28

29 **Highlights**

30

- 31 • The venom proteome of the monocled cobra, *Naja kaouthia*, is presented
- 32 • Most abundant venom components are three-finger toxins (neurotoxins and
- 33 cytotoxins) and phospholipases A₂
- 34 • Toxicity (LD₅₀) screening identified three-finger toxins as the most medically
- 35 relevant of this venom
- 36 • IgG response from a self-immunized human was significant against several toxins,
- 37 although weak against those with higher toxicity

38

39 **Abstract**

40 The venom proteome of the monocled cobra, *Naja kaouthia*, from Thailand, was
41 characterized by RP-HPLC, SDS-PAGE, and MALDI-TOF-TOF analyses, yielding 38
42 different proteins that were either identified or assigned to families. Estimation of relative
43 protein abundances revealed that venom is dominated by three-finger toxins (77.5%;
44 including 24.3% cytotoxins and 53.2% neurotoxins) and phospholipases A₂ (13.5%). It also
45 contains lower proportions of components belonging to nerve growth factor,
46 ohanin/vespryn, cysteine-rich secretory protein, C-type lectin/lectin-like, nucleotidase,
47 phosphodiesterase, metalloproteinase, L-amino acid oxidase, cobra venom factor, and
48 cytidyltransferase protein families. Small amounts of three nucleosides were also
49 evidenced: adenosine, guanosine, and inosine. The most relevant lethal components,
50 categorized by means of a 'toxicity score', were α -neurotoxins, followed by
51 cytotoxins/cardiotoxins. IgGs isolated from a person who had repeatedly self-immunized
52 with a variety of snake venoms were immunoprofiled by ELISA against all venom
53 fractions. Stronger responses against larger toxins, but lower against the most critical α -
54 neurotoxins were obtained. As expected, no neutralization potential against *N. kaouthia*
55 venom was therefore detected. Combined, our results display a high level of venom
56 complexity, unveil the most relevant toxins to be neutralized, and provide prospects of
57 discovering human IgGs with toxin neutralizing abilities through use of phage display
58 screening.

59 (199 words)

60

61 **1. Introduction**

62 Snakebite is a serious medical condition affecting a large number of people
63 worldwide; especially in impoverished rural areas of Asia, Africa and Latin America
64 (Gutiérrez et al., 2006; Warrell, 2010a). Asia is the continent where the majority of these
65 bites take place, and also where most deaths occur (Alirol et al., 2010; Chippaux, 1998;
66 Kasturiratne et al., 2008). Currently there are 29 recognized extant species of terrestrial
67 cobras assigned to the genus *Naja* (Uetz and Hošek, 2015). Of these, 11 species are found
68 in Asia, and 18 inhabit Africa (Uetz and Hošek, 2015; Wallach et al., 2009). Among the
69 cobras, *Naja kaouthia* (monocled cobra) is widespread in southern Asia and responsible for
70 a significant part of the bites recorded (Viravan et al., 1986; Warrell, 1995; Kulkaew et al.,
71 2009). A study in Bangladesh discovered records of 764 snakebites during 1988-1989, of
72 which 34% of the 168 deaths (22% case fatality) were attributed to the cobras *Naja naja*
73 and *N. kaouthia* (Warrell, 2010b). *N. kaouthia* occurs from north-eastern India, Bangladesh
74 and Bhutan, across southern China, southward to northern Peninsular Malaysia (Prakash et
75 al., 2012; Wüster, 1996) and is common in most of its range (Stuart and Wogan, 2012). *N.*
76 *kaouthia* is adapted to a broad range of habitats, including agricultural land, human
77 settlements, and bigger cities. However, its natural habitat includes paddy fields, swamps,
78 mangroves, grasslands, scrublands and forest (Stuart and Wogan, 2012). The diet of *N.*
79 *kaouthia* covers a broad range of animals from frogs, snakes, small birds to mammals (Cox
80 et al., 1998), and even fish (Kyi and Zug, 2003). *N. kaouthia* is assessed as Least Concern
81 at IUCN Red List of Threatened Species because of its large distribution, tolerance of a
82 broad range of modified habitats, and is reported to be in abundance (Stuart and Wogan,
83 2012). In Thailand it has been reported that many cases of hospitalization due to snakebite

84 were caused by *N. kaouthia* (Kulkeaw et al., 2009). Human envenomings by *N. kaouthia* are
85 predominantly characterized by neuromuscular paralysis which in severe cases ends up in
86 respiratory paralysis, and by local tissue damage, i.e. swelling, necrosis and blistering
87 (Warrell, 1995; Wongtongkam et al., 2005).

