Abstract

This paper reviews databases on material recycling (primary as well as secondary production) used in life cycle assessments (LCA) of waste management systems. A total of 366 datasets, from 1980-2010 and covering 14 materials, were collected from databases and reports. Totals for CO₂-equivalent emissions were compared to illustrate variations in the data. It was hypothesised that emissions from material production and the recycling industry had decreased over time due to increasing regulation, energy costs and process optimisation, but the reported datasets did not reveal such a general trend. Data representing the same processes varied considerably between databases, and proper background information was hard to obtain, which in turn made it difficult to explain the large differences observed. Those differences between the highest and lowest estimated CO₂ emissions (equivalents) from the primary production of newsprint, HDPE and glass were 238, 443 and 452%, respectively. For steel and aluminum the differences were 1,761 and 235%, respectively. There is a severe lack of data for some recycled materials; for example, only one dataset existed for secondary cardboard. The study shows that the choice of dataset used to represent the environmental load of a material recycling process and credited emissions from the avoided production of virgin materials is crucial for the outcome of an LCA on waste management. Great care and a high degree of transparency are mandatory, but advice on which datasets to use could not be determined from the study. However, from the gathered data, recycling in general showed lower emission of CO₂ per kg material than primary production, so the recycling of materials (considered in this study) is thus beneficial in most cases.

Keywords: Life cycle inventory (LCI) databases, Waste recycling, Plastics, Paper, Cardboard, Glass, Aluminum, Steel, Life cycle assessment (LCA), CO₂ emission

1 Introduction

The reuse and recovery of resources from municipal waste contribute to sustainable development, and in the future, together with waste prevention, they will be a strong focus in many parts of the world (European Commission, 2011; Hoornweg et al., 2013). Companies and public authorities will be forced to use life cycle approaches to identify the best options for future waste management systems, including recycling. To carry out a life cycle assessment (LCA), there is a need for life cycle inventory (LCI) data to ensure a representative assessment. LCI data on waste management processes involved in recycling, including source separation, collection, transport and upgrading of recyclables, are readily available (for example, Merrild et al., 2012). However, LCI data on the actual industrial recycling of recovered materials can be found in external databases. LCI data on the remanufacturing of materials recovered from solid waste must include the environmental load of the manufacturing process employed to convert recovered materials into a new material (henceforth called ‘secondary’), as well as the environmental load credited as a result of avoiding virgin material production (henceforth called ‘primary’). In 2006, the UK Waste and Recovery Action Programme published a hefty review of LCA studies on recycling versus incineration and landfilling (WRAP, 2006). The review presented variations in the results taken from the studies, but did not look into the inventories behind the LCAs.

Many databases containing remanufacturing LCI data are available. However, selecting the right dataset out of the many published since 1980 for a specific LCA model is not particularly straightforward despite the existence of various guidelines (ISO, 2006; European Commission, 2010). ISO standard 14044 (ISO, 2006) and the ILCD Handbook (European Commission, 2010) describe the data quality requirements for LCIs. However, data quality indicators are typically not documented in the available datasets. There are a large number of waste-specific LCA models (e.g. EASE-WASTE, WRATE, MSW-DST) (Gentil et al., 2010) as well as generic LCA models (e.g. SIMAPRO, GaBi, Umberto) and databases (e.g. Ecoinvent, US LCI, ELCD) in use, but there has been little discussion in the literature as to what dataset is most appropriate for a given LCA study, and no comparison has been made between these different data sources.

To assess data quality used in LCAs, Weidema and Wesnaes (1996) provided the pedigree matrix. This system ensures an overview of the relevance of a dataset for a given assessment. The matrix is used for LCA studies, and the scoring of the data is linked to the scope of the study. Factors to consider when assessing data quality include the age of the data, the level of detail in the background description and the technical and geographical representativeness.

The goal of this study was to provide an overview of the challenges involved in choosing representative datasets for material recycling and virgin material production processes. Challenges come in the form of the transparency of databases and documentation on background information for datasets. For a quantitative assessment of multiple databases, CO₂-equivalents was selected as an indicator parameter for environmental load, and its value was used to compare data across a range of recyclable materials found in available data sources.

2 Databases and choosing datasets

LCI databases on material recycling processes come from a variety of sources, the major ones of which are large public and commercial databases such as Ecoinvent (2013), PE International (2013), U.S. Life Cycle Inventory Database (US LCI, 2013) and the European reference Life Cycle Database (ELCD, 2013). These databases may also be accessed through commercial LCA modelling tools, including Simapro (PRé, 2013), Umberto (Ifu Hamburg, 2013) and GaBi (PE International, 2013). In addition, there are a number of smaller models dedicated to specific applications (municipal waste, packaging materials, fuels, biofuels, etc.) which have accompanying databases (e.g. EA-SETECH (Clavreul et al., 2014) and SWOLF (Levis et al., 2013)).

