(Received 25 September 2015; revised 1 June 2016; accepted 8 June 2016; published online 13 July 2016)

This study proposes a binaural extension to the multi-resolution speech-based envelope power spectrum model (mr-sEPSM) [Jørgensen, Ewert, and Dau (2013), J. Acoust. Soc. Am. 134, 436–446]. It consists of a combination of better-ear (BE) and binaural unmasking processes, implemented as two monaural realizations of the mr-sEPSM combined with a short-term equalization-cancellation process, and uses the signal-to-noise ratio in the envelope domain (SNRenv) as the decision metric.

The model requires only two parameters to be fitted per speech material and does not require an explicit frequency weighting. The model was validated against three data sets from the literature, which covered the following effects: the number of maskers, the masker types [speech-shaped noise (SSN), speech-modulated SSN, babble, and reversed speech], the masker(s) azimuths, reverberation on the target and masker, and the interaural time difference of the target and masker. The Pearson correlation coefficient between the simulated speech reception thresholds and the data across all experiments was 0.91. A model version that considered only BE processing performed similarly (correlation coefficient of 0.86) to the complete model, suggesting that BE processing could be considered sufficient to predict intelligibility in most realistic conditions.

I. INTRODUCTION

Cherry (1953) coined the term “cocktail party problem” to describe the ability of listeners to “recognize what one person is saying when others are speaking at the same time.” It is known that this ability is typically improved if the listeners can use both of their ears, relative to either ear alone, and if the target and maskers are spatially separated. Various models have been designed to disentangle which part of this binaural advantage can be attributed to a selection process between left versus right ear (i.e., a “better-ear” process), a purely binaural process where the signals from both ears interact, or a combination of both. The models typically focused on a few aspects affecting speech intelligibility at a time, such as the spatial separation of the target and the maskers, the effects of reverberation on the target or on the maskers, the role of temporal fluctuations in the masker, and the effects of multiple interferers. None of the models can account for all of these aspects at once. In the current study, recent advances in monaural intelligibility predictions are combined with binaural modeling approaches in an attempt to provide a model that can account for all of the aforementioned aspects.

Binaural intelligibility models usually combine a monaural model with some form of binaural processing to capture binaural cues attributed to head shadows and binaural interactions (Bronkhorst and Plomp, 1988). When a masker is placed elsewhere than in front of the listener, the head casts an acoustical shadow on the side opposite to the source. If the target is placed towards the ear that is in the shadow, the target-to-interferer ratio (TIR) is improved for that ear, yielding a better ear (BE), which helps the listener understand the target. These level cues are denoted as interaural level differences (ILDs). Correspondingly, different source azimuths produce different interaural time differences (ITDs). Binaural interactions rely on the ITD between target and maskers to facilitate their segregation, denoted as “binaural unmasking” (BU). The equalization-cancellation (EC) theory (Durlach, 1963) suggests that binaural unmasking can be explained by the ability of the central auditory system to “cancel” the interferers, effectively maximizing the target-to-interferer ratio.

A. Models with independent processing of ILDs and ITDs

Binaural models that predict intelligibility in spatial conditions tend to consist of a combination of two components that realize the BE and the BU processes. For example, the model of Lavandier and Culling (2010) first evaluates the BE contributions by selecting the best long-term target-to-interferer ratio for each peripheral channel, using stationary speech-shaped noise (SSN) convolved with the binaural impulse responses between the listener and the sources as the target and masker “probe signals,” and combining them using the speech intelligibility index (SI) weights (ANSI, 1997). The BU path evaluates the binaural masking level difference (BMLD) in each channel using an equation based on the EC concept, which incorporates the ITDs of the target and masker, as well as the interaural coherence of the masker (Culling et al., 2005). The BMLD values are also combined...
using the SII weights, and then summed with the BE to yield the overall binaural advantage, relative to the colocated condition. Their model could account for conditions with an anechoic target and a noise masker placed at different distances and azimuths in three different rooms. However, because the model considers anechoic targets only, it cannot capture the effects of reverberation on the target itself because reverberation does not strongly affect the envelopes of the convolved SSN probe signals. Furthermore, it is limited to stationary maskers and thus cannot account for intelligibility changes due to amplitude modulations in the maskers because the model only considers the long-term properties of the signals.

This model of Lavandier and Culling (2010) was expanded to include head shadow and multiple stationary maskers in anechoic (Jelfs et al., 2011) and reverberant conditions (Lavandier et al., 2012). Those two model versions used binaural room impulse responses (BRIRs) directly to calculate the TIRs and BMLD values. Although those extended model implementations are computationally more efficient and have more predictive power than the previous one, they still have the same inherent limitations, i.e., they cannot account for any release from masking due to modulations in the maskers and cannot describe effects of temporal smearing of the target at low direct-to-reverberant ratios. Those are similar to the limitations of the SII, on which those models are based; the models would predict good intelligibility at infinite SNRs but low direct-to-reverberant ratios, which is in contrast to the reduced intelligibility observed in such conditions.

Collin and Lavandier (2013) proposed another extension of the original work of Lavandier and Culling (2010) to account for the effects of modulated interferers, whereby the BE and BU calculations are performed in short-time frames of 12 ms on the filtered signals, rather than directly on the BRIRs. The short-time frames are averaged over the duration of the signals, similar to the processing in the extended speech intelligibility index (ESID) (Rhebergen and Versfeld, 2005). Collin and Lavandier used an SSN target, rather than speech, because it was assumed that gaps in the speech would produce negative TIRs even though they carry information that should contribute positively to the intelligibility. Collin and Lavandier (2013) varied the masker distance as well as its modulation depth using either stationary SSN, 1-, 2-, or 4-talker modulated SSN. The model was demonstrated to qualitatively account for the correct trends in the data for different masker distances and modulation depths, although measured and simulated effects were small (from less than 1 dB to about 2 dB). However, while the short-time approach seemed successful when predicting intelligibility in modulated maskers, it would fail to account for the effects of reverberation on the speech because SSN is used instead of speech for the target signal.

