The main objective of this study is to explore the potential effects of environmentally relevant arsenic (As) levels on oxidative stress biomarkers of great tits (Parus major) in Harjavalta, Finland. Nestlings were orally dosed with As in three experimental groups (Control, Low and High As groups: 0, 0.2 and 1 µg/g/d) and were compared with those living in the vicinity of a copper-nickel smelter, an As source (Smelter group, 0 µg/g/d). We studied a set of antioxidant molecules (glutathione peroxidase, GPx; glutathione-S-transferase, GST; catalase, CAT; superoxide dismutase, SOD; glutathione, GSH) and lipid peroxidation as TBARS (thiobarbituric acid reactive substances) levels. Feces were collected to measure As concentrations. Fecal As concentrations were significantly higher in the Smelter and High groups, followed by the Low group, and finally the Control group with significantly lowest levels. Although nestlings from the High As group showed higher GST and SOD activity and

GSH and TBARS levels than the Control group, no significant differences were found. CAT activity was significantly lower in the High As group, while GPx was significantly higher in the Smelter group when compared to the Control group. The lower CAT activity in the High As group may reflect the ability of this metalloid to deplete the activity of this antioxidant enzyme. The higher GPx activity in the polluted environment may reflect higher level of oxidative stress in nestlings from this area, probably due to the exposure to a mixture of metals and the associated limitation of resources (lower food quality and quantity) demonstrated before, showing the importance of secondary pollution effects on birds.

MP115 Effects of calcium supplementation and metal pollution on oxidative stress in great tit nestlings

P. Sánchez Virosta, S. Espín, S.R. Ruiz, J. Stauffer, Univ of Turku / Biology; M. Kanerva, Univ of Turku / Dept of Biology; A.J. García-Fernández, Univ of Murcia / Sociosanitary Sciences; T. Eeva, Univ of Turku / Dept of Biology

Different studies have suggested that calcium (Ca) administration may have a protective role against metal toxicity by modulating metal-induced oxidative stress. The present study aims to explore the effects of Ca availability and metal exposure on oxidative stress biomarkers in great tit (Parus major) nestlings. Great tits were supplemented with Ca (Ca-supplemented group) or not supplemented (Control group) during the breeding season in a metal-polluted and a control area in Harjavalta, Finland. Feces were collected to measure metal concentrations. We analyzed antioxidant enzymes (glutathione peroxidase, GPx; glutathione-S-transferase, GST; catalase, CAT and superoxide dismutase, SOD) and lipid peroxidation as thiobarbituric acid reactive substances (TBARS) levels in red blood cells of great tit nestlings. CAT activity was higher in Ca-supplemented nestlings, suggesting that Ca could be involved in the regulation of the antioxidant system by stimulating the activity of this enzyme. The activities of GPx and SOD were significantly higher in the polluted environment, which may reflect higher level of oxidative stress in nestlings from this area, probably due to the higher metal exposure and the poorer condition (nestling size and fledgling number were lower in the polluted area due to lower food quality and quantity). In this sense, GPx activity was positively correlated with metal concentrations in feces and negatively correlated with nestling size. Significant negative correlation was found between TBARS levels and nestling size, suggesting that smaller nestlings suffering from poorer condition have increased lipid peroxidation. However, the lack of differences in TBARS levels between the polluted and unpolluted zone shows that metal exposure seems to be low to directly produce oxidative damage to lipids.

MP116 Dynamic Modeling of Fish-Eating Bird First-Flush Exposure to Toxaphene in a Reservoir Constructed on Contaminated Farm Soil

L.E. Fink, Waterwise Consulting, LLC / Owner and Principal

In 1990 EPA banned all uses of the last of the organochlorine (OC) insecticides, the highly persistent, bioaccumulative and toxic toxaphene, a mixture of polychlorinated camphenes. Subsequently, environmental scientists have been challenged to derive clean-up levels for toxaphene-contaminated farm soils for flooded land uses based on sound science rather than wishful thinking. Wishful thinking resulted in Florida's Lake Apopka disaster, where more than 500 fish-eating birds attracted to newly flooded wetlands on highly contaminated former farmland died from acute exposure to a mixture of rapidly bioaccumulating OCs in toxaphene-stunned fish in late 1998 and early 1999. Subsequently, the U.S. Fish and Wildlife Service adapted the Mackay Level III Fugacity Model to predict exposure of fish-eating birds bioaccumulating OCs from rapidly developing food chains in flooded depressions over OC hotspots to set clean-up levels. Partitioning of each OC is based on its measured or estimated soil/water partition coefficient normalized to organic carbon content (Koc) and subsequent bioaccumulation into each aquatic trophic level is based on its octanol/water partition coefficient (Kow). While the model appeared to reproduce observed OC bioaccumulation patterns when applied to the Lake Apopka wetlands, its deficiencies were obvious, as evidenced by greater bioaccumulation observed in the largemouth bass than the fathead minnow, despite an average lipid content of 3% and 6%, respectively. To correct USFWS model deficiencies, I developed a set of linked spreadsheets with sets of differential equations to model dynamic first-flush release of dissolved organic carbon and the OC from wet soils and subsequent OC dynamic bioaccumulation by a mudworm, and trophic level 1, 2, and 3 fish. The screening-level model was applied to toxaphene-contaminated Woerner Turf parcels in a proposed reservoir footprint in the Everglades Agricultural Area. The results suggest the USFWS model overestimates risks to fish-eating birds foraging in pools over low-lying toxaphene residue hotspots during first-flush flooding when fish at higher trophic levels do not reach steady state before the pools disappear with rising stage. Toxaphene fact sheets also need to be revised to remove erroneously low logKow values that may still be propagated into the derivation of contaminated site clean-up levels approved by responsible environmental protection and consulting wildlife protection agencies.

MP117 Blood and feather heavy metal concentration of a resident and migratory songbird

Z. Cooper, Univ of Georgia – Savannah River Ecology Laboratory; R.B. Bringolf, Univ of Georgia / Interdisciplinary Toxicology Program; A.L. Bryan, Univ of Georgia / SREL; K. Loftis, Univ of Georgia / Center for Applied Isotopes Studies; J.A. Martin, Univ of Georgia Savannah River Ecology Laboratory

Various anthropogenic activities have resulted in concentration of heavy metals and contamination of surrounding environments. Historically, heavy metal contamination at the Savannah River Site (SRS) in South Carolina has resulted from accidental releases of stored waste generated from nuclear weapon production in the early 1950's. Songbirds inhabiting and using resources from these areas have the potential to bioaccumulate metals but there is limited information on metal concentration levels in areas suspected of contamination as well as uncontaminated sites. Nonlethal tissue samples from avian blood and feathers provide a reliable approach for determining the bioavailability of these pollutants. The objective of this study was to survey bioavailable heavy metal contamination at the SRS though blood and feather samples from resident Northern Cardinals (Cardinalis cardinalis) and migratory Great Crested Flycatchers (Myiarchus crinitus). Samples were collected in April and May of 2016. Feather levels of chromium ($F_{1, 43}$ = 11.47, P =0.0015) and lead ($F_{1, 43}$ = 7.04, P = 0.009) were higher in flycatchers (Cr: =3.418 ppm, SD =3.888; Pb: = 0.291 ppm, SD =0.263) than cardinals (= 1.30 ppm Cr, SD =0.356; = 0.1436, SD =0.098). Selenium levels in blood were also significantly ($F_{1,34}$ = 9.83, P =0.004) higher in flycatchers (= 1.529, SD =0.355) than cardinals (= 1.067, SD =0.349). There was no difference in feather or blood concentrations between species for Hg, Ni, Zn, Cu, or Cd. Feather concentrations of Cu in male cardinals were more than females (B =1.119, 85% CL = 0.111, 2.128) in the greatest weighted model (w=0.533). The model with the greatest weight evaluating concentrations of Zn in the feathers of cardinals (w=0.999) indicated males have less than females (B=-46.186, 85% CL = -55.784, -36.588) and one location had less than the other sites (B=-38.198, 85% CL = -72.130,-4.267). Generally, both species had similar levels of all metals. Species differences are likely attributed to diet composition and time spent on their breeding grounds for flycatchers. Even though contaminant levels are below the toxicity thresholds, more research is needed to determine if these low levels of metal contamination can induce chronic stress and affect fitness or susceptibility to diseases and parasites.

MP118 Application of Relative Potency Data for Aroclor 1268 in Birds and Mammals

P.C. Fuchsman, M.H. Henning, Ramboll Environ; D. Pelletier, Ramboll Environ / Office of Research and Development Atlantic Ecology Division; R. Wenning, Ramboll Environ / Ecology Sediment Management; V.S. Magar, Ramboll Environ US Corporation, Chicago, IL

Aroclor 1268 is an unusual PCB mixture containing primarily octa-, nona-, and decachlorobiphenyls. Several lines of evidence indicate that Aroclor 1268 is much less toxic than more typical environmental PCB mixtures. First, concentrations of the most potent (sometimes called "dioxin-like") PCB congeners in Aroclor 1268 are very low. Second, historical toxicity tests using chickens – a particularly sensitive species – indicated a lack of reproductive effects following exposure to Aroclor 1268, while comparable concentrations of other PCB mixtures caused significant reductions in hatching success. Third, a recent toxicity study using mink yielded dose-response relationships that show much lower toxicity compared to more typical PCB mixtures. While non-dioxin-like effects on mink were observed, they occurred only in association with notably high exposures. An Aroclor 1268 study in fish provides additional supporting information, although data on PCB effects of Aroclor 1268 versus other PCB mixtures are from different fish species. Taken together, these lines of evidence support the derivation of relative potency factors to interpret Aroclor 1268 exposures in birds and mammals, relative to toxicity data developed for other PCB mixtures. We provide a case study evaluating PCBs in least terns and bottlenose dolphins residing near an Aroclor 1268-contaminated site in coastal Georgia. Although elevated total PCB concentrations in these species initially prompted concerns regarding potential reproductive effects, such concerns are not justified when the relative potency of Aroclor 1268 is taken into account.

MP119 The Effects of Sub-Lethal Pesticide Exposure on Behavior of Aquatic Vertebrates: A Meta-Analysis

M. Shuman-Goodier, Northern Arizona Univ / Dept of Biological Sciences; C.R. Propper, Northern Arizona Univ / Biological Sciences

Pesticide contaminants are ubiquitous in aquatic environments and pose a threat to biodiversity. Behavioral indicators, commonly used in ecological and toxicological studies to evaluate sub-lethal effects of pesticides on aquatic organisms, create important connections between physiological and ecological processes. Evaluating behavioral shifts in response to exposure can integrate concepts of ecology with the field of toxicology to improve how we evaluate the impacts of pesticide exposure. In order to bridge the toxicological and behavioral literature, and identify chemical classes that denote the largest threat, we conducted a meta-analysis summarizing the effects of pesticides on swim speed and activity of aquatic vertebrates. We found that exposure to environmentally relevant concentrations of pesticides reduced the swim speed of exposed amphibians and fish by 49 percent, and reduced overall activity by 71 percent. There were also differences in the magnitude of this effect across chemical classes, which likely reflect underlying physiological processes. Pyrethroids, carbamates, organophosphates, and triazines all produced a large decrease in swim speed, where as phosphonoglycines and organotins showed no overall effect. Pyrethroids, carbamates, organophosphates, organochlorines, and organotins also produced a large decrease in activity, while phosphonoglycines had no overall effect, and triazines had the opposite effect of increasing activity. Our results indicate that even sub-lethal concentrations of pesticides have strong effects on critical behaviors that affect fitness and alter species interactions in aquatic vertebrate species. We expect our synthesis can be used to identify chemical classes producing the largest sub-lethal effects for further research and management.

MP120 In situ Method for Evaluating the Early Life Toxicity of Contaminated Sediments in Walleye (Sander vitreus)

E. Boulanger, McGill Univ / Natural Resource Sciences; B. Barst, McGill Univ; M.M. Alloy, McGill Univ / Agricultural and Environmental Sciences; M. Houde, Environment and Climate Change Canada / St Lawrence Center; S. Blais, Environment and Climate Change Canada; J. Head, McGill Univ / Natural Resource Sciences

Early life exposure to environmental contaminants can cause persistent effects in fish that are only manifested later in life. In the wild, it is difficult to study the effects of early life exposures since it can be challenging to find fish spawning grounds and it's extremely difficult to track these developing fish once they have hatched. Exposures can be done in the laboratory, but these experiments do not accurately reflect environmental conditions. Here we assess the feasibility of an in situ exposure of developing fish embryos to clean and contaminated sediments in the Saint-Lawrence River. Eyed walleye (Sander vitreus) eggs were placed in Scotty incubators and deployed at two sites (May 2016) in the Saint-Lawrence upstream of Montreal, where the river widens to form Lac Saint-Louis. Sediments at the contaminated site (Beauharnois) are known to be heavily contaminated with PAHs, metals, PCBs, dioxins, and furans. This contamination is most likely due to discharges from the industrial areas and commercial ship traffic nearby. The reference site (Sainte-Anne-de-Bellevue) is located on the western side of Lake Saint-Louis. The walleye egg incubators were placed in protective cages, which were lined with fine mesh, before being completely submerged and anchored at the study sites. After the walleye eggs hatched, larvae swam out of the incubators escape holes and were collected in the protective cage and preserved for molecular analyses. Traditional (e.g. EROD, oxidative stress) and novel (e.g. DNA methylation) biomarkers of exposure to environmental contaminants were measured in larvae from the two sites. In addition, sediment and water samples were collected from each site and were analyzed for metals and polycyclic aromatic hydrocarbons (PAHs). The use of this in situ method, in conjunction with more controlled in vitro and in vivo laboratory-based dosing studies that we have undertaken, will be beneficial for assessing the impact that early life exposure to contaminated sediments has on the health of wild populations of fish.

MP121 Toxicity of silver nanoparticles in biosolid-amended soil to Eisenia fetida: perspectives for the protection of agricultural soils and the environment

A. Lemtiri, A. Shoieb, McGill Univ / Dept of Natural Resource Sciences; F. Piccapietra, Eawag; H. S Dorea, Univ federal de sergipe / Departamento de Química; F. Francis, Univ of Liege / Dept of AgroBioChem Functional and evolutionary entomology Gembloux AgroBio Tech; G. Colinet, Univ of Liege / Dept of Biosystems Engineering SoilWaterPlant Exchanges Gembloux AgroBio Tech; S. Ghoshal, McGill Univ / Dept of Civil Engineering; J.K. Whalen, McGill Univ / Natural Resource Sciences

The growing number of commercial applications using silver nanoparticles (Ag-NP) increases the risk of environmental release and exposure of organisms in natural environments. Land application of biosolids is accepted practice in Canada and viewed as positive for agricultural soils to boost fertility, improve soil structure and enhance soil biological activity for the benefit of crops. Biosolids enriched with Ag-NP may pose an ecological risk to soil organisms and plants, but this is poorly understood. The objective of this experiment was to investigate the impact of Ag-NP and Ag-nitrate ($Ag\text{-}NO_3$) on earthworms Eisenia fetida. Controlled laboratory experiments were conducted with artificial OECD soil and a natural agricultural soil (Brown Chernozem) that were amended with 0 to 1000 mg of Ag-NPs and $Ag\text{-}NO_3$ per kilogram of soil. Earthworms were exposed to Ag-NP in vivo for 28 days and a range of endpoints was assessed, including survival, growth, reproduction and histopathology. In addition, Ag-NP treated soil samples were analysed to determine Ag-NP transformations, including dissolution to Ag^+ in soil pore water with single-particle ICP-MS. Results will be used to propose specific toxicity mechanisms of Ag-NP to the earthworm E. fetida, specifically whether toxic effects were the result of exposure to Ag-NP or dissolved Ag^+. Perspectives on applying biosolids containing Ag-NP as a soil amendment, in the context of sustainable agriculture and environmental protection, will be discussed.

Integrating Life Cycle, Risk and Alternatives Assessment with Exposure Modeling for Chemical Decision-Making

MP122 Chemical Exposure Footprint: Application and Evaluation of the ProScale method in an indoor furniture case study

T. Rydberg, J. Lexén, C. Loh Lindholm, E. Lundström Belleza, IVL Swedish Environmental Research Inst; B. Baradaran, Uppsala Univ

The case study presented is performed as part of IVLs participation in the ProScale consortium, developing a method for estimating hazard and exposure potentials for chemicals in products, in a life cycle perspective. The primary intended use of the method is as an exposure/hazard potential scoring to be provided as additional information in LCA based product performance assessments. The study aims to contributing to the evaluation of the relevance, accuracy and robustness of the ProScale method by applying the draft ProScale method, in a case study covering the Life cycle of a product, and testing alternative approaches in each step of the method, i.e. release/exposure/hazard potential. The chosen product is a sofa, as an example of a product for indoor use, containing a variety of materials and with potential for relevant chemical exposures and hazards to estimate, in the use phase as well as upstream in the production value chain and downstream in the end of life (waste management) phase. Ultimately all substances in all life cycle phases should be covered, but we started by looking at a specific chemical, Melamin, CAS No 108-78-1, as previous work has shown that this substance is common as flame retardant additive in natural rubber latex foam, and has a relatively high release rate in this use, and thus exposure potential. Other substances of interest are, e.g. TCPP, CAS no 13674-84-5, also used as flame retardant in this type of product. A major challenge in this project has been to identify the specific composition of a specific product, therefore a more population level exposure approach has been tested. For each relevant substance in the life cycle, the value chain has been identified. Then for each life cycle phase, the exposure has been characterized using, to the extent possible, predefined exposure categories from REACH, "PROCs". This allows for exposure potential estimate using the dedicated tool ECETOC TRA. For consumer exposure during use also other approaches have been tested. These exposure potentials have been combined with the hazard potency factor, as described in another submission to this conference about ProScale. The presentation will display preliminary result regarding hot spots in the life cycle of the sofa, in terms of the chemical exposure footprint

Novel Mechanisms of Nanomaterial Toxicity Through Direct Exposure or Indirect Interactions with Environmental Components

MP123 Determination of Carbon Nanotube Phytotoxicity in Heat Stressed Crops

J. Jordan, J.E. Canas-Carrell, Texas Tech Univ / Environmental Toxicology; P. Payton, USDA-ARS Cropping Systems Research Laboratory; D. Tissue, Western Sydney Univ / Hawkesbury Inst for the Environment

Climate change, which is currently of great concern to the science community and general public, may lead to dramatic changes in weather patterns. These changes dictate a better understanding of how ecosystems might be affected, including effects on crop growth as well as the fate and toxicity of contaminants. Carbon nanotubes (CNTs) are currently used in a wide-range of commercial and agricultural applications. The increasing use of CNTs in fertilizer, pesticide, and herbicide delivery systems could have direct, unintended consequences on soil health, the microbiome, and managed and native ecosystems. Limited studies have examined the impact of CNTs on abiotic stress response and potential consequences on plant CNT uptake with respect to plant performance and subsequent potential human exposure to CNTs. In this study, the effect of CNTs in soil on plant performance under periodic thermal stress (heat waves) was examined. Cotton and tomato were grown in soil spiked with multi-walled carbon nanotubes (MWCNTs) (100 mg/kg soil) under two temperature regimes with natural lighting: 1) Control T = 28/18°C day/night and 2) Elevated T = 32/22°C day/night. The impact of elevated growth temperature and the interaction with MWCNTs on water use efficiency (WUE) was measured, along with the impact of periodic heat waves on photosynthesis. Preliminary analysis of this data indicates that the presence of MWCNTs in soil significantly decreased WUE in cotton, but not in tomato. Exposure of cotton plants to MWCNTs under heat stress had a negative effect on plant growth and photosynthetic rate. These results may add a new variable to the equation for CNT effects on plants. Past studies have shown that results vary depending upon plant species and CNT type. Climate may exacerbate the impact of CNTs on plant growth.

MP124 Modulation of Immune Defense Responses of Fathead Minnows exposed to Single-Walled Carbon Nanotubes

H.E. Johnson, Univ of Florida / Environmental and Global Health; S. Robinson, Univ of Florida / Envirionmental and Global Health; A. Simons, Univ of Florida / Dept of Environmental and Global Health; A. Bikkasani, Univ of Florida; A.S. Kane, Univ of Florida / Dept of Environmental and Global Health; J.H. Bisesi, Univ of Florida / Environmental and Global Health; T. Sabo-Attwood, Univ of Florida / Environmental Global Health

Single walled Carbon Nanotubes (SWCNTs) are being used in the production of a number of industrial and commercial products yet little is known about the potential environmental and human health impacts of these materials. Previous work in our lab has shown that SWCNTs can alter the activity of toll-like receptors (TLRs), proteins that act as a first line of defense against invading pathogens. Our lab has also observed, in mammalian systems, that increased viral titers occur with pre-exposure of cells of mice to SWCNTs. To date, no studies have investigated whether SWCNTs can alter viral infectivity in fish through modulation of normal immune defense responses that include TLRs. To begin to address this question, fathead minnows (Pimephales promelas) were fed a commercial diet containing SWCNTs, for 96 hours and the levels of the viral responsive TLR3 was measured by qRT-PCR in various sections of intestinal tissue (proximal, middle, distal). Data from these experiments show that TLR3 expression was significantly increased in distal intestinal tissues while no change in expression occurred in proximal and middle sections. To determine if the SWCNTs altered viral susceptibility, we exposed fish to SWCNTs for 7 days followed by a second exposure to Polyinosinic:Polycytidylic acid (Poly I:C), an RNA analog that is a TLR3 agonist used to mimic viral infection. Following exposures, fish were euthanized and blood was analyzed for changes in white blood cell (WBC) populations. Preliminary results show altered WBC populations (neutrophils) that are consistent with viral infections. Currently we are investigating how the SWCNTs may be altering this response and the associated mechanisms that contribute to these effects. These studies highlight a novel sub-lethal mechanism of toxicity that should be considered for nanomaterials.

MP125 Overcoming Carbon Nanomaterial Interference in qPCR Assessments of Gene Expression Changes in Exposure Experiments

C. Lavelle, Univ of Florida / Physiological Sciences; S. Hume, S. Hentschel, Univ of Florida / Dept of Environmental and Global Health; L. Smith, Univ of Florida / Physiological Sciences; T. Sabo-Attwood, Univ of Florida / Environmental Global Health

Interference in standard assays by nanomaterials (NM) is commonly observed and can lead to inaccurate or misinterpreted results. There are a number of reasons that account for such interference including altered absorbance and fluorescence readings and chemical reactivity with and sorption of assay reagents. Through recent experiments investigating gene expression changes in human lung cells exposed to NMs we found that specific carbon nanotubes impaired at least one step in the qRT-PCR pipeline. Our initial results showed that amplification of target and reference genes was altered in a NM dose-dependent manner. The average quantification cycles (Cq) for the reference gene GAPDH in control and pristine single-walled carbon nanotube (SWNT) exposed samples were consistent at 15.8 and 15.5 cycles, respectively. However, samples exposed to 20 µg/mL surface-hydroxylated multi-walled carbon nanotubes (MWNT) exhibited delayed amplification presenting with an average Cq of 20.6 cycles. To pinpoint whether the interference was occurring during RNA quantitation, reverse transcription (RT) or PCR steps we used a multiple quantitation strategies, PCR and RT inhibition curves. These experiments showed that the greatest interference occurred during the RT step. Since we only observed interference with functionalized MWCNTs we hypothesized that these select NMs were adsorbing vital RT reagents and limiting cDNA synthesis. To improve the RT process we increased the amount of available reagents by doubling the reaction volume. A second strategy was to add BSA (0.4 µg/µL) to reduce the available binding sites thereby limiting reagent adsorption by MWNTs. Results revealed that both strategies improved the cDNA synthesis. For example, doubling the RT reaction volume stabilized GAPDH Cq values between controls and 20 µg/mL MWNT treated samples, decreasing the Cq difference to 1.5 cycles while addition of BSA was more effective and decreased the difference to 0.69 cycles. These studies highlight the need to run proper interference controls when working with NMs. Data further support the notion that not all NMs impact assay interference equally and in fact, select properties, such as surface functionalization, are important determinants to assay variability and accuracy. Determining mechanisms by which different NMs interfere with standard assays will allow for better assay designs to limit interference and produce high quality results.

MP126 Global gene expression profiling in zebrafish (Danio rerio) exposed to nanoparticles of maghemite (y-Fe2O3)

J. de Souza Filho, Univ of Brasilia – UnB / Dept of Genetics and Morphology; R. Rios Villacis, Univ of Brasilia / Dept of Genetics and Morphology; B. Piña, Spanish National Research Council – CSIC / Environmental ChemistryInst of Enviromental Assessment and Water Research; R. Bentes de Azevedo, A. Pic-Taylor, Univ of Brasilia – UnB / Dept of Genetics and Morphology; J. Forte Mazzeu de Araújo, Univ of Brasilia – UnB / Faculty of Medicine; C. Koppe Grisolia, Univ of Brasilia – UnB / Dept Genetics and Morphology

Iron oxide nanoparticles (IONPs) have been used for several biomedical applications, such as contrast agent for magnetic resonance imaging. However, the potential toxicity of various IONPs in the environment is not well understood yet. To gain insights into the toxic mode of action of IONPs, a gene expression analysis was performed on adult male zebrafish exposed to 96 h treatment with maghemite NPs (average diameter of 0.5 µm) at 37.2 mg/L and 74.4 mg/L, compared to a control group (without treatment). The transcriptome profile (Affymetrix GeneChip Zebrafish Gene 1.0 ST Array) was obtained from hepatic RNA and the data analyzed using R. Gene Ontology analysis was conducted with the DAVID bioinformatics resources 6.7. Microarray analysis showed significant changes in expression of 953 genes (ANOVA, $p < 0.05$). Hierarchical clustering of the significantly changed genes separated control samples from the group treated with 74.4 mg/L maghemite NPs, whereas samples treated with 37.2 mg/L maghemite NPs falled somewhere in between. Maghemite NPs induced changes in a concentration-dependent manner. Partitioning Around Medoids algorithm established two as the optimal number of clusters to classify the 953-gene dataset. Cluster 1 (380 genes) included genes whose mRNA abundance increased with maghemite NPs exposure, whereas genes included in Cluster 2 (573 genes) showed a parallel decrease in maghemite NP-treated animals relative to control. A clear dose-response was observed for most genes included in both clusters, consistently with the hierarchical clustering data. Functional analysis of genes included in clusters 1 and 2 shows several cellular functions affected by the exposure to maghemite NPs. Among the genes up-regulated by NPs there is an overrepresentation of functions related to cation/metal binding and epithelium and embryo development. These genes include several typical stress proteins, like HSPB1. We consider that this cluster reflects the physiological response to the presence of the iron NPs and some associated distortion with the cation balance in the cells. Conversely, genes whose expression decreases upon maghemite NPs exposure shows an enrichment of translation- or ribosome-related genes, suggesting a decrease on the ability of the cell to produce new proteins. We propose that these changes indicate an inhibitory effect on cell metabolism. Our results shed light on the molecular mechanisms of liver toxicity of IONPs.

MP127 Investigation of the influence of carbon nanotubes on the bioavailability of mixtures of PAHs to P. promelas

E.N. Linard, P. van den Hurk, Clemson Univ / Biological Sciences; C.M. Lee, Clemson Univ / Environmental Engineering and Earth Sciences Dept

Due to the high adsorption affinity of carbon nanotubes (CNTs) for organic contaminants, these materials are often suggested as an ideal substrate for pollution remediation. CNTs significantly reduce the bioavailability of a range of polycyclic aromatic hydrocarbons (PAHs) in single solute exposures to a variety of organisms. It is important to note though, that in both waste water treatment facilities and in the environment, CNTs will interact with more than one organic contaminant resulting in adsorption competition among the compounds present. Studies have found that adsorption capacity and affinity for individual PAHs in mixtures can be significantly altered due to competition and interaction among the PAHs at CNT adsorption sites. To date, no study has investigated the bioavailability of mixtures of PAHs adsorbed to CNTs though this is a much more likely scenario to occur environmentally and may elicit different trends in bioavailability than previously observed in single-solute scenarios. The goal of the present research was to investigate the adsorption behavior of PAH mixtures on CNTs and how this relates to the resulting bioavailability of the PAHs present. Bi-solute adsorption isotherms of a suite of PAHs to CNTs were established in conjunction with quantifying the bioavailability of the two competing CNT-adsorbed PAHs to Pimephales promelas (fathead minnow) using bile analysis via fluorescence spectroscopy. Ratio comparison of the fish response to each PAH present in treatments with and without CNTs provide insight to the interaction occurring between the PAHs at the CNT surface. Previously established results indicate that bioavailability of CNT-adsorbed PAHs is a function of adsorption behavior and the PAHs physical characteristics, where molecular configuration and size were found to be significantly influential. Preliminary data suggest that when in mixtures, linear PAHs outcompete the angular isoform for adsorption sites on CNTs causing angular PAHs to be more bioavailable. This is attributed to differences in adsorption capacity of CNTs for chemically similar yet structurally different PAHs. In addition, data suggests that in mixtures, PAHs containing a non-aromatic ring, such as FLU, are more bioavailable than fully aromatic PAHs due to fully aromatic PAHs adsorbing more strongly. Results of this work will help to provide insight into the effectiveness of CNTs to reduce PAH bioavailability in more realistic scenarios.

MP128 Novel toxicity associated with emerging hybrid nanomaterials in aquatic systems

S. Robinson, Univ of Florida / Envirionmental and Global Health; H.E. Johnson, Univ of Florida / Environmental and Global Health; D. Das, Univ of Texas at Austin; J.H. Bisesi, Univ of Florida / Environmental and Global Health; N.B. Saleh, Univ of Texas / Dept of Civil Architectural and Environmental Engineering; T. Sabo-Attwood, Univ of Florida / Environmental Global Health

Engineered nanomaterials (NMs) represent a diverse class of extremely small particles (< 100nm) that are being widely used in industrial sectors such as energy, electronics, and sensing. As these applications demanded higher performance, the field of materials research has shifted its focus from using singular NMs (carbon only, metal only) to those comprised of several distinct types of NMs linked together, termed nanohybrids (NHs). Linking single NMs in this capacity is likely to create new properties and behavior in environmental and biological settings that have not yet been predicted or studied. We hypothesize that NHs alter fish growth and bioenergetics differently than individual nanoparticle constituents and that these effects are consistent with novel NH properties such as morphology, mechanical stiffness, and band gap. To test this notion, we synthesized a set of metal-carbon nanotube NHs (MWCNT + TiO_2 + ZnO) with high degree of control and exposed fathead minnows aqueously to the NHs and singular components following a standard EPA 96 hour toxicity testing regime. Fish were monitored for mortality and growth. These endpoints were coupled with high-throughput contemporary measurements of mitochondrial dysfunction and oxidative stress. We also characterized physical morphology, mechanical stiffness, band gap and distribution of metal/metal oxides on nanotubes and compared these measurements between NHs and individual component materials. Preliminary data show that carbon nanotube-metal NHs produce distinct effects on fish growth and mitochondrial function and that these effects are coupled to unique material properties. This work is timely in that it will lay the foundation for further research in understanding NHs in complex but relevant environments and reveal novel properties and mechanisms of action in biological systems that have not been studied. Furthermore, the work will generate critical and fundamental knowledge to better understand the environmental interaction of a set of complex hierarchical nanomaterials.

MP129 In vitro to in vivo extrapolation of nano titanium dioxide cytotoxicity in Zebrafish (Danio rerio)

M.M. Alloy, McGill Univ / Agricultural and Environmental Sciences; G. Sunahara, McGill Univ; N. Basu, McGill Univ / Dept of Environmental Health Sciences

Titanium dioxide nanoparticles ($nTiO_2$) are one of the most studied nanoparticles in the toxicology literature, as well as being one of the most heavily utilized nanoparticles today. Uses include but are far from limited to cosmetics, sunscreens, solar energy production, and in surface coatings with self-cleaning and biofouling resistant properties. Nanoparticle enhanced products whose end use places them outside (e.g. surface coatings) have the potential to emit nanoparticles directly into surface waters without filtration through storm water runoff. Although $nTiO_2$ is among the more thoroughly studied nanoparticles, a recent Web of Science search on the topic of “nanoparticle” with either “TiO2” or “titanium dioxide” in the article title and refined to “toxicology” suggested there are relatively few fish studies (112) on $nTiO_2$ compared to mammalian in vivo and in vitro studies (345) in the literature. The majority of the fish studies only use in vivo or in vitro, but do not investigate both. Among fish model organisms the zebrafish (Danio rerio) was chosen for its extensive in vivo use in existing non-nanotoxicological literature, ease of culture, and the availability of a well established cell line. Zebrafish hepatocytes (ATCC CRL-2643) were exposed to a range (0.001 µg/mL to 10.0 µg/mL) of $nTiO_2$ to assess cytotoxic response using the resazurin metabolism assay. Experiments using a factorial design are on-going to investigate the effects of sera on $nTiO_2$ interaction with cells. Hepatocytes will be exposed to the determined EC_{50} in several treatments varying the amount of sera present in the exposure medium (0% fetal bovine serum ,0% trout serum to 10% fetal bovine serum, 5% trout serum). Cellular uptake of $nTiO_2$ will be qualified by TXRF and quantified by ICP-MS. $nTiO_2$ partitioning within the cell will be investigated by subcellular fractioning and quantification of titanium within the fraction. Oxidative stress indicators (e.g. TBARS, SOD, Catalase) and stress proteins (e.g. hsp 70, HIF-1α) will be used as endpoints. In vitro model results will be compared to in vivo exposure of D. rerio embryos to similar concentrations of $nTiO_2$. As with the in vitro investigations, uptake will be quantified, and partitioning in subcellular fractions will be determined. These studies are expected to narrow the gap between $nTiO_2$ in vitro models and in vivo observations in teleost fish.

MP130 Investigation of Toxicity of Perovskite Nanomaterials (a new solar cell nanomaterial) in Zebrafish and Linkage to Release of Pb2+

D. Patsiou, F. Liu, T.F. Fernandes, T. Henry, Heriot-Watt Univ / School of Life Sciences

Next generation solar cells incorporate perovskite-based nanomaterials (NMs) that demonstrate high stability and efficient capture of solar energy for the generation of electricity. While the attributes of perovskite nanomaterials are being realised, any potential consequences of the technology, including their toxicology upon release into the environment, must be assessed. Perovskite materials have the ABX_3 crystal structure and as a standard they are methyl ammonium lead halides. The chemical reactions of perovskite materials in the aqueous phase can lead to release of Pb^{2+} and consequent toxicity in aquatic organisms. The aim of this research is to assess the toxicity of two perovskite nanomaterials ($CH_3NH_3PbI_3$ and $CH_3NHNH_3PbBr_3$) in zebrafish larvae and the linkage to Pb^{2+} toxicity. A dilution series of the two perovskite NMs for acute toxicity tests (96-h exposure) and metallothionein 2 (mt2) expression (24-h exposure) were prepared in parallel with Pb^{2+} dilution series. The 96-h median lethal concentration (LC_{50}) for both perovskites was greater than 200 mg/L in zebrafish larvae (exposure from age 72 hours post fertilization), indicating no acute toxicity. Positive mt2 expression was observed in relationship with Pb^{2+} (as lead nitrate) concentration after a 24-h exposure (R^2=0.91). Mt2 expression increased with perovskite NMs higher concentration (0 to 80 mg/L of Pb^{2+} that perovskite particles contain according to molecular weight) in a positive dose-response relationship, and was consistent with Pb^{2+} (as lead nitrate) dilution series (0 to 80 mg/L). Determination of mt2 gene expression suggests that much of the toxicity can be attributed to the presence of Pb^{2+} in the perovskite NMs.

MP131 PAHs Sorption to NMs in the Aqueous Phase Assessed by Evaluation of Bioavailability in Larval Zebrafish

D. Patsiou, F. Liu, Heriot Watt Univ / School of Life Sciences; M.R. McCoustra, Heriot Watt Univ / School of Engineering Physical Sciences; T.F. Fernandes, T. Henry, Heriot-Watt Univ / School of Life Sciences

Engineered nanoparticles (NPs) have unique physicochemistry that includes high surface area, surface reactivity, and photoactivity. In the aqueous phase, NPs can sorb substances and subsequently undergo complex chemical reactions that alter the chemistry of sorbed substances. Understanding NP-substance sorption is an important consideration for managing the environmental risks of NPs. Among the most commonly used NPs are TiO_2-NPs which have photo-activity and have been shown to sorb various substances in the aqueous phase, including toxic substances. Polycyclic aromatic hydrocarbons (PAHs) are a group of important environmental toxicants that can have UV-enhanced toxicity and have potential to sorb to NPs. The aim of this research was to investigate the sorption of PAHs to NPs under UVA illumination. In particular, the objectives of this study were to assess the phototoxicity of TiO_2-NPs, Si-NPs, and PAHs (anthracene and benzo(a)pyrene), sorption of PAHs to NPs and how this association affects bioavailability and toxicity in larval zebrafish. This was addressed by evaluating the sorption of PAHs to NPs by assessment of changes in expression of target biomarker genes including cytochrome P450 1A (cyp1A), superoxide dismutase (sod1) and DNA repair (ddb2), in larval zebrafish, following exposure to these substances and particles with and without UVA irradiance. Zebrafish larvae (age 72 hpf) were exposed (24 h) to anthracene (0-30 µg/L) in synthesised freshwater (OECD 236). Preparations were exposed to 80 kJ/m^2 UVA at the end of the 24 h exposure, and larvae were sampled for extraction of RNA and RT q PCR. Photo-activated anthracene increased cyp1A expression in a positive dose response relationship while when NPs were present in solution, no induction of the gene was observed. Expression of cyp1A increased with concentration of benzo(a)pyrene (no UVA exposure). No changes in cyp1A expression were observed when TiO_2 NM105 or Si-NPs were present in the dilution series. In contrast, when a smaller TiO_2 particle (4-8 nm dimeter) was added in the dilution series, the expression of cyp1A was significantly reduced (GLM, p< 0.001), suggesting that sorption processes are surface area dependent. Future work will investigate the association between NMs and benzo(a)pyrene after UVA irradiance to assess whether the UVA photoactivation of the particle surface occurs and leads to changes in sorption processes.

