21 **Abstract**

22 Sound waste management and optimisation of resource
23 recovery require reliable data on solid waste generation and
24 composition. In the absence of standardised and commonly
25 accepted waste characterization methodologies, various
26 approaches have been reported in literature. This limits both
27 comparability and applicability of the results. In this study, a
28 waste sampling and sorting methodology for efficient and
29 statistically robust characterisation of solid waste was
30 introduced. The methodology was applied to residual waste
31 collected from 1442 households distributed among 10
32 individual sub-areas in three Danish municipalities (both single
33 and multi-family house areas). In total 17 tonnes of waste were
34 sorted into 10-50 waste fractions, organised according to a
35 three-level (tiered approach) facilitating comparison of the
36 waste data between individual sub-areas with different
37 fractionation (waste from one municipality was sorted at "Level
38 III", e.g. detailed, while the two others were sorted only at
39 "Level I"). The results showed that residual household waste
40 mainly contained food waste ($42\pm 5\%$, mass per wet basis) and
41 miscellaneous combustibles ($18\pm 3\%$, mass per wet basis). The
42 residual household waste generation rate in the study areas was
43 3-4 kg per person per week. Statistical analyses revealed that
44 the waste composition was independent of variations in the
45 waste generation rate. Both, waste composition and waste

46 generation rates were statistically similar for each of the three
47 municipalities. While the waste generation rates were similar
48 for each of the two housing types (single-family and multi-
49 family house areas), the individual percentage composition of
50 food waste, paper, and glass was significantly different between
51 the housing types. This indicates that housing type is a critical
52 stratification parameter. Separating food leftovers from food
53 packaging during manual sorting of the sampled waste did not
54 have significant influence on the proportions of food waste and
55 packaging materials, indicating that this step may not be
56 required.

65 **1 Introduction**

66 Accurate and reliable data on waste composition are crucial
67 both for planning and environmental assessment of waste
68 management as well as for improvement of resource recovery
69 in society. To develop the waste system and improve
70 technologies, detailed data for the material characteristics of
71 the waste involved are needed. Characterization of waste
72 material composition typically consists of three phases: first
73 sampling of the waste itself, then sorting the waste into the
74 desired number of material fractions (e.g. paper, plastic,
75 organics, combustibles, etc.), and finally handling,
76 interpretation and application of the obtained data. The
77 sampling and sorting activities themselves are critical for
78 obtaining appropriate waste composition data. The absence of
79 international standards for solid waste characterization has led
80 to a variety of sampling and sorting approaches, making a
81 comparison of results between studies challenging (Dahlén and
82 Lagerkvist, 2008). Due to the high heterogeneity of solid
83 waste, the influence of local conditions (e.g. source-
84 segregation systems, local sorting guides, collection equipment
85 and systems), and the variability of sampling methodologies
86 generally limits the applicability of waste compositional data
87 in situations outside the original context.

88 The quality of waste composition data are highly affected
89 by the sampling procedure (Petersen et al., 2004). Solid waste

90 sampling may often involve direct sampling, either at the
91 source (e.g. household) (WRAP, 2009) or from a vehicle load
92 (Steel et al., 1999). Vehicle load sampling is often carried out
93 by sampling the waste received at waste transfer stations
94 (Wagland et al., 2012), waste treatment facilities, e.g. waste
95 incinerators (Petersen, 2005), and landfill sites (Sharma and
96 McBean, 2009; Chang and Davila, 2008). While logistic
97 efforts can be reduced by sampling at the point of unloading of
98 waste collection vehicles, a main drawback of this approach
99 may be that the sampled waste cannot be accurately attributed
100 to the geographical areas and/or household types generating
101 the waste (Dahlén et al., 2009). This limits the applicability of
102 the obtained composition data. On the other hand, collecting
103 waste directly from individual households and/or from a
104 specific area with a certain household type, allow the waste
105 data to be associated with the specific area (Dahlén et al.,
106 2009). Additionally, as most modern waste collection trucks
107 use a compaction mechanism (Nilsson, 2010), waste fractions
108 sampled from such vehicles have been affected by mechanical
109 stress and blending, which leads to considerable difficulties in
110 distinguishing individual material fractions during manual
111 sorting (European Commission, 2004). Owing to the
112 mechanical stress and the blending processes from collection
113 trucks, cross-contamination between individual fractions may
114 occur, leading to further inaccuracies that can neither be

115 measured nor corrected afterwards.

116 To ensure uniform coverage of the geographical area
117 under study, stratification sampling is often applied. This
118 involves dividing the study area into non-overlapping sub-
119 areas with similar characteristics (Dahlén and Lagerkvist,
120 2008; Sharma and McBean, 2007; European Commission,
121 2004).