B. Models combining the SII and the EC concept

In the binaural speech intelligibility model (BSIM) (Beutelmann et al., 2010), which is a revision and simplification of the original implementation (EC/SII; Beutelmann and Brand, 2006), the BU process is implemented as a frequency-independent equalization and cancellation (Durlach, 1963) of the long-term signals received at each ear. The SII is then used to evaluate the intelligibility based on the effective TIR in each frequency band. The reference SII value corresponding to the speech reception threshold (SRT) is selected only once for all conditions and is defined as the SII predicting 50% intelligibility for the monaural presentation of the Oldenburg Sentence Test in noise (Wagener et al., 1999). The BSIM could predict SRTs of normal-hearing (NH) listeners in conditions with colocated target and stationary SSN maskers, as well as with spatially separated target and maskers, in anechoic conditions and in three different rooms (a listening room, a classroom, and a church). Beutelmann et al. (2010) also extended the BSIM to account for fluctuating maskers by computing the SII after EC processing in short time windows with an effective length of 12 ms. The extension was named short-term BSIM (stBSIM). The stBSIM could account for the release from masking due to modulated maskers in anechoic conditions, but was less accurate when reverberation was introduced; the mean differences between predicted and observed SRTs varied between $-4.1$ and $-2.7$ dB. Furthermore, similar to the model of Lavandier and Culling (2010) and its extensions, the stBSIM cannot account for the effects of reverberation on the speech itself because it cannot separate the useful from the detrimental part of the speech.

Rennies et al. (2011) proposed several modifications of the long-term BSIM to better account for the deleterious effect of reverberation: (1) an extension based on the modulation transfer function, (2) a compensation factor based on the room “definition” (a room acoustical property), and (3) a separation of the speech signal based on the useful and detrimental parts. Extension (2) provided the best fit of the three models in anechoic and reverberant conditions with stationary maskers. Although the proposed modifications increased the predictive power of the model, they also reduced its generality because the model now required access to the room impulse response in addition to the speech and noise signals.

Wan et al. (2010) introduced an application of the EC model of Durlach (1963), which they later denoted as the steady-state EC model (SSEC). Their approach is similar to that of the BSIM (Beutelmann et al., 2010) but differs in a few important ways: the decision device based on the SII selects the best SNR from the left ear, the right ear, or from the cancelled pathway for each frequency channel, rather than from the cancelled pathway only; the EC process resolution is limited by applying frequency-independent and time-varying jitters in both amplitude and time to the output of each peripheral filter, instead of adding uncorrelated noise to each ear signal; a different SII criterion is selected for each combination of number of maskers, and type of maskers, rather than using a single SII criterion. The model was evaluated for different masker types, 1 to 3 simultaneous maskers, and different masker azimuth angles. Wan et al. (2010) showed that the model could predict SRTs of the oldenburg sentence test in noise correctly when the maskers were SSN or speech-modulated SSN, but failed when the maskers were speech or reversed speech.
Wan et al. (2014) proposed the short-time EC model (STEC) to extend the SSEC. In contrast to the SSEC, the equalization parameters of the EC process are calculated in overlapping 20 ms windows and can vary as a function of time, which improves cancellation of the dominant masker across time. The cancelled signal is then resynthesized from the short-time windows and the SNR is calculated from the long-term spectrum. This means that only the BU process is applied in a short-time fashion and not the BE process. The STEC predictions were more accurate in conditions with speech-modulated SSN; however, the agreement with the data was worse than with the SSEC for reversed-speech maskers. The STEC described the spatial release from masking occurring with speech maskers slightly better than the SSEC did, but it still failed to account for the large 9 dB release from masking observed in Marrone et al. (2008) when two speech maskers are moved from being colocated with the target to being placed at ±15° azimuth angles. This may be due to differences in informational masking (IM) across the conditions. The STEC still has the same inherent limitation as the SSEC in that the model fitting has to be done for each combination of masker type and number of maskers. Further, it has never been tested in reverberant conditions.

C. Modulation-domain models

In contrast, Van Wijngaarden and Durlman (2008) extended the speech transmission index (STI) (Houtgast and Steeneken, 1973; IEC, 2003) to consider binaural hearing. The STI considers the integrity of the modulations of a reference signal (or speech) after processing as the decision metric, assessed by the modulation transfer function (MTF). The MTF can capture the effects of reverberation on speech because of the reduction in modulation in the reference signal. The binaural interaction of the binaural STI is based on interaural cross-correlograms. Van Wijngaarden and Durlman (2008) showed that the binaural STI extension could account for consonant-vowel-consonant (CVC) word scores for stationary maskers presented in multiple rooms (anechoic, a listening room, a classroom, and a large church). However, this approach is limited because it cannot be extended to more realistic conditions where the maskers are also modulated, since modulations are then coming from both the target and maskers and they can no longer be distinguished.

In order to account for different amounts of target and masker modulations, Jørgensen and Dau (2011) proposed the monaural speech-based envelope power spectrum model (sEPSM), which considers the signal-to-noise envelope power ratio (SNRenv) at the output of a modulation filterbank (Ewert and Dau, 2000) as the decision metric. In addition to conditions with additive maskers, the sEPSM can also account for the effects of reverberation, as well as noise reduction via spectral subtraction because it captures the increase in the masker’s modulation power after processing. The sEPSM was extended to account for conditions with fluctuating maskers by using a “multi-resolution” process (Jørgensen et al., 2013). In the corresponding multi-resolution model, the mr-sEPSM, the SNRenv is calculated in windows of different length [akin to the ESII of Rhebergen and Versfeld (2005)] according to the center frequency of the modulation filters. The mr-sEPSM was validated using various fluctuating noises, including cafe noise, two-band speech modulated noise, the international speech test signal (Holube et al., 2010), and a reversed talker. In contrast to the SII and STI metrics, the SNRenv metric can account for both the effects of reverberation on the target and the masker as well as for the release from masking due to fluctuations in the maskers. However, the model has not yet been applied to spatial conditions using two-ear processing. Therefore, using the mr-sEPSM framework in a binaural model could yield a model that can account for all the aforementioned aspects of binaural speech intelligibility: the spatial separation of the target and the maskers, the effects of reverberation on the target and on the maskers, the role of temporal fluctuations in the masker, and the effects of multiple interferers.

None of the models previously mentioned can account for the deleterious effects of colocated concurrent speakers on speech intelligibility. The difference between the measured intelligibility and intelligibility predicted using energy-based model is often labeled as “informational masking.”

D. Proposed modeling framework

Here, a model is proposed that combines concepts from different modeling approaches. Specifically, it integrates a short-time equalization-cancellation process (Wan et al., 2014), a temporal modulation filterbank (Dau et al., 1997; Ewert and Dau, 2000), the SNRenv metric (Jørgensen and Dau, 2011), and a better-ear process in the envelope power domain. The model was evaluated using a set of critical experimental conditions from the literature to tease apart the contributions of the decision metric, the short-time processing, the better-ear process, and the binaural unmasking for predicting intelligibility in spatial conditions. Experiment 1 focused on conditions with multiple maskers in anechoic conditions, experiment 2 considered conditions with only a single masker, but in a reverberant environment, and experiment 3 investigated a single-masker condition where only ITD but no ILD information was provided.