A total of 26 databases and sources were identified for this study, including the 366 material datasets for 14 materials presented in Table 1. Another 46 potential sources of LCI data were identified but not included due to language issues, closed websites, a prohibitive fee structure or because the data were not fully compatible with this study. The authors have licences for Simapro and GaBi – LCA tools which give access to many of the databases. No other licences were bought, and therefore some available databases were not included, even though these might be of good quality and up to date (e.g. Umberto (Ifu Hamburg, 2013)). All data sources were identified by searching the internet, starting from the ELCD homepage which provides a comprehensive list of databases and sources. Scientific search engines (Web of Knowledge (2013) etc.) were also used to find scientific papers and relevant research reports.

2.1 Data selection criteria

The focus of this study was on data representing material production based on primary and secondary materials, including fibre (copy paper, cardboard, corrugated cardboard, newsprint), plastics (HDPE, LDPE, LLDPE, PET, PVC, PS, and PP), steel, aluminum and glass. The criteria for inclusion were that the material should be pure in an industrial context and preferably not a product, i.e. a steel ingot versus metal cans. In some cases products were included, for example in the case of glass, since most recycled glass comes from containers used for food and beverages.

Datasets were selected on the basis that it was possible to quantify CO₂-equivalent emissions, as this parameter was used as an indicator for dataset comparisons. CO₂ emission levels also provide an indication of the type of energy used in the dataset; for instance, high CO₂ emissions would indicate the high consumption of resource-demanding materials or of fossil energy. Datasets that were outliers in terms of CO₂-equivalents were specifically scrutinised to identify special conditions, as discussed below. CO₂-equivalents for biogenic CO₂ were considered to be zero, which is consistent with the definition for modelling biogenic carbon in waste management systems (Christensen et al., 2009; Muñoz et al., 2012).

Data documentation should describe the origin and age of the data, whether the data were measured, calculated or estimated, what was excluded, a careful description of the system boundaries and the organisation responsible for the data development. Unfortunately, complete documentation was never available and datasets with partial documentation were included.

2.2 Representative data

A representative dataset is one that embodies the assessed process, or the closest similar process, and detailed knowledge in this respect is required to know which process is most illustrative. This issue cannot be solved by applying Weidema and Wesnaes's (1996) pedigree matrix, though. For example, while HDPE manufacturing processes may be similar globally, the same cannot be said

for paper, where each manufacturing facility tends to be unique and processes a specific set of fibre types that may vary over time. This makes it difficult to model a typical national average paper plant while a site-specific of an individual paper plant can be well-defined.

In the context of recycling, it is important to identify datasets that reflect industrial production processes where a good mix of scrap materials and virgin materials is used. Such processes are commonplace, but of course they do not provide separate data on virgin and recycled material manufacturing. Good documentation is critical to determine the net difference in increasing, for example, scrap recycling (actual process substituting and the actual substitution ratio). The energy used in production, in particular electricity, is usually a key contributor to an LCI. Thus, the documentation should be detailed about energy use, particularly in view of quantity and quality. The impacts caused by using electricity and applying heat vary a great deal between countries because of the different mix of energy sources. Therefore, it is important to use non-aggregated data in LCI datasets, in order to identify the contribution made by the energy use and potentially to change the process if the dataset is to be used in a different region with a different electricity fuel mix.

2.3 Description of material recovery from municipal solid waste for recycling

This section provides an overview of the key characteristics of the materials that are typically recycled from solid waste and are considered in this study, including copy paper, newsprint, cardboard, corrugated cardboard, container glass, steel, aluminum and plastics (high density polyethylene (HDPE), low density polyethylene (LDPE), linear low density polyethylene (LLDPE), polyethylene terephthalate (PET), polypropylene (PP), polyvinylchloride (PVC) and polystyrene (PS)).

2.3.1 Fibre materials

Copy paper, newsprint, cardboard and corrugated cardboard are all made from wooden fibre pulp. The pulp is produced from wooden materials by applying kraft, sulphite, mechanical or chemical-mechanical pulping methods (IPPC, 2001). The production of paper requires substantial amounts of water and energy. Copy paper consists of wood fibres, and it is used for writing and printing. The lignin that occurs naturally in the raw material is removed through chemical pulping to produce copy paper. Newsprint is used for newspapers and advertisement inserts and has a lower quality requirement compared to copy paper. It is produced from mechanical pulp, which means that the lignin is not removed. Cardboard, sometimes referred to as linerboard or container board, is used, for example, for hardback book covers and food packaging. Corrugated cardboard, also known as kraftliner or testliner (recycled materials), is used for boxes and containers for shipping. This type of fibre-based material is often a mixture of primary and secondary fibres.