122 In order to reduce the volume (amount) of waste to be
123 sorted, the waste sampled from each sub-area is usually coned
124 and quartered before sorting into individual waste material
125 fractions (Choi et al., 2008; Martinho et al., 2008). Although
126 this reduces labour intensity, the approach has shown to
127 generate poorly representative samples (Gerlach et al., 2002).
128 Because of the heterogeneity of residual household waste
129 (RHW), the material in a waste pile (or cone) is unevenly
130 distributed (Klee, 1993). Instead, sampling from elongated flat
131 piles and from falling streams at conveyor belts is
132 recommended to generate more representative samples (De la
133 Cruz and Barlaz, 2010, Petersen et al., 2005). While elongated
134 flat piles can be used on most waste materials, sampling from
135 falling streams at conveyor belts may potentially induce
136 additional mechanical stress if not appropriately applied.
137 However, only few studies have applied these mass reduction
138 principles for solid waste sampling prior to the manual sorting
139 in fractions. The waste sampled from a specific sub-area could

140 also be split into a desired or calculated number of sub-samples
141 (European Commission, 2004, Nordtest, 1995). This method
142 can provide mean and standard deviation for each waste
143 fraction, and may be argued as cost-effective (Sharma and
144 McBean, 2007). However, the main drawback is the splitting,
145 which can introduce a bias. Additionally, the obtained standard
146 deviations are highly associated with the number of samples
147 and the size (mass or volume) of the samples, which vary
148 considerably across literature (Dahlén and Lagerkvist, 2008).
149 In order to avoid any bias from mass reduction , sorting all the
150 collected waste from an individual sub-area would be
151 necessary (Petersen et al., 2004).

152 In addition to the influence from waste sampling, also the
153 subsequent sorting procedures can influence the results for
154 household waste composition. The overall material fraction
155 composition is directly related to the sorting principles applied
156 for dividing waste materials into individual fractions, e.g. to
157 which extent is food packaging and food materials separated,
158 how are composite materials handled, and how detailed
159 material fractions are included in the study? The influence of
160 food waste sorting procedures has been investigated by
161 Lebersorger and Schneider (2011). While the influence of food
162 packaging on food waste in this particular case was shown to
163 be insignificant, the influence of food packaging on other
164 material fractions in the waste (e.g. packaging material) has

165 not been examined.

166 Inconsistencies among existing solid waste
167 characterisation studies, e.g. definitions of waste fractions,
168 may cause confusion and limit comparability of waste
169 composition data between studies (Dahlén and Lagerkvist,
170 2008). While Riber et al. (2009) published a detailed waste
171 composition for household waste, including 48 waste material
172 fractions, more transparent and flexible nomenclature for the
173 individual waste material fractions is needed to allow full
174 comparability between studies with varying numbers of
175 material fractions and sorting objectives. Such classification
176 principles exist, but only for certain waste types and often
177 developed for other purposes: e.g. classification of plastics
178 based on resin type (Avella et al., 2001), the European Union's
179 directive on Waste Electrical and Electronic Equipment
180 (WEEE) (European Commission, 2003) and grouping of
181 Household Hazardous Waste (HHW) (Slack et al., 2004).

182 The overall aim of the paper was to provide a consistent
183 framework for municipal solid waste characterisation activities
184 and thereby support the establishment of transparent waste
185 composition datasets. The specific objectives were to: i)
186 introduce a waste sampling and sorting methodology involving
187 a tiered list of waste fractions (e.g. a sequential subdivision of
188 fractions at three levels), ii) apply this methodology in a
189 concrete sampling campaign characterising RHW from 10

190 individual sub-areas located in three different municipalities,
191 iii) evaluate the methodology based on statistical analysis of
192 the obtained waste datasets for the 10 sub-areas, focusing on
193 the influence of stratification criteria and sorting procedures
194 (e.g. the influence of sorting of food waste packaging on other
195 packaging materials), and iv) identify potential trends among
196 sub-areas in source-segregation efficiencies.

197 **2 Materials and methods**

198 **2.1 Definitions**

199 RHW refers to the remaining mixed waste after source
200 segregation of recyclables and other materials, such as HHW,
201 WEEE, gardening and bulky waste. Bulky waste refers to
202 waste such as furniture, refrigerators, television sets, and
203 household machines (Christensen et al., 2010). Source-
204 segregated material fractions found in the residual household
205 waste are considered as miss-sorted waste fractions. Housing
206 type consists of single-family and multi-family house. Here
207 single-family house corresponds to households with their own
208 residual waste bin, while multi-family house corresponds to
209 households sharing residual waste bins, e.g. common
210 containers in apartment buildings. Food packaging is
211 packaging containing food remains or scraps. "Packed food"
212 waste represents food items inside packaging while "unpacked
213 food" waste is food discarded without packaging. Within this
214 paper, the terms "fraction" and "component" was used

interchangeably. The data are presented as mean and standard deviation (Mean $\pm$ SD) unless otherwise indicated.

2.2 Study area

The sampling campaign covered residual waste collected from households in three Danish municipalities: Aabenraa, Haderslev and Sønderborg. These municipalities have the same waste management system including the same source segregation scheme. They introduced a waste sorting system using a two-compartment wheeled waste bin for separate collection of recyclable materials from single-family house areas (Dansk Affald, 2013). One compartment was used for collection of mixed metal, plastic, and glass; the other compartment for mixed paper, board, and plastic foil. However, in multi-family house areas, a Molok system and joint full service collection points (joint wheeled container) were used for the collection of RHW and source-sorted materials for recyclables. The waste bins had volumes between 60 to 360 litres in the single-family house area and between 400 to 1000 litres in the multi-family house area.