88 Enzymatic activities and toxicity of the venom of *N. kaouthia* have previously been
89 studied (Pakmanee et al., 1998; Mukherjee and Maity, 2001; Das et al., 2013). Furthermore,
90 a qualitative proteome of the venom has been reported showing the presence of 61 proteins
91 belonging to 12 protein families (Kulkaew et al., 2007). The most prominent component is
92 the long α -neurotoxin α -cobratoxin (Richard et al., 2013), constituting about 25% of the
93 venom (Kulkaew et al., 2009) and belonging to the three-finger toxin family, of which *N.*
94 *kaouthia* venom has several other members (Kulkaew et al., 2007). Other proteins that have
95 been studied include phospholipases A₂ (PLA₂s) (Joubert and Taljaard, 1980a; Reali et al.,
96 2003; Doley and Mukherjee, 2003), L-amino acid oxidases (Tan and Swaminathan, 1992;
97 Sakurai et al., 2001), cardiotoxins (Joubert and Taljaard, 1980b; Fletcher et al., 1991;
98 Debnath et al., 2010; Jamunaa et al., 2012), and nerve growth factors (Kukhtina et al.,
99 2001). However, a proteomic analysis of this venom that integrates an estimation of relative
100 protein abundances together with a detailed screening of the toxicity of its various
101 components, is pending. An integrated functional and proteomic characterization of *N.*
102 *kaouthia* venom is relevant not only for a deeper understanding of the composition of the
103 venom and its relationships to toxicity, but also to establish a basic platform for
104 antivenomic analyses.

105 Developing more potent antivenoms with better safety profiles is of medical
106 relevance. Besides the traditional animal-derived antivenoms generated by immunization of
107 horses with pools of snake venoms (Gutiérrez et al., 2011), various alternative approaches

108 have been pursued at the experimental level in order to generate more specific antibody-
109 based therapies aimed at neutralizing the most important toxins in the venom. One
110 approach has been to raise murine antibodies specific towards relevant *N. kaouthia* toxins
111 (Charpentier et al., 1990; Masathien et al., 1994). Another approach for identifying potent
112 antitoxins is phage display screening (Roncolato et al., 2015). By using this methodology,
113 inhibitors against *N. kaouthia* toxins have been identified for both PLA₂s (Chavanayarn et
114 al., 2012) and α -cobratoxin (Stewart et al., 2007; Kulkaew et al., 2009; Richard et al.,
115 2013). These studies discovered inhibitors through screening of phage display libraries
116 based on heavy chain fragments obtained from llama. Although promising, it could,
117 however, be argued that llama-derived inhibitors, despite being much smaller than whole
118 IgG antibodies and therefore likely to be less immunogenic, are still non-human. An
119 alternative to overcome this problem is based on modern antibody humanization procedures
120 (Safdari et al., 2013). In another study, inhibitors based on human single chain Fv (scFv)
121 fragments from non-immunized donors were developed (Kulkaew et al., 2009). These scFv
122 fragments were not effective in rescuing mice injected with venom, which is likely to be
123 due to naïve origin of the gene library for these fragments, since none of the human donors
124 had been exposed to snake venom. Thus, the search for novel approaches to generate
125 human antibodies against cobra venom toxins remains a challenge.

126 With this study, we report for the first time a venomics-based quantitative
127 estimation of the proteome and a full protein lethality profile for *N. kaouthia* venom, in
128 order to lay the foundation for developing a recombinant antivenom by identifying the most
129 relevant toxins present in this venom. Furthermore, we uncover the presence of human IgG
130 antibodies specific to *N. kaouthia* venom in the serum obtained from a unique individual
131 exposed to low doses of a wide variety of snake venoms over a period of more than 25

132 years. The binding ability of his antibodies, as well as of those from a person bitten twice
133 by the Southern Burrowing Asp, *Atractaspis bibronii*, was tested against the different
134 venom fractions from *N. kaouthia*, in comparison to a healthy volunteer unexposed to snake
135 venoms. Finally, the neutralizing ability against *N. kaouthia* venom of the purified human
136 IgG antibodies was evaluated in a mouse model.

137

138 **2. Materials and Methods**

139 *2.1 Snake venom*

140 *Naja kaouthia* venom was obtained from Latoxan SAS, Valence, France. The
141 venom is a pool collected from several specimens, originally from Thailand.

142

143 *2.2 Venom separation by reverse-phase HPLC and SDS-PAGE*

144 Following the 'snake venomomics' analytical strategy (Calvete, 2011), crude venom
145 was fractionated by a combination of RP-HPLC and SDS-PAGE separation steps. Venom
146 (2 mg) was dissolved in 200 μ L of water containing 0.1% trifluoroacetic acid (TFA;
147 solution A) and separated by RP-HPLC (Agilent 1200) on a C₁₈ column (250 x 4.6 mm, 5
148 μ m particle; Teknokroma). Elution was carried out at 1 mL/min by applying a gradient
149 towards solution B (acetonitrile, containing 0.1% TFA): 0% B for 5 min, 0–15% B over 10
150 min, 15–45% B over 60 min, 45–70% B over 10 min, and 70% B over 9 min, as previously
151 described (Lomonte et al., 2014a). Manually collected fractions were dried in a vacuum
152 centrifuge, redissolved in water, reduced with 5% β -mercaptoethanol at 100 °C for 5 min,
153 and further separated by SDS-PAGE in 12% gels (Bio-Rad). Proteins were stained with
154 colloidal Coomassie blue G-250, and gel images were acquired on a ChemiDoc[®] recorder
155 using ImageLab[®] software (Bio-Rad).

