15.4	
Grade V	E ₅	≥ 2	16.2	16.0	
Grade IV	E ₅	≥ 3	16.3	16.0	
Grade III	E ₅	≥ 5	16.4	16.1	
Grade II	E ₅	≥ 6	16.4	16.2	
Grade I	E ₅	≥ 0.9DO _{sat}	16.9	16.7	
Grade III	E ₂₀	≥ 5	17.0	-	
Grade III	NT	≥ 5	16.5	-	
Grade III	dm	≥ 5	18.8	-	15.3
Grade III	ct	≥ 5	17.6	-	7.4
Grade III	cwt	≥ 5	16.4	-	0.1
Grade III	pg	≥ 5	16.5	-	0.5
Grade III	v	≥ 5	16.4	-	0.1

The simple local sensitivity analysis shows that the total costs are highly sensitive to water demands. A 10% increase of the water demands leads to more severe water scarcity and increases the total costs by 15.3%. Demands of the most expensive users remain fulfilled with groundwater (at a cost of 2.5 CNY/m³) while cheaper water uses will be more curtailed. The water curtailment costs are less sensitive; a 10% increase in curtailment costs increases the total costs by 7.4%. Here, the demands of the most expensive water uses will remain fulfilled with groundwater (no additional costs) while the cost of curtailing the cheaper water uses will increase. The average marginal value per m³ of water demand supplied or curtailed is 1.44 CNY/m³. With all water already allocated, a 10% increase in the water demand causes more curtailments and more groundwater pumping both at marginal costs higher than 2 CNY/m³. Moreover, BOD load is proportional to water allocation. Increased water treatment, curtailment or dilution is therefore required. In comparison, a 10% increase in the curtailment costs affects only the users that are curtailed. The total costs show almost no sensitivity towards increases of the wastewater treatment costs, pollution generation and river flow velocity.

In Figure 5, the aggregated water allocation patterns are presented for the individual users at the two downstream nodes across the water quality scenarios. Each bar shows the portion of the water demand that is fulfilled using the different water sources. With tighter water quality requirements, more groundwater is allocated to the users at node 1, while the users at node 2 receive an increasing share of the surface water. Compared to the baseline scenario without water quality, wheat agriculture receives more water in all the water quality scenarios.

Figure 5: Stacked bar plots of how the water demands of the downstream users were satisfied in each scenario at predicted minimal costs. Each bar shows the percentage distribution between the three water sources (surface water, groundwater and SNWTP water) and water curtailments. The water demands are indicated above all subplots. The baseline scenario without water quality and compliance with five water quality grades (grade I, II, III, IV, and V) are presented, allowing comparison of the allocation pattern. The two nodes are denoted n_1 and n_2 .

In Figure 6, the annual surface water and groundwater allocations are presented for the two nodes. Again, a clear shift from surface water to groundwater at node 1 and an increase in surface water at node 2 is observed, as water quality constraints become increasingly tight. This shows that it is optimal to use surface water to dilute the pollution releases at node 1. The higher flow between the nodes reduces the need for wastewater treatments at node 1 and the degradation of BOD between the nodes allows further pollutant releases at node 2. Finally, a small increase in water curtailments can also be observed at both nodes with stricter water quality constraints.

Figure 6: Annual allocation to and curtailment of the users at node 1 and node 2 for the baseline scenario without water quality (B) and the five water quality grades (grade I, II, III, IV, and V). Water reserved for ecosystems is shown with the node 2 data. With higher DO_{min} constraints, the surface water allocations are shifted towards the users at node 2 to utilize the water for dilution. This surface water is replaced with groundwater and SNWTP water at node 1. A small increase in water curtailments can also be observed at the stricter water quality scenarios.

The non-allocated in-stream flow available to ecosystems is presented in Figure 7 for water quality grade I and grade V. In these scenarios, the minimum flow constraint is set to 5% of the natural runoff, indicated by the grey line. Apart from four flooding events, latest in 1996, releases are exactly 5% of the natural runoff, when complying with grade V. The minimum flow constraint is therefore binding. If stricter water quality is enforced, the releases of water available to the ecosystems increase, and the minimum flow constraint is now only binding in some of the years. Increased releases of non-allocated water are required to dilute the BOD loads from node 2. Pollution dilution plays an important role in the optimal management policy, which underlines the importance of coupling water quality, and water quantity management. The decrease in both surface water and groundwater allocations with the strictest water quality grades are caused by increased curtailments of the wheat agriculture.

Figure 7: Simulated annual non-allocated river flow available to ecosystems for water quality Grade I and Grade V. The cheapest policy in dry years with strict water quality requirements (Grade I) is to dilute the pollution by increasing the non-allocated flow. With less strict water quality (Grade V), the non-allocated releases for ecosystems follow the lower bound (Q_{min}).