Collection frequencies for the residual waste were every two weeks in single-family house areas and every week in multi-family house areas. Garden waste, HHW, WEEE and bulky waste from single and multi-family house areas could be disposed of, either at recycling stations or collected from the premises on demand. However, food waste was not separately

240 collected and was disposed of in the RHW bin. This study
241 focused not on the source-segregated materials (bulky waste,
242 garden waste, and other source-segregated materials), but rather
243 on the characterisation of the residual waste consisting of a
244 mixed range of materials of high heterogeneity.

245 **2.3 Waste sampling procedure**

246 The three municipalities were subdivided into sub-areas
247 distinguished by housing type. RHW was sampled directly
248 from households in each of the 10 sub-areas; three sub-areas
249 were from Aabenraa, three from Sønderborg, and four from
250 Haderslev. As such, the sampling campaign focused on the
251 overall waste generation from the individual sub-areas and the
252 associated housing types, rather than the specific waste
253 generated in each household.

254 To avoid changes of the normal waste collection
255 patterns within the areas (see section 2.2) potentially leading to
256 changes in household waste disposal behaviour, the waste was
257 collected following the existing residual waste collection
258 schedules.

259 A single RHW collection route was selected in each
260 sub-area by the municipal authorities responsible for the solid
261 waste management. The distribution of households along the
262 selected routes was representative for each sub-area with
263 respect to the volume of RHW bins and the size of the
264 households. The number of selected households in each sub-

265 area was between 100 and 200, as recommended by Nordtest
266 (1995).

267 Based on these conditions (households samples
268 representativeness and number of households), the number of
269 selected households were computed and reported in Table 1,
270 which also shows the amount of waste collected and sorted
271 from each sub-area. In total, 426 households in Aabenraa, 389
272 households in Sønderborg and 627 households in Haderslev
273 were selected. Overall, 779 households were distributed in four
274 multi-family house areas, and 663 households in six single-
275 family house areas.

276 In total, six tonnes of waste was collected and sorted
277 from multi-family house areas and 11 tonnes from single-
278 family house areas (overall 17 tonnes). The waste was sampled
279 during spring 2013. Any effects from seasonal variations on
280 waste composition and generation rates were not investigated
281 in the study.

282 *Table 1 about here*

283 **2.4 Sorting procedure**

284 In order to avoid errors from waste splitting, the entire waste
285 sampled from each sub-area was sorted as a “batch” and the
286 waste from the 10 sub-areas was treated each as a “single
287 sample”, resulting in 10 individual samples from the three
288 municipalities. This means that as a result of the sorting
289 campaign, waste data (waste composition and waste generation)

290 for 10 individual sub-areas were obtained.

291 For this reason, the waste was collected separately from
292 each sub-area without compacting (e.g. the waste was not
293 collected by a compaction vehicle). The waste was then
294 transported to a sorting facility, where it was unloaded on a
295 tarpaulin, and filled in paper sacks for weighing and temporary
296 storage. The paper sacks were labelled with ID numbers. Each
297 paper sack was weighed to obtain the “dry mass” before filling
298 in the waste. Thereafter, the filled paper sacks were weighed
299 before and after all sorting activities to quantify mass losses
300 during sorting and storage. The mass loss was calculated as the
301 difference in net mass of waste before and after a process. The
302 errors due to contamination during sorting process and storage,
303 e.g. the migration of moisture from food waste to other
304 components (paper, board, plastic, etc.) and paper sacks, and
305 evaporation was negligible (see Supplementary material D for
306 mass losses). The average mass loss was 1.7%, and thus below
307 3% (Lebersorger and Schneider, 2011). No adjustments of the
308 waste data from errors due to mass losses were applied in this
309 study.

310 Figure 1 illustrates the waste sorting procedure and the steps
311 applied. A tiered approach for material fraction sorting was
312 developed as illustrated by Levels I to III in Table 2, to allow
313 comparison between datasets with different needs for sorting
314 and data aggregation. For example, one study may focus on

315 detailed fractionation of food waste (e.g. addressing avoidable
316 and non-avoidable food), while another study may only wish to
317 characterize food waste by a few overall fractions (e.g.
318 vegetable and animal derived food waste). Categorizing the
319 fractions in levels (e.g. Levels I to III) would thereby still allow
320 comparison between such two studies, at an overall level. In the
321 context of the sub-areas, all collected waste from each sub-area
322 was sorted separately. This was done according to Level I in
323 Table 2, corresponding to 10 material fractions. To provide
324 further details, waste from one municipality (Aabenraa) was
325 selected for more detailed sorting according to Level II & III.
326 The waste from Haderslev and Sønderborg was sorted only at
327 Level I. As such, the datasets from these three municipalities
328 represent examples of sorting campaigns carried out at different
329 levels of complexity; nevertheless, the tiered approach allows
330 comparison between the datasets at Level I.

331 Food packaging containing remaining food was
332 separated as an extra fraction and subsequently sorted
333 separately into the individual material fractions as shown in
334 Table 2. Food waste including beverage was easily removed
335 from the packaging. However, in some cases tools were used
336 e.g. to open containers, or packaging was compressed as much
337 as possible to remove food waste e.g. from tube packaging.