II. MODEL DESCRIPTION

A. Overall model structure

Figure 1 shows a sketch of the model proposed in the present study, which is an extension of the monaural mr-sEPSM (Jørgensen et al., 2013). The model consists of realizations of the monaural mr-sEPSM for the left and right ear, and a “central” pathway where binaural unmasking takes place using an EC process (Wan et al., 2014). In contrast to the original mr-sEPSM, the model employs a binaural processing stage. Binaural processing is limited by peripheral transduction, which does not preserve fine-structure information at high frequencies (Bernstein and Trahiotis, 1996). Peripheral transduction is therefore modeled using half-wave rectification and low-pass filtering. A binaural selection stage combines the outputs of the left, right and central pathways. The subsequent output is then converted to intelligibility using an ideal
observer concept. The extension to the mr-sEPSM is presented below; further details and justifications about the mr-sEPSM approach can be found in Jørgensen et al. (2013).

B. Monaural processing stage

The inputs of the model are the noisy speech and the noise alone for each ear. The first stage of each monaural model consists of 22 gammatone filters covering the frequency range from 63 Hz to 8 kHz with a third-octave spacing. The channels are processed further only if the level of the noisy speech for that channel is above the diffuse-field threshold in quiet (ISO, 2005). The envelope of each channel, and performed in short overlapping time frames. A time-frequency unit is denoted as $U(p, k)$, where $p$ again denotes the peripheral filter, and $k$ is the $k$th frame, which differs from the $i$th segment of the modulation-domain multi-resolution process. Each frame, $k$, is 20 ms, whereas the multi-resolution segments, $i$, can vary in duration. The overlap between frames is 50% (10 ms). The equalization process in each unit selects the optimal ITD, $\tau_0$, and the optimal ILD, $\omega_0$, using the following equations:

$$\tau_0(p, k) = \arg \max_{\tau} \{ \rho_{p,k} \}, \quad |\tau| < \frac{\pi}{\omega_p},$$

$$\omega_0(p, k) = \sqrt{\frac{F_{N,L}(p, k)}{F_{N,R}(p, k)}},$$

where $\rho_{p,k}$ is the normalized cross-correlation function of the left and right ears within the unit, $F_{N,L}(p, k)$ and $F_{N,R}(p, k)$ are the masker energy for the left and right ear, respectively, and $\omega$ is the center frequency of channel $p$. The unmasked output, $Y_{p,k}(t)$, for the unit $U(p, k)$ after cancellation is calculated as

center frequencies below one-fourth of their respective peripheral-filter center frequency are used (Verhey et al., 1999).

The output of each modulation filter, $n$, is segmented in non-overlapping rectangular windows of durations inversely proportional to the center-frequency of the respective modulation filter, e.g., the windows at the output of the 8 Hz modulation filter are 125 ms long. The power, $P_{\text{env},i}(p, n)$, of each segment, $i$, is defined as the variance of the segment,

$$P_{\text{env},i}(p, n) = \frac{1}{[E(p, t)]^2} \frac{1}{2} |\tilde{e}_i(p, n, t) - \tilde{e}_i(p, n)|^2,$$

where $p$ is the corresponding peripheral filter, $E(p, t)$ is the envelope at the output of the peripheral filter, $e_i(p, n, t)$ is the envelope at the output of the modulation filter for the segment $i$, $t$ is time, and the overbar indicates the average over time. $\tilde{e}_i$ is the average over a time segment, $i$, of varying duration according to the center frequency of the modulation filter. $E$ is averaged over the whole sentence duration. The lower limit of the envelope power is set to $-30$ dB relative to 100% amplitude modulation.

The SNR$_{\text{env},i}$ for each segment is computed from the envelope power of the noisy speech and the noise alone,

$$\text{SNR}_{\text{env},i}(p, n) = \frac{P_{\text{env},S+N,i}(p, n) - P_{\text{env},N,i}(p, n)}{P_{\text{env},N,i}(p, n)},$$

where $S+N$ denotes the noisy speech and $N$ denotes the noise alone.

C. Binaural processing stage

The binaural unmasking stage is implemented as described in Wan et al. (2014). The jittered peripheral envelopes from the monaural stages are used as inputs to the EC process. The EC processing is assumed to be independent in each channel, and performed in short overlapping time frames. A time-frequency unit is denoted as $U(p, k)$, where $p$ again denotes the peripheral filter, and $k$ is the $k$th frame, which differs from the $i$th segment of the modulation-domain multi-resolution process. Each frame, $k$, is 20 ms, whereas the multi-resolution segments, $i$, can vary in duration. The overlap between frames is 50% (10 ms). The equalization process in each unit selects the optimal ITD, $\tau_0$, and the optimal ILD, $\omega_0$, using the following equations:

$$\tau_0(p, k) = \arg \max_{\tau} \{ \rho_{p,k} \}, \quad |\tau| < \frac{\pi}{\omega_p},$$

$$\omega_0(p, k) = \sqrt{\frac{F_{N,L}(p, k)}{F_{N,R}(p, k)}},$$

where $\rho_{p,k}$ is the normalized cross-correlation function of the left and right ears within the unit, $F_{N,L}(p, k)$ and $F_{N,R}(p, k)$ are the masker energy for the left and right ear, respectively, and $\omega$ is the center frequency of channel $p$. The unmasked output, $Y_{p,k}(t)$, for the unit $U(p, k)$ after cancellation is calculated as

FIG. 1. Diagram of the model structure. Solid lines denote the path of the speech-plus-noise ($S+N$) mixture and the dash lines show the path of the noise alone ($N$). The values $\tau_0$ and $\omega_0$ represent the optimal parameters selected by the equalization process.

\[ Y_{p,k}(t) = W_k(t) \left\{ \frac{1}{\sqrt{a_0(p,k)}} E_L(p,t) \left( t + \frac{\tau_0(p,k)}{2} \right) \right. \]
\[ \left. - \sqrt{a_0(p,k)} E_R(p,t) \left( t - \frac{\tau_0(p,k)}{2} \right) \right\}, \quad (4) \]

where the subscripts \(L\) and \(R\) denote the left and right ear, respectively, and \(W_k(t)\) is a rectangular window function for the frame \(k\), which can be expressed as
\[ W_k(t) = \begin{cases} 1, & (k \times 10) \text{ ms} \leq t \leq (k \times 10) + 20 \text{ ms}, \\ 0, & \text{otherwise}. \end{cases} \quad (5) \]

Subsequently, the binaural signal, \(B_p\), is reconstructed for each channel by summing over all overlapping frames
\[ B_p(t) = \frac{1}{2} \sum_k Y_{p,k}(t). \quad (6) \]

The unmasked outputs for the noisy speech, \(B_S + N_p\), and the noise alone, \(B_Np\), are then used as inputs to the modulation filtering stage of the mr-sEPSM, and, subsequently, to the SNR\(_{\text{env}}\) calculation. This yields BU-SNR\(_{\text{env}}\)(\(p, n, t\)), a binaurally unmasked SNR\(_{\text{env}}\), for each peripheral channel, modulation channel, and multi-resolution frame.