Paper recycling is done by mechanically or chemical-mechanically pulping the paper (IPPC, 2001), a process which results in shortening the fibres and a subsequent reduction in strength. Mixing recycled paper with primary material is often required to meet paper strength specifications (Christensen & Damgaard, 2010a).

2.3.2 Glass

Soda-lime glass, lead crystal and crystal glass are produced globally in the largest amounts (IPPC, 2013). Container glass for food and beverages is made of soda-lime glass and constitutes 50-60% of the total amount of glass produced globally (IPPC, 2001), as well as a much larger percentage of the non-durable glass that becomes waste after a single use. Glass, which is produced at 1500-1600°C, can be found in clear, green or brown finishes. Clear glass is produced from quartz sand with low amounts of iron oxides, whereas manganese, iron, nickel and cobalt oxides are added to the production of brown glass, and chromium, cobalt and vanadium oxides are added to green glass (Christensen & Damgaard, 2010b).

The removal of foreign objects, sorting by colour, size reduction and cleaning are the main steps involved in pre-treating glass before recycling, although some uses (e.g. as a drainage material) allow for the input of mixed colours (Christensen & Damgaard, 2010b).

2.3.3 Plastics

Plastics can be classified as thermoplastics and thermosets. Examples of thermoplastics are polyethylene (PE), polyethylene terephthalate (PET), polyvinylchloride (PVC), polypropylene (PP), polystyrene (PS) and expanded polystyrene (EPS). Examples of thermosets are epoxide (EP), phenol-formaldehyde (PF), and polyurethane (PUR). Thermoplastics can be shaped by heating and will maintain their shape after cooling, whereas the melting point of thermosets is high enough that they will burn before they melt, which makes them hard to recycle (Christensen and Fruergaard, 2010). The aforementioned plastics are derived from crude oil through the distillation of naphtha. Some plastics may also be produced from natural gas by cracking it into ethylene. Additional monomeric chemicals are added, depending on the type of plastic produced (Plastic Europe, 2005).

Polystyrenes are divided into four types: polystyrene (PS), general purpose polystyrene (GPPS), high impact polystyrene (HIPS) and expandable polystyrene (EPS). The datasets presenting PS are generic, since the specific type was not specified further. The four types of PS are all produced with styrene as an input, but EPS also includes pentane. The production of GPPS and HIPS involves the input of butadiene.

Plastic recycling can be done either by feedstock recycling or mechanical recycling. Feedstock recycling breaks down the plastic to monomers, which can then be used in refineries and chemical production. Mechanical recycling includes shredding, cleaning, melting or granulation (Christensen and Fruergaard, 2010), and it produces quality products only when the materials are void of contaminants, sorted into a single type of polymer and sufficiently segregated according to the colour required for end use. For example, when containers are recycled in black plastics, sorting by colour is not important.

2.3.4 Steel

The major technologies used for the production of steel are electro ovens and oxygen blast furnaces. These technologies produce the same type of product but use different levels of energy consumption and therefore different emissions. Electric arc furnaces convert iron and steel scrap into steel by

heating the materials with a high-power electric arc. In a basic oxygen furnace, oxygen is injected over molten iron (Worldsteel, 2012), while alloyed steel is iron mixed with other metals (e.g. chromium, nickel and tin) to enhance and customise the properties of the steel.

Steel scrap recycling is carried out in either an electric arc furnace or a basic oxygen furnace. An electric arc furnace can receive 100% scrap metals, while in the basic oxygen furnace scrap is limited to 25-30% of the total amount of metal (Damgaard and Christensen, 2010). Given the dominance of two technologies with different emission characteristics, an LCA should typically use a weighted average of emissions. Globally, it is estimated that the majority of post-consumer scrap is processed in electric arc furnaces (IISI, 2005), so this can be considered the representative technology in most cases.

2.3.5 Aluminum

The mining of bauxite, as well as alumina oxide refining, are the first steps in aluminum production, following which anode production, alumina smelting via electrolysis and finally refining take place (Aluminum Association, 2010). Alumina smelting and anode production consume large amounts of electricity, and they are possibly very CO₂-intensive.

Waste aluminum cans are shredded, ferrous metals are sorted out and the aluminum is de-coated before melting and mixed with primary aluminum (Aluminum Association, 2010). Other types of waste aluminum do not need de-coating, and the rest of remanufacturing process is the same as for the cans (Aluminum Association, 2010).