MP132 Effects of ingestion of antimicrobial nanoparticles on endogenous microbiota and pathogen resistance in rainbow trout

N. Brande-Lavridsen, Univ of Tennessee / Center for Environmental Biotechnology; T. Vishnivetskaya, R. Strange, D. Williams, K. Ritter-Gordy, Univ of Tennessee; T. Henry, Heriot-Watt Univ / School of Life Sciences

Incorporation of engineered nanoparticles (NPs) into consumer products is increasing rapidly and contamination of the environment with potential exposure of organisms has become a realistic concern. Ingestion of NPs by organisms is an environmentally relevant exposure route and effects on gut health and physiology are important. The antimicrobial activity of some NPs (e.g. Ag- and Cu-NPs), which is useful in medical and personal care products, could have negative effects on beneficial/protective bacteria within the digestive system of organisms. The importance of healthy endogenous gut microbiota on overall organism health is increasingly recognized and has important implications on immune system function and resistance to pathogens. Our objective was to investigate effects of ingestion of food containing NPs (Ag-NPs, Cu-NPs) or bulk material controls ($AgNO_3$, $CuSO_4$) on gut microbial community, immune system function, and pathogen resistance in juvenile rainbow trout (Oncorhynchus mykiss). Fish were exposed to 50 mg metal (as NP or bulk material) per kg feed (or control feed) for 56 days and sampled for assessment of gut microbial community (by Illumina 16s rRNA gene amplicon sequencing and analysis in MG-RAST), gut health (gene expression and histopathology), and immune system function (hematology, gene expression). After the exposure, fish were challenged with the bacterial pathogen Yersinia ruckeri, the causative agent of enteric redmouth (ERM) disease in rainbow trout. We found that dietary exposure to Ag-NP and Cu-NP (or bulk controls) did not affect growth or survival, but initial evaluation of gut microbiota suggest that feed treatments do change the abundance of various bacterial genera. Within one week of exposure, fish displayed clinical signs of ERM disease (external lesions) and mortality was 57 (9-100) %, but there was no significant difference among feed conditions. Associations between changes in gut microbiota, immune system function, and pathogen infection are currently under investigation.

MP133 Enhanced and differential genotoxicity of titanium dioxide nanoparticles by expression of human CYP genes in yeast cells

T. Jiang, Northeastern Univ / Dept of Civil and Environmental Engineering; N. Gou, Northeastern Univ / Civil and Environmental Engineering; X. Wen, Northeastern Univ / Dept of Civil and Environmental Engineering; C. Vulpe, Univ of Florida, Gainesville / Physiological Science; M. Fasullo, State Univ of New York Polytechnic Inst / College of Nanoscale Science and Engineering; A. Gu, Northeastern Univ / Dept of Civil and Env Engineering

Titanium dioxide nanoparticles ($nTiO_2$) are increasingly being manufactured with extensive applications in a wide range of fields. Due to their unique physicochemical properties including high redox potential and large surface-area to mass ratio, $nTiO_2$ may exert an adverse health impacts. Although $nTiO_2$ have been classified as possible carcinogens to humans, data on their genotoxicity remains limited and controversial. The production of reactive oxygen species has been postulated to play a role in $nTiO_2$ genotoxicity. However, most existing studies have not considered the role of cellular metabolism activity in assessing the genotoxicity of $nTiO_2$. Here, a toxicogenomics-based in vitro genotoxicity assay using GFP-tagged yeast reporter strains, covering key protein biomarkers indicative of all the recognized DNA damage repair pathways, was employed to elucidate the genotoxic potential and mechanisms of $nTiO_2$. In addition to the original yeast reporter library, two GFP-tagged yeast reporter strain libraries transformed with human CYP1A1 or CYP1A2 gene were constructed to investigate the potential modulation of $nTiO_2$ genotoxicity after P450 metabolism. The genotoxicant 4-nitroquinoline-1-oxide and a non-genotoxic agent tetracycline were used as positive and negative controls, respectively, to validate the assays. Then the genotoxicity of CYP1A1-dependent chemical benzo[a]pyrene-7,8-dihydrodiol and CYP1A2-dependent chemical aflatoxin B_1 as well as $nTiO_2$, were assessed in three reporter libraries, the first with no CYP expression, the second expressing CYP1A1 and the third expressing CYP1A2. These studies found a lack of appreciable $nTiO_2$ genotoxicity as indicated by the GFP-tagged reporter strains in the absence of CYP metabolism and a significantly elevated indications of genotoxicity after activation by both CYP1A1 and CYP1A2 enzymes ($p = 0.0075$ and 0.0032 respectively). The intracellular ROS production measurement indicates significantly higher ROS ($p < 0.05$) in yeast expressing either the CYP1A1 or CYP1A2 enzymes (2.17 and 3.03 times higher respectively). We also detected mitochondrial DNA damage suggesting mitochondria as likely one of the target sites for oxidative damage by $nTiO_2$ after metabolic activation by both human CYP enzymes. These data thus indicate that the genotoxicity of $nTiO_2$ is enhanced by human CYP1A1 and CYP1A2 expression and is associated with elevated oxidative stress, and suggest that similar toxicity could occur in human cells.

MP134 Evaluation of the toxicity of newly synthesized titanium dioxide nanoparticles

M. Ozmen, İnonu Univ / Biology; A. Gungordu, Inonu Univ, Fac. Arts & Science / Biology; S. Erdemoglu, Inonu Univ, Fac. Arts & Science / Chemistry; N. Ozmen, İnonu Univ / Biological Sciences Dept; E. Akgeyik, İnonu Univ / Chemistry Dept; M. Asilturk, Akdeniz Univ / Dept of Materials Science and Engineering; S.L. Harper, Oregon State Univ / EMT

Titanium is one of the most commonly used metals for cosmetic products, fabrics, dye and other household industry. The production, number and significance of titanium based nanomaterials (NPs) such as TiO_2 are growing very fast, but information about toxic effects and interactions of the TiO_2NPs with living systems is contradictory in the literature. Understanding the impacts of nanomaterial exposure in ecosystems is important to appropriately protect the environment from increased NP pollution, particularly in aquatic systems. Therefore, we evaluated toxicity of newly synthesized, differently-doped or core-shell NPs using Xenopus laevis and Danio rerio embryos. Toxicity of NPs was also evaluated in Chlamydomonas reinhartii, Daphnia magna neonates and using inhibition of bioluminescens of Vibrio fischeri. Our results showed that S- or Mn-doped TiO_2NPs did not cause significant lethality on X. laevis and D. rerio embryos after 96 hours up to 500 mg/L NP exposure. However, D. magna neonates were adversely affected by both materials after 48h exposure in higher concentrations. Toxicity of Mn-doped TiO_2 was higher than S-doped TiO_2 to daphnids. We found that none of the core-shell NPs elicited a concentration-related lethality or malformations to frog or zebrafish embryos up to 250 mg/L exposure. Tested NPs did not cause growth inhibition of X. laevis embryos or algae after 96 h of exposure at any concentration. Microtox tests with V. fischeri supported our results that no toxic effect was found for any of the NPs tested. While none of newly synthesized TiO_2 based NPs were acutely toxic to the aquatic organisms tested here, the interaction of photocatalytically active NPs with organic pollutants may lead to secondary toxicity effects from redox alterations of the chemical or TiO_2NPs. Acknowledgement: This bilateral collaborative project was supported by grants from The Scientific and Technological Research Council of Turkey (TÜBITAK) (Project #113Z561) and National Science Foundation (NSF) in The USA (Project #1438165).

MP135 Identification of Biomarkers in Corn Subsequent Silver Nanoparticles Exposure

N. Chavez Soria, The Univ at Buffalo / Dept of Chemistry; M. Bisson, State Univ of New York-Buffalo / Dept of Biological Sciences; E.G. Atilla-Gokcumen, D.S. Aga, State Univ of New York-Buffalo / Dept of Chemistry

Nanomaterials are increasingly used in agriculture, energy production, and biomedical application due to their unique properties and characteristics. There is limited information available regarding their exact chemical makeup, raising concerns for their impact on the environment and human health. Many of the nanomaterials contain metals and one of the most popular nanoparticles contain silver, which is known to be toxic in its ionized form. Silver nanoparticles (AgNPs), have a core-shell silver structure and are used in many facets of the industry, including: clothing, food packaging, cosmetics, and electronic products, mostly due to their antimicrobial properties. Due to their wide range of applications, AgNPs containing materials are disposed of in land fills, introducing a pathway for AgNPs contamination in the environment. In addition, AgNPs can leach out from products during washing, reach wastewater treatment plants, and accumulate in biosolids. Consequently, the land-application of biosolids to fertilize fields or usage of reclaimed water can lead to the unintentional exposure of AgNPs to crops. The goal of our project is to understand the impact of AgNPs on hydroponically grown corn with emphasis on monitoring the molecular response of the organism to AgNPs exposure. Specifically, the corn's root systems are investigated, as they are the route for initial exposure. Corn plants were exposed to AgNPs, and changes in hydrophilic metabolite composition of the roots were determined using liquid chromatography tandem quadrupole time of flight mass spectrometry. Additionally, silver concentrations were determined in corn leaves and roots via inductively coupled plasma mass spectrometry to determine the fate of AgNPs in corn. Evaluating the impact of changes in metabolite composition will be critical for identification of biomarkers of AgNP exposure. Preliminary results have shown a clear difference between treatments, the identification of species that differentiate during AgNP treatment are to be determined. Correlating the silver concentration in corn and changes in metabolites will provide insights on the mechanism and interactions between nanomaterials and this agricultural crop. Investigating the effects that AgNPs have on food crops is paramount for understanding the potential toxicity and the metabolic changes associated with AgNPs contamination.

MP136 Toxicological evaluation and photocatalytic degradation capability of newly synthesized nanoparticles

N. Ozmen, İnonu Univ / Biological Sciences Dept; S. Erdemoglu, Inonu Univ, Fac. Arts & Science / Chemistry; A. Gungordu, Inonu Univ, Fac. Arts & Science / Biology; M. Asilturk, Akdeniz Univ / Dept of Materials Science and Engineering; E. Akgeyik, İnonu Univ / Chemistry Dept; M. Eren, D. Ozhan Turhan, İnonu Univ / Biological Sciences; M. Ozmen, İnonu Univ / Biology

Due to recent developments in nanomaterial engineering technology, TiO_2 nanoparticles (NPs) are being used for core-shell NP particle production for efficient photodetection capability to effectively remediate organic pollutants in aqueous environments. However, limited information is available in the literature to evaluate potential risks of the materials and single-species toxicity tests are inadequate to predict the effects of chemicals in an ecosystem. Therefore we compared the toxic effects of newly synthesized TiO_2 NPs using the African clawed frog (Xenopus laevis) and zebrafish (Danio rerio) embryos in a 96 h toxicity test for comparison of their toxicity. To this aim, the toxic effects of pure TiO_2 and core-shell TiO_2 (SiO_2@TiO_2) NPs were evaluated. On the other hand, the photocatalytic degradation capability of the NPs were evaluated using disperse red 65 dye, which is in widespread use, highly toxic and a potential pollutant for aquatic ecosystems. According to 96 h subacute toxicity tests, none of the NPs represented toxicity potential on test organisms and they did not cause any developmental malformations on X. laevis and D. rerio embryos. On the other hand, the LC50s of disperse red 65 were determined as 4.67 mg/L (4.40-4.99) and 1.74 mg/L (1.56-1.96) for frog and zebrafish embryos, respectively, in 96 h toxicity tests. Due to the high toxicity potential of the dye, 20 mg/L (4-11X higher concentration of LC50s) concentrations were treated with 0.3% catalysts for up to 4 h in optimal conditions. According to our results, the tested dye caused different types of malformations on both test organisms. After the photocatalytic degradation, pure TiO_2 NPs enabled up to 94% degradation of the dye within the 1 h exposure period and SiO_2@TiO_2 NPs degraded 88.32% of the dye within 3 h. The lethality effect on X. laevis embryos was completely dissipated after 3 h of photodegradation of the dye. However, although lethal effects were relatively decreased for zebrafish embryos, they were not completely removed. Pure TiO_2 NPs were also most successful for decreasing the lethal effect after 4 h photocatalysis compared to SiO_2@TiO_2 core@shell structure. This may be related to total effective mass and total surface area of pure and core@shell NPs for photocatalytic capability. Acknowledgement: This project was funded by The Scientific and Technological Research Council of Turkey (TÜBITAK) (Project #113Z561).

MP137 Form and toxicity of copper released into marine systems from conventionally and nano-sized copper treated lumber

A.N. Parks, Southern California Coastal Water Research Project / Toxicology; M.A. Cashman, Univ of Rhode Island / Geology Dept; S. Fogg, Oak Ridge Associated Universities; M.G. Cantwell, USEPA; D.R. Katz, K.T. Ho, R.M. Burgess, USEPA / Atlantic Ecology Division

The fate and effects of pristine engineered nanomaterials (ENMs) in simplified systems have been widely studied; however, little is known about the potential release and impact of ENMs from consumer goods, especially lumber that has been treated with micronized copper. Micronized copper solutions contain copper complexes predominately in the 10-700 nm size range, and are used in lumber to prevent microbial degradation and fouling. In this work, the goal was to determine the rate, concentration, and form of copper released from commercially available pressure treated lumber samples (blocks and sawdust) exposed to an aqueous system. Lumber tested included Southern Yellow Pine (SYP) treated with micronized copper azole (MCA) at 0.96 and 2.4 Kg/m^3, alkaline copper quaternary (ACQ) at 0.30 and 9.6 Kg/m^3, and chromated copper arsenate (CCA) at 40 Kg/m^3. The experimental system included wood cubes cut from the outer 2 cm surface of the lumber or the equivalent mass (4 g) of sawdust submerged in 250 mL of media (0, 1, 10, and 30 ppt filtered natural seawater) in polyethylene bottles, and mixed on a shaker table at 120 rpm. Water samples were taken at 8 hours, and on days 1, 2, 7, 14, and 28 for the blocks and days 1, 2, 3, 7, 17, and 28 for the sawdust. Subsamples included unfiltered water (defined as 0.45 µm – filtered water for the sawdust), and water filtered through a 0.1 µm polyethersulfone (PES) syringe filter, and a 3000 Dalton centrifugal filter, which were analyzed using ICP-AES to determine the total, nano+ionic copper (< 0.1 µm subsample), and approaching ionic copper (Americamysis bahia) were used to confirm the results of the size-based analyses for the 0 and 30 ppt treatments, respectively. Overall these results suggest that the form of copper released from treated lumber is ionic and that little nanocopper is present in the aqueous phase. This finding suggests the risk associated with nanocopper treated lumber can be addressed with existing copper ion-based modeling approaches and regulations.

MP138 Environmental fate and transport of titanium dioxide nanoparticles in municipal wastewater effluent in outdoor stream mesocosms

B. Castellon, Baylor Univ / Environmental Science; L. Baker, Baylor Univ / Dept of Environmental Sciences; P.S. Watkins, Baylor Univ / Dept of Environmental Science; R.S. King, Baylor Univ / Dept of Biology; C.W. Matson, Baylor Univ / Environmental Science

Titanium dioxide (TiO_2) nanomaterials are ever more widely used for many applications and across many industries. As their production and use continues to increase so does the risk of release into aquatic environments. However, risk assessments for engineered nanomaterials have been challenging. While there is a growing body of research on the toxicity of TiO_2 nanoparticles (NPs), risk assessments must also account for TiO_2 NP behavior, fate and transport, and bioavailability at environmentally relevant concentrations in complex ecosystems. Here, we present fate and transport results of a 35-day stream mesocosm study. TiO_2 NPs were added continuously for 28 days into 20 m long artificial streams running partially recirculating municipal wastewater effluent to reach nominal TiO_2 concentrations of either 5 mg L^{-1} (high) or 50 µg L^{-1} (low), in addition to control streams with only effluent. Results from ICP-MS analyses for Ti concentrations in water indicate that the low streams remained similar to the controls, ranging from 1-8 µg L^{-1}, indicating that the low concentration was environmentally relevant, especially for effluent-dominated waters. On the other hand, the high streams had concentrations that remained relatively stable throughout the dosing period at 100-300 µg L^{-1}. There was up to an 80% decrease of Ti in the water column 1 day after cessation of dosing in both the low and high streams, followed by a less dramatic steady decrease in the final week of the study. Periphyton concentrations in control and the low streams similarly did not differentiate from each other, with concentrations of 100-600 mg Ti kg^{-1} dry weight, with no observed accumulation or increase in Ti concentration throughout the 28 day exposure period. However, periphyton Ti concentrations in high streams increased throughout the first 28 days, reaching concentrations of 2,500-10,800 mg Ti kg^{-1} dry weight. A 40% decrease in Ti concentration was observed at day 35, 7 days after cessation of Ti treatment. The riffle, run and pool habitat types had differing concentrations of Ti in periphyton as a result of location relative to the dosing site and/or flow conditions and water depth. Periphyton in the run section with fish grazing activity had lower concentrations of Ti than in the ungrazed sections, indicating that both stream region and level of disturbance influenced Ti concentrations in periphyton.

MP139 Phytoplankton taxonomic community dynamics during a whole lake nanosilver addition

A. Conine, D. Rearick, Trent Univ / Biology; M.J. Paterson, IISD-Experimental Lakes Area; M.A. Xenopoulos, P. Frost, Trent Univ / Biology

Due to its increasing use as an antimicrobial, many recent studies have examined the impacts of nanosilver on aquatic taxa. In short term studies, phytoplankton have been found to have a higher tolerance to nanosilver than other trophic levels such as zooplankton and bacteria. However, effects of nanosilver on phytoplankton communities over the longer term and under more natural conditions have not yet been tested. We performed a whole lake nanosilver addition experiment at the Experimental Lakes Area in which we added 15 kg of nanosilver to a lake over two consecutive ice-free seasons. Phytoplankton communities and silver concentrations were monitored in the study lake and a reference lake for two years prior to and two years during additions to monitor whether any changes occurred. Nanosilver accumulated in the phytoplankton community and ranged between 0.2-4.5 µg Ag/mg C during additions. This amount accounted for up to one fifth of the total silver in the water column. Seasonal and annual variation in the composition of phytoplankton biomass was apparent, but nanosilver had little effect on the overall phytoplankton biomass or taxonomic composition, despite accumulation in the phytoplankton community. Succession in phytoplankton community composition in the treatment lake did not differ from that of the reference lake and both were highly synchronous. Overall, we demonstrate that nanosilver at environmentally relevant concentrations is not particularly harmful to phytoplankton. Because nanosilver binds to phytoplankton it could buffer the impacts of nanosilver to other parts of the ecosystem.

MP140 An Ecosystem Scale Experiment: Fate and Effects of Silver Nanoparticles Following Whole-lake Addition at the Experimental Lakes Area

D. Rearick, Trent Univ / Environmental and Life Sciences; K. Cetinic, A. Conine, Trent Univ / Biology; L. Telgmann, Trent Univ / Chemistry; J. Tonin, Trent Univ / Biology; H. Hintelmann, C.D. Metcalfe, Trent Univ / Water Quality Centre; P. Frost, M.A. Xenopoulos, Trent Univ / Biology

The potential release of nanoparticles into aquatic environments is raising global concerns. As antimicrobials, silver nanoparticles (AgNPs) are among the most prominent nanoparticles in use. Despite this, their fate, long-term toxicity, and ecological relevance have yet to be investigated under natural settings. To better understand environmental significance, we released AgNPs (NanoAmor 30-50 nm PVP capped) into a lake at the Experimental Lakes Area. We added a total of 9 kg in 2014 and 6 kg in 2015 using a dosing system set on the shore of the lake to simulate a point source addition. Overall, AgNPs remained suspended in the water column and were detected throughout the lake and in the lower food web. Mean total Ag increased to up to 7.5 µg/L in 2014 and 17.5 µg/L in 2015 at the center buoy location. Total Ag concentrations were highly dynamic seasonally both in the epilimnion and hypolimnion depending on the physical, chemical and biological patterns of the lake. Single particle ICPMS analysis revealed 90.7% of the particles had a diameter that was less than 100 nm in August 2014 suggesting large agglomerates were infrequent in the water column. Ag accumulated in all lower food web components. At the center buoy location Ag accumulated in the bacterioplankton up to 1.4 µg/L, in phytoplankton up to 3.5 µg/L, in zooplankton up to 56 µg Ag/g dry mass, and in macroinvertebrates up to 26 µg Ag/g dry mass. At the end of the second year of addition, we found concentrations of Ag in the lake sediments up to 4.73 µg Ag/g dry mass, indicating AgNP settling from the water column. Despite AgNP being measured throughout the lake, we found no effects on the lake food web. For example, chlorophyll concentrations varied similarly between the exposed and reference lakes and leaf-litter decomposition rates were similar between the exposed lake and other reference lakes at the ELA. The presence of dissolved and particulate organic matter likely reduced toxicity. Our experiment provides the first whole-lake perspective toward AgNP fate and toxicity, suggesting small scale experiments may overestimate environmental responses.

MP141 Mechanisms for toxicity of a next generation energy storage nanomaterial to Daphnia magna

J. Bozich, Univ of Wisconsin, Milwaukee / SFS; M. Hang, Univ of Wisconsin Madison; R. Hamers, Univ of Wisconsin Madison / Dept of Chemistry; R. Klaper, Univ of Wisconsin-Milwaukee / School of Freshwater Sciences

While previous studies have investigated the behavior of simple metal oxides, emerging technologies such as energy storage are utilizing more complex and multi-component nanoscale metal oxides consisting of layered structures and redox-active metals. Energy storage materials may be made of a wide range of transition metals depending on application. Furthermore, these materials may be substituted for others to achieve different properties or to increase environmental compatibility. First-generation materials such as lithium cobalt oxide (LCO) are being replaced by next-generation nanomaterials such as lithium nickel manganese cobalt oxide (NMC). Next-generation electric vehicles are predicted to utilize more than 100 kg of nanoscale Li-NMC per vehicle as a battery cathode material, leading to many potential exposure scenarios. In this study, we are comparing LCO to NMC as a model system for assessing the potential environmental impact of nanomaterials for energy storage and to determine if metals within these materials may be substituted to mitigate environmental impact. We chose Daphnia magna as a surrogate for assessing the environmental impact of these materials. The impacts of these particles on D. magna were determined in acute and chronic assays, measuring endpoints such as body size, reproduction and mortality. Acute studies demonstrated no effect on daphnid mortality up to 25 mg/L whereas chronic studies show significant impacts to daphnid reproduction at the lowest concentration tested, 0.25 mg/L. Lithium cobalt oxide caused similar impacts to reproduction and survival at concentrations four times less than NMC nanoparticles. Toxicity from metal dissolution was accounted for and showed no effect, leading us to believe that this is a nanomaterial-specific impact either through direct contact and localization of metal ions or through a nanomaterial-specific impact on physiology. Lastly, our study investigated gene expression. Results indicate down-regulation of a number of important genes related to metabolism in nanomaterial exposures that did not correlate with exposures to the background dissolved metals in solution. This study shows that we may be able to mitigate negative biological impacts by altering battery material chemical composition.

MP142 Effects of natural suspended matter on toxicity of silver nanoparticles to Daphnia Magna

J. Kim, B. Lee, Chonnam National Univ / Oceanography

Silver nanoparticles (AgNPs) have been widely used in many commercial products, such as appliances and antibacterial products. Thus, there are increasing concerns for the potential environmental risks of AgNPs to aquatic ecosystems. However, various environmental variables impact the toxicological effects of AgNPs to aquatic organisms. In addition, the influence of various natural suspended particles on the behavior and toxicity of nanoparticles has rarely been studies. Therefore, the purpose of this study was to elucidate the impact of natural suspended matters on the toxicity of silver compounds including AgNPs and $AgNO_3$ to Daphnia magna. To determine LC50 values, D. magna were exposed either to a range in concentration of $AgNO_3$ or AgNPs in artificial hard water under static conditions for up to 48h. The median lethal concentration (LC50) of AgNPs and $AgNO_3$ to D. magna were 22 µg/L and 1.8 µg/L, respectively. After 48 hours of exposure to $AgNO_3$ and AgNPs, D. magna mortality showed an inverse relationship with concentration of suspended particles including algae and seston. Thereafter, $1x10^4$ ~ $1x10^6$ cells/ml of a phytoplankton Selenastrum capricornutum or 50 ~ 250 mg/L of montmorillonite were suspended either in 4 µg/L of $AgNO_3$ or in 40 µg/L of AgNPs. The mortality of D. magna in $AgNO_3$ medium was significantly reduced from 100% to < 2% with an increase of suspended particles; either by increasing the algal concentration from $1x10^4$ cells/ml to $1x10^6$ cells/mlor by increasing montmorillonite concentration from 100 mg/L to 250 mg/L. Similarly, the mortality in AgNPs treatments was significantly decreased from 100% to < 15% either by increasing montmorillonite concentration from 50 mg/L to 150 mg/L or by increasing algal concentration from $1x10^4$ cells/mlto $1x10^6$ cells/ml. The reduction of mortality was accompanied with reduction in dissolved Ag^+ concentrations in the exposure media; dissolved Ag^+ concentration decreased with increasing time and suspended particle concentration. In particular, the Ag^+ concentrations were below a detection limit at the highest suspended particle concentrations after 48h exposure in the both media. Our study clearly demonstrates the significant role of natural suspended particles in reducing the toxicity of silver compounds, which was largely explained by a reduction in dissolved Ag^+ concentration.

MP143 Mediation of Metal Toxicity to Meiobenthic Copepods by Polyvinylpyrrolidone Coating of Silver Nanoparticles

T. Chandler, Univ of South Carolina; M. Baalousha, Univ of South Carolina / Dept of Environmental Health Sciences Arnold School of Public Health; J. R. Lead, Univ of South Carolina / Center for Environmental NanoScience and Risk Arnold School of Public Health; M. Losavio, M. Sikder, Univ of South Carolina / Dept of Environmental Health Sciences Arnold School of Public Health

As commercial and industrial uses for silver nanoparticles increase – principally as biocides – environmental releases through sanitary waste discharge and degradation of Ag-nano containing products are growing. Most silver-induced toxicity in aquatic systems is from metal dissolution to free Ag-ion, although more generally there is a residual effect which cannot be explained by free ion alone. The capping of Ag nanoparticles (Ag-nanos) by organic polymers such as polyvinylpyrrolidone (Ag-PVP) has been proposed as a means to stabilize Ag-nanos in solution. The possibility of Ag-nano toxicity reduction via particle coating was explored using Ag-PVP as a model particle and full-lifecycle comparative exposures of copepods to seawater-dissolved reference $AgNO_3$ (0, 20, 30, 45, 75 ug · L^{-1}) versus treatment PVP coated Ag-nanos (same concentrations) using the meiobenthic copepod Amphiascus tenuiremis per ASTM E2317-04(2012) methods. Over the full lifecycle, $AgNO_3$ dissolved in 30S seawater at only 30 ug · L^{-1} was significantly lethal to copepods (45% of test population dead in 26 days) with mating success cut in half and fecundity reduced 40%. In contrast, Ag-PVP at 30 ug · L^{-1} produced only 19% population death by 26 days with no negative effects on mating success or fecundity. Response data for stage-specific survival rates, sex ratios, mating success and fecundity were modeled via Leslie (Lefkovich) matrices to project an integrated population response model for these two forms of seawater-associated Ag. PVP-coated particles produced a population doubling time of 3-4 generations across all test concentrations except the control (i.e., 2 generation doubling time). $AgNO_3$ at 20 ug · L^{-1} pushed population doubling-time to 4 generations versus 2; and > 30 ug · L^{-1} pushed copepod populations to extinction in 9-12 generations. Ag nanoparticle coating by PVP appears to slow particle dissolution and thus confer population-relevant protection from the stronger toxicity observed for rapidly-dissolving $AgNO_3$ in seawater.

MP144 Cellular Specific Responses of the Eastern Oyster, Crassostrea virginica, to PolyDOTs

D. Smith, UNC Charlotte / Dept of Biology; N.H. Levi-Polyachenko, Wake Forest Univ School of Medicine / Plastic and Reconstructive Surgery; A.H. Ringwood, UNC-Charlotte / Dept of Biology

Polymer dynamic organic theranostic spheres (PolyDOTs) are currently being studied as a potential to be used in photothermal ablation treatment of cancer. If shown to be successful, these PolyDOTs will be mass-produced and it is expected that they, like any other engineered nanoparticle (ENP), will be found in the ambient environment. The specific PolyDOTs used in these studies are P3HT/BSe PolyDOTs and are activated to thermally ablate cancer cells by 808nm of near infrared light. In order to investigate the potential of even greater toxicity (e.g. potentiation) due to solar exposure, which includes UV radiation, infrared radiation, and longer wavelengths of light, the PolyDOTs were exposed to the sun for 12 hours and effectively "charged". Once charged, hepatopancreas and gill tissues from the eastern oyster (Crassostrea virginica) were exposed to various concentrations of both uncharged and charged PolyDOTs for 24 hours, and the effects of the PolyDOTs on lysosomal destabilization were analyzed using the Neutral Red assay, cell viability was analyzed using the MTT assay, and free radical damage was analyzed using the lipid peroxidation assay. Preliminary data from the lysosomal toxicity assays with in vitro hepatopancreas tissues exposed to PolyDOT particles showed that there were increased rates of lysosomal destabilization in charged exposures compared to uncharged. The MTT toxicity assay showed that there were no statistically significant differences between the exposure groups when tissues were exposed to both charged and uncharged PolyDOTs. Studies like these are important for understanding the effects of ENPs on oysters, and are also important for understanding the broader ecological impacts of ENPs on other species and estuarine ecosystems.

MP145 Accumulation of dissolved silver and silver nanoparticles in liposomes used as a model membrane

C. Guilleux, INRS-ETE / INRS Eau Terre Environnement; P. Campbell, Université du Québec, INRS / INRS Eau Terre Environnement; C. Fortin, Univ of Quebec / INRS Eau Terre Environnement

The increasing presence of nanomaterials in consumer products has led the scientific community to study the environmental fate of these contaminants of emerging concern. Understanding their transformations and interactions with living organisms is a crucial step in the study of their impacts on aquatic ecosystems. Silver nanoparticles, used mainly for their antibacterial properties, are among the most common nanomaterials. How they interact with aquatic organisms, especially how they cross the biological membrane, remains uncertain. In this project, we are studying the uptake of dissolved silver and silver nanoparticles by liposomes. These unilamellar vesicles composed of phospholipids have long been used to model natural biological membranes. This allows studying the potential uptake of silver by passive diffusion through the phospholipid bilayer. The liposomes were synthesized in a pH 6 buffer using extrusion techniques and potential membrane leakage was monitored throughout. Size exclusion chromatography was used to remove the outer buffer and the liposomes were then exposed over time to silver under different conditions where Ag^+, $AgS_2O_3^-$ or $AgCl^0$ were the dominating species. At the end of the exposure, Ambersep GT74 cation exchange resin (0.3 g per sample, > 95% efficient) was used in order to bind the non-assimilated dissolved metal. Similar experiments were conducted with the complexes $HgCl_2$

and $Cd(DDC)_2$, both hydrophobic and known to diffuse passively through the biological membranes. Finally, liposomes will also be put in contact with 5-nm PVP-coated silver nanoparticles. For these experiments, a second size exclusion chromatography step will be used to separate silver nanoparticles and exposed liposomes. The uptake kinetics of Ag^+, $HgCl_2$ and $Cd(DDC)_2$ show no increase over time, unlike $AgS_2O_3^-$ and $AgCl^0$, which appear to go through the phospholipid bilayer. This seems in contradiction with our initial hypothesis that lipophilic Hg and Cd complexes would be able to cross the membrane while silver would not.

MP146 Interaction of Nanoparticles with Model Bacterial Surfaces

E. Caudill, Univ of Wisconsin – Madison / Chemistry; J. O'Rourke, Univ of Wisconsin Madison; J. Buchman, K. Johnson, Univ of Minnesota; H. Frew, Augsburg College; A. Vartanian, Univ of Illinois at Urbana Champaign; Y. Zhang, Univ of Wisconsin Madison; C. Haynes, Univ of Minnesota; V. Feng, Augsburg College; C. Murphy, Univ of Illinois Urbana-Champaign; R. Hamers, Univ of Wisconsin Madison / Dept of Chemistry; J.A. Pedersen, Univ of Wisconsin – Madison / Soil Science

Bacteria are ubiquitous in terrestrial and aquatic environments and perform critical functions within these ecosystems. The interaction of bacteria with nanomaterials released into such environments may elicit adverse effects or result in nanoparticle transformation. One of the primary modes of nanomaterial interaction with bacteria involves contact with the bacterial cell surface. Our objective was to determine the critical chemical components of Gram-negative and Gram-positive bacterial cell surfaces that govern nanoparticle interaction. To study these interactions, we constructed model Gram-negative bacterial cell surfaces containing lipopolysaccharides and isolated Gram-positive peptidoglycan with covalently bound wall teichoic acids (anionic glycopolymers). We used cationic nanoparticles as a model system for nanoparticles with an inert core and positively charged surface. We employed complementary spectroscopic, imaging, and in situ microgravimetric techniques to study the interaction of these nanoparticles with model bacterial cell surfaces. We found that the extent of nanoparticle attachment to model Gram-negative cell surfaces is dictated by concentration and type of lipopolysaccharides. Preliminary solid-state NMR results suggest that positively charged diamond nanoparticles associate with wall teichoic acids. We expect that our results will ultimately inform the assessment of risk posed by nanomaterials released into the environment, as well as nanoparticle manufacturing to modulate interactions with Gram-negative and Gram-positive bacteria.

MP147 Aggregation, sedimentation, dissolution and bioavailability of quantum dots in estuarine systems

Y. Xiao, Country Garden Holding Company Limited; K.T. Ho, R.M. Burgess, USEPA / Atlantic Ecology Division; M.A. Cashman, Univ of Rhode Island / Geology Dept

Due to increasing use in flat screen applications, solar cells, ink–jet printing, and medical devices, cadmium-based quantum dots (QDs) are among the fastest growing classes of engineered nanomaterial. These wide-ranging consumer product applications and end of use disposal issues assure that QDs will eventually enter the marine environment. In order to understand the fate and transport of CdSe QDs in estuarine systems, the aggregation, sedimentation, dissolution, and bioavailability of CdSe QDs in seawater was investigated. The size of CdSe QDs increased from 40-60 nm to >1 mm within one hr once introduced to seawater, and the diffusion-limited aggregation led to highly polydispersed aggregates with loose structures. As a result, the sedimentation rate of CdSe QD aggregates in seawater was measured as 4-10 mm/day, which was slow considering their relatively large size. Humic acid (HA), as a model natural organic matter, further increased the size and polydispersity of CdSe QDs, and slowed their sedimentation. Natural sunlight and light filters were employed to simulate the photic conditions at different water depths in an estuarine system. It was observed that light played a vital role in promoting the dissolution of CdSe QDs and the release of dissolved Cd. The ZnS shell surrounding the CdSe core also significantly hindered the degradation of CdSe QDs into their ionic components. With sufficient light, the presence of HA increased the dissolution of QDs, while with relatively scarce light, HA alone did not significantly change the dissolution of QDs. Our results demonstrate that the benthic zone in marine systems is the most probable long-term destination of CdSe QDs due to aggregation and sedimentation, despite being affected by slower transport processes than expected. In addition, the benthic community might be exposed to both particulate and ionic forms of CdSe QDs. The bioavailability of QDs to epibenthic organisms was evaluated by using mysid Americamysis bahia as a model organism, and the 7-day LC50s of particulate QDs and dissolved Cd was 290 and 23 ppt, respectively. For this organism, the acute toxicity appears to be largely a result of dissolved Cd from the QDs; however, research on the toxic effects of particulate QDs should be conducted with other animal models where QDs may be lodged in critical tissues such as gills or filtering apparatus, and Cd ions may be released and delivered more directly to those tissues.

MP148 Nanotoxicology of NMC, PAH-AuNP, Citrate-AuNP and D. melanogaster

B. Curtis, School of Freshwater Sciences – Univ of Wisconsin Milwaukee; M. Hang, Univ of Wisconsin Madison; R. Hamers, Univ of Wisconsin Madison / Dept of Chemistry; X. Zhang, Univ of Illinois at Urbana Champaign; C. Murphy, Univ of Illinois Urbana-Champaign; R. Klaper, Univ of Wisconsin-Milwaukee / School of Freshwater Sciences

Due to its mapped, highly tractable genome, high percentage of homologous disease genes to humans, and a short ~10 day life cycle, D. melanogaster is an exceptional model for examining potential toxic effects of exposure to NMC and other nanoparticles. Investigations of the potential environmental impacts of nanoparticles have largely focused on model or simple nanomaterials. The current work exposes Drosophila melanogaster to poly(allylamine) hydrochloride wrapped gold nanoparticles (PAH–AuNPs), and citrate capped gold nanoparticles (Cit–AuNPs) as well as first generation battery materials lithium cobalt oxide ($LiCoO_2$) and complex next-generation battery material lithium nickel manganese cobalt oxide (NMC). This work represents the first steps towards evaluating potential toxic effects of battery-related nanoparticles on D. melanogaster. In initial trials, no significant mortality was observed in D. melanogaster larvae exposed to NMC nanoparticles at 1, 10, 20 or 100 mg/L, utilizing two different methods: nanoparticle-treated food media and nanoparticle-treated aqueous sucrose solution. Previously published studies with Drosophila commonly exposelarvae to nanoparticles via mixture with food media, which introduces additional variables that may affect outcomes. Nanoparticles are less stable when introduced to food media, and homogenous mixing is difficult; and the methods described in existing research are often vague, e.g. nanoparticles were "mixed strongly" into the food media. The work presented here describes a minimal media exposure method in which D. melanogaster embryos hatch directly into treatment media consisting of only nanoparticles and moderately hard water. Results seen in D. melanogaster will be used to compare impacts across various model organisms.

MP149 The Interactive Effects of UV Radiation and Titanium Dioxide Nanoparticles on the Calanoid Copepod, Acartia tonsa

V. Haynes, J. Ward, Univ of Connecticut / Marine Sciences

Titanium dioxide nanoparticles (TiO_2 NP) are used in a variety of consumer goods including paints, sunscreens, skin-care products and anti-microbial agents. As a result of their prevalent use, especially related to beach and boating activities, TiO_2 NP are likely entering the marine environment via direct and indirect inputs. Nanoscale TiO_2 NP are photocatalysts, able to produce reactive oxygen species (ROS) that can damage living cells and cause deleterious effects in some aquatic organisms. This study investigated the effects of commercially available TiO_2 NP on the female calanoid copepod, Acartia tonsa. Four experimental treatments, a) copepods with NP and food, b) copepods with food only, c) NP with food and d) food only, were exposed to three different light conditions (15-hr light, 9-hr light and 0-hr light as a control). Light was supplied by solar lamps that mimic natural light in the visible and UVA/B regions.

An oceanographic optical model, Hydrolight, was used to determine the appropriate environmental light levels for experiments. Initial and final algae concentrations were determined to evaluate the effects on copepod ingestion rate (IR). Egg production rate (EPR) was determined after 24 hours of exposure, and egg hatching frequency (HF) was determined at 48 hours. Preliminary results indicate that there is a both NP and light effect on copepod IR, EPR and HF, compared to the NP and 0-hr light controls. These and other effects will be presented. This work suggests that NP under realistic environmental conditions could have possible organismal and population impacts, and will help to inform future studies on organisms that rely on zooplankton for food (e.g., fish larvae and filter-feeders).