### D. Binaural selection stage

The binaural selection device selects the best SNR\(_{\text{env}}\), denoted as the “binaural SNR\(_{\text{env}}\)” (B-SNR\(_{\text{env}}\)), between the better-ear SNR\(_{\text{env}}\) (BE-SNR\(_{\text{env}}\)) and the binaurally unmasked SNR\(_{\text{env}}\), (BU-SNR\(_{\text{env}}\)), for each multi-resolution segment [note that the \((p, n, t)\) indexing has been omitted for the sake of brevity],
\[ \text{B-SNR}_{\text{env},i} = \max(\text{BE-SNR}_{\text{env},i}, \text{BU-SNR}_{\text{env},i}), \quad (7) \]

where \(\text{BE-SNR}_{\text{env},i}\) is the maximum between the left and right SNR\(_{\text{env},i}\) for each segment
\[ \text{BE-SNR}_{\text{env},i} = \max(\text{SNR}_{\text{env,L},i}; \text{SNR}_{\text{env,R},i}). \quad (8) \]

The B-SNR\(_{\text{env}}\) is then averaged over all segments, \(I_n\), of each modulation channel
\[ \text{B-SNR}_{\text{env}}(p, n) = \frac{1}{I_n} \sum_{i=1}^{I_n} \text{B-SNR}_{\text{env},i}(p, n), \quad (9) \]
yielding a 9 \(\times\) 22 array of values. The time-averaged B-SNR\(_{\text{env}}\) is first combined across modulation filters
\[ \text{B-SNR}_{\text{env}}(p) = \left[ \sum_{n=1}^{9} \text{B-SNR}_{\text{env}}^2(p, n) \right]^{1/2}, \quad (10) \]
and then across peripheral filters
\[ \text{B-SNR}_{\text{env}} = \left[ \sum_{p=1}^{22} \text{B-SNR}_{\text{env}}^2(p) \right]^{1/2}. \quad (11) \]

### E. Decision device

The overall B-SNR\(_{\text{env}}\) is converted to a sensitivity index, \(d'\), of an “ideal observer” (Jørgensen and Dau, 2011), using the relation
\[ d' = k(\text{B-SNR}_{\text{env}})^q, \quad (12) \]
where \(k\) and \(q\) are parameters independent of the experimental conditions. \(d'\) is converted to intelligibility using an \(m\)-alternative forced choice decision model, combined with an unequal variance Gaussian model expressed as
\[ P_{\text{correct}}(d') = \Phi \left( \frac{d' - \mu_N}{\sqrt{\sigma_S^2 + \sigma_N^2}} \right), \quad (13) \]
where \(\Phi\) denotes the cumulative normal distribution. The values of \(\sigma_N\) and \(\mu_N\) are determined by the number of response alternative, \(m\) [see the Appendix of Jørgensen and Dau (2011) for details]. For open-set paradigms, \(m\) is set to 8000, which reflects the number of words in a normal listener’s vocabulary. The value of \(\sigma_S\) is a free parameter fixed by fitting model predictions to speech intelligibility data in a condition with a SSN masquerer. The percentage correct at the output of the model is denoted as B-sEPSM.

Replacing the B-SNR\(_{\text{env}}\) by either BE-SNR\(_{\text{env}}\) or BU-SNR\(_{\text{env}}\) in Eqs. (9)–(13) provides two alternative model outputs, B-sEPSM and BU-sEPSM, where only the better-ear or only binaural-unmasking stages are used, respectively.

### III. METHODS

#### A. Experiment 1: Multiple maskers in an anechoic condition

### 1. Rationale

This experiment investigated the effects of multiple spatially distributed maskers in an anechoic condition on spatial release from masking (SRM) using the data of Hawley et al. (2004). They systematically measured SRTs as a function of masker azimuth, masker type, and number of maskers using the Harvard IEEE corpus (Rothauser et al., 1969). The interferers were either speech (not considered in the current study because of potential differences in informational masking compared to the other conditions), reversed speech (from the same corpus), SSN, or speech-modulated speech-shaped noise (SMSSN). All maskers were matched to the spectrum of the target sentences and either one, two, or three maskers were presented at once. Hawley et al. showed that SRM was larger when multiple voiced interferers were located at different locations from the target, compared to conditions when a single voiced masker was presented. This suggested that a short-term binaural process is critical. Wan et al. (2010) and Wan et al. (2014) used these same data to validate their long-term and short-term EC models.

### 2. Experimental conditions

The Loizou (2007) recording of the Harvard IEEE corpus, sampled at 25 kHz, was used for the target material. The
SSN was also taken from Loizou (2007) and was created by filtering stationary noise to have the same long-term spectrum as the speech material. The SMSSN was created by applying the broadband envelope of a sentence from the speech corpus to the SSN. The envelope was extracted by low-pass filtering the half-wave rectified speech signal with a first-order Butterworth filter with a 40-Hz cutoff frequency (Hawley et al., 2004). The stimuli were spatialized using the head-related transfer functions (HRTFs) of the HMS II artificial head (HEACO Acoustics GmbH, Germany) from the AUDIS database (Blauert et al., 1998), at angles of 0°, 30°, 60° or 90°. One to three maskers were located in the front (0°, 0°, 0°), at the side (90°, 90°, 90°), distributed on the right (30°, 60°, 90°), or distributed to the left and the right (−30°, 60°, 90°) [see Table I in Hawley et al. (2004) for the full layout]. The speech level was fixed at 65 dB sound pressure level (SPL) and the masker levels were independently set to desired SNRs, before HRTF filtering; adding maskers increased the total interferer level.