156

157 *2.3 Protein identification by tandem mass spectrometry of tryptic peptides*

158 Protein bands were excised from the polyacrylamide gels and subjected to reduction
159 (10 mM dithiothreitol), alkylation (50 mM iodoacetamide), and overnight in-gel digestion
160 with sequencing grade trypsin (Sigma), in 50 mM ammonium bicarbonate at 37°C. The
161 resulting tryptic peptides were extracted with 50% acetonitrile containing 1% TFA, and
162 analyzed by MALDI-TOF-TOF on an AB4800-Plus Proteomics Analyzer (Applied
163 Biosystems). Peptides were mixed with an equal volume of saturated α -cyano-
164 hydroxycinnamic acid (in 50% acetonitrile, 0.1% TFA), and spotted (1 μ L) onto an Opti-
165 TOF 384-well plate, dried, and analyzed in positive reflector mode. TOF spectra were
166 acquired using 1500 shots and a laser intensity of 3000. The ten most intense precursor ions
167 were automatically selected and their TOF/TOF fragmentation spectra were acquired using
168 500 shots at a laser intensity of 3900. External calibration in each run was performed with
169 CalMix[®] standards (ABSciex) spotted onto the same plate. For protein identification,
170 resulting spectra were searched against the UniProt/SwissProt database using ProteinPilot[®]
171 v.4 and the Paragon[®] algorithm (ABSciex) at $\geq 95\%$ confidence, or manually interpreted.
172 Few peptide sequences with lower confidence scores were manually searched using
173 BLAST (<http://blast.ncbi.nlm.nih.gov>) for protein similarity and protein family assignment.

174 RP-HPLC fractions corresponding to small molecules, eluting in the initial peaks of
175 the chromatogram, were analyzed by ESI-MS/MS on a Q-Trap[®] 3200 instrument (Applied
176 Biosystems). Samples (10 μ L) were loaded into metal-coated capillary tips (Proxeon) and
177 directly infused into a nano-ESI source (Protana) operated at 1300 V. Spectra were
178 acquired in positive Enhanced Resolution mode. nESI-MS performed in this instrument
179 was also used to determine the isotope-averaged mass of intact proteins in selected peaks

180 from the RP-HPLC separation. For this purpose, mass spectra were acquired in Enhanced
181 Multicharge mode in the m/z range 700-1700, and deconvoluted with the aid of the
182 Analyst[®] v.1.5 software (ABSciex).

183

184 *2.4 Relative protein abundance estimations*

185 The relative abundances of the venom proteins identified were estimated by
186 integrating the areas of their chromatographic peaks at 215 nm, using the ChemStation[®]
187 software (Agilent), which correlates with peptide bond abundance (Calvete, 2011). For
188 HPLC peaks containing several electrophoretic bands, their percentage distributions were
189 assigned by densitometry, using ImageLab[®] (Bio-Rad).

190

191 *2.5 Nucleoside and FAD analysis*

192 The presence of selected nucleosides (adenosine, inosine, guanosine), and flavine
193 adenine dinucleotide (FAD) was determined by spiking a sample of 1 mg of venom with 10
194 μg of each nucleoside or FAD, respectively, and separating it by reverse-phase HPLC as
195 described in section 2.2. If the nucleoside or FAD peak coincided with a peak already
196 present in a crude venom sample (as judged by the increment in the height of the peak), and
197 if this venom peak showed an ESI-MS spectrum similar to that of the nucleoside or FAD,
198 the identity of venom component was judged to be the same as the nucleoside or FAD.
199 Further confirmation of the molecular identities of the nucleosides was obtained by
200 acquiring their collision-induced dissociation MS/MS spectra in positive mode, using the
201 Enhanced Product Ion tool of the Analyst v1.5 in the QTrap 3200 mass spectrometer as
202 described (Laustsen et al., 2015). The abundance for nucleosides given in Table 1 is only
203 indicative of an approximate value, due to differences in absorbance at 215 nm between

204 nucleosides and proteins.

205

206 *2.6 In vitro enzymatic activities*

207 *2.6.1. Phospholipase A₂ activity*

208 PLA₂ activity was assayed on the monodisperse synthetic chromogenic substrate 4-
209 nitro-3-octanoyloxybenzoic acid (NOBA) (Holzer and Mackessy, 1996). Twenty-five µL
210 containing various amounts of venom were mixed with 200 µL of 10 mM Tris, 10 mM
211 CaCl₂, 0.1 M NaCl, pH 8.0, and 25 µL of NOBA to achieve a final substrate concentration
212 of 0.32 mM. Plates were incubated at 37 °C for 60 min, and absorbances were recorded at
213 405 nm in a microplate reader. Samples were assayed in triplicates.

214

215 *2.6.3 Proteinase activity*

216 Variable amounts of venom (10 to 40 µg) were added to 100 µL of azocasein (10
217 mg/mL in 50 mM Tris-HCl, 0.15 M NaCl, 5 mM CaCl₂ buffer, pH 8.0), and incubated for
218 90 min at 37 °C. The reaction was stopped by addition of 200 µL of 5% trichloroacetic
219 acid, and after centrifugation (5 min, 13,000 rpm), 150 µL of supernatants were mixed with
220 100 µL of 0.5 M NaOH, and absorbances were recorded at 450 nm. The absorbance of
221 azocasein incubated with distilled water alone was used as a blank, being subtracted from
222 all readings (Wang et al. 2004). Samples were assayed in triplicates.