MP150 The Comparative Study of Silver Nanoparticles and Ionic Silver Exposure on Organ Pathology of Sprague-Dawley Rats

P. Jacob, Marist College

Silver nanoparticles (AgNPs) have potent physical, chemical and anti-bacterial properties, which has lead to their application in a wide variety of industrial and medical products. This study investigated the toxicity, distribution, and accumulation of AgNPs in the digestive tract, liver, spleen, brain, and bone tissue of female Sprague-Dawley rats. In addition, the effect of Ag ions was also examined. The experimental specimens were exposed to AgNPs synthesized using cetyltrimethyl ammonium bromide (CTAB) as a stabilizer through the reduction of silver nitrate ($AgNO_3$) with sodium borohydride ($NaBH_4$) in water. The solutions were administered orally in water for an 18-day period. The following treatments were established: colloidal AgNP 20 ppm daily, silver ions (Ag^+) from silver nitrate ($AgNO_3$). The following controls were prepared: CTAB control with a concentration of 1mM and tap water. Experimental behavioral observations were conducted. At the termination of the experiment, the rats were sacrificed by CO_2 overdose and organs were collected for further analysis. Throughout the experimental exposure, the rats receiving the AgNPs became visibly more lethargic, their fur coat lost its luster, and the animals shed their fur in tufts. Significant time difference between treatments was observed during the euthanasia process. The rats exposed to the AgNPs treatment died in approximately 20-30 sec, 1 min in $AgNO_3$ rats, 2 min in CTAB rats, while in the tap water control the lethal exposure was about 3-4 minutes. Rats in AgNPs treatment had visible hepatomegaly and splenomegaly. They also had much thinner and more brittle veins that snapped upon touching. The gross observations suggest that the administration of AgNP's orally had an adverse effect on the health and systematic functions of Sprague-Dawley rats.

MP151 Nanoparticles feeding exposure to the marine amphipod Parhyale hawaiensis: absorption in hemolymph

M. Vannuci-Silva, Campinas State Univ; M. Artal, Univ of Sao Paulo – USP / Toxicology and Toxicology Analysis; A. dos Santos, S. Cadore, Campinas State Univ; T. Henry, Heriot-Watt Univ / School of Life Sciences; G. Umbuzeiro, School of Technology – UNICAMP / LEAL

Silver nanoparticles (AgNP) tend to agglomerate in the aqueous phase and settle to sediment surfaces where they present risk of toxicity to deposit feeding organisms. Amphipods, like Parhyale hawaiensis, are a key deposit-feeding species and an excellent model for evaluation of AgNP toxicology. We hypothesized that exposure of P. hawaiensis via ingestion of food contaminated with AgNPs would lead to absorption of Ag into internal tissues and toxicity. The first task was to establish a method for measuring silver concentration in the hemolymph of these very small organisms (e.g., P. hawaiensis has 5 to 10 mm length when adult). Silver nanoparticles < 100nm (Sigma Aldrich) or elemental Ag (from AgCl, Sigma Aldrich) were incorporated (500 mg kg^{-1}) into formulated fish feed pellets as described in Merrifield et al (2013). Each adult organism was placed individually into a plastic container (100 mL of reconstituted saline water), and fed daily with control, AgNP, or AgCl amended feed pellets. After 1 hour, each organism, was washed and placed into a new plastic container with clean salt water to ensure that the exposure was only via food. After 4, 7 and 14 days of exposure, hemolymph (approximately 0.5 µL per organism) was collected. An Agilent 7700x Inductively Coupled Plasma Mass Spectroscopy was used for Ag determinations. The results showed that a higher amount of silver was absorbed from AgNP feed than silver from AgCl in all exposure times. In the case of AgNP feed, increase of silver concentration was related to exposure duration. From chemical analysis of the hemolymph, it appeared that ingested silver is more bioavailable to as AgNP than when it is salt in form (AgCl). Microscopy of organisms is underway to evaluate if the nanoparticles are absorbed as particles or Ag ions. The ability to analyze metals concentrations in the hemolymph of P. hawaiensis extends the importance and utility of this organism as a model for ecotoxicology.

MP152 Exploring impacts of complex nanomaterials using the nematode C. elegans

N. Niemuth, Univ of Wisconsin – Milwaukee / School of Freshwater Sciences; M. Hang, Univ of Wisconsin Madison; R. Hamers, Univ of Wisconsin Madison / Dept of Chemistry; X. Zhang, Univ of Illinois at Urbana Champaign; C. Murphy, Univ of Illinois Urbana-Champaign

The nematode C. elegans is an extremely well-studied model organism and represents a powerful tool for elucidating mechanisms of toxicity of nanomaterials. Nanotoxicology exposures have to-date focused largely on simple materials such as silver, but manufactured nanomaterials with potential environmental impacts are likely to be complex. The work presented here represents the initial stages in the exploration of the interactions of complex nanomaterials using the powerful model organism, C. elegans. Adult nematodes were exposed to the complex next-generation battery material Lithium Nickel Magnesium Cobalt Oxide (NMC) as well as negatively and positively-charged gold nanoparticles: citrate-capped gold (Cit-Au) and poly(allylamine) hydrochloride-wrapped gold (PAH-Au) spheres. Nanomaterials were mixed with OP50 bacteria and spread on solid NGM plates, simulating a sediment-type exposure. Animals were observed and scored alive/dead daily until the end of their lifespan. In contrast to results observed in aquatic exposures with animal models such as Daphnia magna; NMC, Cit-Au, and PAH-Au did not cause increased mortality in C. elegans, even at concentrations as high as 100, 10, and 10 mg/L respectively. These results suggest that media may play an important role in toxicity of nanomaterials, but represent only the beginning of explorations of complex nanomaterial interactions using C. elegans. The well-studied and amenable nature of this organism make possible future studies taking advantage of gene-expression, gene-knockdown and knockouts, GFP-reporters, and myriad types of microscopy.

Assessing Risks of Pesticides to Federally Listed (Threatened and Endangered) Species at a National Level – Part 2

MP153 A Refined Aquatic Ecological Risk Assessment for the California Tiger Salamander Potentially Exposed to Malathion

R.L. Breton, Intrinsik Environmental Sciences, Inc.; G.E. Manning, Intrinsik Environmental Sciences, Inc. / Dept of Biology; Y.H. Clemow, Intrinsik Environmental Sciences, Inc.; M.F. Winchell, Stone Environmental, Inc. / Environmental Systems Modeling; L. Padilla, Stone Environmental, Inc.; S.I. Rodney, Intrinsik Environmental Sciences, Inc.; J. Hanzas, Stone Environmental, Inc. / Agrochemical Fate and Exposure; T.L. Estes, B. Toth, K. Budreski, Stone Environmental, Inc.; D. Moore, Intrinsik Environmental Sciences US, Inc.; P. Whatling, FMC Corporation / Senior Manager of Regulatory Science

The California tiger salamander (CTS; Ambystoma californiense) is endemic to the California grasslands. CTS is federally threatened throughout California and endangered in Santa Barbara and Sonoma Counties. Under the Federal Insecticide, Fungicide and Rodenticide Act, the United States Environmental Protection Agency (USEPA) registers pesticides for use in the US. Registration or reregistration of a pesticide is the authorization of a "federal action" under the Endangered Species Act. As such, USEPA is required to ensure that pesticide registration actions are unlikely to jeopardize threatened and endangered species or their critical habitat. In 2010, USEPA issued its malathion effects determination for the CTS. Based on its conservative and deterministic risk assessment, USEPA made a Likely to Adversely Affect determination for the CTS. After the release of the National Academy of Sciences panel report (NAS, 2013), the USEPA, Fish & Wildlife Service, National Marine Fisheries Service and the US Department of Agriculture adopted an interim approach for conducting endangered species assessments for pesticides. The Interagency Interim Approaches consist of three steps: (1) a conservative analysis to determine which listed species could be exposed, (2) refined analyses to determine risks to individuals, and (3) population modeling to determine if species are in "jeopardy" from pesticide use. The Interagency Interim Approaches are currently being tested with three case study pesticides including chlorpyrifos, diazinon and malathion. Draft Biological Evaluations for these three chemicals were released by USEPA in April 2016. In light of the current interim approaches and the need for improved risk estimation, a refined assessment was carried out and focused on direct and indirect effects to the CTS. A custom approach to modeling malathion exposures in surface waters inhabited by CTS was developed for the refined assessment. This approach consisted of using the Pesticide Root Zone Model and Variable Volume Water Model along with input parameters customized to reflect soils, slopes, weather, crop and pond geometries observed in CTS habitat range. We also used a weight-of-evidence approach and evaluated independent lines of evidence (e.g., field and mesocosm studies, monitoring data and incident reports). Based on the results of the weight-of-evidence assessment, currently labeled uses of malathion are unlikely to result in direct or indirect effects to CTS.

MP154 A Refined Ecological Risk Assessment for the Delta Smelt Potentially Exposed to Malathion in California

G.E. Manning, Intrinsik Environmental Sciences, Inc. / Dept of Biology; R.L. Breton, Intrinsik Environmental Sciences, Inc.; M.F. Winchell, Stone Environmental, Inc. / Environmental Systems Modeling; L. Padilla, Stone Environmental, Inc.; Y.H. Clemow, S.I. Rodney, Intrinsik Environmental Sciences, Inc.; J. Hanzas, Stone Environmental, Inc. / Agrochemical Fate and Exposure; T.L. Estes, B. Toth, K. Budreski, Stone Environmental, Inc.; D. Moore, Intrinsik Environmental Sciences US, Inc.; P. Whatling, FMC Corporation / Senior Manager of Regulatory Science

The Delta smelt (Hypomesus transpacificus) is an annual fish endemic to the Sacramento-San Joaquin Estuary. The species was listed as threatened on March 5, 1993 by the United States Fish and Wildlife Service (US FWS). Under the Federal Insecticide, Fungicide and Rodenticide Act, the US Environmental Protection Agency (USEPA) registers pesticides for use in the US. Registration or reregistration of a pesticide is the authorization of a "federal action" under the Endangered Species Act. As such, USEPA is required to ensure that pesticide registration actions are unlikely to jeopardize threatened and endangered species or their critical habitat. In 2010, USEPA issued its malathion effects determination for Delta smelt (DS). Based on its conservative and deterministic risk assessment, USEPA made a Likely to Adversely Affect determination for the DS. After the release of the National Academy of Sciences panel report (NAS, 2013), the USEPA, FWS, National Marine Fisheries Service and the United States Department of Agriculture adopted an interim approach for conducting endangered species assessments for pesticides. The Interagency Interim Approaches consist of three steps: (1) a conservative analysis to determine which listed species could be exposed, (2) refined analyses to determine risks to individuals, and (3) population modeling to determine if species are in "jeopardy" from pesticide use. The Interagency Interim Approaches are currently being tested with three case study pesticides including chlorpyrifos, diazinon and malathion. Draft Biological evaluations for these three chemicals were released by USEPA in April 2016. In light of the current interim approaches and the need for improved risk estimation, a refined assessment was undertaken and focused on direct and indirect effects to the DS. The Soil and Water Assessment Tool (SWAT) was used to predict aquatic EECs in the water bodies within the DS critical habitat. The application of the SWAT model considered all uses of malathion within the watershed draining into the California Delta, including the Sacramento and San Joaquin drainages. We also used a weight-of-evidence approach and evaluated independent lines of evidence (e.g., field and mesocosm studies, monitoring data and incident reports). Based on the results of the weight-of-evidence assessment, currently labeled uses of malathion are not expected to result in direct effects to DS and would rarely affect its aquatic invertebrate prey.

MP155 Refined Aquatic Exposure Estimates based on Species Data from the Pilot Biological Evaluations

N. Snyder, R. Vamshi, Waterborne Environmental, Inc.; J. Amos, Waterborne Environmental, Incorporated / Geospatial Data Technologies; A. Ritter, D. Perkins, K. Jones, R. Gali, Waterborne Environmental Inc

The draft biological evaluations (BEs) released by USEPA assessing three pilot chemicals utilized a regionalized assessment methodology for assessing exposure to endangered species living in aquatic environments. Aquatic exposure was assessed using several fixed receiving water (habitat) dimensions, referred to as aquatic bins. The BEs also included a detailed summary of USFWS information regarding habitat waterbodies and species locations. In this presentation, a tiered exposure assessment methodology is proposed that builds off of the scenario based exposure methodologies, but also extends beyond and utilizes species relevant data as early in the process as feasible. Refinements addressing habitat hydrodynamics with appropriate modeling approaches will be presented as refinements using readily available modeling tools and conservative assumptions. In the presentation of results, USEPA clearly identified extreme exposure predictions and expressed desire for ideas on refinements. This presentation seeks to answer that call in a species relevant and specific manner that allows for scaling to the appropriate chemical use footprint with focus on species habitat area. Results allow for use in screening level deterministic risk assessments. They can be further integrated with surrogate species dose response curves or sensitivity distributions for a species focused probabilistic risk expression. Temporal analysis could also be derived from the results. Implementing a species focused analysis framework using actual habitat data to inform model refinements also provides the opportunity to incorporate mitigating factors in the exposure assessment. Model tools should incorporate naturally occurring landscape mitigating factors (i.e. landscape based treatment buffers from listed stream habitats, percent crop area) as well as label or management based mitigation measures (i.e. drift buffers or protected lands). The goal of a national assessment should be to generate relevant exposure estimates by including best available data in a pragmatic way.

From Source to Sink: Consumer Product Chemical Exposures and Exposure Pathways

MP156 Assessing Risk for Consumer Products Under California's Proposition 65 Regulations

A. Singhal, Exponent; M. Posson, A. Jones, J. Schenk, P.J. Sheehan, Exponent / Occupational and Environmental Health Risk Assessment

Proposition 65, formally known as the Safe Drinking Water and Toxic Enforcement Act of 1986, is a California initiative that requires businesses to warn consumers if exposures to listed chemicals exceed their chemical-specific Safe Harbor Levels. Over 900 chemicals potential carcinogens and reproductive toxicants spanning various industries such as food, drugs, consumer products, cosmetics, etc. are listed and the list is continually being updated. It is critical that businesses planning on selling their products in California ensure that their products are Proposition 65-compliant. However, demonstrating compliance may be convoluted because in many cases Safe Harbor Levels have yet to be developed (e.g., recently added bisphenol-A[BPA]); due to the type of user involved (e.g., consumer or worker); types of chemicals involved (e.g., carcinogen or reproductive toxicant); and the varying routes of exposure (e.g., dermal, inhalation and/

or ingestion routes). Here, we provide case studies of different approaches on conducting Proposition 65 risk assessments using real world examples of consumer and worker products using different listed chemicals. Cases discussed include: 1) inhalation exposure to salon workers from formaldehyde in hair products; 2) dermal and ingestion exposure to children from diethyl hexyl phthalate (DEHP) and BPA in bath toy products; and 3) dermal exposure to consumers from nickel (Ni) in wearable products. These case studies show the diversity of approaches that are used to assess risk from everyday use of common consumer products.

MP157 Environmental Obesogens: An Emerging Concern

B.G. Loganathan, Murray State Univ / Dept of Chemistry Watershed Studies Inst

Human exposure to environmental pollutants has been potentially attributed to the worldwide prevalence and dramatic increase of obesity and type 2 diabetes over the last four decades. World Health Organization estimated 1.5 billion adults worldwide are overweight or obese and the number of type 2 diabetes increase from 153 to 347 million between 1980 and 2008. Earlier studies using animal models have reported that low doses of bisphenol A (BPA), phthalates, DDT, TBT and other persistent organic chemicals and some heavy metals such as cadmium, arsenic, lead etc., can make animals fat and gain weight. However, these chemicals cause similar harms to humans is still need to be elucidated. According to the 2015 Alliance for a Healthier Generation, the Commonwealth of Kentucky is the 7th most obese state with (35.7%) in the U.S. for children and 5th most obese state for adults (33.2%). Our study in western Kentucky dealing with the environmental levels of above mentioned chemicals were: 172-2950ng/g BPA in indoor dust; 6.8-356 ng total butyltins/g dry wt. sediment from Kentucky Lake; 32-107 ng total butyltins/g dry wt. in freshwater mussel tissues from Kentucky Lake; 1.65-1.81 ng BPA/L in Clarks River Water, Kentucky; 63-414ng total PCB/g dry wt fish from Kentucky Lake; 8.2-990 ng perfluorooctane sulfonate (PFOS)/g dry wt. solid waste samples from wastewater treatment plant from Murray, Kentucky; 11-130ng PFOS/mL blood sera of females and 19-164 ng PFOS/mL blood sera of males from Kentucky. The results show the presence of potential obesogens in environmental and biological tissues including human blood sera from western Kentucky, however, these levels cause obesity in human or animals is yet to be determined.

MP158 Framework for modeling the release of chemicals during the use phase of consumer products

M. Tao, Univ of California, Santa Barbara / Bren Hall of Environmental Science and Management; D. Li, Univ of California, Santa Barbara / Bren School of Environmental Science and Management; R. Song, Univ of California Santa Barbara; S. Suh, Univ of California Santa Barbara / Bren School; A.A. Keller, Univ of California Santa Barbara / Bren School of Environmental Science and Management

Chemicals contained in consumer products have become the focus of recent regulatory developments including the California Safer Consumer Products Act. Quantifying the amount of chemical releases during the use phase of consumer products, however, is a challenge, limiting our ability to understand the impacts of these chemicals used in consumer products. This study presents the current progress of the framework under development for estimating the release of chemicals during the use phase of consumer products when product-specific chemical release measurements are lacking. First, quantitative structure-function relationship (QSFuR) is developed using over 8,000 chemical-function pair data as training data. Second, the quantity of chemicals entering into different product streams is estimated based on market size data of nine major functional use categories. Third, chemical releases are estimated per each chemical use scenario using the Specific Environmental Release Categories (SPERCs) data developed by the European industry sector groups and trade associations. The framework currently considers 10 functional uses and linked them with 15 different products. Together with the complied release factors, the framework can provide quantitative estimated release amount to indoor air, outdoor air, wastewater, and soil for the input chemical. In the future, additional functional uses, market size data, and release factors will be further incorporated to improve the coverage and precision on release estimates for this framework. The framework helps understand the potential risk of organic chemicals in consumer products when empirical release factors are not available, and can help decision makers make informed decisions considering potential use phase impacts.

MP159 Hand-to-mouth contact frequency among adults: A review of the literature and recommendations for future studies

A. Gauthier, R.C. Lewis, R. Kalmes, Exponent, Inc.

Environmental agents may be transferred to the hands after contact with a contaminated surface, such as a consumer product. This transfer may consequently pose an opportunity for inadvertent ingestion should hand-to-mouth contact occur. A key determinant of exposure from this route is frequency of hand-to-mouth contact. In theory, the more frequent the hand-to-mouth contact, the greater the probability for exposure. Historically, due to their prevalent hand-to-mouth behavior, infants and young children have been the primary focus of research on this subject matter. Among adults however, this has been an under-researched aspect of human behavior in the peer-reviewed literature. The current study analyzed 11 key publications of adult hand-to-mouth behavior in adults. The analysis showed that the current state-of-the-science largely does not address the nuances of hand-to-mouth behavior that are essential for accurately characterizing exposures from this pathway. Although this information is necessary to accurately characterize exposures and resultant human health risks, and evaluating regulatory compliance in certain contexts (e.g., Proposition 65), many data gaps remain. Due to the lack of relevant data, investigators often rely on hand-to-mouth contact data that may not necessarily be contextually-specific, which can contribute to error in estimated exposures. Results from a recent hand-to-mouth study associated with specific consumer behaviors are presented. Additional more detailed research is needed on hand-to-mouth behavior in adults as this will greatly refine judgements of exposures and associated human health risks.

MP160 Health Risks from Chemicals During the Use Phase of Consumer Products – Current Knowledge and Information Gaps

D. Li, H. Park, S. Suh, Univ of California Santa Barbara / Bren School of Environmental Science and Management

Health risk from chemicals in consumer products has become a major concern and gave rise to regulatory developments including the Safer Consumer Products Act. However, it remains a challenge for consumer, industry, and regulators to identify which chemicals should receive priority in scrutiny. This study reviewed previous literatures on chemical risks from the use phase of consumer products. Based on past research, this study aimed to elucidate what type of chemicals possess highest potential hazard for the use phase of consumer products. In addition, available research and regulation efforts on chemicals found in the review were summarize to identify potential chemicals that may be understudied. To match the scope of this study, the chemical should be 1) artificially manufactured; 2) added to consumer products to achieve certain functions; 3) not a drug or food; 4) route of exposure not originated from the general environment or occupational environment. 215 peer-reviewed papers in the past decade on chemicals commonly found in consumer products were reviewed and 122 unique individual chemicals or chemical groups were identified. The patterns between the chemical's functional use, product application, toxicity, and exposure routes are semi-quantitatively assessed and analyzed with Bayesian Inference. Randomly selected 122 chemicals from the USEPA CPCat database Chemicals were subjected to the same analysis to serve as control group. Results showed chemicals used in toys, baby products, personal care products, cosmetics, have evidence for carcinogenicity or causes cardiovascular disease, have multiple exposure pathways are more likely to be banned in the United States. Interestingly, rat oral LD50 value does not provide any indication of the likelihood for a certain chemical be banned in the United States. This study provided not only an overview of the most concerned chemicals, but also may help industries and regulators identify what combinations of product application, toxicity, and exposure of new chemicals would pose more risk to consumers.

MP161 Identification and Toxicological Evaluation of Unsubstituted PAHs and Novel PAH Derivatives in Pavement Sealcoat Products

I. Titaley, Oregon State Univ / Dept of Chemistry; A.C. Chlebowski, L. Truong, Oregon State Univ / Dept of Environmental and Molecular Toxicology; R.L. Tanguay, Oregon State Univ / Environmental Molecular Toxicology; S.L. Massey Simonich, Oregon State Univ / Dept of Environmental and Molecular Toxicology

High concentrations of polycyclic aromatic hydrocarbons (PAHs) have been known to be contained in pavement sealcoat products. Unsubstituted PAHs are the most commonly detected PAH group in pavement sealcoat products. However, the analysis of PAH derivatives is still limited or none at all. This study is aimed at this research gap by determining the concentrations of PAH derivatives, including, ten heterocyclic-PAHs (Hetero-PAHs), twenty six nitrated-PAHs (NPAHs), and ten oxygenated-PAHs (OPAHs) in coal-tar and asphalt based sealcoat products, as well as time point scrapes after application of a coal-tar based product. Twenty three unsubstituted PAHs, ten methyl-PAHs (MPAHs), and eleven high molecular weight-PAHs (MW302-PAHs) were also analyzed. Benzo[a]pyrene-carcinogenic equivalent (B[a]P_{eq}) concentrations for the coal-tar based products was calculated and we found that, with the inclusion of MW302-PAHs not previously measured in sealcoat products, there was an increase of 4.1 to 38.7% in B[a]P_{eq} concentrations. We also hypothesized that photochemical transformation to NPAHs and OPAHs on sealcoated surfaces should be considered as degradation pathway of unsubstituted PAHs. The Ames assay was used to evaluate the mutagenicity of the samples. We found that the coal-tar based products were mutagenic, but not the asphalt based products. To evaluate the toxicity of sealcoat samples, the zebrafish developmental test was used. This toxicity test indicated that fractions where NPAHs and OPAHs eluted were associated with the most significant adverse effects. Overall, our results contribute to the assessment of the potential human health impact of pavement sealcoat products.

MP162 Identifying and addressing contaminant sources impacting an urban estuary

R. Sutton, M.D. Sedlak, San Francisco Estuary Inst; E. Houtz, ECL California Dept of Toxic Substances Control / Environmental Chemistry Lab

Urban estuaries often harbor high concentrations of anthropogenic contaminants, resulting in elevated exposures and impacts to wildlife. Proactive, collaborative, and sustained monitoring of estuarine environments can aid in early detection of contaminants of concern, inform source identification and control options, and demonstrate the long-term impacts of control actions. The Regional Monitoring Program for Water Quality in San Francisco Bay (RMP) conducts special studies and status and trends monitoring in San Francisco Bay, California, USA, the largest estuary on the west coast of North America. Throughout its 25-year history, the RMP has maintained a strong collaboration among regulators, regulated dischargers including wastewater and stormwater agencies, and independent scientists, which has aided detection of contamination derived from consumer and industrial products before it causes major impacts to wildlife. The RMP develops and disseminates scientific information specifically relevant to source identification and potential control actions on contaminants such as flame retardants, perfluorinated stain-repellants and surfactants, pesticides, and personal care product ingredients. Long-term monitoring has also allowed the RMP to track the recovery of the Bay following management actions including chemical phase-outs and bans. This presentation will summarize common challenges to pollution prevention activities to highlight areas where research by independent scientists is needed. Examples include a) the lack of information on chemicals in consumer or industrial products; b) the diversity of uses and sources for many chemicals of concern; and c) early identification of chemicals of concern when data gaps for chemical production, environmental occurrence, and ecological impacts are common. As a respected source of independent science for regional and state water quality managers, the RMP serves as a clearinghouse for applied science that directly informs key management decisions to reduce environmental contamination.

MP163 Identifying Flame Retardant Chemicals in Polyurethane Foam From Consumer Products: Trends in Use Reflecting Shifts in the Flammability Standards

E. Cooper, B. Luukinen, E. Hodzic, Duke Univ / Nicholas School of the Environment; C. Clark, Duke Univ / Nicholas School of Environment; L. Ferguson, Duke Univ / Dept of Civil and Environmental Engineering; H.M. Stapleton, Duke Univ / Nicholas School of the Environment

Before 2005, PentaBDE was a common flame retardant (FR) additive in polyurethane foam containing residential furniture, and it's believed that the heavy use of PentaBDE in furniture in the US and Canada contributed to higher exposures among the countries populations. Following the phase-out of PentaBDE, the use of several alternate FRs increased, which included many organophosphate esters such as tris (1,3-dichloroisopropyl) phosphate (TDCIPP). However, in 2013 TDCIPP was banned from use in furniture in several US states. Around the same time, the State of California altered the residential flammability standard (TB 117) from an open flame test to a smolder ignition test. Given these changes, it is important to understand which chemicals (if any) are still being used in residential furniture in order to evaluate human exposure and health risks. In early 2014, the Duke University Superfund program developed a free public service to test polyurethane foam for FRs. This service has allowed us to build a database of FR use in consumer products and evaluate temporal changes in chemical use. As of May 2016, 1179 samples were analyzed, 50.9% of which contained an identifiable FR. Major product categories were sofas and love seats (456), chairs (120), mattress pads (117) and child car seats (99). TDCPP was the most frequently detected FR, followed by Firemaster®550 (FM550) > Tris (chloropropyl) phosphate (TCPP) > PentaBDE (a PBDE commercial mix). With the exception of 3 products, PentaBDE was not observed in products purchased post-2005, concordant with the 2005 voluntary phase-out. TDCIPP detection across all samples containing a FR dropped from 48.7% to 32.9% in products purchased before and after 2013, possibly reflecting industry response to California's 2013 change to flammability standard TB117 and/or the addition of TDCIPP to Prop65. Concomitant with the decrease in the use of TDCIPP we observed an increase in the use of TCPP as well as a non-halogenated aryl phosphate mixture containing isomers of tertbutyl phenyl diphenyl phosphate. We also report on the identification of a new FR, tetrakis(1-chloropropan-2-yl) (oxybis(ethane-2,1-diyl)) bis(phosphate), which we detected in 4.5% of FR-containing products, most of which were child products. These findings highlight trends in FR use and the value of this service to capture data on FRs in consumer products.

MP164 IFRA Environmental Standards and RIFM Program Advances Update for 2016

A. Lapczynski, RIFM / Environmental Specialist; D.T. Salvito, Research Inst for Fragrance Materials Inc / Dept of Environmental Science; C. Gonzalez, M. Vey, IFRA

To assure safety of fragrance ingredients in consumer products, International Fragrance Association expanded the fragrance industry's self-regulatory safety program with the development of IFRA Environmental Standards for both risk and hazard in 2008. Fragrance material risk assessments for these Standards are incorporated in the Research Institute for Fragrance Materials' (RIFM) testing program in coordination with its Expert Panel. To identify materials for risk assessment refinement, fragrance materialswere screened using the RIFM Environmental framework and 2008 IFRA volume of use survey as reported for both Europe and North America. The Framework for this evaluation was published in Environment Toxicology and Chemistry (Salvito et al., 2002, 1301-1308). In addition, hazard assessment on these materials was also performed and reviewed. As a result nearly 3,000 materials were screenedwith preliminary risk quotients estimated to rank priority materials for risk assessment refinement. In an effort to provide greater transparency to the IFRA Environmental Standards, RIFMreports the most recent results of these additional tests (for both risk and hazard assessments) at both the annual SETAC NA and Europe meetings. These studies include persistence testing (ready biodegradation tests and die-away studies), bioaccumulation, and acute and chronic aquatic toxicity. Incorporating these new data in a second tier risk and hazard assessment for these materialswill also be presented.

MP165 Integrating Exposure Science into Consumer Products Regulations

A. Doherty, California Dept of Toxic Substances Control / Safer Consumer Products Program; D. Molin, State of California / Safer Products and Workplaces Program

California's Safer Consumer Products (SCP) program represents a new and transparent approach to regulating Chemicals of Concern in consumer products. SCP's regulations dictate that the California Department of Toxic Substances Control (DTSC) use a narrative standard to evaluate and identify product-chemical combinations on the basis of potential for exposure to a chemical in the product to contribute to adverse impacts to human health or the environment. This allows SCP to take a precautionary approach and integrate emerging data and approaches into the product-chemical prioritization process. In turn, SCP can influence the reduction of Chemicals of Concern in the environment by requiring manufacturers to consider the full life cycle of their products when selecting alternatives to avoid regrettable substitutions. There are an ever-increasing number of product-chemical combinations that are of concern for humans and the environment alike, but information about the source of these contaminants and relevant exposure pathways is often lacking. To be able to prioritize and list product-chemical combinations, SCP must have an understanding of human and environmental exposures and exposure pathways to Chemicals of Concern in consumer products. This talk will focus on how the SCP program uses exposure data to evaluate product- chemical combinations as well as the importance of exposure data for manufacturers completing an Alternatives Analysis. It will also highlight some of the reasons that this information is not always available, including analytical limitations, changing product formulations, and information gaps in conceptual models to understand the sources of environmental and human exposures.

MP166 Organophosphorus flame retardants: environmental occurrence, human exposure, and toxicity

S. Lee, J. Lee, Seoul National Univ; K. Choi, Seoul National Univ / School of Public Health

Polybrominated diphenyl ethers (PBDEs) have been gradually replaced with alternative flame retardants such as organophosphorous flame retardants (OPFRs) due to their persistence, bioaccumulation, and toxicities. OPFRs such as chlorinated and non-halogenated OPFRs, e.g. tris(2-chloroethyl) phosphate (TCEP), tris(1,3-dichloro-2-propyl) phosphate (TDCPP), tris(1-chloro-2-propyl) phosphate (TCPP), triphenyl phosphate (TPHP), resorcinol bis-diphenyl phosphate (RDP) and bisphenol A bis-diphenyl phosphate (BPA-BDPP), have been reported in various environmental media and in humans worldwide. In this study, information on physicochemical properties, occurrence in indoor environments, human exposure, and toxicity of these chemicals were reviewed, and areas warranting further investigation were identified. In house dust and indoor air, the highest levels of TCEP, TDCPP and TCPP were reported in Asia. Exposure sources for TPHP, RDP and BPA-BDPP in residence were electronic devices or furniture. In human urines, higher levels of diphenyl phosphate (DPHP) and bis(1,3-dichloro-2-propyl) phosphate (BDCPP) were detected in children than in adults. Urinary DPHP and TPHP levels were associated with those detected in floor dust or hand wipes. In vitro and in vivo studies showed endocrine disrupting potential of TPP, TCEP, and TDCPP. Limited epidemiological evidences suggest adverse effects on reproduction. However, for TCPP, RDP and BPA-BDPP little is known about their toxicities. Considering increasing levels of exposure to these chemicals among humans, efforts are warranted to identify their exposure sources, and to investigate toxicological and health consequences.

MP167 Sources of Fipronil in Urban Aquatic Environments

K. Moran, TDC Environmental, LLC

Currently used pesticides have been found in urban runoff, municipal wastewater, and urban aquatic environments throughout the USA, sometimes at concentrations that exceed aquatic life protection benchmarks. Fipronil has among the highest detection rates for insecticides in California urban runoff and urban waterways. Recent measurements have revealed the presence of fipronil in California municipal wastewater influent, effluent, and sludge. In urban runoff, municipal wastewater effluent, and urban waterways total fipronil concentrations are reaching—and in some cases exceeding—levels known to cause toxicity to sensitive aquatic organisms. In California, fipronil has relatively few approved uses—it is only registered for structural pest control and pet treatments; it is not approved for agricultural or general landscape use. Its short list of allowable uses simplifies the process of identifying surface water exposure pathways. A preliminary conceptual model of fipronil use and transport from urban areas to surface waters was developed, based on a literature review, pesticide product labels, environmental fate data, California pesticide sales and reported use data, pesticide retail shelf surveys, and wastewater and urban runoff monitoring data. Fipronil can be washed into indoor (sewer) and outdoor (storm) drains during or after outdoor pesticide applications or as a consequence of pesticide handling activities. Source investigations guided by the model clarified the relative magnitude of each fipronil source. Growing evidence suggests that the primary source of fipronil in urban runoff is treatment of impervious surfaces around buildings–particularly surfaces that drain across paved areas to piped storm drain systems (i.e., directly connected impervious areas like building driveways and front walkways). Wastewater influent monitoring data, product information, and data from the literature characterizing transfer from application locations to other surfaces suggest pet flea and tick products are the primary source of fipronil in municipal wastewater. The refined conceptual model, which now reflects major fipronil sources and aquatic exposure pathways, provides a framework to guide development of strategies for reducing urban fipronil water pollution. The growing scientific understanding of fipronil pathways to surface water advances insights into exposure pathways for other products used in similar locations in urban environments.

MP168 Sunscreen Safety for Kids: A Risk Assessment of a Common Preservative

J. Lemay, K. Zu, Gradient; L. Zhang, VU Univ Amsterdam / Animal Ecology; J. Goodman, Gradient

Phenoxyethanol is a common preservative used in cosmetic products to prevent bacterial growth. Research and regulatory agencies worldwide conclude that phenoxyethanol poses no risk if it makes up less than 1% of a cosmetic product. Most recently, the European Union affirmed the safety of phenoxyethanol for use as a preservative with a maximum concentration of 1%. Despite these assertions, concern has arisen that the regulatory limit for phenoxyethanol may not provide an adequate margin of safety for infants and small children. Therefore, we conducted a hazard and risk assessment for phenoxyethanol in children's personal care products. We first conducted a hazard assessment of phenoxyethanol in its neat form, considering both dermal and oral exposure. We found that, although no studies have directly evaluated the carcinogenicity of phenoxyethanol, available evidence indicates a lack of genotoxicity. Also, laboratory animals dermally exposed generally experienced no adverse effects. Following oral exposure, some toxicity occurred at very high doses. In two-generation studies, no adverse effects were observed in offspring unless the dose was high enough to cause maternal toxicity. We identified the points of departure (PODs) of phenoxyethanol from the hazard assessment, then calculated children's exposures from using multiple personal care products containing phenoxyethanol. We evaluated one common brand and divided its products for children into two broad categories: lotions/creams and bathing products. For each category, we selected the products with the highest concentrations of phenoxyethanol to calculate hypothetical exposures. We estimated typical exposures possible for a child using regular lotions, sunscreen lotions during time outdoors, and body wash at bath time. Our margin of exposure (MOE) analysis determined that the typical exposure scenarios were more than 200 times less than to the PODs identified in the hazard assessment. We conclude that the available evidence indicates that phenoxyethanol, present at < 1% of formula in personal care products, does not pose a health risk to infants or small children.

Business Examples of Chemical Alternatives Assessment

MP169 The Sustainability Consortium – Common Chemical Evaluation Framework

C. Helt, S. Lewis, C. Mars, K. Dooley, The Sustainability Consortium

Consumer and advocacy group concerns related to the potential human health and environmental impacts associated with chemical exposure are growing in the home and personal care industry. These concerns are reflected both in retailers' sustainability policies and commitments around chemicals and in manufacturers' attentiveness to the development of "greener" products. Accordingly, retailers and brand manufacturers have focused on identifying high priority chemicals, disclosing these chemicals to consumers, and promoting safer ingredient choices through alternatives assessment and informed substitution. Though these efforts aim to provide progressive solutions to specific concerns regarding chemical hazards, unilateral action by individual retailers or manufacturers increases the risk of gridlock, system inefficiency, and lack of market acceptance of any given solution. To ensure that actionable and lasting progress can be made, The Sustainability Consortium (TSC) has convened members and invited participants to develop a framework that uses best and transparent approaches for ingredient selection and product safety evaluation. The framework, presented in this paper, consists of four facets of ingredient and product assessment – function, list inclusion, hazard assessment, and risk assessment – with a process flow chart that provides a means for enhanced transparency and support for evaluating and choosing ingredients to create safe products that function as intended. When completed, the framework could be used by retailers, manufacturers, and NGOs in a multitude of ways: to facilitate decision making for ingredient and product safety evaluation, as a decision support tool for product/ingredient development to create safe products, as a basis for defining leadership levels and activities, and as a communication tool to disclose current approaches for ingredient selection and product safety evaluation. Ultimately, when implemented in combination with current TSC metrics, this framework will contribute to enhanced communication on chemical safety issues throughout the value chain while driving the development of safe and more sustainable products.

MP170 Examination of three approaches for selecting candidate chemicals for an AA

A.M. Mason, American Chemistry Council / CPTD; B. Howard, American Chemistry Council / Value Chain; S. Arnold, The Dow Chemical Company; S. Risotto, American Chemistry Council; T. Kingsbury, TKingsbury LLC

As the community of practice identifies and assesses candidate chemicals for new product development, it faces a variety of challenges when evaluating alternatives. On the one hand there is a desire to reduce and/or eliminate hazardous ingredients and create new products applying practices in green engineering and chemistry; on the other hand there is a need to meet customer expectations and to develop a product that performs effectively and is cost efficient. Overall, the desired outcome for any assessment of alternative chemicals or products is to identify those that perform similarly or better than its predecessor, be measurably safer for the user and the environment, and have an economic profile comparable to the chemical or product it replaces. Assessors can choose a set of candidate chemicals using a number of approaches: 1) use hazard alone, 2) use a comparative combination of hazard and exposure, or 3) use a more expanded set of criteria that include hazard and exposure plus performance and product use. This presentation will use two generic product formulations to outline the information from each of these three approaches to demonstrate how the decisions change with the approach used.

MP171 Automated human and environmental exposure estimation to support prioritization of chemical alternatives in product development

J.P. Rinkevich, P. Beattie, J. Orchard-Hays, M.C. Ruhter, SciVera LLC

New regulations and market pressures are driving companies to implement enhanced business processes that improve understanding of the human and environmental health characteristics of chemicals in products and processes. Chemicals considered for use in products and processes present varying hazard characteristics for human and/or environmental endpoints. Some chemicals may show high hazard for one endpoint while others may indicate high hazard for other endpoints. These varying characteristics offer opportunity for exploration of hazard-related tradeoffs between alternative chemicals in specific product or process applications. In addition to a review of chemical hazards, other attributes such as technical and functional performance, market availability, and cost factor into the viability of alternatives. The practice of Alternatives Assessment (AA) can incorporate contextual review of chemical use and predicted exposure to facilitate prioritization of alternative chemicals for a specific application. Doing this work at scale, for dozens or hundreds of chemicals, requires automation for reasons of efficiency and economy. Screening-level exposure estimation and corresponding risk characterization, when automated via computer software, can assist in the rapid, consistent, and cost-effective processing of AAs where human and environmental hazard characteristics vary across potential alternatives in a common application. This talk will present specific examples using the cloud-based software SciVeraLENS® to illustrate automated exposure estimation. The examples presented will show how automated screening-level exposure assessment and risk characterization can support the growing need throughout the consumer product value chain to evaluate chemicals in context of use, at scale, to enhance product and process sustainability attributes.