3 Results

Table 2 presents minimum and maximum values in terms of CO₂-equivalent per kg of material. The mean, standard deviation and number of datasets are also presented. In total, 366 datasets were evaluated, 270 of which represented primary production and 96 secondary production. Information on the data found for the primary and secondary production for each material is discussed in this section.

Figures 1-14 present CO₂ emissions from the primary and secondary production of the 14 materials studied. The name of each dataset, as shown in Figures 1-14, shows the data source by reference to the numbers in Table 1. The year of the data collection is also presented, where available. The data represent different geographical areas – some are for a specific country (Switzerland, Germany, Sweden, etc.) while other datasets represent larger regions such as Europe or the USA. A few represent a global average. As noted in the figures, several datasets did not include geographical relevance.

To use LCI data properly in a specific study, it is important to identify from the background information which process is actually represented. The purpose of Figure 1-14, however, is primarily to illustrate significant differences in emissions which will dramatically affect the results of an LCA involving the recycling of materials. To put these data in context, estimates of emissions associated with other waste management activities are presented, namely collection (47-57 kg CO₂-eq/tonne (Eisted et al., 2009), separation in sorting

plants (11 kg CO₂-eq/tonne (Fitzgerald et al., 2012), landfilling in an average U.S. site (26 kg CO₂-eq/tonne (Levis and Barlaz, 2011) and combustion (324–480 kg CO₂-eq/tonne (Larsen and Astrup, 2011)).

Table 2: Intervals for the primary and secondary production of materials and the number of datasets included in the study.

Primary/Secondary production	Material	Lowest value	Highest value	Mean	Standard deviation	Number of datasets
		kg CO ₂ /kg of material				
Primary	Copy paper	0.04	4.08	1.24	1.02	26
Secondary	Copy paper	0.38	1.56	0.73	0.41	11
Primary	Newsprint	1.29	3.08	2.22	0.65	6
Secondary	Newsprint	0.22	1.86	0.89	0.60	12
Primary	Cardboard	0.70	3.89	1.85	0.99	8
Secondary	Cardboard	0.61	0.61	-	-	1
Primary	Corrugated card-board	0.49	2.46	1.14	0.45	17
Secondary	Corrugated card-board	0.31	1.26	0.82	0.31	11
Primary	Glass	0.24	1.10	0.74	0.20	24
Secondary	Glass	0.07	0.86	0.46	0.26	8
Primary	Plastic HDPE	0.70	3.10	1.88	0.68	14
Secondary	Plastic HDPE	0.21	0.53	0.35	0.12	6
Primary	Plastic LDPE	0.89	3.11	2.02	0.65	11
Secondary	Plastic LDPE	0.19	0.89	0.45	0.31	4
Primary	Plastic LLDPE	0.65	2.04	1.65	0.46	8
Secondary	Plastic LLDPE	-	-	-	-	0
Primary	Plastic PET	1.16	5.48	3.43	1.12	21
Secondary	Plastic PET	0.11	1.10	0.53	0.31	7
Primary	Plastic PP	1.14	4.44	2.41	1.01	12
Secondary	Plastic PP	-	-	-	-	0
Primary	Plastic PVC	0.92	4.07	2.41	0.69	30

Secondary	Aluminum	0.40	8.37	2.18	2.54	22
Datasets in total						366

Fibre materials

Energy efficiency in the fibre production industry is reported to have improved considerably since 2000. One of the world's leading companies for paper and pulp production, Stora Enso, reports a

decrease in electricity consumption of 6% from 2007-2011 (Stora Enso, 2011). The branch organisation International Paper reports a decrease of 7% in total energy used from 2007-2010 (IP, 2010) and the European Pulp and Paper Industry reports a decrease of 11.7% in specific primary energy used from 1991-2010 (CEPI, 2011). This might suggest that new datasets would show less CO₂ emissions, but such a trend was not evident in the present study. There are two possible explanations for the lack of a trend. First, newer datasets may still be relying on old data and second, uncertainty in the data may be considerably greater than the maximum reported decrease in energy consumption.

For primary newsprint, American data show higher CO₂ emissions per kilogram of primary and secondary newsprint than European data, due to the mix of energy sources used. Most datasets for paper production in Europe come from Sweden, where a major part of the energy mix is made up of hydropower and energy from biomass, which results in less fossil CO₂ emissions than the average energy mix in Europe and USA. Note, however, that certain amounts of fibre produced in one country are undoubtedly consumed – and perhaps recycled – in another country. In addition, environmental impacts associated with hydropower electricity production do not currently take into account whether or not the flooding of land may have reduced the stock of forestry biomass, a vital source of CO₂ uptake (Hertwich, 2013).