223

224 *2.7 Toxicological profiling*

225 *2.7.1 Animals*

226 *In vivo* assays were conducted in CD-1 mice, supplied by Instituto Clodomiro
227 Picado, following protocols approved by the Institutional Committee for the Use and Care

228 of Animals (CICUA), University of Costa Rica. Mice were housed in cages for groups of
229 4–8, and were provided food and water *ad libitum*.

230

231 *2.7.2 Toxicity of crude venom and isolated toxins*

232 The lethality of the whole venom and fractions or isolated toxins was tested by
233 intravenous (i.v.) injection in groups of four mice (18–20 g body weight). Various amounts
234 of venom or fractions/toxins were dissolved in phosphate-buffered saline (PBS; 0.12 M
235 NaCl, 0.04 M sodium phosphate buffer, pH 7.2), and injected in the caudal vein, using an
236 injection volume of 100 μ L. Then, deaths occurring within 24 hr were recorded. Median
237 lethal dose (LD₅₀) was calculated by probits (Finney, 1971), using the BioStat[®] software
238 (AnalySoft).

239 The toxicity of venom fractions was initially screened by selecting a dose based on
240 fraction abundance. The dose was selected to assess whether the fraction would score above
241 or below 5 according to the Toxicity Score defined by Laustsen et al. (2015), which
242 represents the ratio of protein fraction abundance (%) in the venom divided by its estimated
243 LD₅₀ in CD-1 mice by i.v. injection. Fractions that were not lethal at this dose (yielding a
244 Toxicity Score < 5) were considered as having insignificant toxicity. All fractions that were
245 lethal at this level, and some fractions killing mice at a Toxicity Score level between 1-5
246 were further evaluated, and precise LD₅₀ values were further determined for them. Groups
247 of 3-5 mice per dose were used in order to minimize the use of experimental animals.

248

249 *2.8 Preparation of human IgGs and human serum*

250 *2.8.1 Donor 1*

251 This donor has over a period of 25 year injected himself with sub-lethal amounts of
252 venom from the following snakes: *Viridovipera* (formerly *Trimeresurus*) *stejnegeri*,
253 *Trimeresurus nebularis*, *T. macrops*, *T. popeorum*, *T. trigonocephalus*, *T. albolabris*, *T.*
254 *venustus*, *Bothriechis schlegelii*, *Crotalus enyo enyo*, *Naja kaouthia*, *N. naja*, *N. siamensis*,
255 *Agkistrodon contortrix*, *A. bilineatus*, *Bothrops asper*, *Crotalus oreganus*, *Crotalus*
256 *oreganus helleri*, *Cerastes cerastes*, and *Micrurus fulvius*. In the last 5 years, this individual
257 has been injecting himself with venom from *Naja kaouthia* on an average of every 2 weeks.
258 Brian Lohse has a written consent from the Danish scientific ethical council (H-3-2013-
259 FSP60) to use the blood sample from this donor according to the law of the ethical
260 committee § 2.1. After having provided written and oral information about the project to
261 this donor, written consent was given for obtaining blood samples and for performing the
262 experiments included in the present work. The donor requested the inclusion of his name to
263 be acknowledged in publications.

264

265 2.8.2 Donor 2

266 Donor 2 is an entomologist, who was unfortunate to be bitten twice by the snake
267 *Atractaspis bibronii* (Southern Burrowing Asp) during fieldwork in August 2013. After
268 having provided written and oral information about the project to this donor, written
269 consent was given for obtaining blood samples and for performing the experiments here
270 included. The donor requested the inclusion of his name to be acknowledged in
271 publications.

272

273 2.8.3 Blood sampling for obtaining IgGs

274 200 ml of blood was sampled from each donor in Vacuette[®] tubes of 4 mL,
275 containing Z Serum Clot Activator (Greiner bio-one). Every tube was gently tilted up and
276 down ten times as soon as it was filled with blood to ensure thorough mixing with the
277 coagulation factor. The tubes were kept at room temperature until full coagulation (30 min).
278 Then, tubes were centrifuged at 3000 g for 10 min, and the serum was transferred to
279 cryotubes and stored at -20 °C.

280

281 *2.8.4 Protein A purification of IgG antibodies*

282 After filtration of serum through a 0.45 µm membrane, the procedure accompanying
283 the Protein A Antibody Purification Kit (PURE1A, Sigma-Aldrich) was followed in order
284 to obtain human IgG antibodies in solution at physiological pH. IgG antibodies were stored
285 at 4 °C.

286

287 *2.8.5 Preparation of human serum from healthy volunteer*

288 Blood was obtained from a healthy donor to serve as a negative control. After
289 clotting, serum was separated by centrifugation, and stored at – 20 °C.