338 All waste fractions from Aabenraa, including food
339 packaging containing remaining food leftovers were

340 subsequently sorted according to the three levels in Table 2
341 (Level I, II and III). For instance, plastic waste was sorted by
342 reading the resin identification label on the plastic. Unspecified
343 plastic represented plastic where no resin identification label
344 was present. Metal fractions were sorted into ferrous and non-
345 ferrous using a magnet. As the contents of "special waste"
346 including WEEE and HHW were very low, this fraction was
347 sorted only to Level II.

348 The waste sampled from each sub-area was sorted
349 under the same conditions, by a professional team, within a
350 week from the sampling day. This sorting time may minimize
351 any physical changes of the samples as recommended by
352 European Commission (2004).

353 *Figure 1 about here*

354 **2.5 Waste fraction nomenclature**

355 The waste fraction nomenclature was mainly adapted from
356 Riber et al. (2009) and other literature (Steel et al., 1999, Dixon
357 and Langer, 2006), and the Danish National Waste register
358 (Danish EPA, 2014). Naming conventions for the individual
359 material fractions may be affected by local traditions and may
360 be ambiguously defined. Special care was taken here to ensure
361 consistent naming of fractions and avoid potential misleading
362 names. The tiered fraction list is shown in Table 2 and consists
363 of 10 fractions at Level I, 36 fractions at Level II, and 56
364 fractions at Level III. This nomenclature allowed transparent

365 classification while still facilitating flexible grouping of waste
366 fractions and comparison between the individual areas. For
367 example, we used food waste and gardening waste instead of
368 organic waste, which by definition includes more than food
369 waste and gardening waste. Here, food waste comprises food
370 and beverage products that are intended for human
371 consumption, including edible material (e.g. fruit and
372 vegetables, and meat) and inedible material (e.g. bones from
373 meat, eggshells, and peels) (WRAP, 2009). Paper was divided
374 into advertisements, books & booklets, magazines & journals,
375 newspapers, office paper, phonebooks and miscellaneous paper.
376 Miscellaneous paper was then further subdivided into
377 envelopes, kraft paper, other paper, receipts, self-adhesives,
378 tissue paper, and wrapping paper. Plastic waste was subdivided
379 according to resin type (PET, HDPE, PVC, LDPE, PP, PS,
380 Other resins) (Avella et al., 2001) and unidentified plastic
381 resins for plastic with no resin identification. Special waste was
382 categorised as batteries (single batteries and non-device specific
383 batteries), WEEE and HHW. WEEE and HHW were further
384 split into components defined by the EU directive on WEEE
385 and HHW.

386 *Table 2 about here*

387 **2.6 Statistical analysis**

388 The waste generation rate (WGR) and composition of the
389 residual waste were analysed by the Kruskal-Wallis test and

390 the permutation test (Johnson, 2005) to identify significant
391 differences among the three municipalities and between the
392 two housing types. Furthermore, the Kolmogorov-Smirnov test
393 (Johnson, 2005) was applied to identify cases when the
394 proportion of at least one fraction in the overall composition
395 was significantly different between housing types or among
396 municipalities. Based on Spearman's correlation test (Johnson,
397 2005) a correlation matrix between the WGR and percentages
398 of individual waste fractions was determined (Crawley, 2007).
399 Correlations between the WGR and individual waste fractions
400 were used to determine whether variations in WGR also
401 influenced the waste composition, while correlations between
402 waste fractions were used to identify potential trends in the
403 households' efficiency in source segregating of recyclables
404 (e.g. based on leftover recyclables in the residual waste). The
405 test of the correlation for significance addressed whether the
406 correlation's coefficients were statistically significant or
407 significantly different from zero (Crawley, 2007).

408 Waste composition data were reported and discussed
409 based on the relative distribution of fractions in percentages of
410 wet mass (as opposed to the quantity of wet mass of individual
411 waste fraction) to ensure scale invariance and enable
412 comparison of waste composition from different areas
413 (Buccianti and Pawlowsky-Glahn, 2011). Additionally,
414 percentage composition data remove the effects from WGR

415 (since in the study area, the WGR varies according to sub-
416 areas), which could otherwise lead to "false" correlations
417 (Egozcue and Pawlowsky-Glahn, 2011). This approach allows
418 comparison of different waste composition data. However,
419 waste composition data in percentages are "closed datasets"
420 because the proportions of individual fractions are positive and
421 add up to a constant of 100 (Filzmoser and Hron, 2008). As
422 such, these data require special treatment or transformation
423 prior to statistical analyses (Aitchison, 1994; Filzmoser and
424 Hron, 2008; Reimann et al., 2008). Here, log-transformation
425 was applied since "the log-transformation is in the majority of
426 cases advantageous for analysis of environmental data, which
427 are characterised by the existence of data outliers and most
428 often right-skewed data distribution" (Reimann et al., 2008).