MP172 Case Studies in Reducing Aquatic Risks of Personal Care Products Using the GAIA Algorithm to Drive Selection of Alternative Ingredients

J.K. Saxe, EcoSafety Sciences; R. Predale, L. Ricicki, Johnson & Johnson Consumer Companies; R. Sharples, Johnson & Johnson Medical Devices; D.J. Caldwell, Johnson & Johnson / Environment Health Safety Sustainability

Personal care products (PCPs) are used globally and are typically emitted to the environment in wastewater under normal use. As water quality concerns due to industrial point sources decrease, regulators and scientists have begun focusing on this class of compounds as a possible water quality concern because of its widespread use. Businesses selling PCPs thus have a motivation to compile, interpret, and use any available data on potential risks to the natural environment as a guide for sustainable decision making regarding ingredients to select or avoid in PCPs, to minimize the potential for adverse environmental effects. We describe how the Global Aquatic Ingredient Assessment (GAIA) algorithm for scoring environmental hazards is used as an initial decision tool, and then, resulting potential risk due to the selected PCP ingredients is checked. GAIA incorporates information on environmental persistence, bioaccumulation potential, aquatic toxicity of the parent compound and degradants, excess toxicity from ecological endocrine disruption effects, and the potential for producing photochemical smog. The algorithm yields numeric scores that discern modest differences in environmental hazard potential by aggregating empirical and modeled data for disparate endpoints using a system of weighting and penalties. Because of its ease of use by non-experts in environmental risk assessment, GAIA has been used as a front-line decision tool by formulators; however initial hazard-based decisions are prone to certain errors, which have been avoided through downstream risk assessment using several different approaches, depending on business needs. Case studies on the use of GAIA plus additional data to guide product development include: (1) the combination of GAIA scores with product efficacy yields an initial decision framework with an estimate of relative risk, demonstrated for two bath cleansing products; (2) competing shampoo formulations, driven by hazard-based GAIA scores, are compared in terms of relative aquatic risks, which are estimated using effluent modeling and risk ratios, demonstrating significant risk reductions; and (3) the absolute incremental risk due to the use of surfactants in a shampoo is estimated for commodity surfactants having less favorable GAIA scores and their alternative, a novel surfactant having a more favorable GAIA score, by using effluent modeling, environmental monitoring data, and risk ratios, confirming benefits of the alternative.

MP173 Alternatives Assessment of non-fluorinated DWR Products utilizing the GHS-Column Model

R.C. Buck, The Chemours Company / Fluoroproducts; K. Schubert, The Chemours Company

Textile brands and retailers are facing increasing pressure from stakeholders to replace a number of chemicals in their supply chain with “safer alternatives”. Many brands and retailers face a dilemma because they often have no “easy to use” tool in their hands to assess whether or not an alternative might be a preferred choice. The GHS-Column Model is a no cost practical tool that could fulfill this need. This hazard-based model was developed by the Institute for Occupational Safety and Health of the German Social Accident Insurance (IFA) and provides clear and practical guidance on how to rank six different hazard factors on five different levels, including ranking for data gaps. The GHS-Column Model is a quick and facile first level assessment to screen in or screen out potential alternatives based on hazard data from a product safety data sheet (SDS). The GHS-Column Model was utilized to assess 11 different non-fluorinated durable water repellent (DWR) products. Results of this assessment will be presented and context will be provided how the outcome can benefit downstream customers to identify potential substitutes on their journey to better alternatives.

Scientific Advances Supporting Aquatic Life Water Quality Criteria Derivation

MP174 Advancing Uncertainty Characterization in Support of Aquatic Life Water Quality Criteria Derivation: Why and How

D. McLaughlin, NCASI

Numeric water quality criteria (WQC) derived to protect aquatic life represent potentially useful tools for the management of water quality and aquatic ecosystems. Ideally, these criteria reflect a sound scientific rationale using the best available science and provide useful estimates of pollutant levels that present unacceptaable risks to these ecosystems. An important challenge for the criteria derivation process is the characterization and communication of uncertainties in the science that supports numeric criteria. Without meaningful information on uncertainties, the utility of a numeric criterion for water quality management cannot be sufficiently assessed. This is especially important for criteria for substances that are derived using limited empirical data. Existing procedures used by the U.S. Environmental Protection Agency to derive numeric WQC such as the 1985 Guidelines (Stephan et al. 1985) provide little guidance on quantitative methods that may be used estimate uncertainties. Expanding this guidance would improve the transparency of aquatic life criteria, provide a more complete assessment of the state of the underlying science, and could help prioritize areas of research needed to improve the predictive value of aquatic life WQC. This presentation will review the limitations of uncertainty characterization in some published USEPA aquatic life WQC documents, and present examples illustrating the use of Monte Carlo simulation, binary classification techniques, and receiver operating characteristic curves that may be used to address these limitations.

MP175 Applying Adverse Outcome Pathways (AOPs) to Derivation aquatic PNECs for Two Typical Phenolic EDCs

Y. Wang, J. Wang, National Marine Environmental Monitoring Center/ China

More recently, adverse outcome pathways (AOPs) has been proposed as a novel concept that effectively take the consideration of toxic mode of action (MoA) and aid to guide ecological risk assessment (ERA) of chemicals. Assessing ecological risk of endocrine disrupting compounds (EDCs) is increasingly important due to its ubiquity in aquatic environment and endocrine effects on organisms. In the present study, from the point view of AOP, we derived aquatic predicted no-effect-concentrations (PNECs) of two typical phenolic EDCs, i.e. bisphenol A (BPA) and 4-nonylphenol (NP). Laboratory chronic toxicity data for BPA and NP on aquatic organisms were collected and grouped by whether they are associated with AOP, based on which endpoints include not only reproductive effects but also biochemical, genetic effects. By log-normal statistical extrapolation method, we calculated aquatic PNECs of BPA with values of 0.6 and 7.04 ?g/L, and NP with values of 0.22 and 3.9 ?g/L for AOP-related and non-AOP-related endpoints, respectively. The present results showed that classification of toxicity data can provide lower AOP-related PNECs and keep aquatic organisms from adverse effect such as endocrine disrupting effect more appropriately. The ecological risk assessment framework raised in this study can also be applicable for other types of EDCs with different molecular initiating events such as binding with androgen receptor and thyroid hormone receptor.

MP176 Aquatic fungal secondary metabolites contamination of water

N.M. Magwaza, UNISA / Nanotechnology and sustainability Research Unit; E.N. Nxumalo, UNISA / Nanotechnology and water sustainability Research Unit; B. Mamba, UNISA / Nanotechnology and water sustainability; K. Ntushelo, UNISA / Agricultural and Environmental Sciences; T. Msagati, Univ of South Africa / Nanotechnology and water sustainability

Fungi are ubiquitous microorganisms and they can be found in food, environment, water etc., and they are classified as heterotrophic organisms since they cannot make their own food. Some waterborne fungi produce antibiotics or compounds that can be used as soil improver but some produce toxic secondary metabolites (mycotoxins) and may therefore pose a hazard to both animals and humans. The presence of harmful fungi in drinking water may result in changes in water taste and odour among other negative effects. In this work, water samples were collected from Roodeplaat Dam in Gauteng province and they were transferred on potato dextrose agar (PDA) growth media supplemented with streptomycin sulphate for inhibition of bacterial growth. DNA was extracted directly from fungal mycelium followed by polymerase chain reaction and detected using the primer pair ITS1F (forward) and ITS4 (reverse). The smears obtained from 1% agarose gel showed the presence of fungal DNA in samples collected from Roodeplaat Dam. Both beneficial and toxic fungal species were found to be present in the sample as identified after Sanger sequencing. Two bands were obtained from the gel and they corresponded to Talaromyces flavus and Penicillium ochrochloron. In addition, extracellular metabolites produced by these fungal species were extracted using solid phase extraction (SPE) method from Dam water and identified using high resolution liquid chromatography quadrupole time of flight mass spectrometry (LC-QTOF-MS) and NMR for further confirmation of the metabolites.

MP177 Derivation of BLM-based Ambient Water Quality Criteria for Lead Following USEPA Guidelines: A Comparison with European Approaches

D.K. DeForest, Windward Environmental LLC; K. Brix, EcoTox / Zoology; P. Van Sprang, ARCHE; R.C. Santore, Windward Environmental, LLC; M.J. Chowdhury, International Lead Association / Manager Environment

The U.S. Environmental Protection Agency's (USEPA's) current ambient water quality criteria (AWQC) for lead (Pb) in freshwater were developed in 1984. The criteria are adjusted for hardness, but more recent studies have demonstrated that other parameters, especially dissolved organic carbon (DOC) and pH, have a much stronger influence on Pb bioavailability. These recent studies have been used to support development of a biotic ligand model (BLM) for Pb in freshwater, such that acute and chronic Pb toxicity can be predicted over a wide range of water chemistry conditions. Following USEPA guidelines for AWQC development, and using a methodology consistent with that used by the USEPA in developing its recommended BLM-based criteria for copper in 2007, we propose acute and chronic BLM-based AWQC for Pb in freshwater. In addition to the application of the BLM approach that shows ability to better account for site-specific Pb bioavailability, the toxicity datasets presented here are also much more robust than in 1984 and there are now sufficient chronic Pb toxicity data available that use of an acute-chronic ratio (ACR) is no longer necessary. Over a range of North American surface waters with representative water chemistry conditions, proposed acute BLM-based Pb criteria ranged from approximately 20 to 1000 µg/L and chronic BLM-based Pb criteria ranged from approximately 0.3 to 40 µg/L. Differences exist between US and European approaches used for driving AWQC or aquatic safe thresholds of metals. The key differences include the use of genus means, EC20s, and exclusion of algae and plants from the sensitivity distribution in the US versus the use of species means, NOEC/EC10s, and inclusion of algae and plants in the sensitivity distribution in the EU. Additionally, the approach to distribution fitting is also different. In order to understand the implication of methodological differences, a set of ecological threshold concentrations of Pb derived for selected European freshwater scenarios will be compared with the proposed chronic Pb AWQC.

MP178 Development of Site-Specific Water Quality Criteria: A Detailed Look at Water-Effect Ratio (WER) Testing and Application

J. Nusz, Exponent, Inc.

Water quality standards (WQSs) more generally applied (i.e. national, tribal or state-mandated) for the protection of aquatic biota may be overprotective or underprotective, depending on the specific conditions present at a given site. Site-specific water quality criteria (SSWQC) may be more appropriate when, for example, species native to the site are very different than species used to derive the more general WQSs, naturally occurring pollutant concentrations in a stream segment exceed the national criteria for aquatic life uses, or when site-specific water characteristics may affect the toxicity of contaminants. USEPA Regulation 40 CFR 131 allows states and tribes to develop site-specific water quality criteria (SSWQC) and generally grants approval if the criteria are supportive of the designated water uses and are based on supported scientific rationale. This is often reflected in a permit (e.g. NPDES) or developed for specific bodies of water. Additionally, SSWQCs can be developed for approval by local governments as a part of the Environmental Impact Assessment (EIA) process necessary for the international permitting of many types of facilities. There are several scientifically justified approaches for development of SSWQC development for which EPA provides guidance (e.g. recalculation procedure, water-effect ratio (WER) procedure and resident species procedure). Deciding which approach to take depends on the characteristics of the site in question as well as the types of data available. Each of these approaches and circumstances under which they may be efficiently applied will be presented. Furthermore, a hypothetical example application of the WER procedure for deriving a SSWQC for a tailings pond discharge permit, under international context, will be provided.

MP179 Development of Water Quality Guidelines for Copper Using the Biotic Ligand Model

S. Dixit, Environment and Climate Change Canada / Environment and Climate Change Canada; R.C. Santore, Windward Environmental, LLC

The bioavailability and aquatic toxicity of metals can be influenced by physical and chemical characteristics of the water such as hardness, pH and dissolved organic carbon. The National Guidelines and Standards Office (NGSO) of Environment and Climate Change Canada has developed a number of water quality guidelines (WQGs) for the protection of aquatic life for metals and is evaluating the latest tools and approaches for considering toxicity modifying factors (TMFs) in guidelines derivation. Single-variable regression analyses were considered in the past to account for individual TMF (e.g., hardness), followed by the incorporation of multiple TMFs (e.g., hardness, pH, DOC) using multiple linear regression (MLR). The NGSO is now considering the biotic ligand model (BLM) approach for developing long-term water quality guidelines for copper. The BLM allows consideration of a diverse set of water quality parameters which are known to impact copper toxicity, including pH, DOC, calcium, magnesium, sodium, carbonates, etc. The approach taken to develop a BLM-based water quality guideline for copper involved compilation and evaluation of chronic toxicity data following the CCME guidance (2007), evaluation of model performance with the chronic toxicity dataset, and utilization of the BLM to normalize the chronic toxicity dataset to site-specific chemistry conditions to construct species sensitivity distributions (SSD).

MP180 Frameworks for Addressing Aquatic Life Effects from Time-Variable Toxicant Exposures

C.G. Delos, Great Lakes Environmental Center / Mail Code

USEPA's existing procedures for deriving aquatic life criteria, last revised in 1985, offer little rigor for addressing the time variability of exposure, and lack reproducible procedures for deriving either the averaging period or the target frequency of attainment, two of the three components of a criterion. In the context of aquatic life criteria development, this work describes approaches that can offer a unified perspective on the affected percentage of species, individuals, and time. It discusses differences between simple approaches relying only on a statistical distribution of concentrations, and complex approaches that, in time-variable applications, can (a) normalize the effects on life stages having different sensitivity and duration, (b) normalize for chronic lethal versus sublethal effects, and (c) account for innate differences among species abilities to replace individuals lost to toxicity (that is, differences in recovery time). This work describes practical approaches that can be applied to national, state, and site-specific criteria.

MP181 How do organisms regulate accumulation of toxics, pharmaceuticals, and nutrients?

W. Beckon, US Fish and Wildlife Services / Division of Environmental Contaminants

All kinds of organisms exert a simple form of non-homeostatic regulation over their internal concentrations of a wide variety of substances: essential elements, toxic metals and other contaminants, and even novel pharmaceuticals. At higher exposure concentrations, organisms incorporate proportionately less of the chemical to which they are exposed. This regulation occurs regardless of whether the exposure is dietary or more direct environmental exposure. Thus, in general, bioconcentration "factors", bioaccumulation "factors", and trophic transfer "factors" are not constants, but steadily decline with increasing exposure. Evidence collected so far suggests that this phenomenon is usually due to a decline in the uptake rate "constant" and/or, usually to a lesser extent, an increase in the depuration rate "constant" with increasing exposure. Therefore, contrary to common expectations, first order kinetics are not generally adequate to describe the processes of uptake and depuration. The physiological bases for this widespread form of regulation remain to be clarified.

MP182 Refinement and Validation of Target Lipid Model-Derived HC5 to Conform to REACH Guidelines

J. McGrath, HDR inc.; C. Fanelli, Mutch Associates LLC; D.M. Di Toro, Univ of Delaware / Civil and Environmental Engineering; T. Parkerton, ExxonMobil Biomedical Sciences Inc. / Toxicology & Environmental Science; A.D. Redman, Exxon Mobil Biomedical Sciences / Toxicology and Environment Science Division; M. Leon Paumen, ExxonMobil Biomedical Sciences / ExxonMobil Biomedical Sciences TES Division; K. den Haan, CONCAWE / Petroleum Products Safety

The Target Lipid Model (TLM) has been extensively validated for predicting the toxicity of narcotic chemicals, such as petroleum hydrocarbons, and the USEPA has adopted the TLM framework for deriving water and sediment guidelines for chemicals that demonstrate a narcotic mode of action. The TLM was extended to derive HC5 values, concentrations below which only 5 percent of species should be adversely affected. The European Chemical Agency identified several shortcomings where the derivation of the TLM-derived HC5 did not conform to the requirements under the REACH regulation. These shortcomings included insufficient species representation in the acute and chronic toxicity databases, the use of chronic endpoints that were not appropriate for use in risk assessment, databases of critical target lipid body burdens (CTLBB) and acute to chronic ratios (ACRs) were not log normally distributed and the omission of a co-variance term in the HC5 equation. These shortcomings were addressed by expanding the acute and chronic databases to include the required taxonomic groups and increase the overall number of observations and revising the HC5 equation as appropriate. The resulting CTLBB and ACR databases conformed to the requirements under REACH for use in risk assessment. The revised HC5 values are scientifically valid and were demonstrated to be protective of chronic effects from exposure to petroleum hydrocarbons.

MP183 The Effects of Sensitivity Bias in Species Sensitivity Distributions and Possible Effects on Water Quality Guidelines

K.E. Croteau, D.K. DeForest, R.C. Santore, Windward Environmental, LLC

Since the mid-1970s, thousands of studies have evaluated the toxicity of various chemicals to aquatic organisms. Results from many of these studies have been used to develop species sensitivity distributions (SSDs) for deriving water quality guidelines. Recently, there has been more emphasis on evaluating the toxicity of sensitive organisms rather than the entire range of sensitivities. The SSD is intended to inform the derivation of criteria for the protection of all species, not just those that were included in the SSD. The over-emphasis of the more sensitive end of the SSD can contribute to a skew in the observed distribution such that the shape of the distribution is distorted from what it would be if all species could be tested, which ultimately affects the derived criterion value. The way in which the SSD is analyzed could potentially mitigate the effects of the sensitivity bias, but to what extent? Although most parties use a specific percentile of the SSD (e.g., 5^{th} percentile) as a regulatory benchmark, there is not a global consensus on what method should be used to derive that benchmark. The type of statistical distribution that is assumed and how much of the dataset (i.e., full or truncated) is used for defining the 5^{th} percentile of the distribution are two ways in which the United States and European Union differ in their approaches. How much do these choices of distribution and truncation impact the 5^{th} percentile, with and without an over-emphasis on the sensitive end of the SSD? This presentation will attempt to answer these questions through numerical examples and statistical resampling of data. We will discuss how an emphasis on more- or less- sensitive organisms in the SSD would affect the 5^{th} percentile estimate's conservatism, and how the method of deriving the 5^{th} percentile influences the outcome.

MP184 Use of SeqAPASS for the Identification of Susceptible Taxa to Inform Derivation of Aquatic Life Criteria

C. LaLone, USEPA / Mid Continent Ecology Division; D.L. Villeneuve, G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory

The 1985 U.S. Environmental Protection Agency (EPA) Guidelines for Deriving Aquatic Life Criteria (ALC) require acute and chronic toxicity testing with a fixed list of taxa that cover aquatic organisms from vertebrates, invertebrates, and plants. In considering Guideline revisions, there is interest in employing new and readily available technologies to inform chemical-specific selection of test species based on scientific evidence for susceptibility as a means to eliminate unnecessary animal testing, reduce cost, and gain the most applicable data for decision making. Further, when toxicity testing is completed on selected organisms, advances in methods for species extrapolation could be implemented to gain a greater understanding of how representative the data are of other species from the same taxonomic group. A publically available computational application for informing such considerations is the U.S EPA's Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS; https://seqapass.epa.gov/seqapass/) tool. SeqAPASS facilitates cross species comparisons of chemical molecular targets based on evaluation of protein similarity. The underlying assumption is that if a chemical is known to act on a specific protein to initiate toxicity in one species, conservation of that protein in another species provides a line of evidence that the second species could also be susceptible to a given chemical. Depending on the degree of characterization of the selected protein and existing knowledge about the chemical-protein interaction, SeqAPASS derives susceptibility predictions by evaluating similarity from alignments of primary amino acid sequences, functional domains (e.g., ligand-binding domain), and individual amino acid residue(s) important for maintaining protein structure or for direct interaction with the chemical. Such data can be used to identify species that are likely (or unlikely) susceptible to a given chemical, therefore aiding in selection of appropriate test species. Additionally the data would be useful in understanding how broadly toxicity test data derived from one species may be extrapolated to others. In short, evaluation of cross species protein and structural conservation using SeqAPASS provides a rapid and cost effective method for deriving a line of evidence for chemical-specific testing strategies that may be useful in the revised ALC Guidelines. The contents of this abstract neither constitute nor reflect official USEPA policy.

MP185 Variability and Uncertainty in Use of Mean Effect Concentrations for Aquatic Life Criteria Derivation

T.K. Linton, Great Lakes Environmental Center / River Falls WI Office; C.G. Delos, Great Lakes Environmental Center / Mail Code; K. Taulbee, Great Lakes Environmental Center / Research Scientist; C. Voros, G.J. Smith, Great Lakes Environmental Center

The acquisition of acceptable toxicity test data from the open literature to fulfill taxonomic diversity requirements representing a minimum eight families (the MDR) is a critical element in aquatic life criteria (ALC) derivation. In EPA's criteria derivation procedure, the geometric mean of all acceptable test level data for a species is the Species Mean Value (SMV), and the geometric mean of all acceptable species level values is the Genus Mean Value (GMV). The genus level values are arranged in a sensitivity distribution (SD), and the final acute or chronic value (FAV, FCV) is the 5th centile concentration of that SD. To date there has been no formal analysis of the reliability of mean toxicity values for representing sensitivity of species at any taxonomic level. It is not uncommon for a single acute or chronic effect concentration from a single toxicity test with a species to serve as the basis for the SMVs or GMVs. To better understand the variability and uncertainties in the use of mean toxicity values for ALC development, we examined several chemical-specific acute criterion datasets to determine the variability in the underlying values used to calculate Species Mean Acute Values (SMAVs) and Genus Mean Acute Values (GMAVs). The analysis focused on variability of LC50s, variability of SMAVs within a genus, and variability of GMAVs within a family. Our recommendation based on preliminary findings is that the variability of LC50s within a species suggests that an SMAV based on a single LC50 is too uncertain to use for criteria derivation, and that it is advisable to use a surrogate species whose SMAV is based on three or more LC50s, provided an SMAV for more than one species within the genus is available. The applicability and ramifications of our recommendation to re-calculation of the acute criterion will be presented, as well as findings from a similar exercise to better understand the variability and uncertainties in the use of mean toxicity values for chronic criterion development.

Environmental Chemistry

MP186 Supercritical CO2 Extraction and GC-MS Analysis of Fatty Acids Composition of the Oil from Leaves, Seeds and Husks of Moringa oleifera

E. Obi, Texas Southern Univ Dept of Environmental Science and Technology / Environmental Interdisciplinary Sciences

There has been a significant role played by plants in maintaining human health, and improving the overall quality of human lives for decades. Humans have used plants as traditional remedies to alleviate illnesses and promote the overall quality of lives due to the belief that plants have natural substances in them capable of promoting human health. Moringa oleifera has been shown through prior research to be a medicinal plant with a difference. It is a multipurpose tree used as spice, for cooking, as cosmetics oil and more importantly as medicinal plant. Moringa oleifera plant cultivated in Nigeria were characterized for the presence of biologically active phytochemicals and fatty acid contents using supercritical CO_2 extraction technique to extract the plant parts and GC/MS for structure elucidation of the compounds found. The extracts of the plant were characterized for the presence of fatty acids like oleic acid, linoleic acid, linolenic acid, hexadecanoic, hydrocarbons etc. The crude oils were derivatized by transesterification process to convert them to their corresponding fatty acid methyl esters (FAMEs) by methylation method using 1% boron trifluoride in methanol. FAMEs were analyzed using gas chromatography equipped with mass spectrometry (GC-MS) and eleven fatty acids were found in all samples. The dominant saturated fatty acid found in all samples was palmitic acid ranging from 7.8% of the total fatty acids in seeds to 22.4% in leaves. The leaves contain the chemical group of most interest; Linolenic acid (18:3n-3) which is the omega-3 polyunsaturated fatty acids at 37%. The major monounsaturated fatty acid in the seeds and husks were Oleic acid (18:1n-9), an omega 9 fatty acid at 79% and 77% respectively. All samples contained the following saturated fatty acids; palmitic (C16:0), palmitoleic (C16:1n-9), stearic (C18:0), arachidic (C20:0), and behenic (C22:0) acids. Several other fatty acids were detected in all samples at trace amounts. The presence of these bioactive and therapeutically potent compounds make Moringa oleifera a therapeutically potent plant in which further study of the plant may lead to development of novel agents used to treat various disorders.

MP187 Modulation of the physiological and biochemical effects of copper nanoparticles in kidney beans (Phaseolus vulgaris) treated with kinetin

S. Apodaca, Univ of Texas-El Paso / Chemistry; A. Lazarski, J.R. Peralta-Videa, The Univ of Texas at El Paso / Dept of Chemistry; J.P. Flores-Margez, Universidad Autónoma de Ciudad Juárez / Instituto de Ciencias Biomédicas; J.A. Hernandez-Viezcas, J. Gardea-Torresdey, The Univ of Texas at El Paso / Dept of Chemistry

The environmental fate and effects of nanoparticles (NPs) are not well understood, despite their increased usage throughout modern technology. Long term studies on plants exposed to NPs under realistic environmental conditions is lacking. Within agriculture, copper (Cu) NPs have been indicated as a potential solution towards fungal and bacterial remediation. Plant hormones are also sought as a bio-based alternative to improve crop quality and yield. Kidney beans (Phaseolus vulgaris) are an important food crop that is widely produced and consumed worldwide. In this study, kidney bean plants were grown in potting soil treated with copper nanoparticles (nCu), bulk copper (bCu) and copper chloride ($CuCl_2$) at concentrations of 50 and 100 mg/kg^{-1} for 45 and 90 days. At 15 days of growth, 10 and 100 µm of kinetin (KN) was applied to plants. Plant tissue samples were harvested during the juvenile stage, and seeds were collected at the time of maturity. Physiological and biochemical parameters were investigated. Enzyme activities and chlorophyll content were evaluated through ultraviolet-visible spectroscopy (UV/vis) as plant stress indicators. Cu uptake and translocation were determined via inductively couple plasma-optical emission spectroscopy (ICP-OES). Seed micro and macronutrients were also quantified. There was a decrease in selenium for the 10 µm KN+100 ppm $CuCl_2$ treatment and all 100 µm KN treatments, under detectable limits with current methodology, as well as a 19 to 22 percent reduction in zinc for nCu treatments at both KN concentrations. Protein content was found to be higher in bCu treatments (27.92 and 28.23%) and lowest in the 100 µm KN+100 ppm $CuCl_2$ treatment (20.35%). For future work, KN content in soil and plant tissues will be studied. While results demonstrate thus far that the combination of nCu and KN is not significantly toxic to kidney bean plants, bCu and $CuCl_2$treatments have shown negative impacts.

MP188 Accumulation of metals in the lichen Flavoparmelia caperata

D. Brown, Marietta College / Biology and Environmental Science; J. Ste Marie, Marietta College

This study assessed the accumulation rate of metals in transplanted lichens (Flavoparmelia caperata) in relation to distance and direction from a ferro-manganese alloy factory in the Ohio River Valley. F. caperata collected at a control location was rinsed and placed in plastic mesh packets and exposed at various locations. Exposures lasted from one to 6 months, and it was found that by 5 months the transplanted lichens were reaching steady state, with regards to metal concentrations. By 5 months the metal levels in transplanted lichens were also approximately the same as lichens obtained from the transplant locations. Distance from the manganese source was strongly correlated with accumulation, with the closest transplant site having the highest concentrations of Mn (288.18 µg/g). Lichen samples were acid digested, and metal concentrations (Cr, Cu, Fe, Mn, and Ni) were determined using atomic absorption spectroscopy. Exposures were also conducted each month for a complete calendar year to look at seasonal variations in accumulation. The purpose of this part of the study was to compare accumulation of metals in lichens transplanted one kilometer to the north, south, east and west of the point source and relate those levels to wind direction and precipitation during the exposure period. Weather data for the area was obtained from a NOAA weather station located just outside of the Ohio River Valley. Based on prevailing winds from the southwest, we expected the highest metal concentrations to be observed to the north and east of the ferro-manganese alloy factory. However, for more than half of the months the highest metal levels were found at the western transplant site. We are currently working to understand how local weather conditions in the river valley may have impacted transport and deposition, to better understand why the observed results did not match what was expected.

MP189 The Effect of Cations on the Extractability of Organic Chemicals Adsorbed to Soil

D. Riggs, S. Chea, M. Metea, Smithers Viscient; K. Malekani, Smithers Viscient / Environmental Fate and Metabolism; S. Kang, Smithers Viscient

Sorption is an important factor in determining the potential impact of chemicals in the environment. There are many factors that affect the adsorption of chemicals to soil including, but not limited to; size, shape, molecular structure, polarity, solubility, configuration, polarizability and charge distribution of a chemical. Furthermore, soil has many characteristics that affect adsorption including cation exchange capacity (CEC), pH, clay content, particle size, ionic strength, as well as others.

Although hydrophobic partitioning has been recognized to have a large role in sorption mechanisms, other processes such as cation exchange and surface complexation with cations also have a role in sorption to soil. Exchangeable cations commonly found in the environment (Na^+, Ca^{2+}, Mg^{2+}, K^+) influence the adsorption of organic chemicals to soil. The current study utilizes different cations found in the environment to extract organic chemicals that are adsorbed to soil for analysis. This technique uses the cation exchange capabilities of the soil to remove the organic molecule by substituting the cation on the soil for the cation that is in the extraction solvent. Different cations were tested with various oxidation states including K^+, Na^+, NH_4^+, Mg^{2+}, Fe^{2+}, and Al^{3+}. Seven organic chemicals were tested using this extraction technique. Tests were conducted in four different soils with varying characteristics. The analysis showed that extractability increased for extraction solvents containing monovalent cations (K^+, NH_4^+, and Na^+) which demonstrate that cation exchange can be used as a viable technique to extract adsorbed organic chemicals from soil. The increase in extractability will allow for a more accurate evaluation of potential bioavailability and fate of organic chemicals in the environment.

MP190 Availability of arsenic and antimony in contaminated soils assessed by DGT, sequential extraction, and bioassay with water spinach (Ipomoea aquatica)

L.K. Ngo, Univ of Wollongong / Chemistry; W.W. Bennett, P.R. Teasdale, Griffith Univ / Griffith School of Environment; D.F. Jolley, Univ of Wollongong / School of Chemistry

The enrichment of soil arsenic (As) and antimony (Sb) is posing a potential threat to the environment and human health. However, the biogeochemical behavior and plant uptake of the emerging element (Sb) is poorly known and generally assumed to be similar to that of As. In this study, the lability of As and Sb under agricultural conditions in long-term contaminated soils was assessed. Three series of test soils were prepared by mixing a historically As and Sb-contaminated soil with three uncontaminated soils with varying properties. These were mixed at different ratios to produce concentration gradients. The labile As and Sb in these soils were measured by diffusive gradients in thin films (DGT, C_{DGT}), soil solution analysis (C_{sol}), and sequential extractions (SEP), which were compared with the bioaccumulation of As and Sb in different compartments of the water spinach (Ipomoea aquatica) grown in these test soils in pot experiments. Regardless of measurement techniques, the results showed that both As and Sb were less labile and strongly associated with soil solid phases, and that As was consistently more labile than Sb although total As concentrations in soils were lower than total soil Sb (e.g. 1400 mg As/kg and 2300 mg Sb/kg, respectively). The SEP showed that in historically contaminated soils, the As associated with amorphous and crystalline Fe oxides were the dominant phases, while Sb was primarily found in the residual phase. The DGT measurements revealed that the resupply of As from solid phases to soil porewater varied with soil properties, whereas the resupply of Sb was consistently very low in all soil types. The bioassay demonstrated differences in metalloid uptake mechanisms. Irrespective of soil types, more As was accumulated in roots than Sb, however As translocation from roots to shoots was lower than Sb. Correlation analysis showed that the As and Sb in plant tissues were significantly correlated with their bioavailable concentrations obtained from DGT, soil solution, and SEP, in which DGT was a better predictor for As in tissues than other measures (greater correlation coefficients). Arsenic in plant roots were more highly correlated with bioavailable As in soils than shoot uptake, the opposite was true for Sb. This study provided a greater understanding of the behavior of As and Sb and the sensitive technique for predicting bioavailable As and Sb in long-term contaminated soils to I. aquatica.

MP191 Comparison of the biogeochemical behavior of arsenic and antimony in contaminated soils and their uptake by water spinach (Ipomoea aquatica)

L.K. Ngo, Univ of Wollongong / Chemistry; W.W. Bennett, P.R. Teasdale, Griffith Univ / Griffith School of Environment; D.F. Jolley, Univ of Wollongong / School of Chemistry

The increasing input of As and Sb into the environment is putting pressure on human and environmental health. Currently there is very little known about the biogeochemical behavior of Sb and its uptake mechanisms by plants, and it is generally assumed to be the same as that of As. This insufficient data may lead to mis-interpretation of Sb behavior. In addition, their competitive effects on their uptake by plants has been poorly studied. In this study, diffusive gradients in thin films (DGT) and a sequential extraction procedure (SEP) were used to investigate the partitioning and availability of As and Sb in three series of soils amended with As only, Sb only, and mixture of As and Sb. These soils were prepared in a concentration gradient. The bioavailable As and Sb measured by DGT and SEP were compared with the bioaccumulation of As and Sb in water spinach (Ipomoea aquatica) grown in these soils in pot experiments. The results showed that the association of Sb with various soil binding sites was different from that of As and that the movement of Sb from more available to less available forms was quicker than that of As. This was illustrated by the fact that Sb was dominant in both amorphous and crystalline Fe oxides, while As was predominantly found in amorphous Fe oxide and specifically sorbed fractions. The DGT revealed that As was partially resupplied from solid phases to soil porewater, while the resupply of Sb was very low. The bioassays demonstrated the differences in As and Sb uptake mechanisms. The bioaccumulation of Sb in the plant tissues was much less than that of As due to the lower bioavailable Sb in soils. Both As and Sb were mainly accumulated in I. aquatica roots. Saturation of As uptake by I. aquatica and growth inhibition of plants grown in As treatments were observed, but these were not observed for Sb. The bioaccumulation of Sb in I. aquatica grown in soils amended with both As and Sb was much higher than that in soils amended with Sb only. As and Sb in plant tissues were highly correlated with the bioavailable As and Sb in soils measured by DGT and SEP, in which Sb uptake was better predicted. This study provided a better understanding about the behavior of As and Sb in contaminated soils and was the first to evaluate the competitive effects of As and Sb on their uptake by edible plant. These techniques are useful measures in predicting bioavailable As and Sb in recently contaminated soils to I. aquatica.

MP192 Effect of chemical speciation on the bioaccessibility of soils contaminated and spiked with heavy metals

E. Elikem, Univ of Saskatchewan / Soil Science; D. Peak, Univ of Saskatchewan

Heavy metal contamination continues to be a major environmental problem and current exposure guidelines set by risk assessors are based on total metal concentration. The total concentration of a potentially toxic metal in soil, while indicative of the extent of contamination, tells little about the bioaccessibility of the metal. Rather, several studies have suggested that the bioaccessibility of a metal is dependent on its chemical form, which in turn is affected by soil properties and processes. To evaluate the effect of chemical speciation on bioaccessibility, five soil types were spiked with a metal mixture comprised of copper (Cu), lead (Pb), nickel (Ni), cobalt (Co) and zinc (Zn) using three methods: metal oxides, metal nitrates plus leaching and roasted metals. Total metal concentration in each soil was determined using inductively coupled-mass spectroscopy (ICP-MS). Speciation of metals was determined using X-ray Diffraction (XRD) and X-ray Absorption Near Edge Structure (XANES) techniques. The former was used to determine metal-mineral phases, while the latter was used to determine the oxidation states of the metals. Oral bioaccessibility is being determined using the Simulator of the Human Intestinal Microbial Ecosystem (SHIME). It is expected that outer-sphere complexed metal species would be more bioaccessible than inner-sphere complexed, surface precipitated and solid phase metal species.

MP193 Spatial Contaminant Trends in a Great Lakes Area of Concern

J. LaFontaine, Great Lakes Inst for Environmental Research, Univ of Windsor / GLIER; K.G. Drouillard, A. Grgicak-Mannion, Univ of Windsor / Great Lakes Inst for Environmental Research

Sediment Samples from the Huron-Erie Corridor (HEC) (St. Clair River, Lake St. Clair and Detroit River) were collected using a stratified-random approach in a 2013-2014 survey to evaluate sediment chemistry. The results are compared and contrasted with a similar study conducted in 2004. The sediment chemistry analyses consisted of grain size, TOC, total mercury, trace metals, PCBs, PAHs and OCs. At the corridor scale there were distinct differences noted in the distribution of organic and metal contaminants. Temporal comparisons yielded distinct changes with respect to certain trace metals ($p < 0.001$) while others were shown to display no change with time. A Geographic Information System (GIS) was used to map and assess hazard index information while the Getis-Ord GI* geospatial statistic tool was used to characterize regional zones of high and low contamination for selected contaminants.

MP194 Ambient Sediment Quality Conditions in Minnesota

J.L. Crane, Minnesota Pollution Control Agency / Environmental Analysis Outcomes Division

Minnesota is known for its bountiful water resources, ranging from the pristine Boundary Waters Canoe Area Wilderness in northeastern Minnesota to urban waterways affected by human development. The first broad assessment of ambient sediment quality conditions has been conducted across the state. Sediment chemistry and particle size data were evaluated to provide a snapshot of the statistical range of analytes and to determine if these concentations were influenced by major watershed land uses in 54 randomly selected lakes. Data on surficial sediments included: metals and metalloids, parent and alkylated PAHs, PCB congeners, legacy organochlorine pesticides, TCDD/F congeners, PBDEs, total organic carbon, and particle size fractions. A suite of contaminants were compared to their corresponding Level I and Level II sediment quality targets (SQTs) for the protection of benthic organisms. Multivariate statistical methods were used to tease out relationships in complex data sets, and environmental forensic methods were used to identify major sources of PAHs. In addition, ambient background threshold values of contaminants were calculated for the 95% upper tolerance limit with 95% coverage. Mean probable effect concentration quotients (PEC-Qs) were calculated to distill data from a mixture of contaminants into one unitless index. Nearly 43% of lake samples had mean PEC-Qs below the Level I SQT, while the other 57% of lakes were between the Level I and II SQT values. No lakes exceeded the Level II SQT for mean PEC-Qs, for which harmful effects on benthic invertebrates would be more likely to occur. Urban lakes were more contaminated than lakes from other watershed land uses. In particular, historical uses of sodium arsenite in one urban lake contributed to arsenic concentrations that exceeded the Level II SQT value. Some metals (e.g., copper, nickel) were naturally enriched in northeastern Minnesota due to geological deposits of minerals containing these metals. Total PAH concentrations were < 1 mg/kg dry wt. in lakes outside of urban areas, and coal-related combustion and vehicle emissions were major sources. DDT metabolites were commonly detected, especially p,p'-DDE, as were PCDD/F congeners and homolog groups. Most PCDD/F toxic equivalents were between the Level I and II SQT values. BDE 209 was detected in 84% of samples. These results will be used to help prioritize agency activities related to ambient sediment quality, and for future status and trends work.