290

291 *2.9 Immunoreactivity of human IgGs against venom fractions by ELISA*

292 Wells in MaxiSorp plates (NUNC, Roskilde, Denmark) were coated overnight with
293 0.6 µg of each HPLC venom fraction dissolved in 100 µL PBS. Then, wells were blocked
294 by adding 100 µL PBS containing 2% (w:v) bovine serum albumin (BSA, Sigma) and
295 leaving the plates on a mixer at room temperature for 1 h. Plates were then washed five
296 times with PBS. A dilution of each human IgG pool in PBS + 2% BSA was prepared such
297 that the concentration of IgG proteins was 86 µg/mL (as measured by their absorbance at

298 280 nm on a NanoDrop[®] 2000c instrument, Thermo Scientific). Then, 100 μ L of these IgG
299 solutions were added to the wells, after which the plates were incubated for 2 h, followed
300 by five additional washings with PBS. Then, 100 μ L of a 1:2000 dilution of affinity-
301 purified goat anti-human IgG (gamma-chain specific) antibodies conjugated to alkaline
302 phosphatase (Cappel, Organon Teknika) in PBS + 2% BSA was added to each well. The
303 plates were incubated for 2 h, and then washed five times with FALC buffer (0.05 M Tris,
304 0.15 M NaCl, 20 μ M ZnCl₂, 1 mM MgCl₂, pH 7.4). Color development was achieved by
305 the addition of 100 μ L *p*-nitrophenyl phosphate (1 mg/mL in 9.7% v/v diethanolamine
306 buffer, pH 9.8). The absorbances at 405 nm were recorded (Multiskan FC, Thermo
307 Scientific) at several time intervals.

308

309 2.10 Neutralization studies with human IgGs

310 After purification according to section 2.8.4, the human IgGs were kept refrigerated.
311 Six months later, 3 mL of IgGs were dialyzed against 2 L of PBS overnight and
312 lyophilized. The IgGs were reconstituted in 500 μ L PBS and the protein concentration was
313 measured on NanoDrop to be 14 mg/ml. IgG was mixed with venom at a ratio of 78 mg
314 IgG/mg venom and incubated at 37 °C for 30 min. Aliquots of 120 μ L of this mixture,
315 containing 4 LD₅₀s of venom, were then injected i.v. into a group of four mice (18-20 g)
316 and deaths occurring within 24 hr were recorded.

317

318 3.0 Results and Discussion

319 3.1 Venomics

320 A proteomic characterization of *N. kaouthia* venom coupled with an estimation of
321 its protein relative abundances was, with this study, carried out for the first time. Twenty-

322 eight peaks from the venom were resolved by RP-HPLC. The first three fractions eluting
323 from the column were non-peptidic, while the remaining 25 peaks were further resolved
324 into 50 protein bands by SDS-PAGE separation (Fig.1). In-gel digestion and MALDI-TOF-
325 TOF analysis of these yielded a total of 38 identified proteins, while only 4 remained
326 unknown. Altogether, the unidentified venom components represent less than 1% of the
327 total venom protein content, while the rest were either identified or assigned to protein
328 families (Table 1). A previous qualitative proteomic profile was reported for this venom,
329 describing matches to 61 orthologous proteins classified into 12 groups (Kulkaew et al.,
330 2007). Of these, oxoglutarate dehydrogenase complex was identified on the basis of a
331 single peptide that matched such enzyme from a prokaryote (*Burkholderia cenocepacia*),
332 while serum albumin likely corresponds to contaminating traces derived from slight trauma
333 that may occur during venom collection (see for example Lomonte et al., 2014b). In
334 addition, the previous study considered cardiotoxins and cytotoxins as two different protein
335 groups, in spite of these two names being used to refer to the same type of toxins,
336 structurally classified within the three-finger toxin family (Kini and Doley, 2010). Our
337 results are concordant with the remaining eight protein families detected by Kulkaew et al.
338 (2007), but further expand the proteomic profile of *N. kaouthia* venom with the addition of
339 members belonging to the nerve growth factor, ohanin-like/vespryn, C-type lectin/lectin-
340 like, nucleotidase, phosphodiesterase, L-amino acid oxidase, and cytidyltransferase protein
341 families (Table 1 and Fig.2), and moreover, providing a quantitative estimation of their
342 relative abundances in the venom.

343 Peaks 1 to 3 were analyzed by direct infusion using nESI-MS/MS, since they did
344 not show proteins by gel electrophoresis. Peaks 2 and 3 had molecular masses of 268 Da
345 and 283 Da, respectively, and the nucleoside analysis by HPLC (Fig.3) revealed their

346 identities as adenosine and guanosine, respectively. Also, a trace of inosine between peaks
347 2 and 3 was detected by the nucleoside analysis by HPLC (Fig.3).

348 All peptidic peaks were tested *in vivo* for acute toxicity, except for peaks 23 and 26,
349 which yielded very low amounts of proteins (Table 2), and peaks 24, 27, and 28, which
350 correspond to metalloproteinases, enzymes known to be inactivated by the RP-HPLC
351 separation procedure. In Fig.2, the overall protein composition of the venom of *N. kaouthia*,
352 expressed as percentage of total protein and nucleoside content, is represented. Two main
353 families predominate in the venom: Three-finger toxins (3FTx; 77.5%, of which 24.3% are
354 cytotoxins, the rest being neurotoxins) and PLA₂s (PLA₂; 13.5%). In partial agreement with
355 previous findings, the major single component of the three-finger toxins was determined to
356 be alpha-elapitoxin-Nk2a (α -cobratoxin), a long-chain neurotoxin. However, in our results,
357 this toxin represented 32.3% of the whole venom, which is significantly higher than the
358 reported values of 23-25% (Kulkaew et al., 2009). This increase might reflect either
359 geographical variations in venom composition or differences in methodology. As other α -
360 neurotoxins, alpha-elapitoxin-Nk2a is able to bind to nicotinic receptors at the motor end-
361 plate of muscle fibers, thus generating a flaccid paralysis leading to respiratory failure and
362 death (Ultsintong et al., 2009; Alkondon et al., 1990). This type of neurotoxin is
363 responsible for the life-threatening neuromuscular paralysis in human victims of neurotoxic
364 cobra bites (Warrell, 1995).