The shadow prices of the last unit of water supplied to the users in each time step are presented in Figure 8. The shadow prices in the baseline scenario are generally lowest, whereas the shadow prices of the scenario with water quality grade IV are highest. Intuitively, the stricter water quality scenarios should have higher shadow prices, as the value of water for dilution increases. Instead, grade I and III fall in between the baseline and grade IV. This is caused by the additional wastewater treatment costs, which are not reflected in Figure 8. The shadow prices are the values of storing water and represent the trade-off with the future and represent the additional costs, which should be targeted in e.g. taxation in an opportunity cost pricing scheme. Besides these shadow prices, allocation are also associated with marginal wastewater treatment costs. An increase of the marginal treatment costs will equally reduce the shadow prices, thereby keeping the total water value constant.

Figure 8: Simulated average annual shadow prices for three water quality grades and a baseline scenario without water quality included.

Figure 9 presents the aggregated annual BOD reduction of the user effluents. To comply with stricter water quality constraints, dilution is clearly increasingly combined with BOD removal. At the lower water quality grades, the constraint is set to a fixed minimum DO concentration, whereas the water quality is constrained to at least 90% of the saturated dissolved oxygen level in the grade I scenario. The temperature-corrected saturated oxygen concentration varies between 7.9 and 14.6 mg DO/l, and a constraint at 90% of these concentrations is therefore significantly stricter than a flat constraint of, e.g., 5 mg DO/l as in grade III. In the lower water quality grades, the winter months with high saturated DO levels allow more dilution. Naturally, the much stricter constraint in the grade I scenario requires increased BOD removal.

Figure 9: Simulated annual BOD reduction for different water quality grades.

The baseline scenario illustrates some of the problems that can be expected when water is managed without consideration of water quality. The management policy, proposed by the baseline scenario, results in median BOD concentrations equal to 87 mg BOD/l at node 1 and 200 mg BOD/l at node 2. In 25% of the time, the BOD concentrations will exceed 870 mg BOD/l at node 1 and 1090 mg BOD/l at node 2. To put this into context, it is important to note that dissolved oxygen in a fully saturated water body will be completely depleted, if exposed to 30 mg BOD/l in June and 65 mg BOD/l in March. The available data are highly uncertain, but the NT scenario indicates that dilution and curtailment alone can solve a large part of the problems at a relatively low cost.

In this study, BOD is used to demonstrate how the proposed modeling framework can handle complex nonlinear water quality constraints for a single pollution compound and two pollution nodes. However, both the number of pollutants and pollution nodes can be expanded at additional computational costs, given that the pollution processes are not coupled in time. Pollutant sorption to sediment, nutrient leaching from groundwater or other processes, which couple multiple time steps, require separate state variables. Within the SDP framework, this will cause strongly increased computation times due to the well-known *curse of dimensionality* associated with the SDP framework.

Conservative pollutants, e.g. salt, are a class of pollutants which can easily be handled. The nonlinearity, caused by the multiple decision variables in the computation of pollutant concentration (Eq. 12), requires continued use of the GA-LP setup, but the pollutant concentration calculations will be much simpler. Moreover, the water quality constraints can target the pollution concentration directly at the nodes, which further simplifies the optimization.

Any degradation processes, which can be computed from the initial concentration without involving additional decision variables, can also be accommodated in the model. The limits are mainly processes coupled in time, and complex degradation pathways, which prevent estimation of the pollutant concentration remaining from node 1 at node 2. As an example, the complex feedback loop between algae growth and ammonia concentration is difficult to include. Instead, simplified first order degradation and constraints on, e.g., formed nitrite concentration can be accommodated.

4 Conclusion

This study demonstrates how a hydroeconomic optimization approach can be used to guide sustainable river basin water resources management under uncertain runoff and given water quality constraints. The coupled GA-LP formulation is a powerful and flexible approach to solve nonlinear sub-problems in the context of SDP. The model contributes to solving highly coupled and complex water management problems and has a great potential for application in real-time decision support.

The developed decision support tool is used to compare the economic impacts of complying with various water quality grades. The water scarcity and operational costs of the baseline scenario are estimated to 15.6 billion CNY/year. Compliance with water quality grade III increases the costs to 16.4 billion CNY/year. While the increases in the total costs are in general small relative to the costs of water scarcity, the optimal water allocation policy is highly affected. Dilution plays an important role in the optimal policy and releases of unused in-stream flow available to the ecosystems increases significantly as the water quality criteria are becoming stricter. Moreover, relocation of surface water is observed with an increasing amount of surface water allocated to the downstream users, thereby utilizing the water for dilution of upstream pollution discharges. The large impacts on the optimal water allocation policy underline the importance of coupling water quality to water quantity in water resources management studies.