429 Data analysis was carried out with the statistical
430 software R. Data for three municipalities (Sønderborg,
431 Haderslev, and Aabenraa), two housing types (single and
432 multi-family), and two sorting procedures (with and without
433 including food packaging in the food waste component) were
434 investigated. The influence of including food packaging in the
435 food waste fraction was modelled by comparing two waste
436 composition datasets: 1) data from the sorting campaign where
437 food packaging was separated from food waste and added to
438 the relevant material fraction, and 2) a "calculated" dataset
439 where the mass of food packaging was added to the food waste

440 fraction.

441 Based on the compositional data and the WGR
442 obtained for each sub-area, aggregated waste compositions
443 (corresponding to Level I) were computed for each
444 municipality and each housing type. These waste compositions
445 accounted for the relative distribution of housing types and
446 number of households among sub-areas (Statistics Denmark,
447 2013).

448 **3 Results and discussion**

449 **3.1 Comparison with previous Danish composition** 450 **data**

451 The detailed composition of the RHW from Aabenraa is shown
452 in Table 3 for Level I & II and in Table 4 mainly for Level III.
453 Food waste (41-45%) was dominating the waste composition,
454 and it consisted of vegetable food waste (31-37%) and animal-
455 derived food waste (8-10%). Plastic film (7-10%) and human
456 hygiene waste (7-11%) were also important RHW fractions.
457 The proportion of miss-sorted material fractions was estimated
458 to be 26% of the total RHW, of which 20 to 22% were
459 recyclable material fractions (see Table 3). These results were
460 comparable with those found in a previous Danish study, which
461 found values of 41% food waste, 31% vegetable food waste
462 and 10% animal-derived food waste (Riber et al., 2009).
463 Although, the households in the previous study did not source
464 segregate board, metal and plastic, the percentages of board
465 (7%), plastic (9%), metal (3%) glass (3%), inert (4%) and

special waste (1%) were also similar in the two studies. The main differences between these studies were related to the detailed composition of paper and combustible waste. Despite the fact that paper (advertisement, books, magazines and journals, newspapers, office paper and phonebooks) was source-segregated in both studies, in our study paper contributed with 7-9% of the total waste (4% was tissue paper, see Table 4), while Riber et al. (2009) reported a paper content of 16% (mainly advertisement, newsprints and magazines). Although variations in source-segregation schemes may potentially explain these differences, other factors such as sorting guides, income levels, demographics and developments in general consumption patterns may also affect data.

Table 3 about here

3.2 Comparison between municipalities

RHW compositions for the Level I fractions for each sub-area are shown in Figure 2. For all three areas, food and miscellaneous combustible waste were the largest components of the RHW. Paper, board and plastic constituted individually between 5 and 15% of the total RHW. The proportion of special waste was less than 1% and was the smallest fraction of the total RHW.

The waste generation rates for RHW were expressed in kg per person per week and estimated at 3.4 ± 0.2 in Aabenraa, 3.5 ± 0.2 in Haderslev, and 3.5 ± 1.4 in Sønderborg. Waste

491 composition between municipalities showed minor differences.
492 The highest percentage of food ($44\pm3\%$) and plastic ($15\pm1\%$),
493 and the lowest percentage of miscellaneous combustible waste
494 ($15\pm4\%$) were found in Sønderborg. The highest miscellaneous
495 combustible waste ($19\pm4\%$) was in Haderslev, while the
496 highest inert ($4\pm4\%$) was in Aabenraa.

497 The composition and the WGRs for each municipality
498 are compared in Table 5 based on the Kruskal-Wallis test. No
499 examples of significant differences in either WGR or waste
500 composition could be observed for the three municipalities.
501 This may indicate that in areas with identical source-
502 segregation systems and similar sorting guides for households,
503 data for individual sub-areas (municipalities) may statistically
504 represent the sub-areas. While this conclusion is only relevant
505 for the specific material composition (Level I) and the socio-
506 economic and geographical context, the results also suggest
507 that the composition data may be applicable to other similar
508 areas (e.g. similar housing types, geography, etc.) in Denmark.
509 In contrast to this, a review of waste composition analyses in
510 Poland (Boer et al., 2010) showed high variability in waste
511 composition and WGR between individual cities. According to
512 Boer et al., 2010, these differences could be attributed to
513 different waste characterisation methods used in each city, and
514 to differences in waste management systems between these
515 cities. Therefore, a consistent waste characterisation

516 methodology was recommended to facilitate any comparison of
517 solid waste composition among these cities.

518 Table 6 provides an overview of waste compositions
519 corresponding to Level I for a range of studies in literature.
520 Most of these studies found that food waste was the
521 predominant RHW fraction, although the percentage of food
522 waste varied considerably among studies. For instance, food
523 waste accounted for 19% of the total RHW in Canada (Sharma
524 and McBean, 2007), 25% in Wales (Burnley et al., 2007), 30%
525 in Sweden (Bernstad et al., 2012) and 56 % in Spain (Montejo
526 et al., 2011). On the other hand, RHW contained only 12 % of
527 food waste after paper (33%) and wood (24%) in South Korea
528 (Choi et al., 2008). Similarly, in Italy food waste was only 12 %
529 of RHW, which was predominantly made of paper (39%) and
530 plastic (27%) (AMSA, 2008). These differences may be related
531 to: i) socio-economic and geographical factors (consumption
532 patterns, income, climate,) (Khan and Burney, 1989), ii) waste
533 management system (source-segregation, waste collection
534 systems), iii) local regulation (Johnstone, 2004), and iv) waste
535 characterisation methodology (type of waste characterised,
536 terminology as well as waste sampling and characterisation
537 methodologies) (Beigl et al., 2008). The comparison between
538 composition data clearly illustrate the difficulties related to
539 comparison and applicability of aggregated data.