365 An interesting finding, discovered by the lack of high acute toxicity in the rodent
366 model (Table 2), and reinforced by the difference in human IgG binding in the ELISA
367 assays (Fig.6) was that the protein identified in peak 10 as alpha-elapitoxin-Nk2a appears to
368 correspond to a closely related homolog. In order to validate this, both peak 10 and peak 6

369 (known to contain alpha-elapitoxin-Nk2a) were analyzed by nESI-MS/MS (Fig.5),
370 according to which their masses were 7619 and 7826 Da, respectively (alpha-elapitoxin-
371 Nk2a has a reported mass of 7831 Da according to:
372 <http://www.uniprot.org/uniprot/P01391>). Thus, peak 10 should be a homolog of alpha-
373 elapitoxin-Nk2a sharing peptide sequences (Table 1), but different by 207 Da in total mass.
374 Since the toxicity of this protein is markedly lower in comparison to alpha-elapitoxin-Nk2a,
375 further studies to determine its complete amino acid sequence and bioactivities could be of
376 interest, as it represents nearly 10% of the venom proteome.

377 In addition to α -neurotoxins, other representatives of the three-finger toxin family
378 detected in *N. kaouthia* venom proteome are the so-called 'cytotoxins' (Table 1). These
379 toxins are known to interact with and disrupt the integrity of plasma membrane of various
380 cell types, thus inducing irreversible cell damage (Konshina et al., 2012). These cytotoxins
381 are responsible for the local necrotic effect characteristic of envenomings by *N. kaouthia*
382 (Warrell, 1995). Also, PLA₂ is commonly an abundant component in the majority of elapid
383 venom proteomes characterized so far, and it was detected in our proteomic analysis in *N.*
384 *kaouthia* venom. PLA₂ activity was confirmed for *N. kaouthia* venom *in vitro*, although it
385 was significantly lower than for *M. nigrocinctus*, a Central American elapid species
386 (Fig.4A). Elapid PLA₂s have been shown to exert a number of toxicological effects, such as
387 myonecrosis (Bhat and Gowda, 1989; Harris, 1991), anticoagulation (Kini, 2005; Doley
388 and Mukherjee, 2003), inhibition of platelet aggregation (Clemetson et al., 2007), and
389 edema (Wang and Teng, 1990). In the case of *N. kaouthia* venom, PLA₂s might contribute
390 to the local inflammatory and necrotizing effects observed in human patients. Furthermore,
391 cardiotoxins and PLA₂s act synergistically to induce cell membrane damage (Harvey et al.,
392 1983), thus potentiating the tissue damaging effect of the venom. Altogether, a high

393 proportion of the components of *N. kaouthia* venom belong to these two toxin families, i.e.
394 three-finger toxins and PLA₂s. This further supports the concept that high diversity within
395 just a few toxin families may be a general theme within elapid venoms (Calvete, 2013;
396 Laustsen et al., 2015). Such idea is supported also by findings of Vonk et al. (2013) on the
397 genome of the elapid *Ophiophagus hannah* (king cobra), in which the three-finger toxins
398 family was found to be highly diversified.

399 In amounts each representing <2% of the total venom content, the venom also
400 contains members of the nerve growth factor (NGF), Ohanin/vespryn (OHA), Cysteine-rich
401 secretory protein (CRISP), C-type lectin/lectin-like (CTL), nucleotidase (NUCL),
402 phosphodiesterase (PDE), metalloproteinase (MP), L-amino oxidase (LAO), Cobra venom
403 factor (CVF), and Cytidyltransferase (CTT) families. The low content of proteinases is
404 further supported by the negligible proteinase activity of the venom upon a general
405 substrate such as azocasein (Fig.4B). Also, regarding non-peptidic material, small amounts
406 were identified to be adenosine, inosine, and guanosine, which have also been detected in
407 other snake venoms (Aird, 2002; Laustsen et al., 2015).

408 The results of toxicity testing of the fractions are summarized in Table 2.
409 Unsurprisingly, the lethality of the venom stems from the presence of potent α -neurotoxins
410 and cytotoxins, with PLA₂s playing a secondary role leading to local tissue damage at the
411 bite wound. A Toxicity Score is shown in Table 2, which takes into account both potency
412 and abundance. Toxins with a higher score, as estimated in mice, are expected to be of
413 higher medical relevance. These are abundant and/or very potent, while toxins with a low
414 score are less medically relevant. Based on this score, it is clear that alpha-elapitoxin-Nk2a
415 is by far the toxin that is most clinically relevant to neutralize, with a value of 326. Some
416 toxins have very low LD₅₀s (particularly fractions 4 and 5), but due to their lower

417 abundance their Toxicity Scores are much lower. Others have intermediate LD₅₀ potencies,
418 but become relevant due to their high abundance (e.g. fraction 16). The cytotoxins present
419 in the venom act by a different mechanism than the α -neurotoxins, providing *N. kaouthia*
420 venom with a dual strategy for prey subduction. It is interesting to note that the
421 accumulated Toxicity Scores for all toxins amount to the same value as the Toxicity Score
422 for the whole venom. This is not the case for the venom from the related elapid,
423 *Dendroaspis polylepis*, which shows evidence of synergism, and where the accumulated
424 Toxicity Scores is considerably lower than the Toxicity Score of whole venom (indicating
425 synergism between the toxins and not simply additive effect) (Laustsen et al., 2015). One
426 interpretation of this finding could be that *N. kaouthia* venom does not exert significant
427 synergism, but instead relies on two complementary strategies for acute toxicity.