A few datasets used consequential system expansion, where it was considered that wood used for primary paper production could have been used for energy production. Therefore, the processes included natural gas for energy production instead of wood, since wood is used for primary paper production. This leads to higher CO₂ emissions, since the other datasets do not include this additional use of natural gas. This kind of system expansion was included in datasets with names such as ‘Incl. altern. use of fuel’, and emissions were higher than for the other datasets. Whether or not such system expansion is appropriate is reliant on the specific study’s objectives.

3.1.1 Copy Paper

Data presented for copy paper production were in the range of 0.04-4.08 kg CO₂-eq/kg of material, taken from 26 datasets. The lowest emission of 0.04 kg CO₂-eq/kg of material represents a European average production of copy paper, but it was not possible to find more information about the low emission in the GEMIS database. Only 11 datasets were found for secondary copy paper production, with a range of 0.38-1.56 kg CO₂-eq/kg of material. Individual ranges were seen for each database for each material within this overall range. The mean for primary production was 1.24 kg CO₂-eq/kg of material and the mean for secondary production was 0.73 kg CO₂-eq/kg of material. One dataset for primary copy paper production was different from the others due to system expansion including an alternative use of fuel.

Data from GEMIS (source 14) were lower than other data presented for the production of copy paper. It was not possible to access documentation for the GEMIS processes due to obsolete links. Thus, the reason for the lower emission figures cannot be determined.

3.1.2 Newsprint

Newsprint is used for newspapers and advertising inserts. Figure 2 shows the data obtained for the primary and secondary production of newsprint. Data found for the primary newsprint were in the range of 1.29-3.08 kg CO₂-eq/kg of material, whereas secondary production provided lower emissions in the range of 0.22-1.86 kg CO₂-eq/kg of material. Six datasets were found for primary production and 12 for secondary production. Most of the datasets for the production of newspaper included a mix of primary and secondary paper, but this was not always clear from the name of the process, perhaps because many paper mills use a mixture of primary and secondary raw materials. Note that emission intervals for primary and secondary production overlapped, which highlights that it is crucial to choose representative data.

3.1.3 Cardboard

Emissions for primary cardboard were in the range of 0.70-3.89 kg CO₂-eq/kg of material. Eight datasets were found for primary production, whereas only one dataset was found for secondary production, giving 0.61 kg CO₂-eq/kg of material (Figure 3).

The data from Avfall Norge were low compared to the other datasets shown in Figure 3. The reason for low emissions was not clear from the available background information. The Norwegian data were modelled in Simapro (PRé, 2013) and it was assumed that Avfall Norge uses the Norwegian energy mix, which consists mainly of hydropower and therefore leads to less CO₂ emissions. The ‘Virgin Cardboard, 1997’ dataset from EASEWASTE, originated in Finland, also had relatively low emissions. The dataset provider used a Swedish energy mix, which includes significant use of nuclear and hydropower, with subsequent low greenhouse gas electricity intensity (kg CO₂/kwh).

3.1.4 Corrugated cardboard/liner

Data for corrugated cardboard are presented in Figure 4. The production of primary corrugated cardboard showed emissions ranging from 0.49-2.46 kg CO₂-eq/kg of material for 17 datasets. Secondary corrugated cardboard emissions were in the range 0.31-1.26 kg CO₂-eq/kg of material from 11 datasets. As for copy paper, it was not possible to acquire outlier documentation from the GEMIS database (source 14).

The ‘Kraft paper, bleached, at plant’ dataset from Ecoinvent (source 7) included the infrastructure of the paper mill, energy production on-site and internal waste water treatment, items that were not included in other datasets. This is why the Ecoinvent data reside at the upper end of the range.

Another outlier is ‘Kraft bleached’ from 1995, taken from the Franklin database (source 13). In this dataset most of the energy comes from industrial burners inputting several types of fuel (coal, residual fuel oil and natural gas). This leads to higher CO₂ emissions than the other datasets presented.

Figure 1: CO₂-eq emissions from the primary and secondary production of copy paper. Numbers in names refer to sources in Table 1. “-”: No data found.

Figure 2: CO₂-eq emissions from the primary and secondary production of newsprint. Numbers in names refer to sources in Table 1. “-”: No data found.

Figure 3: CO₂-eq emissions from the primary and secondary production of cardboard. Numbers in names refer to sources in Table 1. “-”: No data found.

Figure 4: CO₂-eq emissions from the primary and secondary production of corrugated cardboard. Numbers in names refer to sources in Table 1. “-”: No data found.