540 *Table 4 about here*

541 **3.3 Correlations between waste generation rates and**
542 **waste fractions**

543 The correlation test identified significant relationships between
544 WGR and composition of RHW as well as among the
545 proportion of individual waste fractions. The correlation test
546 among the proportion of individual waste fractions was carried
547 out to evaluate whether available free space in the RHW bin
548 could influence source-segregation behaviour of the
549 households. The resulting Spearman correlation matrix is
550 shown in Table 7, where both correlation coefficients and their
551 significance levels are provided.

552 From Table 7, WGR appeared to be negatively
553 correlated with food, gardening waste, plastic, metal and inert
554 waste fractions, and positively correlated with miscellaneous
555 combustibles, board, glass and special waste. However, none of
556 these correlations were statistically significant. This indicated
557 that the percentages of individual waste fractions varied
558 independently of the overall WGR within the study areas. It
559 also suggested that distribution of waste fractions in the RHW
560 might not be estimated based on variations of the overall waste
561 generation rate.

562 The proportion of glass was negatively and highly
563 significantly correlated with the proportion of food waste ($r=-$
564 0.81). Likewise, a high negative correlation between
565 miscellaneous combustible waste and gardening waste was

566 observed ($r=-0.82$). This suggests that when proportions of
567 food waste and miscellaneous combustible waste decreases, the
568 proportions of gardening and glass waste (potentially miss-
569 sorted recyclable glass) increase correspondingly. These results
570 suggest that sorting of glass and gardening waste could be
571 affected by the amounts of food waste and other miscellaneous
572 waste generated by the household.

573 **3.4 Influence of housing type on composition**

574 The weighted composition and WGR for each housing type are
575 presented in Table 8 together with the associated probability
576 values (p -values <0.05 indicate significant difference). RHW
577 from single-family house areas contained significantly higher
578 fractions of food waste than multi-family house areas. On the
579 other hand, RHW from multi-family house areas contained a
580 higher share of paper and glass waste than single-family house
581 areas. However, the p -value ($p=0.123$) of the Kolmogorov-
582 Smirnov test for the overall difference in waste composition
583 was not significant.

584 In Austria, Lebersorger and Schneider (2011) found a
585 statistically significant difference between housing types;
586 however, RHW from multi-family house areas had significantly
587 higher percentage of food waste than RHW from single-family
588 house areas. In Poland for example, Boer et al. (2010) showed
589 that the overall household waste composition depended on the
590 type of housing, because of the differences in heating systems

591 of the households.

592 *Figure 2 about here*

593 *Table 5 about here*

594 **3.5 Influence of sorting practices on composition**

595 Food packaging comprised about 20% of “packed food”, 7% of
596 the total food waste and nearly 3% of the total RHW as shown
597 in Figure 3a. Total food waste consisted of 66% of “unpacked
598 food” waste (30% of the total RHW), 27% of “packed food”
599 waste (12% of the total RHW) and 7% of food packaging.

600 *Table 6 about here*

601 The composition of food packaging is shown in Figure
602 3b. Food packaging consisted of plastic (50%), paper and board
603 (25%), metal (10%) and glass (13%). These results were
604 comparable to literature data reporting food packaging to
605 represent about 8% of avoidable food waste (Lebersorger and
606 Schneider, 2011), and food packaging consisting of 40% of
607 plastic, 25% of paper, 22% of glass and 13% of metal
608 (Dennison et al., 1996).

609 *Figure 3 about here*

610 Table 9 presents the composition of RHW based on
611 waste sorting and the probability values from the permutation
612 test. For this case study, no statistically significant effect on the
613 percentage of food waste and the overall RHW composition

614 could be observed from sorting practices for food waste (e.g.
615 whether or not packaging was included in the food fraction).
616 This may be explained by the fact that the food packagings
617 were predominantly made of plastic only contributing with low
618 mass compared to the food waste and other fractions.
619 Consistently, Lebersorger and Schneider (2011) found that the
620 “packed food” waste had a relative high mass compared to its
621 packagings.

622 *Table 7 about here*

623 *Table 8 about here*

624 **3.6 Implications for waste characterisation and** 625 **applicability of composition data**

626 The tiered approach for fractionation of solid waste samples
627 offered sufficient flexibility to organise waste composition
628 data, both at an overall level (e.g. Level I for comparison
629 between municipalities) but also to report more detailed data
630 (for Aabenraa at Level III). The suggested waste fraction list
631 accounted for current European legislation governing the
632 classification of WEEE and HHW, and key characteristics for
633 plastic and metal waste. This type of categorisation enables, to
634 a certain extent, comparison among future and existing studies,
635 and among studies with different focus and need for details.
636 This may potentially increase the applicability of the obtained
637 waste composition data.