3. Simulations

Simulations obtained with the proposed model (B--sEPSM) were carried out for SNRs ranging from −24 to 12 dB in 3 dB increments. The simulated SRTs corresponded to the SNR at which the simulated intelligibility was 50%, using linear interpolation where necessary. The final SRT represented the average SRT for 30 randomly selected sets of target and maskers. The condition with a single SSN masker, colocated with the target, and spatialized using the AUDIS HRTFs was considered as the reference condition. Because word score data were unavailable in this condition, a Gaussian psychometric function, \( c(x) \), with an anechoic SRT, \( \mu_a \), and a standard deviation, \( \sigma \), was first fitted based on the anechoic word score data of Bernstein and Grant (2009) using

\[
c(x) = \frac{\text{erfc}\left(\frac{(x - \mu_a)}{\sqrt{2}\sigma}\right)}{2},
\]

where \( x \) represents the SNRs, \( c \) is the proportion correct, and \( \text{erfc} \) is the complementary Gauss error function. Then, \( \mu_a \) was replaced by the SRT measured by Hawley et al. (2004) in the colocated condition with a single SSN masker (−3.40 dB SNR), yielding a modified psychometric function, \( c'(x) \). The parameters of the model’s ideal observer, \( k \) and \( q \), were adjusted to minimize the root-mean-square error (RMSE) between the simulations obtained with the “left ear” model and the psychometric function \( c'(x) \). The constants \( \sigma_k \) and \( m \) of the observer were fixed to 0.6 and 8000, respectively. The observer parameters were kept constant throughout experiment 1. Table I shows the summary of the ideal observer parameters and constants for all three experiments.

reverberant conditions, using the data of Beutelmann et al. (2010). They measured binaural SRTs in a combination of four different rooms, three target-masker azimuth separations, and three masker types. The speech material was the Oldenburg Sentence Test in noise (Wagner et al., 1999), which consists of a closed set of meaningful five-word sentences. The rooms included an anechoic room, a standard IEC listening room (not used in the current study), a typical classroom (7 × 6.9 × 3.2 m³, approximately 210 m³) and a church (outer dimensions: 63 × 32 × 22 m, approximately 22 000 m³). The interferers were either stationary SSN (stationary), 20-talker babble (babble), or single-talker modulated noise (single-talker). Beutelmann et al. (2010) found an effect of azimuth on the SRM (a 105° separation yielded a larger SRM than a 45° separation) and this effect was largest in the anechoic condition. They also showed that the masker type had a significant effect on the SRM and that speech intelligibility was positively correlated with the modulation depth of the masker. SRM was larger in the anechoic conditions, than in the reverberant conditions. The masker types used by Beutelmann et al. (2010) were similar to the ones used by Hawley et al. (2004) but the different room types are critical to validate that the proposed model can capture the effects of reverberation on SRM.

2. Conditions

The SSN was the one provided with the Oldenburg Sentence Test, which was created by a random superposition of the material’s sentences. The multi-talker babble was the “CD1011RW2” noise from the Auditec CD, created as the mixture of 20 talkers reading different texts (Auditec, 2006). The single-talker modulated noise was the “ICRA5” noise (Dreschler et al., 2001). All stimuli were sampled at 44.1 kHz. The noise level was fixed at 65 dB SPL and the target level was adjusted to the desired SNRs. Both the target and masker levels were adjusted after HRTF filtering. The stimuli were spatialized using virtual impulse responses created with the ODEON software version 8.0 (Kongens Lyngby, Denmark; Christensen, 2005). The anechoic, the classroom and the church conditions were used. Three spatial setups were used: (1) the target and the masker were colocated 3 m in front of the listener, (2) the target was 3 m in front of the listener and the masker was 2 m away, at 105° azimuth, and (3) the target was 6 m in front of the listener and the masker was 4 m away, at −45° azimuth. In the third condition, the listener was placed close to a wall on the right side. See Beutelmann et al. (2010) for complete details about the listening test setup.
3. Simulations

Simulations were obtained for SNRs ranging from −36 to 6 dB in 3 dB steps. The final simulated SRT was the average SRT for 30 randomly selected target and masker pairs. The reference psychometric function, \( p \), was created following Wagener and Brand,

\[
p(L, \text{SRT}, s) = 100 \times \frac{1}{1 + e^{4\text{SRT} - L}},
\]

where \( L \) represents the given SNRs, \( s \) is the slope around the 50% point, and SRT is the SNR at the 50% points. \( s \) was set to 0.18/\text{dB} according to Wagener and Brand (2005, their Table IV) for the OLSA material with an SSN masker, and SRT was the median SRT in the spatialized condition measured by Beutelmann et al. (2010) (−7.23 dB, their Fig. 6) for the same material. The ideal observer parameters in the proposed model were fit such as to minimize the RMSE between the “left-ear” of the model and that psychometric function. The parameters were kept constant for all other conditions in this experiment. The observer’s constants, \( \sigma \), and \( m \) were fixed to 0.9 and 50, respectively, to account for the increased redundancy in the speech material.

C. Experiment 3: ITD-only condition

1. Rationale

Experiment 3 investigated the role of the EC process using a condition where the target and masker were lateralized to the left or to the right, using a fixed interaural delay (ITD) of 687.5 \( \mu \text{s} \) (Löcsei et al., 2015). The speech was played in the presence of SSN that was either lateralized to the same side as the speech, denoted as condition S11, or to the opposite side, denoted as condition S01. Löcsei et al. (2015) found a masking release of about 4 dB when the masker was lateralized to the opposite side. In this condition, no better-ear benefit can be expected because the signal at both ears is the same, except for a short delay used for the lateralization. Therefore, the only cues available should be interaural differences, which should be captured by the EC process.

This experiment was akin to the \( S_s N_0 \) condition often used as an example of pure-tone BMLD [see Levitt and Rabiner (1967), and Culling et al. (2004)]. In such a condition, listeners showed a masking release as large as 12 dB when the target tone was presented out of phase (\( \pi \)), compared to the in-phase presentation of the target (0; Levitt and Rabiner, 1967). Release from masking due to ITD or out-of-phase presentation has successfully been modeled for pure-tone signals (Levitt and Rabiner, 1967) and for speech signals using an EC-like process (Culling et al., 2004).

2. Conditions

The speech material was the DAT corpus (Nielsen et al., 2014), sampled at 48 kHz and recorded with female speakers. The DAT corpus consists of unique meaningful Danish sentences constructed as a fixed carrier sentence with two interchangeable target words. The masker was stationary noise shaped to have the same long-term spectrum as the speech material. The target level was fixed at 65 dB SPL and the masker level was adjusted to the desired SNR.