428 In terms of therapeutic targets, based on their Toxicity Score, the most relevant
429 toxins in *N. kaouthia* venom that should be neutralized by an effective antivenom are (in
430 order of importance): alpha-elapitoxin-Nk2a (P01391), cobrotoxin-c (P59276) and
431 cobrotoxin-b (P59275), and the homolog of three-finger toxin from *Naja atra* (E2IU03),
432 while the cytotoxins are of less importance in terms of overall lethality, although they are
433 likely to play a relevant role in local necrosis, and hence should be neutralized by
434 antivenoms. In addition, neutralization of PLA₂s should also be considered a priority in
435 order to limit local tissue damage from envenomings. Thus, antivenomic studies with *N.*
436 *kaouthia* venom should establish whether antivenoms are able to bind these toxins.

437

438 3.2 Immunoreactivity of human IgGs against venom fractions

439 The isolated human IgGs from the unique individual who had self-injected small
440 amounts of venom from various different snakes, including *N. kaouthia*, showed significant

441 binding ability to isolated venom fractions, clearly above the background established by
442 serum of a healthy donor, or by IgGs from the donor bitten twice by a different snake
443 species (Fig.6). It is evident that the antibody response of the individual exposed to *N.*
444 *kaouthia* venom was higher against larger toxins present in later eluting peaks, while the
445 response was limited against the most important α -neurotoxins (peaks 4, 5, and 6), which
446 could be due to the low immunogenicity of small toxins (Fernández et al., 2011). Therefore,
447 it was not surprising that IgGs were unable to neutralize the lethality of whole venom when
448 mice were challenged with 4 LD₅₀s mixed with IgGs at a level of 0.013 mg toxin per mg of
449 IgGs. Nevertheless, it could be particularly interesting to further investigate these
450 antibodies via phage display screening. In llamas, it has been shown that using naïve
451 libraries for phage display screening did not yield high affinity inhibitors to snake toxins,
452 while excellent inhibitors of alpha-elapitoxin-Nk2a were discovered this way, when a
453 library from an immunized llama was used (Richard et al., 2013). Kulkeaw et al. (2009)
454 were the first to report drug discovery effort using a human phage display library. However,
455 they similarly did not find strong inhibitors of snake toxins, most likely given the fact that
456 their library was naïve. Therefore, using the antibody genes from the unique donor to
457 construct a phage display library, and subsequently screening this library, has the potential
458 to yield toxin inhibitors of therapeutic value. Further studies of the donor's immune
459 response against toxins from other snake species are warranted and may help direct phage
460 display screening efforts towards the generation of new antibodies of human origin.

461

462 **4.0 Concluding remarks and outlook**

463 Differing from previous proteomic studies on *N. kaouthia* venom, the present work
464 combined the cataloguing of venom proteins with an estimation of their relative

465 abundances, together with an assessment of their lethal toxicity for mice. This approach
466 uncovered that the most abundant group of proteins was three-finger toxins, followed by
467 PLA₂s. Based on an evaluation of the accumulation of Toxicity Scores and knowledge
468 about toxin functions, the venom seems to have a dual strategy for prey subduction elicited
469 by α -neurotoxins and cytotoxins, between which pharmacological interaction is speculated
470 only to be of additive value rather than synergism.

471 ELISA immunoprofiling of human IgGs isolated from a human donor, who had
472 repeatedly injected himself with snake venom from various different species, revealed
473 presence of antibodies with high binding ability to several of the isolated venom fractions,
474 although not against the medically most relevant toxins of *N. kaouthia*. Still, the presence
475 of these antibodies opens the prospect of discovering inhibitors of therapeutic value.

476

477 **Acknowledgments**

478 The authors thank Steve Ludwin and Thomas Pape for donation of blood samples
479 for this study. We thank Dr. Steven D. Aird (Okinawa Institute of Science and Technology,
480 Japan) for fruitful discussions about nucleosides present in snake venom. We further thank
481 Jens Kringelum (Technical University of Denmark), Mikael Engmark (Technical
482 University of Denmark), and Alexandra Bak Jakobsen (Denmark) for fruitful scientific
483 discussions. We thank the Department of Drug Design and Pharmacology, University of
484 Copenhagen, and Instituto Clodomiro Picado, Universidad de Costa Rica, for supporting
485 the research. Finally, we are grateful to the following foundations for financial support:
486 Drug Research Academy (University of Copenhagen), Dansk Tennis Fond Oticon Fonden,

678 **Figure legends**

679

680 **Figure 1:** Separation of *N. kaouthia* (A) venom proteins by RP-HPLC (C), followed by
681 SDS-PAGE (B). Two mg of venom were fractionated on a C₁₈ column and eluted with an
682 acetonitrile gradient (dashed line), as described in Methods. Fractions were further
683 separated by SDS-PAGE under reducing conditions. Molecular weight markers (Mw) are
684 indicated in kDa. Coomassie-stained bands were excised, in-gel digested with trypsin, and
685 subjected to MALDI-TOF/TOF analysis for assignment to protein families, as shown in
686 [Table 1](#).