3.2 Glass

Emissions from the production of primary and secondary glass are presented in Figure 5. Datasets for specific colours as well as generic datasets are presented. Primary glass led to emissions of 0.24-1.1 kg CO₂-eq/kg of material and secondary glass gave emissions of 0.07-0.86 kg CO₂-eq/kg of material. The average values for glass production were not considerably different. The mean showed lower emissions for secondary (0.46 kg CO₂-eq/kg of material) than for the primary (0.74 kg CO₂-eq/kg of material) production. Eight datasets were identified for secondary production whereas 24 datasets were found for primary production. The small difference between primary and secondary production suggests that long distance transport of glass prior to recycling may eliminate

the environmental benefits of recycling. Roughly, transport in large trucks results in emissions of 0.091-0.19 kg CO₂-eq/tonne·km (Eisted et al., 2009).

The dataset “Glass – green (primary, 100%)” from the EASEWASTE database does not include any available background information besides a reference number to the EDIP database (Wenzel et al., 1997) and it was not possible to find a reason for the low CO₂ emission compared to the other data presented. It is included here to show the problems with lack of background information.

Figure 5: CO₂-eq emissions from the primary and secondary production of glass. Numbers in names refer to sources in Table 1. “-”: No data found.

3.3 Plastics

Most data for the primary production of HDPE was found as granulate and resin but some datasets do not state the form/type of the material. The emissions from the production of the three types of PE (HDPE, LDPE and LLDPE) are on average similar for the primary production: 1.65-2.02 kg CO₂-eq/kg of materials (Figures 6-8). The differences between the primary and the secondary mean values for the HDPE, LDPE and PET were 81%, 78%, 84% respectively; suggesting that recycling is beneficial with respect to the emission of CO₂.

For HDPE, LDPE and LLDPE the IDEMAT database (source 15) gives lower emission. The dataset is very simple and only includes natural resources and emissions, but it was not possible to find the background information, since the background report is no longer available.

Data from the databases “Industry data 2.0”, “Ecoinvent” and “ELCD” are all based on data from Plastic Europe and the data from these three databases are equal (Figure 8).

The 21 dataset for primary PET showed emissions from 1.16-5.48 kg CO₂-eq/kg of material (Figure 9). In total 7 datasets for production of secondary PET gave emissions in the range 0.11-1.1 kg CO₂-eq/kg of material.

Data presented in Figure 10 for primary PP production were in the range of 1.14-4.44 kg CO₂-eq/kg of PP produced. No data were identified for secondary PP production. Two datasets from Source 20 represented the further processing of resin/granulate of PP to PP film and these gave higher CO₂ emissions than the other dataset due to higher energy consumption.

The PVC data showed emissions from 0.92-4.07 kg CO₂-eq/kg of material for primary production, with a mean of 2.41 kg CO₂-eq/kg of material (Figure 11). No secondary data were identified. The highest emission was from the ETH-ESU 96 ‘PVC high impact’ process. The ETH-ESU 96 database is no longer included as a Simapro database due to obsolescence, but it could still be used from earlier acquisitions. Data from Industry 2.0 (source 17) are provided to Simapro by Plastic Europe (source 20). Despite differences in the ages of the datasets, LCIs are similar.

The CO₂ emissions found in different databases, as presented in Figure 12, are within the range of 1.39-4.36 kg CO₂-eq/kg of plastic produced. Three datasets were found for the secondary production of PS with emissions of 0.85-1.90 kg CO₂-eq/kg of secondary PS.

Lower CO₂ emissions were reported for all types of plastics from the US LCI database (Source 23) compared to the European data from several sources. Data were set up in the US LCI database with ‘dummy’ processes, meaning that the user is expected to specify the energy mix that the processes use. The ‘dummy’ processes contained no data and represented, for example, 1 kWh. In the main dataset the process was called ‘Dummy_Electricity, at cogenerating unit, unspecified/US’, and the process used 0.22 kWh. Tools (e.g. Simapro) including US LCI data did not change the setup of the data, and the empty ‘dummy’ processes were therefore still included in the data, meaning that no emissions were attributed to electrical energy requirement. In addition, some transport processes were included in these datasets as empty ‘dummy’ processes. Therefore, the American data for plastics seem incomplete and they cannot be compared to other datasets. Data are shown here to provide an example of the types of errors that occur in databases.

Figure 6: CO₂-eq emissions from the primary and secondary production of high density polyethylene. Numbers in names refer to sources in Table 1. “-”: No data found.

Figure 12: CO₂-eq emissions from the primary and secondary production of polystyrene. Numbers in names refer to sources in Table 1. “-”: No data found.