MP195 Comparative study of brine treatment using a functionalized nanofibre and an ion exchange resin

E. Omoniyi, Cape Peninsula Univ of Technology Cape Town South Africa / Chemistry; N. Van der Walt, Cape Peninsula Univ of Technology Cape Town South Africa / Analytical Chemistry; L.F. Petrik, Univ of the Western Cape South Africa / Chemistry Environmental and Nano Science Group

In this study, comparative sorption studies of the major metal ions (Mg^{2+}, Ca^{2+}, K^+ and Na^+) in the brine wastewater were performed on hydrophilic materials (PAN nanofibre, PAN+TiO_2 nanofibre, PAN+ZEOLITE nanofibre) and Purolite S950 resin to investigate their uptake performances. For this purpose, PAN nanofibre was electrospun and subsequently doped with 3 wt% each of titanium dioxide and zeolite respectively, in controlled experimental conditions in order to improve its performance. This was followed by the characterization of the respective hydrophilic materials (PAN, PAN+TiO_2 and PAN+ZEOLITE nanofibres) using Fourier transform Infrared Spectroscopy (FT-IR); Scanning electron microscopy (SEM) and X-ray diffraction (XRD). SEM showed that the incorporation of titanium dioxide or zeolite into the PAN structure made the surface rougher than that of the ordinary PAN nanofibre and FT-IR revealed the peaks belonging to titanium dioxide and zeolite respectively, showing the inorganic materials are within the PAN structure. The XRD analysis complemented the FT-IR of the nanofibres by revealing the peaks characteristic of titanium dioxide and zeolite are present on the PAN structure. Batch sorption experiments were carried out to investigate the sorption properties of PAN, PAN+TiO_2 and PAN+ZEOLITE nanofibres for the cations from brine wastewater. Comparative batch studies using PAN, PAN+TiO_2 and PAN+ZEOLITE nanofibres were carried out using Purolite S950 resin as the standard. Parameters which include contact time, effect of temperature, pH, sorbent dose, sorption isotherms were studied in the sorption experiments to understand the sorption phenomena, loading capacity of the sorbents (nanofibres and resin) and the sorption kinetics for the cations from the simulated brine solutions. The results revealed that the Purolite S950 resin was effective in the removal of the divalent metal ions (Mg^{2+} and Ca^{2+}) over the other metal ions, thereby depicting good selectivity towards Mg^{2+} and Ca^{2+} ions. The removal by the Purolite S950 resin followed the order: $Mg^{2+} > Ca^{2+} > K^+ > Na^+$. The binding capacity to the divalent metal ions is influenced by the aminophosphonic acid functional group attached to the resin. The sorption capacities for the metal ions were indicating that the monolayer adsorption occurred on all the sorbents. The order of efficiency and performance of the sorbents can be given as: Purolite S950 resin > PAN+ZEOLITE > PAN+TiO_2 > PAN.

MP196 Determination of Sulfur – Containing Anions in Saline Waters using Negative-Mode Capillary Zone Electrophoresis with Indirect Detection

A. Saeed, Memorial Univ of Newfoundland / Chemistry

Sulfides and sulfur oxyanions (i.e., thiosalts) are found in the environment and in a number of industrial processes. Sulfur oxyanions can impact environmental quality, and can have negative economic consequences. They can be reduced to the toxic and corrosive hydrogen sulfide in anaerobic environments. Whereas oxidative process on sulfide and sulfur oxyanions can lead to acidification of the environment and mobilization of toxic metals. These sulfur compounds can ultimately lead to higher operational costs whether of treatment or refit of damaged equipment. It is important to quantify the major charged sulfur species, such as sulfate SO_4^{2-}, thiosulfate $S_2O_3^{2-}$, tetrathionate $S_4O_6^{2-}$, sulfite SO_3^{2-}, and sulfide S^{2-}, to understand the chemistry and behaviour of sulfur-oxygen species as contaminants in process infrastructure. However, analysis of charged sulfur species in highly saline water is challenging. The accurate quantitation requires baseline separation and absences co-migration, which is particularly hard to achieve it due to the large peaks associated with sulfate and chloride in saline waters. A capillary zone electrophoresis (CZE) method has been developed for the simultaneous quantification of charged sulfur species in highly saline water. The components of the background electrolyte (buffers, flow modifiers, chromophoric probes, etc.) are the most important factors the development of this method. For example, pyromellitic acid (PMA) is chosen as chromophoric probe because it is non-oxidizing, has high molar absorptivity, and is a good mobility match for thiosalts, which reduces dispersion. Indirect detection using a chromophoric probe is needed because some of sulfur oxyanion species have little or no absorbance in the UV. This CZE method has been developed for negative mode, i.e. the anions migrate toward the detector, and the electroosmotic flow (EOF) is away from the detector. By adding hexamethonium hydroxide (HMOH) as an EOF modifier to influence the chemistry of the capillary surface, shorter time of analysis and better peak resolution were achieved. Other factors that were taken into consideration include: the capillary length, separation temperature, potential applied, and used of a stabilizing agent to limit spontaneous oxidation of some of sulfur-containing compounds. Fast analysis with high separation efficiency and improvement in detection sensitivity were achieved with this method. Optimization efforts and results will be presented.

MP197 Formation of Trihalomethanes (THMs) as Disinfection by-Products (DBPs) when Reclaimed Water is Disinfected with Hypochlorite

H. Kassouf, Unversity of South Florida; J.A. Cunningham, Univ of South Florida; L. Mulford, G. Iranipour, Hillsborough County / Analysis and Water Quality

Disinfection is an essential process in the treatment of municipal wastewater before the treated wastewater can be discharged to the environment. Hillsborough County's Northwest Regional Water Reclamation Facility (NWRWRF) in Tampa, Florida, currently uses ultraviolet (UV) light for disinfection. However, this method has proven expensive to implement and maintain, and may not be effective if the light transmission is poor. For these reasons, Hillsborough County is considering switching from UV light to sodium hypochlorite for disinfection. However, hypochlorite (chlorine) disinfection has its disadvantages as well, such as the production of disinfection by-products (DBPs) like trihalomethanes (THM) and haloacetic acids (HAAs), which may have adverse impacts on the quality of surface waters that receive the treated wastewater. Therefore, the objectives of this research are (1) to determine the chlorine demand of wastewater at NWRWRF, (2) to determine the effects of pH, temperature, and water quality on chlorine demand, (3) to quantify the DBP formation potential under different operating conditions, and (4) to determine whether NWRWRF should switch from UV light to hypochlorite for disinfection of wastewater. To inform laboratory experiments, the quality of final effluent was monitored at two nearby wastewater treatment plants that currently use hypochlorite for disinfection. At these two facilities, we observed pH of 7.0–8.0, chemical oxygen demand (COD) of 15–33 mg/L, alkalinity of 200–250 mg/L as $CaCO_3$, chlorine residual of 1.5–6.0 mg/L, and total trihalomethanes of 100–190 mg/L (mostly chloroform). Upcoming laboratory experiments will test for trihalomethane formation over incremental time periods at three different chlorine doses and three different temperatures (representing different seasonal temperatures in Tampa); results of these experiments will be reported in this presentation. Based on the experimental results, the optimal chlorine dose to disinfect the wastewater without exceeding Florida state environmental regulatory limits for THM concentrations will be determined.

MP199 An ultra-sensitive (parts-per-quadrillion) and SPE-free method for the analysis of estrogens in surface water

W. Backe, Minnesota Dept of Health / Public Health Laboratory

Steroidal estrogens often occur in surface water at low concentrations (< 0.5 ng/L) and those low levels, depending on the estrogens present, can cause endocrine disruption in aquatic wildlife. Currently, many analytical methods are not able to detect estrogens at those low concentrations and those that can often require the extraction of several liters of water. To that end, an analytical method is presented that is sensitive to the parts-per-quadrillion (pg/L) for estrogens in surface water without the need for large sample volumes. The estrogens included for study were estrone, 17β-estradiol, estriol, 17α-ethinylestradiol, and equilin. The method consisted of the small-scale liquid-liquid extraction of surface water (7.5 mL) followed by derivation with dansyl chloride. Analyte separation and detection were performed by high-performance liquid-chromatography and tandem mass-spectrometry. A large volume (100 uL) of the sample was injected on-column to increase the analyte mass sent to the detector. The detection limits of the method were 0.045 ng/L for estrone, 0.086 ng/L for 17β-estradiol, 0.030 ng/L for estriol, 0.049 ng/L for 17α-ethinylestradiol, and 0.13 ng/L for equilin. The whole-method accuracy ranged from 93 ± 5.8 % to 105 ± 4.5 % for all the analytes at two different spike levels. Similarly, the precision of the method was less than 8.0 % relative standard deviation. The final method was used to analyze a series of samples from the Mississippi River spanning 51 river miles. Estrone was detected in all of the samples and 17β-estradiol was detected in one. Concentrations of estrone ranged from between the detection and quantification limits up to 0.63 ng/L. Increases in the concentration of estrogens were observed downstream from potential inputs including wastewater and drinking water treatment plants. This work sugests that drinking water treatment plants can also act as sources of micro-pollutatnts. Additional data and/or applications of this method will be presented as they become avalable.

MP200 Modeling Singlet Oxygen Production by Dissolved Organic Matter

J. Laszakovits, Ohio State Univ / Civil Environmental and Geodetic Engineering; Y. Chin, The Ohio State Univ / School of Earth Sciences; A. MacKay, The Ohio State Univ / Civil Environmental and Geodetic Engineering; C. Sharpless, Univ of Mary Washington / Dept of Chemistry

Photodegradation can be an important fate of aquatic contaminants. One route is direct photolysis, where the contaminant absorbs light and subsequently degrades. Many contaminants, though, do not absorb at solar wavelengths. In these cases indirect photolysis may occur via reaction with species generated by a photosensitizer. Among the natural photosensitizers, dissolved organic matter (DOM) is the most ubiquitous, and it produces a number of reactive oxygen species including hydroxyl radical, superoxide, and singlet oxygen ($^1O_2$). $^1O_2$ is of interest because it reacts with several important classes of compounds including phenolates, furans, indoles, and imidazoles. $^1O_2$ will exist in a steady-state as it is formed by DOM and simultaneously relaxes via quenching by water. Because of this, reaction of $^1O_2$ with contaminants follows pseudo first-order kinetics, and the rates can be modeled if the steady-state concentration is known. To predict $^1O_2$ steady-state concentrations several parameters must be known, including the spectral distribution and intensity of sunlight, the absorption spectrum of DOM in the water of interest, and the $^1O_2$ quantum yield (Φ_{1O2}) as well as its wavelength dependence. While the light intensity and DOM absorption are relatively easy to measure, it is challenging and time consuming to measure the Φ_{1O2} wavelength dependence, and it is impractical to measure regularly, as water quality and DOM reactivity change seasonally and spatially. Here, we explore the merits of a simplified modeling approach based on previous work[1-4] showing a correlation between Φ_{1O2} at 365nm and DOM E2/E3 ratios, the ratio of absorption at 254nm and 365nm. Using several DOM samples, we will use Φ_{1O2} predicted from E2/E3 ratios to calculate $^1O_2$ concentrations for comparison with experimental values during irradiation with a broadband solar simulator. A variety of calculation approaches are being explored to define the level of spectral detail required to adapt single wavelength quantum yields for modeling $^1O_2$ concentrations with broadband solar irradiation. Critical comparisons of traditional full-spectrum modeling with simplified calculation approaches will then be presented. References 1. Dalrymple et al. Environ. Sci. Technol. 2010, 44, 5824-9 2. MP201 An analytical method for the determination of emerging contaminants in water samples from Brazilian rivers

T. Oliveira, Univ of Sao Paulo – USP / Quimica e Fisica Molecular; L.R. Diniz, São Paulo State Univ- Inst of Chemistry / Química Analitica; B. Padovan, Instituto de Quimíca de São Carlos / Departamento de Quimica e Fisica Molecular; E.M. Vieira, Univ of São Paulo / Departamento de Quimica e Fisica Molecular

The contamination of the aquatic environment by emerging pollutants such as pharmaceuticals, personal care products and endocrine disruptors has been the focus of recent research due to their potential hazard to human health and the environment. These compounds can enter the environment by direct or indirect routes. They accumulate in soil, sediments and river water, and can be transported over long distances from their sources. Suitable analytical methods are therefore needed to investigate the occurrence and transport of these pollutants in the environment. The purpose of this research was to create an analytical method for the extraction and detection of emerging contaminants in river water samples. Chromatography analysis was carried out using an LC – DAD. The results were satisfactory with a flow rate of 0.8 mL min^{-1}, temperature of 25 °C and a mobile phase of acetonitrile : water with 0.1% of acetic acid. For isolation of the target compounds from the matrix solid phase extraction was applied. The optimization of the extraction procedure was evaluated. With the proposed method it is possible to quantify acetaminophen, methyl paraben, 17β-estradiol, naproxen and diclofenac at concentrations of 10 μg L^{-1} and 20 μg L^{-1} for 17β-estradiol. The method developed will be applied to water samples from the Mogi Guaçu River in the state of São Paulo, Brazil.

MP202 Temporal Changes in Detection Limits of Pesticides in Surface Water

T. McKnight-Whitford, Stantec Consulting Ltd. / Environmental Management; L. Knopper, T. Dan, Stantec / Environmental Services

Stantec Consulting Ltd. (Stantec) investigated possible temporal changes in environmental detection limits (i.e., method detection limits (MDL), limits of quantification (LOQ) and reporting detection limits (RDL)) for pesticides and how, if any, these changes need to be communicated in the context of toxicological risk assessment. The study focused on three conceptual questions: 1) How are pesticides detected in environmental monitoring programs and how have pesticide detection limits changed over time? 2) What effect does the detection limit have on the frequency of detection? 3) How do the changes in detection limits affect the interpretation of risk in terms of exposure of ecological receptors (e.g., fish, invertebrates, aquatic plants) to pesticides? The study included a multiple lines of evidence approach that considered data from an accredited analytical laboratory in Canada; data reported in published peer-reviewed scientific literature; and 25 years of data obtained from a comprehensive surface water monitoring program in California that involved multiple laboratories and agencies. As expected, the records from the analytical laboratory indicated that changes in detection techniques or improvements in existing techniques have resulted in a decrease in detection limits over time. Regardless of the ability to detect pesticides at lower concentrations, results from the scientific literature and from the surface water monitoring program suggest there is no discernable downward trend in pesticide detection limits in surface water between 1990 and 2015. In fact, the literature indicates that there has been an increase in the reported detection limits for some pesticides. This trend is likely related to use of novel techniques that focus on cost and portability, rather than low detection limits. Analysis of the monitoring program data indicates that the detection limit can have a substantial effect on the frequency of detection and confirmed that the lower the detection limit the higher the frequency of detection. However, a higher frequency of detection does not necessarily translate into increased risk for aquatic receptors. Measured concentrations, not simply presence or absence, need to be compared to environmental quality guidelines to make inferences about potential risks to receptors.

MP204 Improved Sample Preparation for the Determination of Persistent Organic Pollutants in Human Milk

W. Guo, DTSC-ECL; A. Holden, California EPA; J. Park, M. Petreas, California Environmental Protection Agency / Dept of Toxic Substances Control Environmental Chemistry Laboratory; F.R. Brown, Environmental Chemistry Laboratory / California Dept of Toxic Substances Control

Although they were banned in 1970s and 2004, respectively, polychlorinated biphenyls (PCBs); organochlorine pesticides (OCPs), and polybrominated diphenyl ethers (PBDEs) are still ubiquitous in the environment and pose adverse health effects in humans and wildlife. Therefore, it was necessary to improve our outdated analytical method for complex matrices like breastmilk that was time consuming, labor intensive and required large volume of solvent usage. We have developed an improved sample preparation method that combines liquid-liquid extraction and automated solid phase clean-up procedures using only 1 mL of milk sample for the analysis of PBDEs, PCBs and OCPs by high resolution GC/MS. This new method improves throughput (minimum of 40 samples per batch run); significantly reduces the solvent amount from 400 mL to 25 mL; shortens the sample preparation time from 5 days to 3 days; has good precision (≤ 10% coefficient of variation for most of the compounds measured) and accuracy (± 20% recoveries for most of the compounds measured in in-house and SRM1954 samples); and reduces background contamination while providing a lower method detection limit. This method has been validated using fortified in-house quality control samples, a standard reference material (SRM1954), as well as fifteen breast milk samples from an epidemiological study with high, medium, and low levels of PBDEs, PCBs, OCPs measured previously using the traditional method. Levels of PBDEs, PCBs and OCPs from the two methods showed acceptable consistencies. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

MP205 Levels of Blood Organophosphorus Flame Retardants and Association with Changes in Human Sphingolipid Homeostasis

F. Zhao, Peking Univ

While a recent toxicological study has shown that organophosphorus flame retardants (OPFRs) may disrupt sphingolipid homeostasis, which plays an essential role in key physiological and pathological processes, epidemiologic evidence is currently lacking. In this study, a total of 257 participants were recruited from Shenzhen, China. Eleven OPFRs were for the first time simultaneously determined in the human blood samples by ultraperformance liquid chromatography tandem mass spectrometry. Six OPFRs, tributyl phosphate (TBP), 2-ethylhexyl diphenyl phosphate (EHDPP), tris(2-chloroisopropyl) phosphate (TCPP), tris(2-butoxyethyl) phosphate (TBEP), triethyl phosphate (TEP), and TPhP were detectable in at least 90% of participants, with the median concentrations of 37.8, 1.22, 0.71, 0.54, 0.49, and 0.43 ng/mL, respectively. Sphingomyelin (SM) levels in the highest quartile of EHDPP, TPhP, TBP, TBEP, TEP and TCPP were 45.3% [95% confidence interval (CI): 38.1%, 53.0%; $p < 0.001$]; 51.9% (95% CI: 45.5%, 58.6%; $p < 0.001$); 153.6% (95% CI: 145.1%, 162.3%; $p < 0.001$); 20.6% (95% CI: 14.5%, 27.0%; $p < 0.001$); 59.0% (95% CI: 52.1%, 66.2%; $p < 0.001$) and 62.8% (95% CI: 55.2%, 70.6%; $p < 0.001$) higher than those in the lowest quartile, respectively, after adjusting for covariates. Sphingosine-1-phosphate (S1P) levels in the highest quartile of EHDPP, TPhP and TBP were 36% (95% CI: -39%, -33%; $p < 0.001$), 16% (95% CI: -19%, -14%; $p < 0.001$) and 36% lower (95% CI: -38%, -33%; $p < 0.001$) than those in the lowest quartile, respectively. A similar pattern emerged when exposures were modeled continuously. We for the first time found the evidence that OPFRs might affect sphingolipid homeostasis in humans.

MP206 Concentrations of Brominated Dibenzo-Dioxins and Furans in Dust from Residences and the Living Quarters of Firehouses

F.R. Brown, J. Dhaliwal, D.H. Tarrant, R. Sarala, M. Petreas, J. Park, Environmental Chemistry Laboratory / California Dept of Toxic Substances Control

Large reservoirs of polybrominated diphenyl ethers (PBDEs) still exist in the United States, even after their production and use have been discontinued. One such reservoir of PBDEs is dust from residential and occupational settings. Previous studies in our group (2010, 2010-2011) have shown high levels of PBDEs in dust from homes and from the living quarters of firehouses in California, collected from vacuum cleaner bags. These studies showed higher concentrations of PBDEs in the firehouse dust than residential dust. Thermal and photodegradation of PBDEs can form polybrominated dibenzo-dioxins and furans (PBDD/Fs) which exhibit similar toxicity to their chlorinated analogs. Thus, exposure to dust that is high in PBDEs may also result in exposure to potentially significant dioxin toxicity. Our group has expanded on these studies of residential and firehouse dust to include PBDDs/Fs. However, dust can be a difficult matrix to work with. Despite their similar structures and toxicity, the cleanup method that we use for chlorinated dioxins and furans does not work for PBDDs/Fs. Therefore, we applied a modified version of the chlorinated dioxin/furan cleanup method to the cleanup of dust samples for PBDDs/Fs. In this modified method, dust samples were extracted using pressurized fluid extraction. Cleanup was accomplished by eluting the concentrated extract through a mixed mode silica gel column, followed by elution through a mixed-mode carbon column in two separate steps, rather than in one combined step as is done with the unmodified method. Samples were analyzed using high resolution GC/MS. For PBDDs in both residential and firehouse dust samples, no 2,3,7,8-susbtituted PBDDs were detected, and of the non-2,3,7,8-substituted PBDDs, only HpBDD was measured at 16.8 and 24.5pg/g, respectively. For 2,3,7,8-substituted PBDFs in residential dust, only 1,2,3,4,7,8,9-HpBDF was detected at high concentration (424 pg/g). For firehouse dust, 2,4,6,8-TeBDF, 1,2,4,4,7,8-HxBDF, and 1,2,3,4,7,8,9-HpBDF were detected at 714 pg/g, 259 pg/g, and 6,100 pg/g, respectively. For total PBDFs in residential dust, only HpBDF was measured at high concentration (514 pg/g). For total PBDFs in firehouse dust, we measured TeBDF (1050 pg/g), PeBDF (213 pg/g), HxBDF (584 pg/g, and HpBDF (10,800 pg/g). The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

MP207 Simplifying Multivariate Statistical Tools: Case Study of Dioxin/Furan Congener Profiles at a Former Wood Processing Site in Puget Sound, WA

W. Hafner, J. Nuwer, T. Hammermeister, NewFields; P. Striplin, Washington State Dept of Ecology

Environmental data sets are complex and highly variable. Multivariate statistical models have long been used to help reduce this variability. However, the outputs of these models are often complex in their own right, requiring discussions about statistics that only further confound, rather than inform, public and regulatory audiences. When applied correctly, data visualization techniques, including simple X/Y graphs and Geographical Inromation Systems (GIS), can be used to display the model results in ways that are both descriptive and intuitive. NewFields has applied a variety of multivariate statistical methods to better explain patterns in data from contaminated sediment sites across the country. A particular focus has been characterizing dioxin/furan congener profiles at wood processing sites in Puget Sound. One of these sites in Budd Inlet (Olympia), WA, will be used as a case study for combining multivariate statistics and visualization techniques to explain patterns in contamination. Several hundred dixon/furan samples have been collected from Budd Inlet over the last decade. Multivariate statistical modeling revealed that three different end-members (unique dioxin/furan congener profiles) contributed nearly 98 percent of the total variance in congener profiles across the Inlet. The three end-members correlated strongly with hog fuel boiler emissions, pentachlorophenol, and polychlorinated biphenyls (PCBs). Nearly all samples represented a mixture of these end-members, making interpretation of the model more difficult. To reduce noise, only samples dominated by one of the end-members were mapped, revealing distinct spatial patterns for each of the three potential sources. These patterns were linked to potential upland pathways, providing a comprehensive link between upland and sediment contamination.

MP208 Estimating detection levels for multi-analyte methods: beyond the EPA MDL procedure

W.T. Foreman, T. Williams, J. Decess, C. Reed-Parker, M.W. Sandstrom, USGS / National Water Quality Laboratory

The U.S. Environmental Protection Agency's method detection limit (USEPA MDL) procedure often is mandated when USEPA methods are used or for studies conducted for federal, state, or local regulatory agencies. The MDL procedure has several well documented limitations, and procedural revisions have been proposed that address some limitations (Federal Register, v. 80, no. 33, p. 9074). One limitation is the requirement that a cumbersome iterative spiking approach be used to ensure that the analyte concentration in spiked test samples is within 1-5 times the determined MDL, as spiking level influences the calculated MDL. This approach is impractical, in part, because it is difficult and expensive to create a solution of analytes, each at the appropriate concentration, for methods with many analytes having differing instrument-response characteristics. Instead, the USGS National Water Quality Laboratory (NWQL) has implemented aspects of ASTM International's within-lab critical level (WCL) estimate procedure (D7782-13) and associated Excel®-based DQCALC® calculator for estimating detection levels (DLs). The WCL procedure uses a multi-concentration (calibration-like) spiking approach well suited for analytes having very different instrumental response, and models the change in standard deviation with spike concentration. It estimates both the MDL and Currie's critical level (Lc), which in theory should closely approximate the MDL value. The NWQL has applied the WCL procedure to inorganic (e.g., nutrients, trace metals) and organic methods (e.g., a direct aqueous injection LC/MS/MS method for 227 pesticides in filtered water having no sample preparation steps and a solid-phase extraction GC/MS method for 83 pesticides with prep steps) to demonstrate the operational advantage of using the multi-concentration spiking procedure. For MS methods, DLs estimated by either procedure using the quantification ion (concentration) were substantially lower than the "true" DL for some analytes because qualification ion responses were too low to confirm analyte presence at the DL. For blank-limited analytes, DLs also were calculated using lab blank data that provide a more accurate, direct estimate compared to those from spike-based procedures, which can be artificially low. Advantages and limitations of the WCL procedure are presented. Any use of trade, product, or firm names is for descriptive purposes only and does not imply endorsement by the US Government.

21st Century Approaches for Cross-Species Extrapolation in Toxicity Assessment

MP209 Characterizing molecular toxicity pathways of selected emerging contaminants to elucidate species-specific sensitivity of three North American fishes

A. Alcaraz, Univ of Saskatchewan – Toxicology Centre / Toxicology Centre; B.K. Eisner, Univ of Saskatchewan / Toxicology Dept; D.R. Schultz, Univ of Saskatchewan / Toxicology; S. Tang, Univ of Saskatchewan; S. Wiseman, Univ of Lethbridge / Biology; P.D. Jones, Univ of Saskatchewan / School of Environment and Sustainability; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

Emerging chemical contaminants (ECC) are ubiquitous in the environment, and have become of increasing toxicological concern to humans and wildlife. ECCs include pharmaceuticals and personal care products, brominated flame retardants, and nanomaterials, among others, which are commonly discharged into surface waters through municipal wastewater and other sources as a result of human activities. However, little is known about the toxicological significance of most ECCs in the aquatic environment. Particularly, little is known about the effects of ECCs to fishes that are of commercial, cultural, and recreational relevance (CRA species) to North America and that are at risk of exposure with ECCs. Therefore, this study aims to investigate the responses and the underlying mechanisms of the exposure to ECCs of three CRA species including lake trout (Salvelinus namaycush), white sturgeon (Acipenser transmontanus), and rainbow trout (Oncorhynchus mykiss). Specifically, the objectives of this study are to (1) characterize critical molecular toxicity initiating events (MIEs) associated with each ECC; (2) assess the conservation of gene expression signatures across fish species; and (3) construct ECC-induced molecular toxicity pathways, and anchor these to apical outcomes. Fishes at early life stages will be exposed to three representative ECCs, namely nanosilver (AgNP), 17α-ethinylestradiol (EE2), or fluoxetine (Prozac). Whole transcriptomic and proteomic coupled with receptor-binding, cellular and biochemical assays will be used to characterize critical toxicity pathways. Finally, mechanistic information from molecular toxicity pathways will be linked with apical responses across higher tier biological organizations. Linking results from open omics analyses with effects at higher levels of biological organization aims to identify and establish relevant biomarkers for environmental risk assessment.

MP210 Determination of Acute and Sub-Chronic Toxicity of Emerging Contaminants in Early Life Stages of Three Canadian Fish Species

D.R. Schultz, Univ of Saskatchewan / Toxicology; S. Tang, Univ of Saskatchewan; J. Alcaraz, Univ of Saskatchewan / Toxicology; B.K. Eisner, Univ of Saskatchewan / Toxicology Dept; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; S. Wiseman, Univ of Lethbridge / Biology; P.D. Jones, Univ of Saskatchewan / School of Environment and Sustainability; D.M. Janz, Univ of Saskatchewan / Toxicology Centre; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

In recent years, emerging contaminants have gained notoriety due to their ubiquity in the aquatic environment as well as the lack of data available regarding their toxicity to wildlife and humans. Emerging chemicals (ECs) of concern such as hexabromocyclododecane (HBCD), silver nanoparticles (AgNPs), short-chain chlorinated paraffins (SCCP), 17α-ethynylestradiol (EE2) and Prozac™ (FLX) primarily enter the aquatic environment as mixtures through municipal wastewater effluent (MWWE). MWWE, which is typically a mixture of industrial, commercial, and household wastes, may be released into receiving waters with little to no treatment, which is not uncommon, especially in rural Canadian municipalities. Most data to date has been garnered using standard laboratory species, which may not be particularly relevant to Northern species considering the potential role of life history, trophic level, physiology, and climate on the species-specific toxicity of chemicals. Consequently, inaccurate extrapolation from standard laboratory species to species native to northern ecosystems is a cause for concern and represents a significant uncertainty factor in ecological risk assessment. In this study, Oncorhynchus mykiss, Salvelinus namaycush, and Esox lucius gametes were exposed to six waterborne concentrations of EE2, FLX, MWWE, and AgNPs, where the lowest doses were selected based on environmental relevance and increased incrementally thereafter. Exposures were continuous flow-through and subsamples were collected at critical developmental stages to assess acute and sub-chronic toxicity of all test chemicals. Initial findings suggest that these three species vary significantly in their sensitivities towards the aforementioned ECs. Ongoing work aims to fully elucidate biochemical and histological anomalies associated with exposures to the six ECs and focuses on characterizing the effects of these ECs on native fish species in comparison to one another as well as standard laboratory fish models. Overall, this work will aid in the development of more appropriate environmental risk assessment strategies for native fishes to EC of concern.

MP211 Lower sensitivity of cyprinid fishes to three acetylcholinesterase inhibitor pesticides: an evaluation based on no effect concentrations

Y. Iwasaki, Toyo Univ / Research Center for Life and Environmental Sciences; M. Jusup, Hokkaido Univ; K. Shibata, Yokohama national Univ; T. Nagai, National Inst for Agro-Environmental Sciences; S. Kashiwada, Toyo Univ / Research Center for Life and Environmental Sciences

Cyprinid fishes are often hypothesized to be less sensitive to chemical stress than other comparable fish species, yet a decisive empirically based evaluation of this hypothesis seems to be lacking from the literature. To fill this gap, we developed a generalized linear mixed model in which no effect concentrations (NEC) of 29 fish species from 14 families exposed to one of three acetylcholinesterase inhibitor pesticides (carbaryl, chlorpyriphos, and malathion) were used as a response variable, whereas (i) the corresponding specific somatic maintenance (SSM) rates and (ii) a categorical variable if a species is Cyprinidae were used as the predictor variables. We included SSM rates in the analysis because a previous study had demonstrated that the SSM rates negatively correlate with the NECs. Our results indicated that the NECs for cyprinid fishes were significantly higher than those for other fishes, suggesting that cyprinids are less sensitive to the three studied pesticides. The SSM rates were negatively related with the NECs, but the actual relationship between the two was not clear, implying that the importance of SSM rates may depend on a taxonomic group tested.

MP212 Comparative behavioral response patterns of two common larval fish models

B. Steele, Baylor Univ / Biomedical Studies; L.A. Kristofco, Baylor Univ / Dept of Environmental Science; J. Corrales, Baylor Univ / Environmental Science; M. Mills, Univ of Washington; E.S. Williams, Baylor Univ; J. Kostal, George Washington Univ; A. Voutchkova-Kostal, George Washington Univ / Chemistry; P. Anastas, Yale Univ / Center for Green Chemistry and Green Engineering; T. Kavanagh, E. Gallagher, Univ of Washington; B.W. Brooks, Baylor Univ / Environmental Health Science Program Dept of Environmental Science

Behavioral responses inform toxicology studies by rapidly and sensitively reflecting molecular initiation events that propagate to physiological changes in individuals. These behavioral response patterns can be linked to a chemical mechanism/mode of action (MOA). For example, behavioral “fingerprints” have been proposed following pharmacological screening studies with zebrafish, which are common models in behavior, developmental, neurotoxicology and other biomedical studies. Whereas the fathead minnow is a common model for aquatic toxicology research and regulatory programs, they have received comparatively little attention in behavioral studies. We employed the zebrafish and fathead minnow models to define toxicant induced swimming activity alterations during interchanging photoperiods. We specifically compared behavioral response patterns among 14 chemicals, each classified according to its anticipated MOA following QSARs developed to predict toxicity to aquatic organisms. The classes consisted of non-polar narcosis (class I), polar narcosis (class II), electrophile/proelectrophile activity (class III), and specifically acting (class IV). Following OECD FET and EPA WET experimental guidelines, zebrafish embryos and fathead minnow larvae were exposed for 96 h to each compound, then observed using a digital behavioral analysis system (ViewPoint). Behavioral observations occurred for 50 minutes (10 minutes acclimation, two 10 minute dark periods, two 10 minute light periods). Zebrafish displayed greater behavioral sensitivities for Bisphenol-A, citalopram, cumenhydroperoxide, dinoseb, hydroquinone, pentylenetetrazole, phenol and perfluorooctanoic acid, whereas the fathead minnow was more sensitive to 1-heptanol, diazinon, indene, r-carvone, tert-butyl hydroperoxide, and xylazine. Additionally, each species displayed different responses to altering light and dark photoperiods. Zebrafish responded to light photoperiods by significantly decreasing swimming activity, whereas fathead minnow displayed an opposite response. Furthermore, each of the compounds produced larval swimming patterns that appear unique to their respective classification. Behavioral studies such as these are ongoing to further characterize fish behavior patterns to diverse industrial chemicals for which behavioral responses and specific molecular initiation events are poorly defined in fish.

MP213 Use of White Sturgeon Data in Development of EPA's National 304(a) Chronic Selenium Criterion for the Protection of Freshwater Aquatic Life

J.R. Beaman, G. Russo, K. Gallagher, USEPA / Office of Water

The U.S. Environmental Protection Agency (EPA) recently updated its chronic aquatic life criterion for selenium to reflect the latest science based on fish reproductive toxicity data, including key data for the white sturgeon (Acipenser transmontanus). A white sturgeon maternal transfer study (Linville, 2006) was evaluated by EPA and incorporated into the aquatic life criterion analysis. Survival and observations of abnormalities (edema, skeletal deformities) from the oldest stage (45) were quantitatively used to derive the EC10 used in the effects analysis for the criterion because these endpoints showed the most significant effect. The resulting EC10 demonstrates that white sturgeon are among the most sensitive freshwater fish species to selenium, based on available data. The white sturgeon is a commercially and recreationally important fish species in the Pacific Northwest, serves as a surrogate for other sturgeon species in the United States, and has a population listed as endangered in the Kootenai River in Idaho and Montana. EPA's 2016 freshwater criterion for selenium is composed of four elements: two fish tissue elements, and two water elements. All four elements are based on reproductive effects in freshwater fish as the assessment endpoint. The EPA derived the water-column values from the egg-ovary value by assessing food chain bioaccumulation at representative field sites across the continental United States.

MP214 The Allometric Relationship Between Acute Toxicity and Individual Body Weight for Fishes Based on Biotic Ligand Toxicity Model :A Case Study as Zinc

C. Lu, Beijing Normal Univ / Beijing Normal Univ Academy of Disaster Reduction and Emergency Managent; Y. Meng, Beijing Normal Univ / Academy of Disaster Reduction and Emergency Management

Prediction of lethal effect on organism of interest that lacks of test data is critical for risk assessment of chemicals on aquatic ecosystems. The author considered body weight of organism plays an important role in counteracting toxic stress imposed by certain chemical. The zinc acute toxicity data for adult or sub-adult fishes were selected form the ECOTOX database. In light of the knowledge that test circumstances such as Ca^{2+}, hardness may throw remarkable influence on the observed toxicity. The author checked and retrieved all details for every record. The acute toxicity data such as 96-hr LC_{50} (18 data) and x-hr LC_{50} (46 data) values of fishes were correlated to corresponding body weights respectively. It showed us that the 96-hr LC_{50} and x-hr LC_{50} both have a significant correlation with body weight (R^2=0.19, 0.38; p-value=0.08, 6.1×10^{-6}). In order to explain the relationship between the acute toxicity and body weight, the author built A Biotic Ligand Toxicity Model (BLTM) based on A Biotic Ligand Model (BLM) which taking competing metal ions such as Ca^{2+} into account. The BLTM with only 4 parameters of no-effect concentration (NEC), killing rate (K_+), maximum elimination rate (K_{gamax}) , and elimination arrearage constant (Beta) were employed to model the Zn 96-hr and x-hr LC_{50} of fishes. Presumably the NEC, Beta, K_+ or K_{gamax} was each modeled to be independent of the body weight by a linear relationship. For the presumed size-dependency, optimization was performed, and finally the "best" model was selected out of the total combinations of size-dependency using the Akaike Information Criterion (AIC). The selected best model indicated that the K_+ and K_{gamax} has a good correlation with body weight whereas the NEC, Beta did not. It shows that NEC=0, Beta=196.0 (1/h), K_+=0.040*log(W) (hl/mg), K_{gamax}=23.4*log(W) (1/h), in which W denotes fish body weight (wet weight, mg). Based on the best model, the exposure time and the weight of fishes were applied to predict the fraction of survival according to BLTM. The predicting survival fractions are in the vicinity of 0.5 for both 18 and 46 data. The author considered the optimized size-dependence of the acute ecotoxicity data across fishes will be helpful for ecotoxicity data prediction and ecological risk assessment. The further research will pay more attention to the nonlinear relationship between the parameters and body weight.

MP215 Comparing toxin-induced cardiac defects in Atlantic sturgeon with those in zebrafish: A novel mechanism of AhR function in PCB-exposed fish

C. Singleman, CUNY Graduate Center / Biology; C. Chambers, National Oceanic and Atmospheric Administration; N. Holtzman, CUNY Graduate Center and Queens College / Biology

Polychlorinated biphenyls (PCBs) and 2, 3, 7, 8-Tetrachlorodibenzodioxin (TCDD) are significant environmental hazards in waterways and soils across the world. These toxins cause a variety of developmental defects in exposed organisms, including severe cardiac defects in fish. When TCDD and coplanar PCBs, including PCB 126, enter the cell they bind to the aryl hydrocarbon receptor, AhR, eventually instigating gene expression of cyp1A. Although cyp1A is expressed in cells with activated AhR, cyp1A does not appear responsible for cardiac or endothelial abnormalities in exposed animals, suggesting an alternate pathway as the cause of these defects. We are identifying the molecular basis of cardiac phenotypes in fish embryos by exploring other proteins activated by AhR. Activated AhR is known to up-regulate many cellular proteins, including tyrosine kinase Src. Activated Src is further known to phosphorylate vascular endothelial cadherin (VE-cadherin), an intercellular junction protein found in cardiovascular endothelial cells. VE-cadherin functions to bind neighboring cells and inappropriate phosphorylation results in the dissociation of intercellular dimers, separating the cells. We hypothesize that up-regulation of Src, by coplanar PCB- and TCDD-activated AhR, leads to VE-cadherin phosphorylation. Thus, PCB 126 and TCDD exposure likely leads to decreased ability of vascular cells to bind appropriately, resulting in organ-level deformities of the heart during important stages of development. Utilizing contaminants at varying concentrations, we examined the effects on heart development of early exposure in Atlantic sturgeon (Acipenser oxyrinchus oxyrinchus) and zebrafish (Danio rerio). Embryos of both species exposed to PCB 126 and TCDD show very similar cardiac looping defects in a dose-dependent manner. These data suggest highly conserved mechanisms of heart development and responses to toxin exposure. Our evaluation of the cellular mechanism of PCBs using zebrafish provides a roadmap for assessing these responses more broadly in other taxa and we expect parallels in Atlantic sturgeon.