638

Table 9 about here

639 High data quality is facilitated since the methodology
640 follows appropriate sampling procedures proposed by Dahmén
641 and Lagerkvist (2008) to minimize sampling errors as described
642 by Pitard (1993): i) heterogeneity fluctuation errors were
643 addressed by stratification, ii) fundamental sampling errors due
644 to the heterogeneity of RHW were reduced by sampling at
645 household level from a recommended sample size (100-200
646 households) to obtain representative results (Nordtest, 2005);
647 iii) grouping and segregation errors, and increment delimitation
648 errors were reduced by avoiding sample splitting and instead
649 sorting the entire waste quantity sampled; and iv) increment
650 extraction errors due to contamination and losses of waste
651 materials were minimized by avoiding compacting the sampled
652 waste during transportation, and sieving before sorting.

653 The case study showed that detailed waste composition
654 of any miss-placed WEEE and HHW required larger sample
655 sizes than was included here (or alternatively that the
656 household source segregation of these waste types was
657 sufficiently efficient to allow only small amounts in the RHW).
658 As both WEEE and HHW should be collected separately, this
659 observation only refers to miss-placed items in the RHW.
660 General characterization of WEEE and HHW should be carried
661 out based on samples specifically from these flows (this was
662 however outside the scope of the study). The manual sorting of

663 plastic waste into resin type was time consuming as resin
664 identification was needed for each individual plastic item;
665 however, the detailed compositional data provided by this
666 effort offer considerably more information than simple
667 categories such as "recyclable plastic" or "clean plastic". This
668 information is indispensable for national or regional waste
669 statistics as basis for estimating the potential of recycling of
670 postconsumer plastics and environmental sound management of
671 non-recyclable plastics. Furthermore, the plastic
672 characterisation based on resin type is needed as input for
673 detailed life cycle assessment and material flow analyses of
674 plastic waste management.

675 Separation of food packaging from food leftovers,
676 however, was found unnecessary because this division into sub-
677 fractions did not significantly influence the waste composition;
678 this clearly reduces time invested in the sorting campaign, but
679 also improves the hygienic conditions during the sorting
680 process. As the statistical analyses indicated no statistical
681 difference in waste composition between municipalities, waste
682 composition data obtained from one municipality could be
683 applied to other municipalities in the study area (provided the
684 municipalities share source-segregation schemes). This may be
685 used as a basis for reducing the sampling area (and thereby
686 overall waste quantities) in a sampling campaign. However, the
687 statistical differences observed between housing types in

688 relation to food, paper and glass waste indicated that
689 representative sampling of RHW should account for variations
690 in housing types between areas.

691 The correlation test showed no statistically significant
692 relationship between the percentage of individual waste
693 fractions and the generation rate of RHW. This indicates that
694 for a specific area (with consistent socio-economic and
695 geographical conditions), waste composition data could be
696 extrapolated and scaled up to the entire municipality or down to
697 individual town-level, regardless of the waste generation rate.
698 The correlation analysis among proportions of individual waste
699 fractions showed that the percentages of miss-sorted glass and
700 gardening waste increases when the proportion of food waste
701 (glass) and miscellaneous waste (gardening waste) decrease.
702 Moreover, when the proportion of miss-sorted glass increases,
703 the proportions of miss-sorted board and metal also increase.

704 **4 Conclusions**

705 The study introduced a tiered approach to waste sorting
706 campaigns involving three levels of waste fractions. This
707 allowed comparison of waste datasets at different level of
708 complexity, e.g. involving different numbers of material
709 fractions. This tiered fraction list was applied on a case study
710 involving residual household waste (RHW) from 10 sub-areas
711 within three municipalities. Sub-areas in two municipalities
712 were sorted only at the first level (overall waste fractions),

713 while waste from one municipality was sorted to the third level
714 (e.g. two sub-levels below the overall waste fractions). The
715 obtained waste data (generation rates and composition) for the
716 individual sub-areas were compared for identification of
717 significant differences between the areas. Based on the
718 statistical analysis, it was found that while overall waste
719 composition and generation rates were not significantly
720 different between the three municipalities, the waste
721 composition from single-family and multi-family houses were
722 different. This indicates that while waste composition data may
723 be transferred from one municipality to another (provided the
724 source-segregation schemes are sufficiently similar),
725 differences in housing types cannot be ignored. As opposed to a
726 more "linear" waste fraction catalogue, the three-level fraction
727 list applied in this study allowed a systematic comparison
728 across the datasets of different complexity.

729 The results of the sorting analysis indicated that food packaging
730 did not significantly influence the overall composition of the
731 waste as well as the proportions of food waste, plastics, board,
732 glass and metal. Specific separation of food packaging from
733 food leftovers during sorting was therefore not critical for
734 determination of the waste composition.

735

736 **Acknowledgments**

737 The authors acknowledge the Danish Strategic Research
738 Council for financing this study via the IRMAR project. The
739 municipalities of Aabenraa, Haderslev, and Sønderborg are also
740 acknowledged for partly supporting the waste sampling
741 campaign.