3.4 Steel

World Steel reports a decrease of 50% in the energy consumption per tonne of crude steel produced in North America, Japan and Europe between 1975 and 2005 (World Steel Association, 2012). In the data presented in Figure 13, however, it was not possible to see such a trend over time. For primary steel production, 41 datasets were found and the variations were substantial (0.4-7.03 kg CO₂-eq/kg steel). The mean for primary steel was 2.21 kg CO₂-eq/kg of steel. Eleven datasets were found for secondary production, and these reported a range of 0.02-2.94 kg CO₂-eq/kg of steel with a mean of 1.3 kg CO₂-eq/kg of steel.

No documentation was found for the GEMIS processes from Czechoslovakia and China, which have high emissions compared to the other datasets presented for steel. Low emissions in the German data from GEMIS were due to the fact that these included only primary steel processing and not mining processes.

The 'Steel (sec)' process from IDEMAT represents emissions from the electro furnace production of 100% secondary steel. The emissions appear high compared to the 'Secondary EAF steel' from US EPA datasets. It was not possible to find adequate background information from IDEMAT for the data.

Figure 13: CO₂-eq emissions from the primary and secondary production of steel. Numbers in names refer to sources in Table 1. “-”: No data found.

3.5 Aluminum

The global average electrical energy used per tonne of primary aluminum decreased by 10 % from 1980 to 2005 (IEA, 2007; McMillan and Keoleian, 2009). Furthermore, the CO₂ emissions caused by the production of primary aluminum decreased by 0.2-37% except for African production (increase of 46%), where a change in energy production went from hydroelectricity to coal-fired production (McMillan and Keoleian, 2009). However, it was not possible to find LCI data to support these developments (Figure 14). For primary aluminum production, the numbers are equal for European data and American data, while differences between primary aluminum production and pri-

mary aluminum goods (sheets, foil and cans) are not significant. This could be due to high energy consumption during the production of intermediate material, whereas the manufacturing of the good is less energy-intensive. Mean emissions for primary aluminum were 13.8 kg CO₂-eq/kg with a range of 9.7-22.7 kg CO₂-eq/kg. For secondary aluminum, the mean was 2.2 kg CO₂-eq/kg with a range from 0.4-8.4 kg CO₂-eq/kg, thus documenting the significant advantage of recycling aluminum.

The process involved in producing aluminum is the same in all datasets taken from GEMIS (source 14), and only the energy source is different, depending on the country-specific mix. The dataset from Norway includes 99.5% hydropower, whereas the Australian dataset includes 77.6% coal, 12.6% gas, 1.3% oil and the remaining sources as hydropower and waste, which causes the large variations between GEMIS datasets.

Figure 14: CO₂-eq emissions from the primary and secondary production of aluminum. Numbers in names refer to sources in Table 1. “-”: No data found.

4 Discussion

Choosing inventory data for an LCA study is difficult, as it is not possible to evaluate data quality (e.g. on the basis of the pedigree matrix from Weidema and Wesnæs (1996)) and choose data when databases are not transparent and background information is scarce or not available. Some datasets appear to be equal, at least according to the name and short description, but the data are different. Large variations were shown for all materials in this study, as summarised in Figure 15.

The mean and standard deviations of the collected data are presented in Figure 15. From the means, it is clear that primary production produces higher emissions than secondary production, thus suggesting in a direct comparison that it is beneficial to recycle. Conversely, Figure 15 also shows the

highest and lowest values, which suggests that it is possible to combine datasets in a way that the recycling of materials does not appear beneficial. Choosing the right dataset for an LCA is therefore very important, since this choice can dramatically affect the results.

Figure 15: Highest and lowest values and mean values of all data found for each material and standard deviation. The grey colour highlights that aluminum has its own axis. No data were found for secondary LLDPE, PP and PVC.

A crucial parameter in the datasets is the provision of energy used, especially electricity, since the per kWh contribution varies considerably based on the type of fuel. As presented in the material sections above, datasets from countries with a high renewable energy input into the national grid had a very low environmental impact (i.e. Norway with 99% renewable electricity, versus 91% coal in Poland (EEA, 2007)). If these datasets are to be used in other countries it is crucial that the user is aware of the importance of this anomaly and has the option to change the grid mix. A number of databases (e.g. GEMIS, Ecoinvent) provide country-specific datasets, where the grid mix is fitted to the country. However, for a number of the datasets, data were aggregated to a level where the user could not identify how large a share of the emissions was related to energy use.