3. Simulations

Simulations were obtained for 30 randomly selected sentences and SSN maskers, and for SNRs from −12 to 9 dB in 3 dB steps. The signals were lateralized to the left or right using a fixed 33 sample delay (687.5 \( \mu \text{s} \)). The final simulated SRT was the average across target sentences. The ideal observer’s parameters were fit to minimize the RMSE between the “left-ear” of the model and the word-scores as a function of SNR in the colocated, S11, condition, as measured by Löcsei et al. (2015). The ideal observer’s \( \sigma \), and \( m \) were set to 0.6 and 8000, respectively (Jørgensen et al., 2013).

IV. RESULTS

A. Experiment 1: Multiple maskers in an anechoic condition

Figure 2 shows the simulated SRTs obtained with the proposed model (B-sEPSM; black squares), those obtained with the better-ear only version of the model (BE-sEPSM; dotted line) as well as the binaural-unmasking version (BU-sEPSM; dashed line) as a function of the masker(s) angle(s). Furthermore, the STEC predictions from Wan et al. (2014) (grey triangles) and the measured data from Hawley et al. (2004) (open squares) are shown. The three columns correspond to one (left), two (middle), or three maskers (right), respectively. The upper panels show data and simulations for the stationary SSN maskers, the middle panels for SMSSN maskers, and the bottom panels for reversed speech. Figure 3 is a replot of the data and predictions of Fig. 2 where the thresholds are represented in terms of a SRM relative to the condition where the target and the maskers were colocated.

Overall, there was a good agreement between the B-sEPSM simulations and the data. The Pearson correlation coefficient across all conditions was 0.91 and the prediction RMSE was 3.0 dB. For the STEC, the correlation coefficient was 0.97 the RMSE was 1.3 dB SNR. Thus, the RMSE was larger for the B-sEPSM than for the STEC but, unlike the STEC, the B-sEPSM was fit only once for all conditions. In contrast, the STEC was fit to the 90° condition for each combination of \( n \) maskers and masker type, i.e., for each subfigure of Fig. 2 (Wan et al., 2014).

In the SSN condition (upper panels), the B-sEPSM simulations were slightly lower than in the data but the amount of SRM was well described for all numbers of maskers. In the SMSSN masker condition (middle panels), the B-sEPSM correctly accounted for the masker-type dependency of the SRTs in the case of the single masker. The B-sEPSM predicted an increase in SRTs with increasing number of maskers, consistent with the measured data; however, the SRTs were on average 4.76 dB larger than in the data in the condition with three SMSSN maskers. The simulated SRM was found to be the same as in the data with two SMSSN
maskers, but was larger by about 4 dB with three maskers when all maskers were at different locations. The B-sEPSM predicted SRTs up to 8 dB higher in the three SMSSN maskers condition compared to the three SSN maskers condition. This is in contrast to the data, where the SRTs differed, on average, by only 1 dB between the SSN and SMSSN conditions when there were multiple maskers. Thus, the addition of a second or third SMSSN masker decreased the SNR\textsubscript{env} more than the addition of SSN maskers. In the reversed-speech masker condition (lower panels), the B-sEPSM simulated SRTs were below the measure ones. However, as in the data, the simulated SRTs increased with the number of maskers, suggesting that the B-sEPSM could correctly account for intelligibility as a function of the number of reversed-speech maskers.

B. Experiment 2: Single masker in reverberant conditions

Figure 4 shows the measured SRTs from Beutelmann et al. (2010) (open squares), together with the B-sEPSM predictions (black squares), the simulations obtained with the better-ear (BE-sEPSM; dotted lines) and binaural-unmasking (BU-sEPSM; dashed lines) versions of the model as a function of the masker azimuth. Furthermore, the stBSIM predictions (grey bullets; replotted from Beutelmann et al., 2010) are shown for comparison. The three columns correspond to the anechoic, classroom, and church conditions, respectively. The upper panels show data and predictions for the stationary masker, the middle panels show the corresponding results for the babble masker, and the bottom panels show the results obtained for the single-talker modulated noise masker.

Overall, there was a good agreement between the predictions and the data. The B-sEPSM Pearson correlation coefficient across all conditions was 0.91 and the average prediction RMSE for the B-sEPSM was 6.5 dB. In contrast, the Pearson coefficient for the stBSIM was 0.89 and the RMSE was 3.65 dB.

In the anechoic condition (left panels), the B-sEPSM produced a larger SRM than that found in the data when the masker was stationary noise or single-talker noise. A similar SRM as in the data was found when the maskers were babble noise. In the classroom condition (middle column), the B-sEPSM accurately accounted for the SRM but there was a negative offset for all masker types. In the church condition...
(right column), the SRM was also correctly accounted for by the B-sEPSM, except for a negative offset which was largest for the single-talker babble noise. Overall, the B-sEPSM offset seemed to be partly due to the BU-sEPSM contributions, which were consistently lower than the BE-sEPSM contributions to the overall SNRenv. Nonetheless, the large offset observed in the reverberant conditions for all maskers was due to the particulars of the intelligibility transformation for the B-sEPSM. The sEPSM framework is sensitive to the type of SSN used in the reference condition; white-noise filtered to have the same long-term average spectrum as speech, and SSN created by the random superposition of speech signals yield different amounts of masking release. A smaller offset could be obtained if the ideal observer was fit to the B-sEPSM, rather than to the “left-ear” SNRenv, but the resulting binaural model could not be analyzed in terms of the benefit compared to one ear alone in the colocated condition.

Figure 5 is a replot of the data and predictions from Fig. 4 as spatial release from masking relative to the colocated condition. The data from Beutelmann et al. (2010) showed that SRM decreased with increasing amounts of reverberation, probably as the result of reduced head shadow effect which decreases the BE benefit (Lavandier and Culling, 2010; Plomp, 1976). Reverberation also decorrelates the signals that reaches both ears, which reduces the efficacy of the EC process (Lavandier and Culling, 2007). These effects were captured by the BE-sEPSM and the BU-sEPSM outputs, respectively, and therefore, by the B-sEPSM, for all masker types, as shown by the correctly predicted SRM (cf. Fig. 5, second and third columns).

Release from masking with a fluctuating masker, relative to a stationary masker, was also reduced in the presence of reverberation; the SRT in the colocated single-talker masker church condition was about 12 dB higher (−18.7 to −6.95 dB SNR) than in the anechoic condition. None of the models accurately predicted this large SRT increase; the B-sEPSM predicted an increase of 3.65 dB and the stBSIM an increase of 6.10 dB.