MP216 High conservation in transcriptomic and proteomic response of white sturgeon to equipotent concentrations of 2,3,7,8-TCDD, PCB 77, and benzo[a]pyrene

J.A. Doering, Univ of Saskatchewan / Toxicology Centre; S. Tang, Univ of Saskatchewan; H. Peng, Univ of Saskatchewan / Toxicology Centre; B.K. Eisner, Univ of Saskatchewan / Toxicology Dept; J. Sun, Univ of Saskatchewan – Toxicology Centre / Toxicology Centre; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; S. Wiseman, Univ of Lethbridge / Biology; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

Adverse effects associated with exposure to dioxin-like compounds (DLCs) are mediated primarily through activation of the aryl hydrocarbon receptor (AHR). However, little is known about the cascades of events that link activation of the AHR to apical adverse effects. Therefore, this study used high-throughput, next-generation molecular tools to investigate similarities and differences in whole transcriptome and whole proteome responses to equipotent concentrations of three agonists of the AHR, 2,3,7,8-TCDD, PCB 77, and benzo[a]pyrene, in livers of a non-model fish, the white sturgeon (Acipenser transmontanus). A total of 926 and 658 unique transcripts were up- and down-regulated, respectively, by one or more of the three chemicals. Of the transcripts shared by responses to all three chemicals, 85% of up-regulated transcripts and 75% of down-regulated transcripts had the same magnitude of response. A total of 290 and 110 unique proteins were up- and down-regulated, respectively, by one or more of the three chemicals. Of the proteins shared by responses to all three chemicals, 70% of up-regulated proteins and 48% of down-regulated proteins had the same magnitude of response. Among treatments there was 68% similarity between the global transcriptome and global proteome. Pathway analysis revealed that perturbed physiological processes were indistinguishable between equipotent concentrations of the three chemicals. The results of this study contribute towards more completely describing adverse outcome pathways associated with activation of the AHR.

MP217 Functional Genomic Screening Using CRISPR-Cas9 Knockout System in Human Cells Identifies Genes Involved in Toxicant Susceptibility

A. Sobh, Univ of California, Berkeley / Nutritional Sciences and Toxicology; M. Tagmount, Univ of Florida / Center for Environmental and Human Toxicology; A. Loguinov, Univ of Florida Gainesville; L. Zhang, Univ of California Berkeley / Division of Environmental Health; M. Smith, Univ of California Berkeley / Division of Environmental Sciences; C. Vulpe, Univ of Florida, Gainesville / Physiological Science

Genome-wide functional screening is a powerful approach to study cellular responses to toxicants. The CRISPR-Cas9 genome-wide knockout system has emerged as a robust tool for loss-of-function (LoF) screening in mammalian cells. In functional toxicogenomics, this system can be used to identify genes whose functions can modulate the toxic effect of a compound. The absence of LoF genetic screening platforms in fish cells necessitates identification of toxicant susceptibility genes in mammalian cells and extrapolation of the findings to fish orthologs. We successfully performed loss-of-function screens in K562, a human erythroleukemic cell line, to identify cellular components affecting sensitivity to certain chemicals. We used a genome-wide CRISPR-Cas9 knockout library (GeCKOv2, library A) that utilizes 65,383 guide RNAs (gRNAs) targeting 19,050 human protein-coding genes and 1,864 miRNA genes. The library constructs were delivered to cells using lentiviral transduction to generate a heterogeneous population of mutant K562 cells with a single targeted gene per cell. The mutant cells were exposed to a sub-lethal dose of each toxicant in addition to the corresponding control conditions for ~ 2 weeks. At the end of the screen, the abundance of a specific mutant in each condition was determined by quantifying the corresponding guide sequence using next generation sequencing. We identified novel genes whose inactivation resulted in increased sensitivity/ resistance to each of the studied toxicants. To assess whether similar toxicity pathways are utilized across species, orthologs of genes identified in our screens can be individually knocked down in zebrafish followed by exposure studies using the same toxicants. Our work further demonstrates the strength of high throughput genetic screening using the CRISPR-Cas9 system in deciphering mechanisms of toxicity and could set a platform to study commonalities and differences in toxicity mechanisms across different species.

MP218 Coral Health Biomarker Studies using Cultured Corals and Field collected Larvae (Montipora capitata) exposed to pyrene, benzene, and gasoline

P. Caldwell, Florida A&M Univ; E. Casley, E. Johnson, Florida A&M Univ / School of the Environment; A.H. Ringwood, UNC-Charlotte / Dept of Biology; F. Kouzminov, Rutgers Univ; M. Gorbunov, Rutgers Univ / Inst of Marine and Coastal Sciences; D.A. Apeti, NOAA / National Centers for Coastal Ocean Science Center for Coastal Monitoring and Assessment; R. Warner, National Centers for Coastal Ocean Science NOAA

Coral reef health is a global concern and characterization of potential anthropogenic impacts requires sensitive indicators. Therefore, rapid and non-destructive methods to assess the health of corals and their symbiotic algae (zooxanthellae) are needed or management and conservation of coral ecosystems. This study evaluated the utility of Fluorescence Induction and Relaxation (FIRe) measurements in field and laboratory studies for monitoring and assessing coral health. Phase I of this study examined three coral species Acropora divaricata, Montipora capricornis and Caulastrea furcata exposed to 50 and 200 ppb Cu,10 and 100 ppb pyrene, or elevated temperature (24-28 C) for 72 hours. FIRe results were compared to measurements of lipid peroxidation and glutathione. Phase II of this study used Montipora capitata larvae bundles collected at the Hawaii Institute of Marine Biology and Pearl Harbor in Oahu, Hawaii. The larvae bundles were exposed to water-soluble fractions of benzene and gasoline for 10 hours. Following FIRe measurements, larvae were analyzed for lipid peroxidation (MDA), glutathione (GSH), glutathione s-transferase (GST), superoxide dismutase (SOD) and ethoxyresorufin o-deethylase (EROD). Biochemical markers detected stress only at the highest contaminant concentrations, while FIRe measurements appeared more sensitive at lower exposure levels. Such integrated assessments using complimentary techniques provide useful data to better understand responses of corals to multiple environmental stressors.

MP219 Phytoremediation potential of some plants growing wildly on polluted soil and water

K. Adegbenro, Univ of Lagos, Nigeria

The study investigates “the use of plants for the remediation of metal-polluted soil sediment, andwater. Four plant samples and two water samples were collected from a canal located at Mesan, Ogun State.The samples were stored in polythene bags and labelled appropriately. The soil samples were collected with the aid of soil auger and air-dried for about one week. The soil samples were sieved while plant samples were pulverized prior to analysis. The heavy metal concentration in the plant, water and soil were determined by the use of the Atomic Absorption Spectrophotometer. The results revealed that Heliotropiumindicum ($D_{L.P}$) accumulated more lead (35mg/g) than other land plants, Amaranthusspinosus ($B_{L.P}$)accumulatedhigh levels of copper (47.5mg/g) and lead (32.1mg/g), Cyperussp ($D_{W.P}$) accumulated high levels of copper (23.2mg/g) and lead (21.4mg/g), Cyclosorusstriatus ($C_{W\text{-}P}$) accumulated high levels of zinc (33mg/g) and Nymphaea Lotus ($A_{W\text{-}P}$) accumulated high levels of copper (20mg/g), chromium (11mg/g) and fairly moderate levels of zinc (12.1mg/g).From the results, it is seen thathyperaccumulating plants could be useful in phytoremediation of contaminated environment. The study concluded that plants that hyper accumulate metals have tremendous potential for application in remediation of metals in the environment.

Hydraulic Fracturing Operations and Issues

MP220 Do air pollutants associated with unconventional oil and gas extraction have endocrine activity?

A. Bolden, K. Schultz, C.F. Kwiatkowski, TEDX The Endocrine Disruption Exchange

In the last decade unconventional oil and gas (UOG) extraction has rapidly proliferated throughout the US and the world. This has occurred largely because of the development of directional drilling and hydraulic fracturing which allows access to fossil fuels from geologic formations that were previously not cost effective to pursue. Due to the locations of formations of interest, sites of UOG activity are increasingly in greater proximity to highly populated areas. This technology is known to use greater than 1000 chemicals such as solvents, surfactants, detergents, and biocides. Further this process also releases a complex mixture of chemicals from the formations including heavy metals, and naturally-occurring radioactive and organic compounds many of which are volatile. Chemicals detected in water near UOG operations have been shown to have endocrine activity. Further recent studies have shown compounds associated with UOG activity to be linked to adverse reproductive and developmental outcomes in humans and laboratory animal models. This study aims to 1) identify air pollutants detected near UOG activity and 2) evaluate the potential endocrine activity of the most frequently detected air pollutants. Using PubMed and Web of Science, studies that measured air pollutants associated with sites of UOG in the US were identified. Titles and abstracts were screened for relevance using pre-determined inclusion criteria. Relevant articles were then reviewed in full to generate a list of the most frequently detected compounds. The most frequent compounds were then assessed for potential endocrine activity by searching PubMed and Web of Science for primary studies that evaluated them for potential estrogenic, androgenic, and thyroidogenic activity. This report summarizes the data from studies measuring air pollutants near sites of UOG including variables such as distance from the UOG site(s), number of studies that detected the compound, and the average and range of concentrations detected from each study. It also describes the endocrine activity of air pollutants most frequently linked to UOG operations. The results of this study provide a basis for prioritizing future research on health impacts associated with UOG activity.

MP221 Ecological Risk Assessment of Coal Seam Gas Hydraulic Fracturing Fluids in Australia

T. Biksey, EHS Support LLC / Director Risk Assessment; C. Peterson, N. Goulding, EHS Support LLC; C. Bevan, CJB Consulting LLC

Coal seam gas (CSG) production in Queensland, Australia, requires a quantitative ecological risk assessment (QERA) as part of the requirements of the Environmental Authority and the Environmental Impact Statement. The QERA process is important in informing the risk manager of the necessary risk information to cost effectively comply with the requirements of the Environmental Authority. This methodology, incorporating best practice national or international standards and guidelines, includes the identification of the hazards of the constituents in the flowback water, compilation of the most appropriate toxicity criteria for each constituent, identification of potential receptors and completed (and significant) exposure pathways, quantification of exposure (expressed as a daily intake or exposure concentration), and calculations of individual constituent risk for potentially complete exposure pathways for each ecological receptor. The conceptual site model for the hydraulic fracturing flowback water identified both terrestrial (kangaroo, Dingo, beef cattle), and aquatic (invertebrates and fishes) ecological receptors that may be exposed to hydraulic fracturing fluids either stored within ponds in the operational areas, or inadvertently released to surface water ecosystems located near the well pads. The QERA estimated potential exposures based on theoretical (mass balance of fracturing chemicals used) and empirical (analytical sampling) concentrations in the flowback water. Biodegradation rates and varied flowback dilution events were used to provide a range of exposure scenarios. The selected assessment endpoints included survival and reproduction of beef cattle, kangaroo, Dingo, and aquatic invertebrates and fish. Because of the proprietary nature of the hydraulic fracturing chemicals, toxicity reference values (TRVs) were developed as predicted no-effects concentrations (PNECs) for aquatic receptors, and body weight scaling TRVs were developed for terrestrial receptors based on applicable effects levels. Limited risks to cattle and native mammals were identified, and only in the most conservative theoretical calculations. Potential impacts could occur if releases of flowback water occurred to limited flow aquatic environments.

MP222 Effect of Hydraulic Fracturing Fluid Components on Chironomus riparius Larvae as a Marker for Aquatic Toxicity of Freshwater

Z. Alali, Seton Hall Univ / Biology Dept; C.S. Bentivegna, Seton Hall Univ / Dept of Biological Sciences

One modern technology that concerns many environmental scientists these days is hydraulic fracturing. Hydraulic fracturing extracts oil and gas from deep underground and has expanded into areas of the United States where production was once considered impractical. Given the increase in hydraulic fracking, there is a risk that chemical components of fracturing fluids could enter fresh waterways and impact aquatic organisms. FracFocus disclosure data lists additives used in fracturing fluid of 39,000 individual oil and gas production wells in the U.S. Additives include sodium chloride as a breaker, friction reducer, scale inhibitor and clay control chemical, and tributyl tetradecyl phosphonium chloride (TTPC) as a biocide to minimize bacterial contamination of hydrocarbons and to reduce bacterial production of corrosive by-products in order to maintain wellbore integrity and prevent breakdown of gellants. Waste water produced from hydraulic fracturing can contain total dissolved solids and Cl exceeding 100,000 mg/L. According to HALLIBURTON company, the concentration of TTPC in fracturing fluid is 0.03% (300 mg/L). In this study, the acute toxicity of TTPC biocide and NaCl were tested using 4th instar Chironomus riparius Results showed that the 48 h LC50 of TTPC was 0.48 mg/L and the LC50 of NaCl was 9368 mg/L. As a part of verifying the mechanism of action of the components, ATP was measured from hemolymph samples of the larvae raised in various concentrations and collected at 6, 12, and 24 h. Results showed that increased levels of TTPC corresponded with decreased levels of ATP. The decrease in ATP levels might be due to loss of cellular and/or mitochondrial membrane integrity.

MP223 Environmental Quality Implications of Unconventional Natural Gas Development: Current Perspectives and Research Needs

B.W. Brooks, Baylor Univ / Environmental Health Science Program Dept of Environmental Science; E. Craft, Environmental Defense Fund / Office of Chief Scientist; B. Escher, Helmholtz Centre for Environmental Research GmbH – UFZ / Cell Toxicology; R.P. Lanno, The Ohio State Univ / Dept of Evolution Ecology and Organismal Biology Subsurface Energy Resources Center; C.L. Meyer, Shell Oil Company / Ecotoxicology; C.T. Natural resource extraction (NRE) activities associated with fossil fuels and chemical feedstocks remain a pressing societal need despite the growth of renewable raw material sources. In recent years, few NRE technologies have received as much attention from the scientific, regulatory and public communities as hydraulic fracturing (HF), commonly known as “fracking”. Though HF is increasingly used to increase the efficiency of conventional natural gas development in shales, coal seams, and tightly compacted sands, the potential risks of HF and related natural gas development on public health and the environment require assessment and management. It is clear that interdisciplinary scientific approaches are necessary to define the implications of HF and other related NRE activities to environmental quality, and to develop appropriate environmental management strategies to meet environmental protection goals. Further, the role that environmental fate processes (e.g. biotic and abiotic degradation, bioaccumulation) play in determining both environmental and human exposures warrants additional scrutiny and management consideration. SETAC held timely Focused Topic Meeting in March 2016 to facilitate information exchange on the state of the science on these focused topics and provide a forum for stakeholder engagement. In addition, breakout groups with scientists and engineers from academia, business and government identified research needs in five areas: 1. Environmental fate assessment of fracturing fluids; 2. Chemical hazard assessment of fracturing fluids; 3. Environmental risks to water resources; 4. Environmental risks to land resources; and 5. Environmental risks of produced water for beneficial reuse. This presentation presents context for these research questions necessary to understand the environmental quality implications of unconventional natural gas development.

MP224 PBT Assessment of Hydraulic Fracturing Fluids from Coal Seam Gas Fields in Australia

T. Biksey, EHS Support LLC / Director Risk Assessment; C. Peterson, EHS Support LLC; N. Goulding, EHS Support, Inc.; C. Bevan, CJB Consulting LLC

The science and fluids used in hydraulic fracturing are constantly evolving, and involve a broad mixture and variety of constituents. Hydraulic fracturing wastes and production water flow containing these constituents have to be disposed or recycled. Coal seam gas (CSG) production in Queensland, Australia, requires a hazard assessment to use and manage these fluids as part of the requirements of the Environmental Authority and the Environmental Impact Statement. The hazard assessment process was conducted to evaluate the constituents used in the hydraulic fracturing fluids that potentially are a concern to human health or the environment based on an assessment of persistence, bioaccumulation, and toxicity (PBT). The PBT assessment provided a framework to assess management requirements, long term environmental risks, and the use of alternative chemicals to produce hydraulic fracturing fluid systems with low toxicity and greater potential for on-site management and reuse. The PBT assessment for the proposed hydraulic fracturing constituents was conducted in accordance with Australian best practice and national or international standards and guidelines. One of the challenges in compiling the necessary PBT data was the proprietary nature of the constituents in the hydraulic fracturing fluids, and the limited experimental data. Therefore, for constituents where available data may not allow a definitive conclusion on the PBT properties, PBT assessment guidance developed by Department of the Environment, Water, Heritage and the Arts, or the PBT assessment guidance for the EU REACH screening criteria, was used to decide whether a substance may potentially fulfill the PBT criteria. Physical-chemical properties, environmental fate and transport, and aquatic and mammalian toxicity data was compiled from routine data used for screening processes (e.g., OECD-SIDS program). The results of a PBT assessment in support of a quantitative risk assessment, and the application to the assessment of two hydraulic fracturing fluid systems to determine which of the two presents a lower overall PBT assessment, will be discussed. The challenges that were encountered because of the proprietary nature of the hydraulic fracturing chemicals are presented, and include confidentiality issues, lack of robust experimental data, and the lack of estimation models.

MP225 Potential Environmental Impacts of Shale Development on Proximate Flora

R. Lupardus, Univ of Northern Colorado / Biology

Chemicals released from active and producing shale wells have the ability to deposit onto surrounding plants, soils or waters, but empirical data are lacking. This deposition might affect species and ecosystem health of proximate flora. We examined potential impacts on Pawnee National Grassland (PNG) vegetation due to shale energy development and release of carcinogenic hydrocarbons referred to as BTEX: Benzene, Toluene, Ethyl Benzene, Xylene. The objective of the research was to quantify the deposition and accumulation of BTEX onto proximate flora. We hypothesized that deposition and accumulation of BTEX onto proximate flora would be greater when wells were pumping and that deposition and accumulation would decrease with time since production. Such knowledge is crucial for science-based development of air pollution control and management strategies. In the spring of 2014 a total of 360 vegetation samples were collected from 5 previously and 15 currently producing shale wells on the PNG. Samples were collected along 50 meter transects in W, NE and SE directions at 20m, 50m and 100m from the production source. Vegetation samples from collection sites were measured for BTEX using gas chromatography and flame ionization detector. Results from the analysis indicate that BTEX were present in a majority of the samples. The mean concentrations (BTEX mg/g veg) for all samples were: Benzene 1.36 E-05, Toluene 2.36 E-06, Ethylbenzene 7.88 E-07, o-Xylene 6.87 E-07 and p-Xylene 8.99 E-06. The highest concentration across all samples was for o-Xylene. Deposition and accumulation of BTEX onto proximate flora was significantly greater, F (9.58) and $p < 0.001$, when wells were pumping, as predicted. Benzene was greater than 30ppm for wells that were pumping up natural gas during the time of sample collection. There was a significant difference between production groups for Benzene F (34.65) and $p < 0.0001$, Toluene F (35.11) and $p < 0.0001$ and o-Xylene F (9.58) and $p < 0.001$. Deposition and accumulation of BTEX onto proximate flora decreased with time since production. These results could have implications for cattle restrictions and safety requirements for, not just cattle, but other wildlife and humans, with daily exposure in close proximity (e.g., within 100m) of a shale production site.

MP226 Framework for an Environmental Effects Monitoring Program for Unconventional Oil and Gas Development in Appalachian Regions of Ohio and West Virginia

R.P. Lanno, The Ohio State Univ / Dept of Evolution Ecology and Organismal Biology Subsurface Energy Resources Center; G. Allen, C. Shank, Ohio State Univ

The Utica/Point Pleasant shale play in eastern Ohio and northwestern West Virginia is the focus of the development of high volume horizontal hydraulic fracturing (HVHHF) oil and gas wells at an unprecedented rate. Concerns exist regarding the environmental and human health risks associated with the hydraulic fracturing process, yet data and methods used to frame these arguments, from both environmentalist and industry perspectives, often lack scientific rigor, transparency, and completeness. Assessing the nature of environmental hazards and risks associated with HVHHF processes, chemicals, and waste products in a controlled, scientific manner is limited by ready, consistent access to these procedures and materials from actual drilling facilities. As a result, very few scientific data are available to the public on the environmental risks posed by drilling to surface and subsurface environments. Additionally, the lack of a comprehensive framework to address the multitude of potential effects of HVHHF often leads to the “cherry-picking” of data and lack of a “big picture” interpretation of effects. Only through ongoing access to active, “transparent” drilling sites with organized well development, sampling strategies, and a unified assessment framework can hypothesis-driven research be conducted to inform best practices to reduce environmental and human health risks associated with shale development. To this end, the Ohio State University is developing the Utica Shale Energy and Environmental Laboratory (USEEL). The USEEL represents a unique partnership between industry, academia, and government in the collection of data to assess the environmental and human health risks associated with HVHHF, as well as baseline lithology, chemistry, mineralogy, and microbial biodiversity contributing to geologic history and hydrocarbon development in shale formations. The first step in the development of a comprehensive plan to assess the potential environmental effects of HVHHF is to build a comprehensive framework based upon underlying, large-scale characteristics of the region in which the study will be conducted. This presentation will outline the use of ecoregions, watersheds, hydrologic unit codes (HUC), and the importance of GIS geospatial database tools in setting the stage in Phase I of developing an environmental effects monitoring framework for HVHHF.

Aquatic Toxicology and Ecology – Poster Only – Part 1

MP227 Do Eukaryotic Species Interactions Drive Freshwater Harmful Algal Blooms Dynamics?

A. Banerji, M. Bagley, USEPA / SED; E. Pilgrim, USEPA / Ecological Exposure Research Division; J.W. Santo Domingo, USEPA / Cincinnati; J. Lu, USEPA ORD Cincinnati; J. Allen, J.M. Lazorchak, USEPA / Office of Research and Development

Harmful algal blooms (HABs) constitute an increasingly frequent and severe threat to human health and the environment worldwide. The USEPA's research into how to anticipate and mitigate HABs emphasizes the important role of abiotic factors such as nutrient pollution and temperature. Though informative, these research efforts may be insufficient by themselves. Accounting for the influences of biotic interactions such as predation, disease, and competition on HAB formation/dissipation may improve the power of HAB prediction and mitigation strategies. In the present study, we use a metabarcoding approach to profile changes in the aquatic community of a multipurpose reservoir in southeastern Ohio, USA, that has recently become prone to summertime blooms of toxic cyanobacteria. Our preliminary data indicate a consistent pattern in which HAB formation coincides with conspicuous spikes in the abundance of herbivorous crustacean zooplankton and rapid declines of green algae. Ongoing analyses are intended to elucidate key community dynamics foretelling HAB formation/dissipation. In addition, controlled laboratory experiments will be used to test hypotheses regarding mechanisms driving these dynamics.

MP228 Consequences of soil erosion and cyanobacterial blooms on the feeding behaviour of a native fish Goodea atripinnis (Goodeidae)

M.A. Gayosso, Escuela Nacional de Ciencias Biologicas, IPN / Hidrobiologia experimental; F. Martínez-Jerónimo, Escuela Nacional de Ciencias Biológicas-I.P.N. / Laboratory of Experimental Hydrobiology; N. Sarma, UNAM Mexico City Campus iztacala / UIICSE; S.S. Sarma, UNAM Mexico City Campus iztacala / Laboratory of aquatic zoology

Eutrophication and cyanobacterial blooms are factors associated with environmental degradation and water pollution by mineral nutrients, which could change the zooplankton consumption by the fish. Turbidity caused by both organic (e.g., cyanobacterial blooms) and inorganic (e.g., soil) particles affect the prey visibility. Little is known about the effect of this two kinds of turbidity on feeding behavior of fish, which mostly depend on vision to pursue their prey. Goodea atripinnis is a member of Goodeidae with restricted distribution in Central Mexico. The aim of this study was to determine if turbidity influences the preference and consumption of cladocerans by G. atripinnis. Prey preference experiments were performed under conditions of organic (Microcystis aeruginosa) and inorganic turbidity (clay) at two levels, 60 and 120 NTU. Five cladoceran species were used as prey (Ceriodapnia dubia, Alona glabra, Simocephalus vetulus, Moina macrocopa, Diaphanosoma birgei) and offered at a density of 1 ind. ml^{-1}). The tests were performed using 50 ml of moderately hard water as medium. Two juvenile individuals of the fish were added and allowed to feed on the mixed cladocerans for 30 minutes. At the end of the experiment the fish were removed and the uneaten prey items in the medium were counted. For determining prey preference Manly's α was used. Our tests showed that turbidity modified the prey preference. Compared to controls, fish in turbidity preferred higher number of prey species. This also increased with increasing levels of turbidity. Further, our results showed that high levels of turbidity adversely affected the prey consumption by G. atripinnis.

MP229 Sub lethal concentrations of Cylindrospermopsin causes lipogenesis, cell cycle disruption, and activation of stress responses on hepatocytes

C. Gonzalez, Univ of São Paulo / Clinical Analyses; E. Pinto, Univ of São Paulo / Faculty of Pharmaceutical Sciences; P. Kubiniok, P. Thibault, Universite de Montreal / Inst for research in immunology and cancer

The production of cyanobacterial toxins in Brazilian continental water reservoirs is widely known and a current public health issue. Cylindrospermopsin (CYN) is a hepatotoxin whose excretion was initially reported by Cylindrospermopsis spp., but later found to de produced by many other cyanobacterial genera. Several toxicity mechanisms have been described for CYN on mammalian cell cultures. The most prominent effect is protein synthesis inhibition, although this mechanism is not yet clear. In order to have a deeper understanding of the consequences of CYN exposure on human hepatocytes, we chose a relative quantitative proteomics approach. Briefly, we quantitated the effects of sub lethal doses of CYN on the up regulation and down regulation of proteins from the overall HepG2 proteome. Here we present results from a shotgun proteomics experiment using stable isotope labeling of amino acids in cell culture (SILAC) and nanoscale LC-MS^2 techniques. Previous results from our laboratory using flow cytometry showed that the treatment of HepG2 cells with 1 µM of CYN during 24 hours, did not produce apoptotic nor necrotic effects. Furthermore, the stimulation of HepG2 cells with 5 µM of CYN during 12 hours, did not caused cell death either. Using these CYN concentrations HepG2 cells were treated during several time intervals up to 24 hours. Of all the biological effects produced by CYN on the proteome of HepG2 cells, lipogenesis was the most constant effect. In many of the time points of the experiment, we detected an up regulation of enzymes related to cholesterol biosynthesis, acetyl-CoA biosynthesis, bile acid biosynthesis and Krebs cycle. Moreover, we found evidence of up regulation of proteins related to cell cycle control, for example MCM proteins involved in control of chromosomal replication, and up regulation of transport proteins related to RAN signaling. Notably cell stress-response proteins showed alterations at concentrations previously considered as sub lethal. Examples of up regulation and down regulation of stress response related proteins include processes like glutathione-mediated detoxification, Nrf2 mediated oxidative stress response and positive acute response proteins. Finally, another relevant effect of the toxin throughout the experiment was the up regulation of enzymes involved in the degradation of several amino acids, most of them aromatic AA. A more comprehensive interpretation of these findings will be available at the meeting.

MP230 Stream Susceptibility Profiles in the Appalachian Mountains

G. Beaubien, MTSU / Biology; C. Olson, Middle Tennessee State Univ; D. McKinney, Tennessee Wildlife Resources Agency; R.R. Otter, Middle Tennessee State Univ / Biology

Tennessee's Ecologically At-Risk Streams – Appalachian Mountain (TEARS-AM) is a three-year eco-toxicological study designed to establish the susceptibility of four naturally reproducing eastern brook trout (Salvelinus fontinalis) streams spanning the latitudinal gradient of Tennessee's Appalachian Mountains. By collecting and examining baseline chemical, geological, biological, and ecological data within these streams, TEARS-AM provides the framework required to determine the stream susceptibility profile and establishes long-term monitoring stations for future studies. Year one data revealed all fish tissue was below detection for polychlorinated biphenyls (< 12.5 PPB) across the four sites while mercury and methyl-mercury were above detection (>3.0 PPM) but at different concentrations based on the site. Water quality results showed an average concentration of 1.04 mg/L, 0.31 mg/L, and 0.908 ng/L for total suspended solids, nitrate/nitrite, and total mercury, respectively when data from all four sites were combined. The abiotic and environmental factors affecting these results will be discussed as well as future plans.

MP231 Fish Captured in Canoas River, SC, Brazil, Exhibited Alterated Concentration of Sex Hormones and Gonad Morphological Alterations

C. Soares, Univ Federal de Santa Catarina / Biochemistry Dept; I. Baptista, A. Paiva, Univ Federal de Santa Catarina

The Canoas River is one of the most important in the Santa Catarina state, Brazil. Several studies have been carried out in several sites of this river, especially in the municipalities of Correia Pinto and Ponte Alta, and the results demonstrate that pollutants are being released in its waters, causing physiological and biochemical changes in fish. This study evaluated possible biochemical and physiological changes, especially changes in the levels of sex hormones such as estradiol and testosterone in native fish, Jundiá (Rhamdia quelen) captured in the city of Otacilio Costa, near a paper and pulp mill. The fish were caught with hook and line, and immediately blood samples were taken using heparinized syringes. Liver, gills and the gonads were also removed, which were weighed and then placed in buffered formalin, 10% for histological analysis. Analyses of the concentration of the testosterone and estradiol showed that fish collected at a site downstream of toxic waste discharge had higher testosterone levels than fish caught in a site upstream. Plasma cholesterol concentration was higher than the control group. For every 10 fish caught nine fish were males, in the site affected by the discharge of effluents, in contrast to the control site. Likewise, histological analyzes showed significant alterations in gills, liver and gonads, particularly in females. The observed biological changes can be correlated with physical and chemical changes of the water, particularly the amount of total phenolics. Support: Fapesc/CNPq

MP232 Genetic diversity of a sedentary fish species from a Neotropical stream under anthropogenic interference

D.G. Ferreira, W. Frantine-Silva, C. Apolinário-Silva, Univ Estadual de Londrina / Departamento de Biologia Geral; B.A. Galindo, Univ Estadual do Norte do Paraná; C.B. Martinez, Univ Estadual de Londrina / Ciencias Fisiologicas; S.H. Sofia, Univ Estadual de Londrina / Departamento de Biologia Geral

Freshwater fishes have experienced declines in their populations worldwide, as consequence of anthropogenic impacts. Environmental pollution, habitat fragmentation, forest destruction, undesirable agricultural practices are among the main threats to freshwater fish fauna. Whatever the cause, is well established that both loss of species diversity and population declines are usually accompanied by a reduction in genetic diversity. In the Neotropics, the anthropogenic threats to freshwater ecosystems are especially intense and persistent, putting at risk one of the richest and most diverse fish faunas in the world. In our study, based on microsatellite markers analysis, we assessed the genetic diversity of Geophagus brasiliensis, a Neotropical fish that exhibits sedentary habits and parental care, showing low levels of genetic diversity. Samples of G. brasiliensis were collected in three sites (high: H, medium: M and low: L) along a stream of 32 km of extension, located in southern Brazil. In its medium section, this stream receives waters from a small tributary that crosses the urban area, which has been impacted for decades with sewage discharge. Individuals of G. brasiliensis (H: 29; M: 23 and L: 30, n=82) were genotyped in eight microsatellite loci. Measures of genetic diversity varied little among samples. The lowest observed and expected heterozygosity values were obtained for sample from H site (H_O = 0.490 and H_E= 0.578), while the highest value was detected for M (H_E = 0.729). The highest mean of alleles per locus (N_A = 6.000), number of effective alleles (N_E = 4.221) and allelic richness (R_A = 5.939) were obtained for the M sample, while the lowest values for these index were obtained for H sample (N_A = 4.500, N_E = 3.124 and R_A = 4.361). Significant F_{IS} values were obtained in all samples. The sample from site M showed the highest value (0.167) and L showed the lowest value (0.081). We also detected significant heterozygote- excess (bottleneck signal) in M and L samples, in both IAM and TPM models. Thus, despite the neutrality of the markers employed, our findings suggest a genetic bottlenecks signs in M and L samples, precisely the two sites downstream the urban tributary stream. Thus, we cannot discard that anthropic impacts could be acting as a selective force on downstream's populations of G. brasilensis.

MP233 Evaluation, identification, and reduction of sources and causes of sublethal toxicity in the effluent discharge from a former mining site

P.J. Downey, FTN assoates, Ltd.; R.E. Lockwood, Ramboll Environ / Dept of Ecotoxicology; S.S. Brown, The Dow Chemical Company / Environmental Remediation and Restoration

A toxicity reduction evaluation (TRE) was completed to identify sources and causes of intermittent sublethal toxicity to Ceriodaphnia dubia (≤ 30% reduction in reproduction) in effluent discharge from a former vanadium mine, and to inform actions to reduce this toxicity. Vanadium was mined at the site from the 1960s until 1986. The TRE combined split-sample toxicity testing among laboratories, spiked effluent testing, toxicity identification evaluation (TIE), and chemical analysis of discharge and contributing water sources (subwatersheds) to evaluate causative factors (e.g., TDS, sulfate, metals) and laboratory variability. Sampling and testing was completed from December 2013 to November 2015 including samples collected during rain events. During this period, insufficient levels of toxicity in the discharge precluded direct identification of chemical causes of toxicity. Toxicity tests on effluent spiked with $CaSO_4$ demonstrated toxicity could not be attributed to SO_4 in the discharge. A toxicity source evaluation showed seep water from a mine spoil area caused sublethal toxicity at concentrations of 5% to 25%. Analysis of flows indicated this seep comprised more than 11% of the effluent up to 50% of the time, and was a likely source of toxicity in the discharge. TIE and chemical evaluation of seep water from the mine spoil area suggested concentrations of manganese (Mn), cobalt (Co), and nickel (Ni), acting alone or together, could account for the observed sublethal toxicity. Additionally, variation among 3 laboratories in the results of split-sample toxicity tests suggested laboratory variability was a factor in evaluating sublethal toxicity to C. dubia, especially at the low levels of sublethal toxicity observed. This information was used to inform site specific reclamation projects. Extensive reclamation focused on covering spoil piles with an impermeable barrier to minimize infiltration of surface water into underlying spoil material and reduce the amount of seepage from the spoil area. Further completion of these activities in the spoil area will focus on minimizing infiltration of surface water into underlying spoil material, reducing seepage, and reducing concentrations of dissolved constituents including Mn, Co, and Ni. Performance monitoring to date indicates continuous improvement in seep management toward the elimination of sublethal toxicity, and discharge biomonitoring will continue as site reclamation proceeds.

MP235 Evaluation of the water quality in dam Tenango, Puebla

G. Barrera Escorcia, M. Mu_oz-Najera, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia; P. Ramirez Romero, U.A.M. Iztapalapa / Hidrobiologia; F.O. Tapia Silva, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia; J.R. Rosas Cedillo, Universidad Autonoma Metropolitana Iztapalapa / Quimica

Dams are hydraulic structures that store water for the population benefit, an example of this is the Tenango de las Flores dam on the north of Puebla State, Mexico. It belongs to the Necaxa hydroelectric system and is connected to the Acatlán and Necaxa dams through tunnels. Tenango supplies water to Necaxa for the generation of hydroelectric energy. Corn, coffee and flowers are cultivated in the surrounding areas and there is a protected woods area of pines and oaks, and medium rainforest. At the same time, the dam is used as a tourist attraction and for fishing. The objective of this study was to assess the water quality of the Tenango dam. Five samplings were conducted in a year. Water physicochemical parameters were measured in situ (pH, dissolved oxygen and temperature). Levels of nutrients were analyzed (nitrites, nitrates and phosphorus); as well as metals (cadmium, chromium, copper and lead). Metals were also measured in fish. The results indicated that the physicochemical parameters are within acceptable levels. Nitrites and phosphorus concentrations always exceeded the acceptable limits for urban use and for protection of aquatic life. Lead and chromium exceeded limits on four samplings. Cadmium and copper behaved similarly, exceeding levels permitted by the Mexican legislation for water in two samplings. Metal concentrations in fish tissues were in agreement with water levels. Based on the concentrations of nutrients and metals, it is concluded that the water of the dam is not suitable for urban use, or for protection of aquatic life. These levels of pollution indicate that aquatic life is at risk due to present contradictory uses of water resources in this dam.

MP236 Evaluating the Effects of Livestock Inputs on Fish Populations and Water Quality in the Pine River

B. Hamilton, Alma College / Environmental Studies; A.D. Harwood, Alma College; M.C. Borrello, Alma College / Environmental Studies; T.P. Keeton, Alma College / Biology

The Pine River, in the Central, Lower Peninsula region of Michigan has a long history of contamination both upstream and downstream of a mill dam located in the town of Alma. Nutrient loading has been measured upstream of the dam due to heavy impacts of livestock facilities and manure application sites along the Pine River and its tributaries. In addition to nutrient loading and decreased levels of dissolved oxygen, excessive concentrations of E. coli bacteria have caused environmental and human health concerns. Additionally, E. coli strains sampled from the Pine River and its tributaries proved to be resistant to multiple antibiotics. E. coli concentrations were quantified in 2015 and were found to exceed safe levels for human contact according to the State Department of Community Health. High bacterial concentrations may affect a large population of anglers that frequently fish in the Pine River at sites where the highest concentrations of E. coli have been reported as well as resident fish populations. The objective of the current study was to evaluate exposure to fish and anglers using both caged and resident fish in the Pine River. Caged juvenile catfish (Ictalurus macrohinus) and bluegill (Lepomis punctatus) were placed at locations upstream of recorded impacts and downstream through locations previously identified as having high concentrations of E. coli. Additionally, resident fish of the Pine River were angled and/or collected via fish shocking at these sites. All fish were identified, evaluated for health, and swabbed to determine concentrations of E. coli. For any E. coli strains identified, antibiotic resistance was determined. At each site where either resident fish were caught or caged fish were placed, general water quality parameters were measured including nutrient and E. coil load. The results of this research may provide the impetus for state officials to address significant and persistent water quality problems sourced in industrial agriculture.