The option to change the energy grid is also crucial if carrying out a consequential LCA. Here the marginal electricity source plays a key role, and the user needs to be able to ensure the use of representative data. For example, McMillan and Keoleian (2009) showed how aluminum production in Europe is a lot less CO₂-intensive in comparison to Asian production. McMillan and Keoleian (2009) also noted that the majority of growth in primary aluminum production was taking place in Asia, so avoided primary production should be based on Asian production data and not on European data. This could be done either by using Asian LCI data or by adopting the marginal energy carrier in these countries. In the latest version of Ecoinvent (v3) (2013), the database now directly offers users the option to use consequential LCIs with flexible energy grids.

The LCA practitioner assessing recycling systems may know the company receiving the materials in a specific case. This company can either recycle the material or export sorted quantities for recycling elsewhere. In the case of export, it is hard for the practitioner to know which data to use for the recycling process or for the substituted process. In many cases the secondary process is not known because secondary materials are traded worldwide, and most likely the substituted process is impossible to identify because the latter is a consequence of how the markets react when more products based on recovered material enter the global market. If data are available, combining different sets of data for secondary and primary production could give an indication of variations in the outcome of the overall material recycling, although it is difficult to judge how representative each combination is for a global market. As a minimum requirement, when primary and secondary manufacturing data are used in an LCA, it is essential to perform sensitivity analyses for exploring the impacts of data uncertainty (Clavreul et al., 2013).

ISO standards (ISO, 2006) describe how to prepare inventory data and how to make background information transparent. This study shows that the standard is seldom followed. Branch organisations, e.g. Plastic Europe, are preparing and publishing inventory data of good quality, which is possible because Plastic Europe has an interest in the quality of the data used in LCAs regarding their production. Data consensus on the subject of industrial production processes could provide good quality inventories and would certainly raise the quality of LCAs. The data should follow the ISO standard and include specified energy data and background information to make the data transparent. Finally, the data should be presented so that they may be disaggregated, for example so that alternate electricity grids can be used.

Providing LCI data in a database requires an awareness of maintenance, since data can become outdated as new technologies are introduced. Commercial databases have more resources available for updating datasets than their publicly available counterparts, and many datasets are available online for free, but these are often inadequate. Moreover, commercial databases may also include obsolete data if they are not maintained.

This study has described some of the challenges related to choosing data for LCA studies, but it is difficult to provide guidelines on which datasets to choose. The goal of this study was to highlight some of the challenges LCA modellers face as a result of large variations in available databases,

and as such it highlights the need for any LCA to carry out a thorough sensitivity assessment, in order to ensure a robust assessment (Clavreul et al., 2013).

Finally, the data in this paper for secondary production represent recyclable materials received at the remanufacturing facility. Material losses occur between deposition into a recycling container and arrival at a remanufacturing facility. Data should therefore not be used to describe anything about the effect of recycling, but be used in a proper context by taking the whole waste management system into account.

5 Summary and conclusions

Inventory data used for LCAs vary in transparency, depending on energy systems and the quality of background information. Therefore, it is difficult for the LCA practitioner to choose the right datasets. A total of 366 datasets were included in this study, in order to gain an overview of the challenges confronting practitioners. The data collected represented 270 datasets for the primary production and 96 datasets for the secondary production of 14 materials. The materials assessed were copy paper, newsprint, cardboard and corrugated cardboard, plastics (HDPE, LDPE, LLDPE, PET, PP, PS and PVC), steel, glass and aluminum. The number of datasets for the recycling of materials was low, and for some materials critically low (e.g. some plastic types), while several datasets on the primary production of materials were present in existing databases. Large variations in CO₂ emissions were observed among datasets representing the same material production. Variations within a factor of 3 to 5 were not uncommon, which could dramatically affect the results of an LCA involving material recycling. Although energy savings have been reported for many industries, a decreasing trend over time in CO₂-emissions per kg of material in the LCI datasets was not identified.

An inherent problem exists in combining datasets for recycling processes and for substituted primary production processes. Often they are only linked through the market, and by choosing datasets representing specific plants or technologies, it is difficult to accurately represent which recycling processes receiving secondary materials trade on the market for recyclables and which primary processes in the market will produce less goods as more recycled products reach a market. Identifying such relations requires perfect and dynamic market information. Even with this information, though, it is not clear how to incorporate shifts in manufacturing location over time in traditional LCAs.

ISO standard 14044 provides clear guideline on how to prepare LCI data. If these guidelines were followed and the quality of the background information was more precise than it is today, it would be easier to choose the right LCIs regarding material recycling.

Plastic Europe provides data for both public and commercial databases by contributing European primary production averages. If more industry associations and branch organisations provided data and included proper background information following the ISO standard, inventory data would be of higher quality, and better inventory data and documentation would make it easier for LCA practitioners to perform LCAs of improved quality.