### C. Experiment 3: ITD-only condition

The left panel of Fig. 6 shows the measured SRTs (open squares) from Lócsei et al. (2015), the B-sEPSM predictions (black squares), as well as the predictions from the better-ear-only version of the model (BE-sEPSM; dotted line and diamonds) and the binaural-unmasking version (BU-sEPSM; dashed line and circles). Target and masker were colocated to the left in the S11 condition. In the S01 condition, the
target was lateralized to the left and the masker was lateralized to the right. The right panel shows the same data and predictions replotted as SRM relative to the S11 condition. The B-sEPSM predicted SRTs lower than the measured ones in the S11 condition even though the model was fitted to that condition. This can be explained by the fact that the B-sEPSM was fit to the “left-ear” output only, rather than to the complete model output. Consequently, there seems to be a small advantage inherent to the binaural presentation in this condition, compared to the monaural presentation. The B-sEPSM produced an SRM of about 2 dB, compared to the 4 dB observed in the data. The BE-sEPSM output predicted no release from masking because there was no BE benefit possible; the masker was identical in both ears except for the fixed delay which is about an order of magnitude shorter than all processing windows in the model. In contrast, the BU-sEPSM output could account for all the SRM observed in the data.

V. DISCUSSION

This study described a binaural extension of the mr-sEPSM model framework, which combined monaural implementations of the mr-sEPSM with the EC model implementation of Wan et al. (2014). The regular mr-sEPSM process was applied to the envelopes at the output of the EC process, and a selection stage selected the best SNRenv from the left-ear, the right-ear—equivalent to better-ear processing—or the binaural unmasking pathway. The model was validated against the data of Hawley et al. (2004), Beutelmann et al. (2010), and of Löcsei et al. (2015). Overall, the correlation coefficients between simulated and measured SRTs were equal to 0.91. See Table II for a summary of all model performances.

A. Comparison to other modeling approaches

Both the proposed model and the STEC (Wan et al., 2014) had correlation coefficients above 0.9 in experiment 1 (Hawley et al., 2004). However, the two models differ in a few important ways. Unlike the STEC, the B-sEPSM required a single parameter fit for the intelligibility transform for the whole experiment, rather than once per sub-condition. In fact, the B-sEPSM, and sEPSM framework in general, requires a single parameter fit per speech material. In contrast, the STEC approach was validated using a different SNR criterion (SNR corresponding to 50% intelligibility) for each type and number of maskers. The generality of the sEPSM approach to model fitting was validated in the current study, as well as in Jørgensen and Dau (2011) and Jørgensen et al. (2013). Given the appropriate reference condition, which is typically in the presence of an SSN masker, the mr-sEPSM and its variants could account for a large range of processing or masker types, which means that the model requires less a priori knowledge about each condition. Another difference is that in the B-sEPSM, the BE and BU pathways are processed using similar time-frames, i.e., all pathways use the same multi-resolution approach to slice the time signals into segments. This means that the B-sEPSM can account for the monaural presentation of speech against a modulated masker because all pathways include short-term processing of the signals, and therefore the B-sEPSM would be compatible with the monaural mr-sEPSM. In contrast, only the BU pathway of the STEC considers a short-term process; the left- and right-ear pathways are applied to the long-term signals only. This is an important limitation of the STEC approach, considering the ability of the auditory system to extract information from BE glimpses, even if they shift across ears (Brungart and Iyer, 2012).

In experiment 2, the proposed model had a similar correlation coefficient as the stBSIM, but a slightly larger RMSE. Both the B-sEPSM and the stBSIM required a single parameter fit to convert the output of their decision metric to intelligibility. Unlike the B-sEPSM and the STEC, which explicitly separate the BE from the BU processes, the stBSIM implicitly includes the BE process in its closed-form calculation of the effective SNR [Beutelmann et al., 2010, their Eq. (12)]. It would be possible, however, to create a BE-only version of the stBSIM by removing the ITD-related parameters from that equation, or conversely, to create a BU-only version of the model by removing the ILD-related parameters. However, this binding of the two binaural processes limits the feasibility of modifying the processes

independently, e.g., to use different time scales for the frame processing, or to introduce different amounts of sluggishness in each pathway (Culling and Summerfield, 1998; Culling and Mansell, 2013).

Neither the model of Lavandier and Culling (2010) nor any of its extensions was considered in the present study (Lavandier et al., 2012; Collin and Lavandier, 2013). Of the extensions, only the one of Collin and Lavandier (2013) could possibly account for the masking release due to fluctuating maskers used in the majority of conditions considered in this study, because it is the only version that includes a short-term process. Those models are fundamentally limited because they cannot account for the effect of reverberation on the speech itself because they are not “signal-based,” i.e., they do not use speech signals as targets, but rather rely on SSN as the target or on binaural room impulses. These simplifications make those model faster to compute than the proposed model as well as the STEC and the stBSIM, which makes them better tools for, e.g., acoustical room design but limits their applicability in certain scenarios.

Compared to the other models [STEC, stBSIM, Lavandier and Culling (2010), and even the binaural STI (Van Wijngaarden and Drullman, 2008)], the B-sEPSM avoids the need for the explicit frequency weighting from the SII. Instead, the frequency and modulation frequency weightings are limiting the processing to “audible” audio and modulation frequencies (Chabot-Leclerc et al., 2014). Therefore, although the B-sEPSM includes the additional modulation-frequency dimension to the model framework, it reduces the number of fitted parameters required.

Overall, the modeling approach taken by the B-sEPSM, the STEC, and the BSIM did not differ largely. All three models combined a short-term EC process with time-frequency-specific cancellation parameters and a (short- or long-term) BE process. The main difference lay in the decision metric used by the B-sEPSM, namely, the $\text{SNR}_{\text{env}}$, rather than the audio SNR, and the fact that the B-sEPSM included an envelope-domain audio-frequency-selective process.

B. Role of the decision metric

The SII-based models would fail in conditions with non-linear processing, such as noise reduction (Rhebergen et al., 2009). The stBSIM as well as the model Collin and Lavandier (2013) are also fundamentally limited in that they cannot account for the effects of reverberation on the speech itself, because they do not use speech as target signal. Only the binaural STI model (Van Wijngaarden and Drullman, 2008), which uses the modulation power reduction after processing as the decision metric, could account for effects of modulation processing, but this approach is also limited because it cannot account for the intelligibility with modulated maskers. The B-sEPSM is the only binaural modeling framework that could account for multiple modulated maskers, reverberation on the target and maskers, as well as non-linear processing. Although these types of processing were not considered in the current study, the mr-sEPSM has been validated in such conditions (Jørgensen and Dau, 2011; Jørgensen et al., 2013; Chabot-Leclerc et al., 2014). No audibility-based model has been demonstrated to account for the change of intelligibility due to amplitude compression (Rhebergen et al., 2009). Although the mr-sEPSM was not shown to account for the deleterious effect of amplitude compression on speech intelligibility, it could account for spectral subtraction, and, also to phase jitter, given the addition of an across-channel process (Chabot-Leclerc et al., 2014).