MP237 Effects of anthropogenic activities on aquatic invertebrate communities in an ecologically important conservation area of South Africa

L. de Necker, Univ of Johannesburg; T. Dube, L. Brendonck, KU Leuven / Laboratory of Aquatic Ecology Evolution and Conservation; V. Wepener, North-West Univ / Unit for Environmental Sciences and Management; N. Smit, North West Univ / Environmental Sciences and Management; J.H. van Vuren, Univ of Johannesburg / Zoology

Temporary wetlands (pans) are some of the most prevalent wetland types worldwide and known as biodiversity hotspots that contribute greatly to regional diversity. Although these aquatic systems are widespread, not only across South Africa but globally, they are not well studied. The Phongolo River Floodplain (PRF) is one of South Africa's largest floodplain systems and is unique to South Africa as it is the only large floodplain that sustains a large number temporary wetlands throughout the dry season. The Ndumo Game Reserve (NGR), located on the PRF, is the only protected area of the floodplain, housing a number of ephemeral and floodplain pans rich in invertebrate biodiversity. Many anthropogenic activities are present in the surrounding area of the NGR, placing a great deal of pressure on the floodplain system. The central aim of this study was to provide baseline information on the biodiversity of aquatic invertebrates found in ephemeral pans across PRF and to determine how this is affected by anthropogenic activities. Water, zooplankton and macroinvertebrate samples were collected from 22 ephemeral pans during February 2014 (wet season). Zooplankton and macroinvertebrates were identified to lowest possible taxon and water analysed for a variety of nutrients. High water temperature and extreme DO concentrations were possible drivers for low aquatic invertebrate biodiversity. Multivariate statistical analyses revealed spatial variation between sites from within the NGR compared to outside the NGR, predominantly driven by aquatic invertebrate biodiversity. A number of pollutant sensitive aquatic invertebrate taxa were found exclusively within the NGR while many pollutant tolerant taxa were prevalent outside the NGR. This suggests that anthropogenic activities are affecting the ephemeral pan biodiversity outside the NGR while the game reserve appears to be protecting biodiversity.

MP238 Changes in Physical Factors following Low-Level Disturbance in a West Virginia Watershed

A. Chapman, Marshall Univ / Environmental Science; M.Y. Armstead, M. Wilson, Marshall Univ / Integrated Science and Technology

Freshwater ecosystems are known to be impaired by disturbances within their watersheds. These disturbances may result from multiple sources ranging from resource extraction to development (e.g. urban, residential, industrial, and commercial). Even low level disturbances have been shown to result in impairment to stream biota within the watershed in landscape-scale evaluations. However, when very low levels of disturbance occur, the mechanisms, which result in impairment to the biological integrity of the freshwater ecosystem, are not well characterized. The objective of this study was to examine the immediate effects of an anthropogenic disturbance of less than 1% of the watershed area on the aquatic ecosystem. Specific parameters presented in this discussion will be changes to the physical factors within the watershed including light intensity, canopy cover, temperature, relative humidity, and evaporation. Baseline conditions were established during a 6-week pre-disturbance period for comparisons of pre- and post-disturbance conditions. A low level disturbance was created by timbering a 0.24 acre area in the 89 acre watershed. Comparisons between pre-disturbance and post-disturbance conditions were evaluated using one-way analysis of variance or Kruskal-Wallis procedures where appropriate. No significant differences were seen in light intensity or canopy cover before and after the disturbance at three monitoring sites located in the upper, middle and lower reaches of the watershed, indicating that the disturbance was not close enough to the stream to affect these physical factors. Evaporation rates were significantly higher ($F=7.03$; $p< 0.05$) and humidity was significantly reduced ($X^2=33.04$; $p< 0.01$) after the disturbance with the greatest effect noted at the monitoring site located in closest proximity to the disturbance. Evaluating the effects of the disturbance on temperature and humidity are complicated due to seasonal variability.

MP239 Assessment of DNA damage in freshwater mussels from the Hamilton Harbour watershed

E.A. Gilroy, Green House Science / Environment and Climate Change Canada; S.L. Witzke, S.D. Campbell, Green House Science; T.J. Morris, K.A. McNichols-O'Rourke, Fisheries and Oceans Canada; J. Salerno, Environment and Climate Change Canada; P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division; T. Theysmeyer, Royal Botanical Gardens; S. de Solla, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division

A variety of chemicals can induce damage to the DNA of animals, which, if not repaired, can lead to a cascade of biological effects at any level of biological organization, from cellular to community and population level. First developed in the 1980s, the single cell gel electrophoresis assay – or Comet assay – is used to visualize and quantify cellular DNA damage. In recent years, a number of studies have used this approach to evaluate DNA damage from exposure to specific chemicals (e.g., PAHs), as well as from complex mixtures of contaminants, such as industrial or municipal effluents. The objective of the present study was to validate the Comet assay in wild freshwater mussels and to quantify the DNA damage in mussels from the Hamilton Harbour watershed in comparison with that in mussels from reference sites in southern Ontario. Giant Floater mussels (Pyganodon grandis) (91 ± 18 mm, n = 68) were collected from three sites: Cootes Paradise; a small stream directly under highway 401 near Campbellville; and in a small agricultural stream in Embro, Ontario. The mussels were brought to the laboratory and held overnight, a small quantity of hemolymph (blood) was collected the next morning, and the mussels were returned to their habitat of origin within 24 hours. The density and viability of hemocytes (blood cells) were quantified by flow cytometry, and the presence and relative quantity of DNA strand breaks were quantified using the Comet assay. The catch per unit effort was lower in Cootes Paradise compared to Campbellville and Embro. Cell density was significantly elevated in the hemolymph of Giant Floater mussels collected in Campbellville and Cootes Paradise, compared to the hemolymph of those collected in Embro. The hemocytes of mussels from Cootes Paradise had significantly greater DNA damage than those of the mussels from Campbellville and Embro, suggesting exposure to genotoxic compounds. As it has been linked to reduced growth, abnormal development and reduced survival, DNA damage, if not repaired, could have repercussions at the individual and community level. Validation of the Comet assay in other aquatic species, and follow-up studies in Hamilton Harbour AOC are under consideration.

MP240 Hydrocynus viittatus's potential as bio-indicator of riverine health: A multiple lines of evidence and multivariate statistics approach

R. Gerber, North West Univ Potchefstroom Campus; N. Smit, North West Univ / Environmental Sciences and Management; I. Wagenaar, J.H. van Vuren, Univ of Johannesburg / Zoology; Y. Ikenaka, Hokkaido Univ / Graduate School of Veterinary Medicine; V. Wepener, North-West Univ / Unit for Environmental Sciences and Management

There is a need for sensitive bio-monitoring and indicator tools in toxicant impact assessment to show the effect of toxicants on fish health in polluted aquatic ecosystems. Histopathological and biomarker assessments of fish tissue are a bio-monitoring tool and allows for early warning signs of disease and detection of long term injury in cells, tissues or organs. The aims of this research was firstly to determine and compare the health status of the tigerfish (Hydrocynus vittatus) from two lowland rivers in Kruger National Park (KNP) that currently have different anthropogenic impacts, secondly to attempt to explain the histological and biochemical changes observed, through the application of a suite of multivariate statistics to relate the changes to biotic levels of selected metals and organochlorine pesticides (OCPs) and thirdly to determine the suitability of H. vittatus as a bio-indicator of riverine health. Tigerfish were caught using rod and reel from the Olifants River (n=37) and the Luvuvhu River (n=34) between 2009 and 2011. Even though fish were considered to be healthy, the general fish health in both rivers improved over time, corresponding to an overall decrease in river pollution, especially in terms of metals in muscle tissue. The incorporation of multiple lines of evidence in tigerfish, including histopathological changes and cellular, organ and whole organism indices, proved to be a valuable tool in using a bio-indicator approach toward river monitoring. These changes serve as an early warning system to more serious health concerns arising if the pollution in the rivers of the KNP is not dealt with. The use of a suite of uni- and multivariate statistics proved helpful in determining the links between fish health and river contamination and further proved to be a valuable tool in assessing spatial and temporal differences in river pollution and the effects thereof on the selected bioindicator.

MP241 Zebra Mussels as Bioindicators of Habitat Quality of the Great Lakes USA

A.H. Ringwood, UNC-Charlotte / Dept of Biology; E. Johnson, A.P. Jacob, K.L. Kimbrough, NOAA / National Centers for Coastal Ocean Science / Center for Coastal Monitoring and Assessment; M. Lowder, UNC-Charlotte; B. Khan, National Research Council of the National Academies / Biology; T.R. Gaspar, Univ of North Carolina at Charlotte / Biology

Bivalve mollusks are valuable bioindicator species due to their sessile lifestyle and filter-feeding capabilities, and their tendency to accumulate contaminants in their tissues. Therefore, bivalves can provide spatial and temporal insights for identifying habitat stress. Freshwater systems can experience persistent anthropogenic inputs (industrial/agricultural runoff, land development, etc.), which can cause long-term impacts on biota and ecosystem health. NOAA's Mussel Watch program has been used to monitor contaminants in aquatic systems and recently has been expanded to include the US Great Lakes as part of the Great Lakes Restoration Initiative. Caging studies were conducted with zebra mussels (Dreissena polymorpha) to evaluate the potential toxicity and bioavailability of contaminants from Great Lakes sites in Lake Michigan and Lake Erie in collaboration with NOAA. NOAA staff conducted caging studies during the summer of 2012 at sites dominated by urban inputs and high levels of PCBs and PAHs (Manistique River, Menominee River, Green Bay, Sheboygan River, Ashtabula River, and Milwaukee Bay); and during the summer of 2015 at the Maumee River, dominated by agricultural runoff and elevated pesticides (such as chlorpyrifos). Harvested mussels were sent to UNC-Charlotte for cellular biomarker analyses (lipid peroxidation and total glutathione for all sites and acetylcholinesterase (ACHE) for the 2015 samples); tissue samples were processed for contaminants by NOAA. There were highly significant correlations between the tissue concentrations of PCBs and PAHs and glutathione levels. Changes in glutathione levels and lipid peroxidation, indicated significant oxidative stress. Increased ACHE levels were also observed in mussels from the Maumee River. These studies indicate that while zebra mussels are typically branded as an invasive species, they can also be a valuable bioindicator species to assess habitat quality and ecosystem health in the Great Lakes and other freshwater locales.

MP242 Navajo Generating Station ERAs: A Successful Communication Strategy that Facilitated the ERA Process Associated with the NGS EIS

L. Martello, Ramboll Environ US Corporation, Emeryville, CA; M. Sorensen, Ramboll Environ US Corporation, Atlanta, GA; K. Leigh, Ramboll Environ US Corporation, Cleveland, OH; P. Leitman, C. Beals, Ramboll Environ US Corporation, Atlanta, GA; A. Smith, Ramboll E&H / Ecology and Sediment Management; C. Paradzick, Salt River Project, Phoenix, AZ; R. Lehn, Peabody Energy, Flagstaff, AZ

Navajo Generating Station (NGS) is a coal-fired electric power generating station located in northern Arizona on land leased from the Navajo Nation. Ecological risk assessments (ERA) were conducted over five discrete areas to evaluate environmental conditions in the vicinity of the NGS to inform the environmental impact statement conducted for compliance with the National Environmental Policy Act and the Endangered Species Act Section 7 Consultation for the federal decisions to authorize NGS operations beyond 2019. A key challenge for the project was to implement technical ERA approaches that allowed for input from multiple stakeholders with widely varying technical knowledge levels, goals and objectives. Stakeholders included the Bureau of Reclamation, the Office of Surface Mining Reclamation and Enforcement, the US Fish and Wildlife Service, the Bureau of Indian Affairs, the US Environmental Protection Agency, the Navajo Nation, Hopi Tribe, and National Parks Service. This presentation focuses on the communication strategy implemented for the project that simplified the understanding of technical concepts, encouraged opportunities for consensus building, endorsed real-time contributions to the ERA process, and facilitated the development of ERA documentation appropriately suited for the needs of the EIS.

MP243 Tracing Deepwater Horizon Oil into Coastal in situ Bacterial Communities

T. Baskerville, J. Sarkoodee-Adoo, Florida A M Univ / School of the Environment; W. Jeffrey, Univ of West Florida / Center for Environmental Diagnostics and Bioremediation; J. Chanton, Florida State Univ / Earth Ocean and Atmospheric Science; J. Cherrier, Brooklyn College / Dept of Earth Environmental Sciences

One year after the Deepwater Horizon oil spill, samples were collected from Barataria Bay, LA (heavily-impacted), Pensacola Bay, FL (moderately-impacted), and Apalachicola Bay, FL (non-impacted) to evaluate spill effects on indigenous bacterial communities. Natural Delta ^{14}C and del ^{13}C abundances were utilized to trace in situ bacterial hydrocarbon remineralization to dissolved inorganic carbon (DIC). Barataria Bay DIC samples were significantly deplete in Delta ^{14}C (-109.98 per mil to +12.48 per mil) relative to that for Apalachicola Bay (+36.31 per mil) indicating hydrocarbon remineralization at the Barataria Bay site. Using dual isotope three endmember mixing models we estimate that between 1 to 12% of the respired DIC at Barataria Bay can be attributed to hydrocarbon remineralization. Bacterial abundances were an order of magnitude higher in Barataria Bay when compared to the Apalachicola Bay which correlated with higher DOC concentrations at the Barataria Bay site. Clone libraries indicate distinct differences in bacterial community structure between sites due to increases in the presence of known oil degrading bacteria in Barataria Bay and Pensacola Bay. Collectively, these results demonstrate that Barataria Bay bacterial communities did utilize oil and show that such a combined biogeochemical and molecular approach can be a powerful tool for evaluating oil intrusion into the marine food web.

MP244 Toxicity Laboratory Intercalibration for Stormwater in Southern California

D.J. Greenstein, Southern California Coastal Water Research Project / Dept of Toxicology; D. Vidal-Dorsch, VDA LCS / Toxicology; K.C. Schiff, Southern California Coastal Water Res.

Because of the expansive urbanization of watersheds in southern California, the monitoring of stormwater has become increasingly important. Nearly a million dollars is spent each year monitoring stormwater toxicity. This work is funded by multiple agencies, conducted by many different laboratories, and uses several test organisms. A group of the agencies, the Southern California Stormwater Monitoring Coalition, has a goal of combining all of the data sets that have been generated to make spatial and temporal comparisons. This is challenging because while the laboratories are using standardized test methods, there are options and room for interpretations in the protocols that allow some variation in procedures. As a result, an intercalibration exercise was conducted to assess the comparability of results between laboratories. A total of nine laboratories tested split samples of dilution water, copper spiked dilution water, simulated runoff and a duplicate of one of these matrices. In the first round, tests were conducted using survival and reproduction of water flea Ceriodaphnia dubia, 96 hr. survival of the freshwater amphipod Hyalella azteca, 48 hr larval development of the salt water mussel Mytilus galloprovincialis, and 72 hr larval development of the sea urchin Strongylocentrotus purpuratus. Each laboratory was allowed to use their normal protocols. The round one results found good comparability for the two marine tests, but relatively poor comparability for amphipod survival and water flea reproduction. A survey of the laboratories indicated several differences in protocols for the two freshwater tests. A second round of testing for just the freshwater tests occurred with more standardization of procedures. Comparability of the amphipod test was greatly improved, but the water flea reproduction endpoint remained relatively poor. For both rounds, the most comparable results were achieved on the simulated runoff samples indicating a possible matrix issue with dilution water samples between laboratories.

MP245 Impact of Metropolitan Stormwater Runoff on Fathead Minnows (Pimephales promelas)

B. Westerhoff, St. Cloud State Univ; D. Fairbairn, MN PCA; H.I. Schoenfuss, St. Cloud State Univ / Aquatic Toxicology Laboratory

Aquatic toxicology has focused on the testing of single compounds and easily traced point source pollution, such as that found in mining, agriculture, and pharmaceutical industry. The focus of this study was to identify how a complex mixture of compounds, found in a major metropolitan stormwater system, would affect body condition, feeding efficiency and survival of fathead minnows (Pimephales promelas). Stormwater runoff was collected during snow melt, two spring and one summer rain event from nine locations in St. Paul and Minneapolis, Minnesota. Twenty-one-day static renewal exposures were conducted for the snow melt and first spring rain events using larval fathead minnows, followed by analysis of competitive feeding assay, body length, and predator escape performance. Results from the snow melt fathead minnow exposure indicate differences in feeding efficiency (ANOVA with Holm-Sidak's post-test, p=0.04,) between stormwater collection sites. Spring rain event exposed fathead minnows display differences in mean body length of 13% and 17%, respectively, shorter than control larvae, in minnows exposed to runoff collected from two inflows to stormwater retention ponds (ANOVA with Holm-Sidak's post-test, p=0.0011).The result of the fathead minnow exposures suggest adverse impacts of stormwater exposure on feeding efficiency and body condition and more study should be devoted to this underexplored source of aquatic contaminants.

MP246 Presence of fecal indicator bacteria in sand by distance and depth at a freshwater recreational beach

F.C. Bailey, Middle Tennessee State Univ / Dept of Biology; M.A. Stallard, Middle Tennessee State Univ / Molecular Biosciences; L.K. Jarnagin, J. Jatko, Middle Tennessee State Univ / Biology

Escherichia coli (E. coli) is a fecal indicator bacteria (FIB) the Environmental Protection Agency and other regulatory agencies use as a surrogate to assess potential water quality impairment from fecal pathogens. Typically, E. coli is assessed in water with little emphasis on other environmental matrices, such as sediment or sand, which can serve as secondary habitats for fecal bacteria once they reach aquatic systems from storm water runoff or other sources. The objectives of this study were to investigate the presence of E. coli in sand at depth (0-10, 10-20, and 20-30 cm) and distance from shoreline (0, 3, 6, 9, 12 m) at a freshwater, inland recreational beach. Samples were collected at 25 transect points from dry beach sand (onshore) and wet sand (offshore) and analyzed for E. coli using the IDEXX culture method. The highest concentrations of E. coli (~8,000 cfu/100g sand) were found in the 0-10cm sections and closest to shore. Findings of FIB in inland beach sand could prompt regulators to create criteria for protection of recreators from potential pathogens in beach sand.

MP247 Antibody Responses to Bacterial Pathogens in Loggerhead, Caretta caretta, and Kemp's Ridley, Lepidochelys kempii, Sea Turtles in the S.E. USA

M.L. Rodgers, C.D. Rice, Clemson Univ / Biological Sciences

Sea turtles are subjected to multiple environmental stressors, including, but not limited to, habitat encroachment, thermal stress, environmental contaminants, plastics, and various pathogens. How these stressors interact to impact the health and immunological fitness of sea turtles is not well understood. One obstacle in better understanding sea turtle immune functions and responses to pathogens is the lack of critical reagents (namely antibody reagents) that recognize their immunoglobulins (Igs). Turtle IgY is analogous to IgG in higher vertebrates, and is similar in function to IgY of birds. Importantly, IgY is the main class of Igs responsible for long term immunological memory in reptiles, and can serve as a marker of exposure and magnitude of response to pathogens, and especially responses to specific antigens derived from pathogens. This study focused on two sea turtle species: loggerhead (Caretta caretta) and Kemp's ridley (Lepidochelys kempii). Several methods to purify IgY were employed, but the most successful technique used Protein A/G columns under low salt concentrations. The final purified product consisted of 65 kDa heavy chains, 23 kDa light chains, and a 40 kDa F(ab)2 fragment, which is similar to bird IgY, though this purification technique does not work in chickens. Purified IgY was used to immunize mice for antibody production. Using these antibody reagents, serum samples from 60 loggerheads and 30 Kemp's ridleys were probed by ELISA and western blots for both total and bacteria-specific IgY antibody responses. Of the nine species of marine bacteria investigated as targets for measuring antibody responses, IgY responses were highest against, E. coli, V. parahaemolyticus, M. marinum, E. rhusiopathiae, and S. agalactiae. Loggerhead turtles recognized more protein bands from bacterial lysates than did Kemp's ridley turtles. Some correlations were found between total serum protein levels and serum titers against bacteria, and between straight carapace length and serum titers. Other measurements taken from these individual turtles, including blood packed cell volume, glucose, and total protein, are similar to measurements seen in other wild, healthy turtles of the same species from the Chesapeake Bay. These data offer a baseline of information for future studies that continue to monitor the health of these two species in their dynamic environment.

MP248 Exploring Different Service Loss Estimation Approaches for Assessing Sediment Injury in Natural Resource Damage Assessment

M.W. Kierski, Exponent / Ecological and Biological Services Practice; P.N. Booth, Ramboll Environ / Ecological Sciences; M. Edwards, Exponent / Environmental and Human Health Consulting; J. Ma, Exponent

Natural Resources Damages Assessments (NRDAs) for injury to sediment typically rely on the use of Habitat Equivalency Analysis (HEA) as a means of determining the scope of compensatory mitigation necessary to offset lost services due to a release. HEA, in turn, is a tool for estimating the spatial dimension of service loss over time and expresses service losses and gains in units of service-acres-years (SAYs) defined as the level of ecological services provided by one acre of sediment habitat over a one year period under baseline conditions. Application of HEA involves two fundamental steps: 1) development of quantitative relationships between concentrations of one or more constituents in sediment and the inferred ecological service loss, and 2) use of geographical information systems (GIS) to conduct spatial analysis of sediment chemistry to determine service losses by unit area (SAYs). The outcome of any HEA analysis is highly sensitive to the assumptions inherent in each of these steps. This presentation focuses on Step 1 of the HEA and compares and contrasts a variety of different approaches for estimating service loss relationships using a real-world data set for a former Tar plant where data were collected (e.g., polycyclic aromatic hydrocarbon (PAH) sediment concentrations, sediment toxicity bioassays, and benthic invertebrate community data) to evaluate the potential service loss associated with the benthic invertebrate community. The data requirements needed for each approach are discussed, along with the strengths and weaknesses of the different approaches, and the effect on the results of the HEA.

MP249 Lethal and sub-lethal effects of elevated CO2 concentrations on marine organisms

C. Lee, S. Hong, B. Kwon, J. Lee, Seoul National Univ / School of Earth and Environmental Sciences; J. Lee, J. Ryu, Anyang Univ / Dept of Marine Biotechnology; Y. Park, Korea Inst of Ocean Science and Technology / Ocean Circulation and Climate Research Division; S. Kang, Korea Research Inst of Ships and Ocean Engineering / Offshore CCS Research Unit; J. Khim, Seoul National Univ / School of Earth and Environmental Sciences

Concern about leakage of carbon dioxide (CO_2) from deep-sea storage in geological reservoirs is increasing because of its possible adverse effects on marine organisms locally or at nearby coastal areas both in sediment and water column. In the present study, we examined how elevated CO_2 affects various intertidal epibenthic (benthic copepod), intertidal endobenthic (Manila clam and Venus clam), sub-tidal benthic (brittle starfish), and free-living (marine medaka) organisms in areas expected to be impacted by leakage. Acute lethal and sub-lethal effects were detected in the adult stage of all test organisms exposed to varying concentrations of CO_2, due to the associated decline in pH (8.3 to 5.2) during 96-h exposure. However, intertidal organisms (such as benthic copepods and clams) showed remarkable resistance to elevated CO_2, with the venus clam being the most tolerant (LpH50 = 5.45). Subtidal species (such as brittle starfish [LpH50 = 6.16] and marine medaka [LpH50 = 5.91]) were more sensitive to elevated CO_2 compared to intertidal species, possibly because they have fewer defensive capabilities. Of note, the exposure duration might regulate the degree of acute sub-lethal effects, as evidenced by the venus clam, which showed a time-dependent effect to elevated CO_2. Finally, Copper was chosen as a model toxic element to find out the synergistic or antagonistic effects between ocean acidification and metal pollution. Combination of CO_2 and Cu exposure enhance the adverse effects to organisms, generally supporting a synergistic effect scenario. Overall, the significant variation in the degree to which CO_2 adversely affected organisms (viz., working range and strength) was clearly observed, supporting the general concept of species-dependent effects of elevated CO_2 Key words: Carbon dioxide, CO_2 Capture and Storage (CCS), pH, Intertidal organism, Subtidal organism.

MP250 Does parent exposure to municipal wastewater effluent exposure influence progeny health or response to endocrine disrupting compounds?

M. Fuzzen, Univ of Waterloo / Biology; H. Dhiyebi, Univ of Waterloo; L. Bragg, M.R. Servos, Univ of Waterloo / Dept of Biology

Over 30 fish species have been reported to show an intersex condition (ova-testes) after exposure to municipal wastewater effluent (MWWE), suggesting that the feminization of male fish is a widespread phenomenon. Previous studies in the Grand River watershed have shown that male rainbow darter (Etheostoma caeruleum) collected near the Kitchener MWWE outfall are feminized. While it is well recognized that MWWE has direct impacts on the sexual development and performance of the F0 generation, little is known about the consequences of MWWE exposure on subsequent generations of fish. The purpose of this study was to determine whether parent exposure history influenced the health, sexual development or response to endocrine disrupting compounds. Progeny of rainbow darter collected from rural (reference) and MWWE exposed sites were exposed to either de-chlorinated tap water (control) or 10% MWWE from 21 to 100 days post hatch (dph). Endpoints assessed included survival, growth, sexual development, and liver transcriptome. While survival from 21 to 100 dph was not effect by either parentage or exposure group, condition was found to be impacted by both variables. Parent exposure resulted in progeny with reduced condition. Similarly, exposed progeny of parents from the R site had lower condition than non-exposed progeny. Exposure of progeny to MWWE resulted in an increase in intersex incidence. Parental exposure experience increased the likelihood of developing intersex condition in both exposed, and non-exposed groups of progeny. When transcriptomes were compare using a principal component analysis, it was found that progeny of parents that had been exposed, but reared in clean water grouped with MWWE exposed progeny (of both parent groups). These findings suggest that there are transgenerational effects of MWWE exposure.

MP251 The Utilization of Copper Water Effect Ratio Studies for Industrial and Municipal Discharges: A Review of Case Studies

M.K. Chanov, EA Engineering, Science and Technology / Ecotoxicology; W.L. McCulloch, EA Engineering, Science, and Technology, Inc., PBC / Ecotoxicology; M. Jirsa, M. Durbano, EA Engineering, Science, and Technology, Inc., PBC

The development of site-specific water quality criteria for individual metals through the performance of water effect ratio (WER) testing has successfully enabled permittees to modify National Pollutant Discharge Elimination System (NPDES) discharge permit single metal permit limits. This testing concept is based on the U.S. Environmental Protection Agency (EPA's) recognition that the metals can be substantially less toxic in an effluent/receiving water matrix than in clean laboratory water, on which the single metal permit limits are often based. Acute toxicity testing conducted concurrently in site water and laboratory water with the toxicant of concern is used to generate a ratio of toxicity from the test results. One metal in particular that has commonly been evaluated through these studies is copper. The toxicity of copper is dependent on site-specific factors such as pH, hardness, total suspended solids and dissolved organic carbon. Copper WER studies conducted by EA have been utilized by industrial and municipal dischargers to obtain site specific water quality criteria. These studies have encompassed a wide range of hardness values (12-200 mg/L) and have yielded water effect ratios ranging from 2.0 to >56.0. This presentation reviews the data and factors affecting the side by side testing results.

MP252 Sewer Effluent in Our Streams : Can aquatic communities survive?

B. Lognion, Philander Smith College; L.M. Jackson, Philander Smith College / Biology

Domestic sewage effluents represent one of the most common causes of degradation of water quality in stream ecosystems. The effects are especially relevant in ecosystems where water is scarce. There is a great need for considering biotic integrity in assessments of aquatic ecosystems, including taxa composition, diversity, and functional organization of living organisms. Using this approach will provide a broader understanding of the processes going on in altered streams. However, it is not clear what patterns should be expected below sewer treatment plant (STP) effluents. Previous studies reported changes in taxa composition that implied a decrease in taxa richness and an increase in dominance because sensitive taxa were eliminated and resistant taxa were enhanced. Several studies found a decrease in total density of macroinvertebrates with increasing nutrient concentrations, while others reported no changes. Few studies considered functional organization in their assessments and their results are not consistent. Even less is known about the effects of point sources on standing crops of benthic organic matter (BOM) although it is a source of food and influences structure and function of streams. The objectives of this study are to examine the response of the macroinvertebrate community to a STP input in a rural and an urban stream during summer when the dilution capacity of streams is lowest and discharge of point sources has higher adverse effects. Effects of the point source on the structure and functional organization of the benthic macroinvertebrate community will be examined. Also, determination if the self-purifying capacity of the stream results in differences between the community located few meters below the STP input and the community located 500 m downstream. Results will be presented at the meeting.

MP253 Seasonal Variation of Oxidative Stress and Histopathological Alterations in Carassius auratus Affected by Effluent from a Sewage Treatment Plant

H. IM, P. Samanta, J. Jung, Korea Univ / Environmental Science and Ecological Engineering

The aim of this study was to identify the influence of effluent discharge from a sewage treatment plant by evaluating oxidative stress and histopathological alterations in crucian carp Carassius auratus collected from upstream, mixing zone and downstream of the effluent discharging point in summer and winter. Sampling was conducted in July 2015 and February 2016. Lipid peroxidation (LPO), catalase (CAT) activity, glutathione S-transferases (GST) activity in gills, liver and kidneys of C. auratus were analyzed. In both seasons, CAT activity of C. auratus collected from the mixing zone and downstream site was significantly higher than that of fish from the upstream site. Histological alterations were also observed in C. auratus and the changes were analyzed semi-quantitatively using mean assessment value (MAV) and degree of tissue change (DTC). The results indicate that the order of magnitude of changes were liver > kidney > gills in both seasons, and the values were higher in samples collected in winter than those collected in summer. In addition, the highest DTC was found in C. auratus collected from the mixing zone followed by downstream site. These findings indicate that fish collected from mixing zone are most affected by effluent discharge and the influence shows seasonal variation.

MP255 Hepatic transcriptome in rainbow darter (Etheostoma caeruleum) exposed to municipal wastewater over time in the central Grand River, Ontario, Canada

P. Marjan, Univ of Waterloo / Biology; M.R. Servos, Univ of Waterloo / Dept of Biology; D. MacLatchy, Wilfrid Laurier Univ / Biology; C.J. Martyniuk, Univ of Florida / Physiological Sciences

There is considerable evidence that contaminants of emerging concern elicit sub-lethal effects at the molecular level in fish residing in urbanized areas. In the present study, a rainbow darter (Etheostoma caeruleum) (RBD) microarray was used to assess hepatic gene expression in fish collected from the Grand River (Ontario, Canada) that had been exposed downstream of the Waterloo and Kitchener municipal wastewater treatment plants (MWWTPs) over four fall seasons from 2011 to 2014. The first objective aimed to determine if transcriptomic responses in male RBDs collected downstream of the two MWWTPs would differ significantly from transcriptomic responses in individuals from a reference site. The second objective was to determine if system upgrades of the Kitchener MWWTP in 2012 resulted in alterations of the RBDs transcriptome indicative of diminished contaminant exposure and system recovery. Temporal responses of differently expressed probes (DEPs) in exposed RBDs differed from those responses in non-exposed RBDs. The magnitude of response in the liver of RBDs exposed downstream of the Waterloo MWWTP was significant in range, and responses varied from 767 to 3,867 DEPs. The range of these responses in RBDs exposed to the Kitchener MWWTP was constricted to 904 to 1,223 DEPs. Gene Set Enrichment Analysis in RBDs from both sites revealed a gradual decrease in the number of impacted gene ontologies over time. Gene network analysis also showed that molecular responses grouped into diverse themes and this was dependent upon the year. There was a noticeable shift in the types of cell pathways affected over time, and the dominant cell pathways affected in the liver previous to upgrades were related to modifications of genetic and cell division (e.g. DNA metabolism, DNA replication checkpoint, genetic stability, genomic instability, autolysis, cell aging) whereas, following the upgrades, cell pathways related to the immune system, reproduction and biochemical processes were preferentially affected. These complex transcriptomic responses in exposed RBDs over time suggest that seasonal factors may play a greater role than the effluent in determining molecular responses. However, it is pointed out that responses are likely the result of both anthropogenic sources and environmental factors, and statistical methods are needed to distinguish the relative contribution of each.

MP256 Chronic Exposure of the Least Killifish (Heterandria formosa) and Mosquitofish (Gambusia affinis) to Treated Sewer Effluent: Can they withstand?

D.T. Bryant, Philander Smith College; L.M. Jackson, Philander Smith College / Biology

The presence of sewer treatment plant (STP) effluents in the aquatic environment has gained major worldwide attention because of the possibility that these effluents may have negative effects the reproductive health of wildlife populations and humans. Concern has been raised that exposure to these effluents can disrupt the endocrine functions of fish exposed to effluent-receiving waters. There is a need for a better understanding of the relative importance of endocrine disruption in relation to sewer effluent toxicity. To investigate impacts of STP effluents on an aquatic environment, a full life cycle in vivo study will be conducted to examine the potential effects of STP effluents in the least killifish (Heterandria formosa) and western mosquitofish (Gambusia affinis). We will test the effects of environmentally relevant concentrations of treated water effluent. Newborn fishes will be exposed to 0, 10, 25, 50, or 75% effluent (with dechlorinated tap water as diluent). Final effluent will be passed through a 100-µm filter before it is supplied to the tanks holding the fish. Solutions will be renewed every 48 hours in a static renewal system. Effects of STP effluent on length, weight, sex ratio, survival rate, time to sexual maturity, vitellogenin induction, population abundance, population dynamics, and incidences of intersex, feminization of males, and masculinization of females in the developing fishes will be examined. Results will be analyzed and presented at the meeting.

MP257 Assessing Load Reduction and Biological Recovery After Wastewater Treatment Upgrades in an Effluent-Dominated Aquatic Ecosystem

H.I. Schoenfuss, St. Cloud State Univ / Aquatic Toxicology Laboratory; D. Martinovic-Weigelt, Univ of St. Thomas; P. Edmiston, The College of Wooster / Chemistry; T. Minarik, MWRDGC / Associate Aquatic Biologist

Many urban aquatic systems are becoming effluent dominated, resulting in the presence of contaminants of emerging concern and subsequent adverse effects on aquatic wildlife. Despite these dramatic alterations, effluent dominated urban systems support many ecosystem services and are used by the nearby human population for recreation. The Metropolitan Water Reclamation District of Greater Chicago is upgrading two billion liter/day wastewater treatment plants to disinfection (UV; chlorination/de-chlorination). The receiving aquatic ecosystem adjacent to these two wastewater treatment plants has been the focus of intense biological and chemical study for the past seven years and provides a unique opportunity to assess two divergent treatment technologies (UV disinfection vs. chlorination/de-chlorination) and to examine how adverse biological effects in exposed fish may be mitigated through effluent disinfection. We exposed male fathead minnows in on-site flow-through exposure systems four times prior to the treatment upgrades and twice since to examine these questions. In addition, we conducted extensive analytical chemistry on effluent samples and employed in vitro assays to examine overall biological activity of effluents prior and following disinfection treatment.

MP258 Biological Effects of Septic Seepage on the Larval Fathead Minnow, Pimephales promelas

L. Warren, St Cloud State / Aquatic Toxicology Laboratory; H.I. Schoenfuss, St. Cloud State Univ / Aquatic Toxicology Laboratory; M. Guyader, C.P. Higgins, Colorado School of Mines / Dept of Civil Environmental Engineering; R. Kiesling, USGS

The potential of On-site Wastewater Treatment Systems (OWTSs) being a non-point source of contaminants into lake systems is a growing concern. Since many lakes are down gradient of OWTSs, the septic seepage easily contacts surrounding groundwater and enters the shallow waters though the hydrological process. Five study lakes were established that included two septic-influenced sites and two reference sites each. To explore the effects of these contaminants on the larval fathead minnow, Pimephales promelas, a 21-day static renewal exposure was completed using pore water collected from septic influenced and reference sites in each study lake. Following the 21-day exposures, larvae underwent behavioral testing that included the analysis of predator avoidance as well as feeding performance. Results indicate declined survival and latency in the septic and positive control treatments. Concurrent pore water analysis will be used to build synthetic mixtures of different septic systems for future laboratory exposures. Exposures like these will help explore the effects of OWTSs on lake ecosystems.

MP259 Genotoxicity and histological damage by anionic surfactant in Zebrafish

C.G. Penagos, Cinvestav-IPN Unidad Merida; A. Zamora Briseño, I. Pérez García, R. Mena Loria, M. Améndola Pimenta, R. Rodríguez Canul, Center for Research and Advanced Studies of the National Polytechnic Inst, Mérida, Yucatán

The anionic surfactant dioctyl sodium sulfosuccinate (DOSS) is one of the main active compounds of some oil dispersants, it is also found in laxatives, cosmetics, and detergents. The toxic effects of this surfactant is still under investigation. The exposition to genotoxic compounds can promote the formation of micronucleus (MN) in erythrocytes, a malformation related with genetic damage and can also lead to histological alterations in different tissues. We evaluate the effect of DOSS exposure on adult Zebrafish analyzing its genotoxic potential using a micronucleus test besides histological alterations assessment by Giemsa and Hematoxylin-Eosin staining respectively. A static bioassay was performed for 96 h in glass aquariums containing different concentrations of DOSS: 0, 10, 50 and 80 mg/L (two replicates/treatment). Twenty adult zebrafish were randomly allocated in each aquarium and four fish from each treatment were sampled at random every 24 h. We collected peripheral blood and main organs. Our results suggest a negative effect of DOSS exposure on Zebrafish, with micronucleous formation in erythrocytes detected at 50 mg/L of DOSS at 72 h, and also we found hypertrophy and hyperplasia in gill. The biological implication of this finding is relevant because DOSS is classified as GRASS.

MP260 Effects of perfluorinated compounds on mitochondrial functions in zebrafish liver cells

J. Lee, Seoul National Univ; K. Choi, Seoul National Univ / School of Public Health; D. Jung, Seoul National School / Inst of Health and Environment

Perfluoroalkyl acids (PFAAs) have been widely used in various industrial and consumer applications as synthetic surfactants. Due to their persistence in the environment and biota, it is necessary to identify the adverse effects of these compounds. Many studies have reported toxicological effects of PFAAs on liver, nervous and endocrine systems, and fetal development. Damages in mitochondria and mitochondria-mediated oxidative stress are suspected to cause this wide range of toxicological effects by disrupting cell homeostasis. In this study, we exposed zebrafish liver cells (ZFLs) to perfluorooctane sulfonate (PFOS), perfluorooctanoic acid (PFOA), and perflurononanoic acid (PFNA) to investigate potential mechanism of adverse effects on mitochondrial function. ZFLs were exposed tofour different concentrations (0.05, 0.5, 5, and 50 μM) of PFOS, PFOA, and PFNA. Following 72 h exposures, transcription of genes that make up the electron transport chain (cytb, atp5a1, coxI, and coxIV) and respond to oxidative stress (p53, gstπ, hmox1, and sod2) were analyzed using quantitative real-time PCR. There were no changes in the gene expressions of ZFLs to PFOS or PFOA. However, PFNA-exposed groups showed altered gene expressions in all genes tested except gstπ. Mitochondrial genes cytb and coxI, and oxidative stress response genes p53 and hmox1 were significantly upregulated at 5 or 50 μM ($p< 0.01$). Also, upregulation of sod2 at 50 μM ($p< 0.05$) and of coxIV and atp5a1 at 5 or 50 μM ($p< 0.05$ and $p< 0.01$, respectively) were observed. These initial results draw attention to potential effects of PFNA on various mitochondrial functions. Assessment of damages in the mitochondria membrane and mitochondrial DNA are under way. This work was supported by NRF 900-20150033 (Republic of Korea).