742

743 **Supplementary material**

744 Supplementary material contains background information about
745 the data used for calculations and detailed data from the waste
746 characterisation campaign.

Table 2: The waste fractions list showing three different levels (Level I, Level II, and Level III)

Level I	Level II	Level III
1-Food waste	1.1 Vegetable food waste; 1.2 Animal-derived food waste	-
2-Gardening waste	2.1 Dead animal and animal excrements (excluding cat litter); 2.2 Garden waste	2.1.1 Dead animals; 2.1.2 Animal excrement bags from animal excrement 2.2.1 Humid soil; 2.2.2 Plant material; 2.2.3 Woody plant material; 2.2.4 Animal straw.
3-Paper	3.1 Advertisements; 3.2 Books & booklets; 3.3 Magazines & Journals; 3.4 Newspapers; 3.5 Office paper; 3.6 Phonebooks; 3.7 Miscellaneous paper.	3.7.1 Envelopes; 3.7.2 Kraft paper; 3.7.3 Other paper; 3.7.4 Receipts; 3.7.5 Self-Adhesives; 3.7.6 Tissue paper; 3.7.7 Wrapping paper
4-Board	4.1 Corrugated boxes; 4.2 Folding boxes; 4.3 Cartons/plates/cups; 4.4 Miscellaneous board.	4.4.1 Beverage cartons; 4.4.2 Paper plates & cups; 4.4.3 Cards & labels; 4.4.4 Egg boxes & alike; 4.4.5 Other board; 4.4.6 Tubes.
5-Plastic	5.1 Packaging plastic; 5.2 Non-packaging plastic; 5.3 Plastic film.	5.i.1 PET/PETE ^a ; 5.i.2 HDPE ^b ; 5.i.3 PVC/V ^c ; 5.i.4 LDPE/LLDPE ^d ; 5.i.5 PP ^e ; 5.i.6 PS ^f ; 5.i.7 Other plastic resins labelled with[1-19] ABS ^g ; 5.i.8 Unidentified plastic resin; 5.3.1 Pure plastic film; 5.3.2 Composite plastic + metal coating.
6-Metal	6.1 Metal packaging containers; 6.2 Non-packaging metals; 6.3 Aluminium wrapping foil	6.i.1 Ferrous; 6.i.2 Non-ferrous (with i=1&2).
7-Glass	7.1 Packaging container glass; 7.2 Table and kitchen ware glass; 7.3 Other/special glass.	7.i.1 Clear; 7.i.2 Brown; 7.i.3 Green.
8-Miscellaneous combustibles	8.1 Composites, human hygiene waste (Diapers, tampons, condoms, etc.); 8.2 textiles, leather and rubber; 8.3 Vacuum cleaner bags; 8.4 Untreated wood; 8.5 Other combustible waste.	8.1.1 Diapers; 8.1.2 Tampons; 8.1.1 Condoms; 8.2.1 Textiles; 8.2.2 Leather; 8.2.3 Rubber;
9-Inert	9.1 Ashes from households; 9.2 Cat litter; 9.3 Ceramics, gravel; 9.4 Stones and sand; 9.5 Household constructions & demolition waste.	-
10-Special waste	10.1 Single Batteries/ non-device specific Batteries; 10.2 WEEE; 10.3 Other household hazardous waste.	10.3.1 Large household appliances; 10.3.2 Small household appliances; 10.3.3 IT and telecommunication equipment; 10.3.4 Consumer equipment and photovoltaic panels; 10.3.5 Lighting equipment; 10.3.6 Electrical and electronic tool (no large-scale stationary tools), 10.3.7 Toys, leisure and sports equipment; 10.3.8 Medical devices (except implanted and infected products); 10.3.9 Monitoring and control instruments; 10.3.10 Automatic dispensers.

^a Polyethylene terephthalate; ^b density polyethylene; ^c Polyvinyl-chloride; ^d Low density polyethylene; ^e: Polypropylene; ^f: Polystyrene; ^g: Acrylonitrile/butadiene/styrene
Numbering of waste fractions: *n*- fractions included in Level I, *n.n* fractions included in Level II, *n.n.n* fractions included in Level III;

^a. Average persons per household; ^b. Miscellaneous combustible waste; ^c total waste sorted;

D: Summary of the mass loss during waste sorting process

Descriptive statistics	Loss(%)	W1(mass per wet basis in kg)	W2(mass per wet basis in kg)
N*	76	76	76
Mean	1.7	16.4	16.1
Median	1.3	12.5	12.3
10% Trimmed Mean	1.6	13.4	13.2
1st Quartile	0.8	10.3	10.1
3rd Quartile	2.3	17.4	17.1
Standard Deviation	1.1	16.9	16.6
Interquartile Range	1.5	7.1	7.0
Median Absolute Deviation	1.0	4.5	4.6

N*: number of paper sacks;

Loss (%) is mass loss during the waste sorting and storage processes;: $Loss = ((W1 - W2)/W1) * 100$, with W1=net wet mass of waste before sorting, W2: net wet mass of waste after sorting;

The average mass loss due to evaporation is 1.7%, which is below 3%.