C. Contributions of better-ear and binaural unmasking processes

The explicit separation of the BE and BU pathways in the B-sEPSM makes it possible to analyze their contributions separately. Moreover, the performance of those alternate models can be an indicator of the respective importance of the processes involved in binaural hearing. Overall, the BE- and BU-only simulations, denoted as BE-sEPSM and BU-sEPSM, respectively, showed good agreements between data and simulations. They are depicted as dotted and dashed lines, respectively, in Figs. 2–6. In experiment 1, the BE-sEPSM had an overall correlation coefficient of 0.83 and the BU-sEPSM a correlation coefficient of 0.90, which both compare favorably with the complete model’s correlation of 0.91 (see Table II for overview). The performances were similar in experiment 2, with a correlation of 0.91 for the BE-sEPSM, 0.92 for the BU-sEPSM, and 0.91 for the complete B-sEPSM. In experiment 3, the BE-sEPSM model failed completely to account for the masking release due to ITDs, as expected, whereas the BU-sEPSM predicted the masking release. The performance of the BE-only model supported the idea that better-ear glimpsing, both in time and in frequency, can account for large parts of spatial release from masking (Brungart and Iyer, 2012; Culling and Mansell, 2013) in realistic conditions. Glyde et al. (2013) suggested this statement to be valid only if the maskers produced mostly energetic masking, i.e., did not cause any confusion between the target and the maskers. This is in contrast to conditions where informational masking may be dominant, such as with certain speech maskers. Therefore, the good performance of the BE-sEPSM can be attributed to the fact that the maskers considered in the present study may have provided a similar degree of informational masking (SSN, SMSSN, multi-talker babble, and reversed-speech).

The BU-sEPSM model performed equally well as the complete model (B-sEPSM) overall, and could account for the entire SRM in experiment 3. The difference in simulated SRT between the BE-sEPSM and the BU-sEPSM can be attributed to the fact that both models used the same “left-ear” reference for the fitting of the ideal observer. This discrepancy suggests that either they should be fitted separately, or that the processes should be modified as to produce the same SNR$_{\text{env}}$ values in the same colocated condition. In experiments 1 and 2, the BU output “dominated” the B-sEPSM output, because its SNR$_{\text{env}}$ values were larger than that of the BE-sEPSM (which leads to lower SRTs), as it is especially clear in Fig. 2. Also, the BU-sEPSM tended to predict a larger masking release than the BE-sEPSM (cf. Figs. 3 and 5). It is unclear if this dominance of the BU
D. Informational masking

The B-sEPSM predicted the correct SRM in experiment 1 with reversed-speech maskers [cf. Fig. 3 although simulated SRTs were lower than the data (cf. Fig. 2)]. A similar difference was observed with the SSEC and the STEC (Wan et al., 2010, 2014) in the same condition. However, the models could not account for the increased thresholds observed when target and speech, or reversed-speech maskers, were colocated (Westermann and Buchholz, 2015b; Carlile and Corkhill, 2015). This limitation was even more clearly illustrated by Wan et al. (2014) in the conditions of Marrone et al. (2008), where the target was placed at 0° azimuth and speech or reversed-speech maskers were either colocated with the target or symmetrically placed around it. The models predicted SRTs lower than the data in the colocated condition because they could not account for the increased IM. In this case, IM is attributed to a failure in bottom-up grouping and streaming caused by target-masker similarities (Shinn-Cunningham, 2008). This is in contrast to the other portion of IM which can be attributed to top-down processes that cannot select the proper stream due to object similarity and target uncertainty (Shinn-Cunningham, 2008).

Being a purely bottom-up model, the B-sEPSM could only be sensitive to the similarity-based IM. However, the B-sEPSM has “perfect” segregation because of its access to the noisy mixture and to the maskers-alone signals and therefore cannot account for any IM. This means that the B-sEPSM requires fitting to a condition without IM, otherwise other simulated thresholds, where IM is not dominant, will be systematically elevated (e.g., in spatially separated conditions). On the converse, simulated SRTs in IM-dominated conditions will be too low if the B-sEPSM is fitted to an IM-free condition, which is the “default” approach for the mr-sEPSM framework. To account for the discrepancy between predicted and measured SRT in IM-dominated conditions, the B-sEPSM would require an estimate of the bottom-up confusion. Chabot-Leclerc et al. (2014) showed that it was possible to capture 7 of the 10 dB of SRM observed when a speech masker was moved, on-axis, from 0.5 to 10 m away from the target in a reverberant environment (Westermann and Buchholz, 2015a) using the long-term sEPSM. Models based on the audio SNR (e.g., SII, BSIM) did not predict any SRM. Therefore, it seems that it is possible to capture some of the similarity/dissimilarity in the envelope-power representation which is not available in the audio domain. Consequently, it should be possible to evaluate the similarity between the speech and maskers using an estimate of the clean speech representation \[ S = (S + N) - N \] and the maskers-alone representation in the envelope power domain. A simple “distance” or “contrast” estimate between the clean speech estimate and the maskers could be a promising measure of confusions. A more complex approach for estimating confusions would be to pair the B-sEPSM with a streaming model (e.g., Elhilali and Shamma, 2008; Christiansen et al., 2014) and combine their outputs considering that there are more confusions in a one-stream percept than in a two-stream percept. It would be particularly interesting to apply this approach to the output of the binaural unmasking pathway considering that BE seems to be sufficient to account for SRM when there is no IM (Glyde et al., 2013; Brungart and Iyer, 2012; Carlile and Corkhill, 2015).

VI. CONCLUSIONS

The B-sEPSM is a general model framework for predicting spatial release from masking in realistic and artificial conditions. It combines an explicit combination of better-ear and binaural unmasking processes using monaural implementations of the mr-sEPSM (Jørgensen et al., 2013) and an EC process (Wan et al., 2014). The B-sEPSM uses the
SNR_{rev} as the decision metric and was shown to predict the SRT dependence on: the number of maskers, different masker types (SSN, SMSSN, babble, and reversed speech), the masker(s) azimuths, reverberation on the target and masker, and the ITD of the target and masker.

ACKNOWLEDGMENTS

The authors thank Rainer Beutelmann for providing the room impulse responses used in experiment 2 and Gustav Lökse for the material used in experiment 3. This research was supported in part by the National Science and Engineering Research Council of Canada (NSERC), Phonak, and the Technical University of Denmark.