687

688 **Figure 2:** Composition of *N. kaouthia* venom according to protein families, expressed as
689 percentages of the total protein content. 3FTx: three-finger toxin; PLA₂: phospholipase A₂;
690 NGF: nerve growth factor; OHA: Ohanin/vespryn; CRISP: Cysteine-rich secretory protein;
691 CTL: C-type lectin/lectin-like; NUCL: nucleotidase; PDE: phosphodiesterase; MP:
692 metalloproteinase; LAO: L-amino oxidase; CVF: Cobra venom factor; CTT:
693 Cytidyltransferase; UNK: Unidentified proteins; NP: non-protein components. A division
694 between cytotoxins (CYT) and neurotoxins (NTX) is given for the three-finger toxins.

695

696 **Figure 3:** Presence of selected nucleosides and FAD in *Naja kaouthia* venom shown by
697 spiking crude venom with 10 µg of nucleosides (adenosine, inosine, guanosine) or FAD and
698 separating the venom components by reverse-phase HPLC. If a the peak of a nucleoside
699 coincides with the peak of a venom component, and if mass determination yielded the same
700 mass for the venom component as calculated for the nucleoside, the venom component was

701 judged to consist of the corresponding nucleoside. *N. kaouthia* venom contains small
702 amounts of adenosine, guanosine, and traces of inosine, but no FAD.

703

704 **Figure 4:** (A) Comparison of the phospholipase A₂ activity between the venoms of *Naja*
705 *kaouthia* and *Micrurus nigrocinctus*. *N. kaouthia* displays some enzymatic activity,
706 although significantly less than *M. nigrocinctus*. (B) Comparison of the proteolytic activity
707 between the venoms of *N. kaouthia*, *M. nigrocinctus*, and *Bothrops asper*, evaluated on
708 azocasein. *N. kaouthia* shows negligible proteinase activity.

709

710 **Figure 5:** Electrospray ionization-mass spectrometry analysis of *N. kaouthia* venom
711 fractions 6 and 10 (see Fig.1 and Table 1). Samples were analyzed in enhanced multi-
712 charge positive mode as described in Methods. Fraction 6 (Nk-6) presented a homogeneous
713 multi-charged series (A) which deconvoluted to an isotope-averaged mass (M_{av}) of 7826.0
714 ± 0.8 Da (B). The multi-charged series of fraction 10 (Nk-10) (C) showed a main protein
715 with M_{av} 7619.0 ± 1.3 Da and a less abundant protein of 7656.0 ± 0.7 Da (D), thus
716 demonstrating difference between fractions 6 and 10.

717

718 **Figure 6:** ELISA-based immunoprofiling of human antibodies (**Donor 1 IgG:** protein A-
719 purified IgG antibodies from Donor 1, **Donor 2:** protein A-purified IgG antibodies from
720 Donor 2, **Human negative:** normal human serum from healthy volunteer, never bitten by a
721 snake) to the fractions of *Naja kaouthia* venom separated by RP-HPLC (see Materials and
722 Methods for details). Toxins with the highest Toxicity Score (4, 5, and 6) are marked with a
723 skull symbol.

724

Table 1: Assignment of the RP-HPLC isolated fractions of *Naja kaouthia* venom to protein families by MALDI-TOF-TOF of selected peptide ions from in-gel trypsin-digested protein bands.

* Cysteine residues are carbamidomethylated, unless underlined. Confidence (Conf) and Score (Sc) values are calculated by the Paragon algorithm of ProteinPilot[®] (ABSciex) ▼ : estimated mass by SDS-PAGE under reducing conditions, in kDa. V : observed isotope-averaged masses as determined by nESI-MS of selected RP-HPLC peaks, in Da. X: Leu/Ile; B: Lys/Gln; Z: pyroglutamate (2-oxo-pyrrolidone carboxylic acid). Possible, although unconfirmed/ambiguous amino acid modifications suggested by the automated identification software are shown in parentheses, with the following abbreviations: ^{ox}: oxidized; ^{dn}: deamidated; ^{ca}: carbamyl; ^{am}: amide; ^{nc}: Na cation; ^{dl}: ammonia loss; ^{di}: delta ^{H2C2}, man: manually interpreted MS/MS spectrum.

Table 2: Median lethal doses (LD₅₀s) of *Naja kaouthia* venom and the RP-HPLC isolated fractions

*<http://snakedatabase.org/pages/LD50.php#legendAndDefinitions>

¹ Toxicity Score was defined as the ratio of protein fraction abundance (%) in the venom divided by its estimated median lethal dose (LD₅₀) for CD-1 mice by i.v. injection.

² Mix indicates that the fraction did not contain a pure, isolated toxin, but instead a mixture of 2-4 different toxins in variable ratios indicated in the table.

N.t. : not tested