MP261 Bioavailability and Bioconcentration Potential of Perfluoroalkyl-phosphinic and -phosphonic Acids in Zebrafish (Danio rerio)

F. Chen, Z. Gong, National Univ of Singapore; B.C. Kelly, Barry C Kelly / Civil Environmental Engineering

Currently, information regarding bioavailability and bioconcentration potential of perfluoroalkyl phosphinic acids (PFPiAs) in aquatic organisms does not exist. The main objective of the present study was to assess uptake and elimination kinetics of PFPiAs in zebrafish (Danio rerio) following aqueous exposure. The results showed that PFPiA exposure can result in very high steady-state bioconentration factors (BCF_{ss}), compared to perfluorocarboxylates and perfluorosulfonates.C6/C10 PFPiA exhibited the highest BCF_{ss}, ranging between 10^7 and 10^{10}, orders of magnitude higher than those for long-chain perfluorocarboxylates. Strong positive relationships were observed between BCF_{ss} versus the membrane-water distribution coefficient (D_{mw}) and the protein-water partition coefficient (K_{pw}) of the studied perfluoroalkyl substances. However, BCF_{ss} exhibited a substantial drop for the very hydrophobic PFPiAs (C8/C10 and C6/C12 PFPiAs). The reduced BCF_{ss} of these long-chain PFPiAs (perfluoroalkyl chain length = 18;$D_{mw} = 10^9$) is likely the result of reduced bioavailability due to interaction with solute molecules/organic matter present in the water phase and/or reduced gill membrane permeability. While PFPiAs can be metabolized to perfluoroalkyl phosphonic acids, the metabolic transformation rate seems insufficient to counteract the high degree of uptake across gill membranes. These findings help to better understand exposure pathways and bioaccumulation behavior of these important perfluorinated acids in aquatic systems.

MP262 Effects of Exposure to Detergents on Freshwater Organisms

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; J. Morales Torres, Universidad Autonoma Metropolitana Iztapalapa / CIENCIAS DE LA SALUD

The toxicity of detergents on aquatic organisms has been evaluated since the 60s, but has only been determined the toxic effects of surfactants and there are few studies of the effects of commercial products. Because in our country are scarce studies with detergents, and wastewater from Mexico city have a considerable contribution of of these products, in this study an evaluation of the toxicity of 2 surfactants (alkyl lauryl sulfonate (LAS), lauryl dimethil (hidroxyetil) ammonium chloride) and 4 trademarks of detergent (Ariel, Foca, Roma and Salvo) was carried out in microalgae (Pseudokirchneriella subcapitata and Monoraphidium sp.), macrophytes (Lemna gibba and Egeria densa), cladocerans (Daphnia magna, D. exilis, Moina macrocopa and Simocephalus mixtus), ostracods (Cypris sp.) and fish (Danio rerio). Toxicity bioassays were made with duration of 48 hours for tests with cladocerans and ostracods, and 96 hours for tests with microalgae, macrophytes and fish. The organisms were exposed to five concentrations of each of the detergents in triplicate (0.1, 1.0, 10, 50 and 100 and/or 100, 200, 400, 800 and 1000 mg L^{-1}) plus one control, without toxic. Each test at least three times repeated. With the data obtained lethal concentration 50 (LC_{50}) was determined by probit method (Probit-EPA, version 1.5). and a comparison between the LC_{50} and confidence intervals was performed to evaluate the statistical significance of the differences between the different treatments with detergents. In toxicity tests were obtained significant differences in the response of species to detergents, P. subcapitata, Monoraphidium sp, D. exilis and Cypris sp. were the most sensitive species and Lemna gibba and Egeria densa macrophytes were less sensitive to these products. The toxicity of detergents containing enzymes was superior compared with detergents not have enzymes in its formulation. Due to the wastewater treatment is limited and often sewage with high concentrations of detergents are discharged directly to aquatic systems, it is important to know the potentially adverse effects of these compounds to propose appropriate measures to reduce the risk which involves their presence in aquatic environments.

MP263 Screening ecological impacts of environmental surface waters using cell-based metabolomics

Q. Teng, USEPA / EMMD / National Exposure Research Laboratory; D. Ekman, H. Zhen, USEPA / National Exposure Research Laboratory; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory; J.E. Cavallin, USEPA / USEPA Mid-Continent Ecology Division; J. Davis, USEPA / National Exposure Research Laboratory; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; T. Collette, USEPA / National Exposure Research Laboratory

Anthropogenic chemicals are routinely detected in aquatic ecosystems downstream from wastewater treatment plants (WWTPs), industrial and agricultural operations, and numerous other sources. Various studies have shown that exposure to such complex chemical mixtures can produce adverse health effects in resident organisms. Metabolomics has the ability to identify sensitive biological impacts produced by such exposures and provide information related to the primary mode of action. To increase throughput, a cell-based metabolomics approach has been developed to identify biochemical indicators of chemical exposures for rapidly assessing environmental impacts to support regulators. In this study, we applied cell-based metabolomics to detect biological impacts of environmental surface waters collected in the St. Louis Bay area, one of 43 Great Lakes areas of concern (AOCs) designated by the U.S. Environmental Protection Agency and Environment Canada. The goal of this study was to evaluate the utility of cell-based metabolomics for rapid and low cost monitoring of biological activity of surface waters receiving treated effluent from a wastewater treatment plant (WWTP) at this AOC. To do so, we first developed a procedure for exposing zebrafish liver (ZFL) cells to media prepared with surface water samples. By analyzing the metabolite profiles of ZFL cells using nuclear magnetic resonance (NMR) spectroscopy and GC/MS, we characterized cellular responses of ZFL cells exposed to the surface waters and assessed the biological impacts of WWTP effluents at this site.

MP264 Metabolic Profiles of Intersex Largemouth Bass: Toward Development of a Non-lethal Biomarker

M.L. Urich, Univ of Georgia; R. Bringolf, Univ of Georgia / Warnell School of Forestry and Natural Resources

Intersex fish have been increasingly reported in rivers and impoundments across the US and around the world. Factors associated with development of testicular oocytes in phenotypic males are most commonly linked to endocrine disruption via exposure to environmental estrogens. Reduced sperm fertility and motility have been reported in intersex fish so the potential exists for population level effects, yet very little is known about alterations of physiological pathways in intersex fish. Current methods to positively identify intersex fish are lethal, requiring sacrifice of large numbers of wild fish; however, recent advances in technology allow for the simultaneous examination of thousands of endogenous metabolites in body tissues, including some that can be collected non-lethally (e.g. blood, mucus). Identification of unique metabolic profiles in intersex fish may aid in identification of key cellular pathways and lead to development of biomarkers in intersex fish. We investigated metabolic profiles of 39 phenotypic male largemouth bass with testicular oocyte counts ranging from 0 – 164 (per longitudinal histological section) from an impoundment in the Piedmont region of Georgia. The relative abundance of several metabolites from the liver, gonad, mucus, and blood plasma was significantly ($p< 0.05$) correlated with the number of oocytes detected in testicular tissues, lending insight to the mechanisms of intersex induction in these fish, and showing promise for the development of a non-lethal biomarker approach. Development of non-lethal biomarkers would greatly enhance our ability to sample larger numbers of wild fish and allow for repeated sampling of individuals, increasing our understanding of biochemical mechanisms, spatial and temporal trends, causative factors and adverse effects of the condition on an individual and population level.

MP265 Biomarkers of exposure to contaminants in three catfishes of Colombia

J.F. Gonzalez, Universidad Nacional de Colombia / Animal Health Toxicology; M. Landines, Universidad Nacional de Colombia; J. Borbón, Unversidad Nacional de Colombia; A. Bohórquez, M. Correal, C. Sánchez, N. García, L. Rodríguez, Universidad Nacional de Colombia

Catfishes are one of the most abundant fish groups in Colombia accounting for 36% of them. However, 44% of the vulnerable and threatened fish species of the country belongs to the order Siluriformes. To evaluate biomarkers of exposure to contaminants, a total of 112 specimens of three catfish species were sampled in three different geographical areas of the country during the rainy and dry seasons of 2013. Fish species included capitán de la sabana (Eremophilus mutisii) from the Bogotá River, capaz (Pimelodus grosskopfii) from Huila and striped bagre (Pseudoplatystoma orinocoense) from the East Plains. Heparinized blood samples served to quantify lead and micronuclei assay whereas plasma was used to measure cholinesterase (AChE and BChE) activities. Liver was frozen in liquid nitrogen after necropsy and used to obtain S-9 fraction for glutathion-s-transferase (GST) and ethoxyresorufin- ortho-deethylation (EROD). Blood lead (interval in µg/dL) was found in 49% of the sampled fish: capitán (n=15), 3.7 – 7.8, 14 out of 15, capaz (n=25), 3.6 – 9.5, 7 out of 25; and striped bagre (n=9), 3.6 – 8.2, 4 out of 9. No fish had micronuclei above the baseline normal values reported. As for AChE and BChE, capitán displayed a significantly lower activity as compared to capaz and striped bagre (anova, $p < 0.05$). Hepatic GST (µmols/mg protein/min) of the three species had significantly different activities among each other: capaz (n=50), 1036 ± 163 [a]; striped bagre (n=30), 736 ± 138 [b]; and capitán (n=23), 422 ± 155 [c] (anova, $p < 0.05$). No significant changes were found between rainy and dry seasons. As for EROD (pmols resorufin/mg protein/min), fish sampled during the rainy season had almost 2-fold EROD as compared to those sampled during the dry season: capaz 2.5 ± 0.4 (rainy), 1.1 ± 0.3 (dry); capitán 0.8 ± 0.18 (rainy), 0.4 ± 0.07 (dry); and striped bagre 1.3 ± 0.3 (rainy), 0.8 ± 0.2 (dry). Along with the biomarkers, water analysis revealed that Total Petroleum Hydrocarbons (TPH) had 5 ppm diesel equivalents in the Bogotá River and 2-5 ppm in the East Plains rivers region, which suggests likely causes for high EROD. In previous studies, organophosphates insecticides were detected in the Bogotá River which could clarify the low AChE /BChE activity in the capitán. The areas studied in this investigation have impacts from coal mining, crude oil extraction and pesticides used which could explain some of the findings of the present work.

MP266 Biomarkers in Gambusia yucatana muscle for the evaluation of PAHs in "cenotes" (sinkholes) of Yucatan, Mexico

A. Arroyo, ICMyL, UNAM / Faculty of Chemistry; G. RODRIGUEZ, UNAM / Facultad de Química; E. Norena-Barroso, Universidad Nacional Autonoma de Mexico / Unidad de Química Sisal

In Yucatan's peninsula, groundwater is the main water supply for human, agricultural and industrial activities. Ground characteristics make recovery and treatment of wastewater very expensive, and it is returned to the aquifer without any treatment. This situation has contributed to an increase of pollutants reports in Yucatan's peninsula aquifer. Polyciclic Aromatic Hydrocarbons (PAHs) are legacy pollutants that are persistent and potentially carcinogenic. This study aimed to evaluate biomarkers in the muscle of mosquitofish (Gambusia yucatana) and its relationship with the presence of PAHs in water and sediment from seven "cenotes" (sinkholes). CYP1A expression, Glutathione-S-transferase (GST) Acetylcholinesterase (AChE), total glutathione (GSH) and lipid peroxides (LPO) were measured in muscle. PAHs in water and sediment were quantified by solid-phase extraction (SPE) and gas chromatography-mass spectrometry (GC-MS). Results indicated seasonal and spatial differences in PAHs concentrations and biomarkers response. Higher concentrations of total PAHs were found in sediments during the dry season and in water during the rainy season. During the dry season, AChE was significantly inhibited in all sampling sites respect to control. Total GSH was higher than control in most of the sampled sites during both seasons. LPO was significantly different to control in only two sites during the rainy season. GST was different to control in few sites, especially during the rainy season.CYP1A was over expressed in many of the sampling sites, especially during the dry season. There was not a clear relationship between the concentration of total PAHs in water and sediment and the response of biomarkers. This could be explained because of the presence of many other pollutants that may also be contributing to the response. This study was financed by grant UNAM-DGAPA-PAPIIT #IA202416 and by the Faculty of Chemistry PAIP program.

MP267 Biomarker responses and organochlorine pesticide accumulation in Müller's clawed frog (Xenopus muelleri) from the Phongolo floodplain, South Africa

N.J. Wolmarans, North-West Univ / School for Biological Sciences; V. Wepener, L. Du Preez, North-West Univ / Unit for Environmental Sciences and Management; M. Ishizuka, Y. Ikenaka, Hokkaido Univ / Graduate School of Veterinary Medicine; N. Smit, North West Univ / Environmental Sciences and Management

The Phongolo River floodplain hosts to the highest biodiversity of all of South Africa's floodplains and is situated in a malaria risk area where vector control is applied through indoor residual spraying (IRS). Persistent organic pollutants (POPs) like organochlorine pesticides (OCPs) are prone to accumulation in aquatic environments, where their stability increases. Aquatic organisms thus have a greater risk of continuous exposure. Amphibians are considered good indicators of ecosystem health. Xenopus muelleri is a fully aquatic amphibian species with highly permeable skin, making this species a perfect fit as indicator for OCPs exposure in the floodplain ecosystem. Biomarker responses are used as indicators of sub-lethal (biochemical) stress and manifest much earlier than conventionally used observable effects such as behavioural- or morphological changes. An array of biomarker response assays were analysed in liver and muscle samples of frogs collected from four surveys over two consecutive high – and low flow seasons. Chemical analysis for 22 different OCPs was carried out on the remaining whole frogs. Results indicated γ-hexachlorocyclohexane (γ-HCH – lindane) and dichlorodiphenyltrichloroethane (DDT – and its derivatives) as the main contributing pesticides. The maximum total OCP concentration in a frog measured at 21,399.0 ng/g lipid. Oxidative stress responses, involving various antioxidant enzyme activity and oxidative damage assays, were observed to have correlations with OCP accumulation along with similar tendencies in acetylcholinesterase (AChE) and Cytochrome p450 (CYP450) exposure biomarkers. Changes in the cellular energy allocation (CEA) of the frogs also corresponded to OCP bioaccumulation. A significant increase in OCP concentrations was measured from 2013 to 2014 regardless of river flow fluctuations. Corresponding responses in oxidative stress and CEA were observed. These results indicated that amphibians accumulated OCPs from the aquatic environment and that biomarker responses corresponded to the presence of these contaminants in their tissue. Further investigation into these response correlations could have a significant impact on the tissue threshold levels for OCPs used in regulatory guidelines.

MP268 Biomarker and Fluorescence Induction-Relaxation Responses of Cultured Corals and Coral Larvae to Bunker and Diesel Oil, Copper and Temperature Stress

P. Caldwell, Florida A&M Univ; E. Casley, C. Jagoe, E. Johnson, Florida A&M Univ / School of the Environment; A.H. Ringwood, UNC-Charlotte / Dept of Biology; E. Provance, Discovery Place; F. Kouzminov, Rutgers Univ; M. Gorbunov, Rutgers Univ / Inst of Marine and Coastal Sciences; D.A. Apeti, NOAA / National Centers for Coastal Ocean Science Center for Coastal Monitoring and Assessment; R. Warner, National Centers for Coastal Ocean Science NOAA

The impacts of stressors such as pollution and climate changes on coral reefs is a global concern, and sensitive and non-destructive methods are needed to assess health of coral reef systems and symbiotic zooxanthellae. This study compared indices of coral stress as measured biochemical methods to Fluorescence Induction and Relaxation (FIRe) measurements, a tool to assess photosystem responses to stressors in the symbiotic zooxanthellae. In Phase I of this study, aquarium cultured corals from three species Acropora divaricata, Montipora capricornis and Caulastrea furcata wereexposed to Cu, pyrene or elevated temperature (24-28C) for 72 hours. FIRe measurements were compared to measures of oxidative stress, lipid peroxidation and glutathione concentrations. In a later study, larval bundles of Montipora capitata during spawning events at a reference site (Hawaii Institute of Marine Biology) and a moderately polluted site (Pearl Harbor Hawaii). The larvae bundles were exposed to concentrations of bunker C oil, marine diesel fuel for 10 hours. Following FIRe measurements, the larvae were analyzed for lipid peroxidation (MDA), glutathione (GSH), glutathione s-transferase (GST), superoxide dismutase (SOD) and ethoxyresorufin o-deethylase (EROD). FIRe proved more sensitive to some stressors than biochemical markers; at high levels of stress results were similar for both techniques.

MP269 Recovery and remaining environmental effects in receiving waters of Swedish pulp and paper mills

M. Karlsson, IVL Swedish Environmental Research Inst; O. Grahn, NordMiljö; Å. Larsson, Univ of Gothenburg / Dept of Biological and Environmental Sciences; M. Malmaeus, IVL Swedish Environmental Research Inst; H. Norrström, ÅF; T. Viktor, IVL Swedish Environmental Research Inst; O. Sandström, SKUTAB

This study, reviews, field studies and research conducted in Sweden during the last 50 years to determine the environmental impact of the pulp and paper industry on aquatic ecosystems. A dozen mills with various process concepts and geographical locations were chosen for in-depth studies of effluent characteristics and the environmental response to changes in effluent load over time. The effluents contain compounds capable to induce fertilising effects, as well as toxic substances causing exposure and health effects in fish. Before actions against water pollution were introduced in the late 1960s large oxygen depleted zones in the receiving waters were common due to high content of organic matter in the effluents and to substantial fibre loss. Organic mercury compounds were widely used as pesticides in the mill operations. Dioxins unintentionally formed when elemental chlorine was used as the main bleaching agent. A number of mitigating actions, such as the shift from sulphite to kraft pulp production, improved technical standard within the mills including modern bleaching techniques, black liquor recovery and effluent treatment have been vital to the recovery process. A substantially decreased load of organic matter and nutrients have led to improved water quality in terms of higher oxygen concentrations, increased Secchi depth and reduced phytoplankton production followed by a slower, but yet significant re-establishment of macrophyte, zoo benthos, and fish communities. In addition, strong reduction of various toxic substances in the effluents has resulted in a good recovery of the fish health status in the receiving waters and in decreasing levels of such substances in sediments and non-migratory fish species. However, remaining, but weaker, disturbances of fish health, e.g., delayed sexual maturity and deviations in physiological biomarkers, are still observed in some areas. As the effects of this kind are observed also in areas where mill operation has closed, historical sediment contamination may be a probable contributing factor. Another factor of importance is the morphometrical characteristics of the receiving areas. Areas with fast water turnover and bottom dynamic conditions unfavourable for sediment deposition have generally recovered faster. To conclude, the study shows that the ecosystem resilience and capability to recover from pollution has been strong, although, in some cases, the mechanisms behind remaining ecotoxicological effects are not fully explained.

MP270 PFOS Impact on Zebrafish (Danio rerio) Cardiac Development Through Gene Expression and Morphometrics

G. Moreno, K. Annunziato, Rutgers Univ School of Environmental and Biological Sciences

Perfluoroalkylated substances (PFAS) are fully fluorinated carbon chains of different lengths with a charged functional group attached, such as carboxylic acid or sulfonic acid. PFAS are frequently found in commercial and industrial products for the purpose of resisting stains, oils, soil, water, and fire-proofing. PFAS have been widely used, from industry to household products. In previous studies from our lab significant effects on pericardial sac size were observed at doses of perfluorooctane sulfonate (PFOS) ranging from 0.02- 2 µM. In the current study we sought to explore the morphometric effects at lower doses (0.0001 µM, 0.001 µM, 0.01 µM, 0.1 µM, 1 µM). The 0.0001 µM group for morphometrics showed statistically significant difference in pericardial sac size as well as total body length. The 0.001µM group showed statistically significant difference in total body length. Zebrafish were also exposed to 2 µM PFOS for 120 hpf and through a specific extraction protocol, the larval hearts were extracted and tested through gene expression. A significant increase in gene expression was observed in, homebox protein (nkx2.5) and ventricular myosin heavy chain (vmhc) following exposure.

MP271 Effects of pyrene, 2-methylnaphthalene, and phenanthrene of early life stages of three aquaculture fishes in Korea

s. moon, J. Lee, NeoEnBiz Co

Marine oil spill accidents give a variety of adverse influences on aquaculture organisms for a long time. Polycyclic aromatic hydrocarbons (PAHs), one of the major crude oil constituents, have been reported to induce developmental inhibition, morphological deformity, histopathological effects and genetic damage on fishes. In this study, we evaluated the impact of the PAHs on early life stages of 3 aquaculture fishes (red sea-bream, Pagrus major, rock bream, Oplegnathus fasciatus, and olive flounder, Paralichthys olivaceus) using pyrene, 2-methylnaphthalene, and phenanthrene. Embryonic development and larval morphology were investigated for each species. The median effect concentration (EC50) was not estimated for pyrene, and phenanthrene for all test species. The EC50s for 2-methylnaphthalene of Pagrus major, Oplegnathus fasciatus, and Paralichthys olivaceus were 12.8, 10.9, and 18.0 µmol/L, respectively. The no observed effect concentrations (NOECs) for pyrene of Pagrus major, Oplegnathus fasciatus and Paralichthys olivaceus were 99, 99, 0.013 µmol/L, respectively. The NOECs for 2-methylnaphthalene of Pagrus major, Oplegnathus fasciatus and Paralichthys olivaceus were 5.5, 5.5, and 3.5 µmol/L, respectively. The NOECs for phenanthrene of Pagrus major, Oplegnathus fasciatus, and Paralichthys olivaceus were 7.0, 224, 0.96 µmol/L, respectively. There was no morphological deformity in the hatched larvae of Pagrus major exposed three PAHs. The spinal curvature and fin deformity were observed in Oplegnathus fasciatus at 11 µmol/L of 2-metylnaphthalene. Pericardial edema, ocular development inhibition, spinal curvature and fin deformity were observed in Paralichthys olivaceus exposed to 0.013 µmol/L of pyrene, 3.5 µmol/L of 2-metylnaphthalene, and 1.0 µmol/L of phenanthrene. It was considered that Paralichthys olivaceus to be more sensitive than Pagrus major and Oplegnathus fasciatus to PAHs. Some embryo of Paralichthys olivaceus successfully hatched in lower concentrations, while morphological deformity was observed in these concentrations. PAHs seem to have large effects on the early life stages of aquaculture fishes.

MP272 Eco-Pharmaco-Stewardship: An Update

J.G. Tell, Merck & Company, Inc. / Global Safety the Environment; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; D.J. Caldwell, Johnson & Johnson / Environment Health Safety Sustainability

The pharmaceutical industry recognizes and understands concerns raised by stakeholders regarding the presence of pharmaceuticals in the environment (PIE). The major source of pharmaceuticals entering into the environment is via patient excretion following use of a medicine that is taken to prevent, cure or alleviate a medical condition. A comparatively smaller contribution to PIE stems from emissions from industry during the manufacture of pharmaceuticals and from the incorrect disposal of unused or expired medicines. Industry is committed to playing a role in addressing concerns about PIE and is actively engaged in minimizing the impact of its activities on the environment. Founded on the principles of product stewardship, the Eco-Pharmaco-Stewardship (EPS) initiative has been developed. It considers the entire life-cycle of the medicine and addresses the roles and responsibilities of all parties involved, including public services, the pharmaceuticals industry, environmental experts, doctors, pharmacists, and patients. The EPS initiative is supported by three 'pillars', which have been identified as the initial key areas of focus for the pharmaceutical industry: Pillar 1 – IMI iPIE project: the identification of the potential environmental risks of existing and new active pharmaceutical ingredients (API) through intelligent and targeted assessment strategies. Pillar 2 – Manufacturing effluents management: the compilation of best industry practices, enabling manufacturers to minimize risks to the environment. Pillar 3 – extended ERA: the refinement of the existing environmental risk assessment (ERA) process for medicinal products to ensure that they remain up-to-date and relevant. The pharmaceutical industry stands ready and willing to work with other stakeholders in evaluating and working on all aspects of the medicines lifecycle that may have a harmful impact on the environment. In all of these endeavors, the key priority remains to ensure patients' access to medicines in cooperation with all stakeholders. The industry believes that the EPS approach can serve to address concerns and inform adequately the existing regulatory paradigm. This poster presents more details on EPS and progress made on these endeavors.

MP273 Trace Element Bioaccumulation in Multiple Snapper Species from the West Florida Shelf

D. Adams, Florida Fish & Wildlife Commission / Fish and Wildlife Research Inst; B.P. Jackson, Dartmouth College / Dept of Earth Sciences; J. Dutton, Texas State Univ / Dept of Biology

The Lutjanidae (snappers) are one of the most important recreational and commercial fisheries complexes in the Gulf of Mexico and play key roles in marine ecosystem function within tropical and subtropical waters worldwide. We analyzed the muscle tissue of 5 diverse snapper species (red snapper, Lutjanus campechanus; gray snapper, L. griseus; lane snapper, L. synagris; yellowtail snapper, Ocyurus chrysurus; vermilion snapper, Rhomboplites aurorubens) for two essential metals (Cu and Zn), three non-essential metals (Hg, Cd and Pb), one essential non-metal (Se) and one non-essential metalloid (As). Snappers (n = 601) were collected from West Florida Shelf offshore waters during the Florida Fish and Wildlife Research Institute's fisheries-independent research cruises and muscle tissue was analyzed for trace elements using microwave digestion and Inductively Coupled Plasma Mass Spectrometry (ICP-MS). All trace elements were detected in all snapper species examined. For the essential elements, Zn was found in highest concentration overall, followed by Se and Cu. For the non-essential elements, As was found in highest concentration, followed by Hg, Pb and Cd. Lane snapper contained the highest concentration of Hg (0.81 µg/g dry wt), with vermilion snapper containing the lowest (0.23 µg/g dry wt), reflecting differences in trophic position. All five snapper species had a Hg concentration below the 1 ppm FDA guideline for human consumption. All species contained relatively low concentrations of Pb, ranging from 0.008 µg/g dry wt in vermillion snapper to 0.078 µg/g dry wt in red snapper. Arsenic was highest in gray snapper (21.8 µg/g dry wt) potentially reflecting the estuarine linkage of this species during early life history stages. This is the first in-depth study to investigate the concentration of multiple trace elements in ecologically diverse snapper species. These results have implications for trace element exposure, trophic pathways, and inshore-offshore habitat linkages that are important for effective management of reef fish populations.

Environmental or Analytical Chemistry – Poster Only – Part 1

MP274 A Pilot Study on the Detection of Select Pharmaceuticals in Hospital Wastewater and Wastewater Treatment Plants (WWTPs) in Doha, Qatar

S.T. Al-Maadheed, H.R. Mokhtar, AntiDoping Lab Qatar; A. Latiff, Anti-Doping Lab Qatar / Toxicology and Multipurpose Lab; H. Hussein, Ashghal Public Works Authority; I. Goktepe, Qatar Univ / Biological and Environmental Sciences

Pharmaceuticals and personal care products (PPCPs) are considered as chemicals of emerging environmental concern in the aquatic environment worldwide. This study was carried out to optimize an analytical method to investigate and quantify the occurrence of eight selected antibiotics: Penicillin, Amoxicillin, Gentamicin, Ciprofloxacin, Tetracycline, Erythromycin, Metronidazole, Clavulanic acid and Caffeine in Hospital Wastewater (HWW), influents and effluents from two wastewater treatment plants (WWTPs) in Doha. The extraction method was based on the automated solid phase extraction (SPE). The analysis of antibiotics in wastewater samples was performed using liquid chromatography – mass spectrometry (LC-MS) with positive ion electrospray ESI (+). The results indicated that antibiotics and Caffeine were widespread pollutants in wastewater. Caffeine exhibited high prevalence (> 100 ng/mL) in HWW and influent samples collected from both Old (OWWTP) and New (NWWTP) wastewater treatment plants. The highest concentration of Metronidazole and Ciprofloxacin were detected in the HWW at levels of 5.46 ng/ml and 1.99 ng/ml, respectively. In effluent samples of NWWTP, Clavulanic acid was the most prominent compound at concentration as high as 84.74 ng/mL. The highest concentration of Erythromycin (7.20 ng/mL) was detected in the OWWTP influent sample. Tetracycline was spotted at levels of ~ 0.2 ng/ml in most of the samples collected during the study. The levels of Amoxicillin, Penicillin, and Erythromycin were not detected in most of the samples collected from all collection points. There were a significant interaction between most of the studied compounds. The statistical analysis showed that there is no significant difference ($P \geq 0.05$) between OWWTP and NWWTP and the methods used in both WWTPs are effective in reducing/removing Caffeine, Penicillin and Metronidazole. The removal efficiency for Caffeine and Penicillin at the NWWTP was 99.44% on average, while OWWTP was effective to remove Caffeine and Metronidazole with removal efficiencies of 95.21% and 90.22%, respectively. These findings demonstrated that the LC-MS method optimized in this study is sensitive and selective to detect such low concentrations of PPCPs and the instrument is a robust and reliable tool that can be easily used in the routine analysis of compounds, like antibiotics, in complex matrices (wastewater).

MP275 A simultaneous detection of disperse dyes in wastewater textiles industry

B.F. Silva, T. Rodrigues, UNESP Inst of Chemistry / Analytical Chemistry; J. Carvalho, M.V. Zanoni, UNESP Inst of Chemistry

The massive use of dyes in the textile industry has raised concern with their wastewater. Untreated effluent can conveniently reach springs and other surface waters causing great damage to aquatic biota and uptake of water treatment plants because of their toxicity and mutagenicity. Their occurrence in these matrices is demanded but is complex due to the high dilution. Among them, the disperse dyes, strongly used in the dyeing of synthetic fibers have demanded attention due to high hydrophobicity, and difficult to be monitored by conventional analytical methods. Although their detection is of great importance in aquatic environments have high retention on reverse phase columns which make their separation exceedingly complex. The aim of this work present an analytical methodology for the detection and simultaneous quantification of disperse dyes widely used in the textile industry, such as: disperse orange 25 (DO25), disperse yellow 3 (DY3), disperse orange 1 (DO1), disperse orange 37 (DO37), disperse yellow 9 (DY9), disperse yellow 7 (DY7), disperse orange 3 (DO3), disperse red 1 (DR1), disperse red 13 (DR13), disperse red 60 (DR60), disperse orange 30 (DO30), disperse red 82 (DR82) and disperse blue 291 (DB291). The industry effluent samples were extracted and analyzed by LC-MS/MS using reversed phase PFP column and acetonitrile:water both containing 1% formic acid in gradient program. The simultaneous analysis of 13 disperse dyes has been validated in accordance with the rules and presented recovery of 70-99%, LD (0.05 – 1 ngL^{-1}), LQ (0.25 – 5 ngL^{-1}), linearity (0.999) and intra- and inter-days precision below 20%. The analysis of real samples confirmed by validation methods indicates the occurrence of DR60, DY3, DO1, DO37, DO30 in the matrices. Other dyes were detected, but not quantified, except for DO3, DY7 and DR13. Disperse dyes can be determined at low concentration by LC-MS/MS in industrial effluents with high precision and accuracy. Our findings show that dyes are present in efluents from textile industry and untreated river water which has been subjected to dyeing-textile discharges.

MP276 An Examination of Soil Microbial Biomass and the Impact of Seasonal Variation

S.P. McLaughlin, Smithers Viscient / Dept of Environmental Fate; K. Campbell, Smithers Viscient / Environmental Fate Metabolism

Soil microbial biomass is an important measure of the health and viability of a soil. It is also used to assess whether a soil is appropriate for testing under such guidelines like the OECD 307 Guideline 'Aerobic and Anaerobic Transformation in Soil' and the EPA Guideline OCSPP 835.4100 'Aerobic Soil Metabolism'. It is used for the same purpose for soil toxicity testing in the OECD 216/217 Soil Microorganisms: Nitrogen and Carbon Transformation Test Guidelines. These guidelines state that a well-established microbial population in soil and one that is appropriate for testing equals 1% of the soil's organic carbon content. This value is important for testing to ensure the soil is representative of soils in nature and can provide accurate degradation rates in soil metabolism studies and meaningful toxicity values in the nitrogen and carbon transformation (a.k.a., soil microflora) testing. A collection of initial soil microbial biomass values has been summarized and presented based on their time of collection during the year. Conclusions are extrapolated from trends in the data concerning seasonality and environmental conditions.

MP277 Assessment of Steroid Hormone Binding Affinity to Titanium Dioxide Nanoparticles in Aquatic Biome and Other Matrices

M. Ellington, V. Nyakubaya, C. Crihfield, West Virginia Univ; L. Holland, West Virginia Univ / Chemistry

Titanium dioxide nanoparticles (nTiO2) are prevalent in many products manufactured today, and the extent of their presence in the aquatic environment is at least 11,000 tons anually. These nanoparticles have unique physiochemical properties, and have been shown to gather in the gonads of fish upon exposure and potentially influence endocrine disruption. As titanium dioxide nanoparticles are used extensively in ingested and topical applications, it is important to understand how these nanoparticles are interacting with other endocrine disrupting chemcials (EDCs), potentially concentrating them in the gonads and acting as an agonist that compounds hormonal imbalance. The effects of endocrine disruption can be severe, leading to a range of maladies from neurological disorders to cancer and reproductive failure. This research will provide a direct correlation between nanoparticle-EDC interaction and reproductive abnormality using biomarkers capable of detecting endocrine disruption in its early stages. Understanding the manner in which titanium dioxide nanoparticles interact with endocrine disruptors would be a milestone in developing better detoxification treatments. The purpose of the research described in this presentation is to assess the impact of titanium dioxide nanoparticles on the model organism danio rerio (zebrafish) by monitoring reproductive failure. The ultimate goal is the complete characterization of nanoparticle behavior in the environment in order to conduct validated flow-through dosing studies in accordance with OECD guidelines. The role of biologics and endocrine disrupting chemicals in the environment were evaluated and molecular binding affinity was quantified using an analytical method based on pH-mediated capillary electrophoresis. With this technique, the impact of titanium dioxide nanoparticle interactions with biomolecules in aquatic systems can be explored, starting from pristine water samples to model protein mixtures, and finally in naturally occurring organic matter.The broader impact of this research will be to provide a holistic view of TiO_2 nanoparticle interactions in the environment to understand the complex role of nanoparticles in aquatic toxicity.

MP278 Bisphenol A removal from water and wastewater using Activated Carbon-alginate and Bentonite-alginate beads

A.L. Loya Posada, Univ of Texas at El Paso / Chemistry; W. Lee, Univ of Texas-El Paso / Chemistry; W. Teoh, Nagaoka Univ of Technology

Bisphenol A (BPA) is a monomer commonly used as a plasticizer on several industrial processes. This compound is later released into the environment by the effluents of wastewater treatment plants (WWTP). It is classified as an Endocrine Disruptor Compound (EDC), which are chemicals of emerging concern that can block or mimic the activity of natural hormones, interfering with the reproductive systems of wildlife and humans. Currently, BPA is not regulated by the federal government in the US and wastewater treatment plants are not designed nor required to remove it. As wastewater effluent for drinking water use becomes a reality in our society, it warrants a need to develop methods to effectively remove BPA from wastewater. The objective of this project is to develop a novel sorption application in which we will incorporate bentonite and activated carbon with the gelling properties of alginate to develop alginate gel-based (hydrogel) adsorbent beads to remove BPA and provide a low cost, non-toxic alternative to the existing removal procedures, in which the preparation won't require nor release any hazardous byproducts. The removal capacities for BPA by these materials will be compared; factors, such as pH and loading, will be investigated to optimize the removal of BPA in water; and the adjusted absorbing conditions will be tested in wastewater for the possibility of future application in wastewater treatment plants or on drinking water filters.

MP279 Caffeine in an Urbanized Estuary: Past and Present Influence of Wastewater Effluents in Boston Harbor, MA, USA

D.R. Katz, M.G. Cantwell, USEPA / Atlantic Ecology Division; J.C. Sullivan, ORISE at USEPA / AED

Caffeine has been identified by previous research as a potential tracer of sanitary wastewater. To further assess the utility of caffeine as a tracer of wastewater sources, samples from 25 sites throughout Boston Harbor were collected and analyzed for caffeine by LC-MS/MS. Caffeine concentrations in Boston Harbor ranged from 15 ng/L in the outer harbor to a high of 185 ng/L in the inner harbor; mean concentrations and median concentrations were 51 ng/L were 33 ng/L respectively. These data were visualized by a simple inverse distance weighting model to improve the understanding of transport and fate dynamics of wastewater derived contaminants. Elevated concentrations of caffeine in the inner harbor during the sampling period were determined to be the result of a combined sewage overflow (CSO) event as well as illicit discharge of sanitary sewage into municipal storm drains. A comparison of contemporary results to data from 1998 to 1999 shows significant reductions in caffeine levels within the harbor. For instance, concentrations were reduced by a factor of approximately 20 at the site of the former wastewater effluent discharge outfall in Boston Harbor. Lower present-day concentrations throughout the harbor were attributed to the relocation of effluent discharge from within the harbor to Massachusetts Bay, and a reduction in the number and discharge volume of CSOs. Spatial distributions of caffeine identified CSOs as the major contemporary source of contaminants to the inner harbor. These results provide additional evidence for the use of caffeine as an effective tracer of sanitary wastewater sources in urban estuaries. Furthermore, these results demonstrate the efficacy of both treated and untreated wastewater effluent reduction strategies put in place to improve the condition of Boston Harbor.

MP280 Characterization of municipal wastewater treatment plant effluent during major process upgrades

L. Bragg, Univ of Waterloo / Dept of Biology; K. McCann, M. Arlos, Univ of Waterloo / Biology; M.R. Servos, Univ of Waterloo / Dept of Biology

The Region of Waterloo has several major waste water treatment plants (WWTP) which are currently undergoing major upgrades to improve effluent quality. These upgrades include improving the aeration systems, UV disinfection and decommissioning of the biosolids storage lagoons. Kitchener was a non-nitrifying carbonaceous activated sludge plant but after significant upgrades is now is fully nitrifying. Waterloo was a partially nitrifying conventional activated sludge plant prior to upgrades and is still partially nitrifying. Both treatment plants still have a number of major upgrades scheduled to come online in the next few years. Regular sampling of the effluent for a variety of emerging contaminants has occurred since 2010 and continued monthly from 2013-2015 during the implementation of major process changes. There has been a major decrease in total ammonia and increase in nitrate from the Kitchener WWTP which correspond to the treatment system upgrades (i.e. nitrification). In the Waterloo WWTP, the pattern of total ammonia and nitrate is much different, reflecting the recycling in the centrate from the biosolids back into the secondary train. The contaminant profiles, including selected pharmaceuticals, personal care products and estrogens, are contrasted over time. Concentrations of selected pharmaceuticals, such as ibuprofen and naproxen, are greatly reduced with increased treatment while other contaminants such as carbamazepine and venlafaxine remain recalcitrant. These improvements have potential significance for the environment downstream of the WWTPs where significant endocrine disruption has been documented, including high expression of intersex in fish.

MP281 Chemical Preservation of Semi-volatile PAH Compounds at Ambient Temperature: A Sediment Sample Holding Time Study

R. Arnold, Chevron Energy Technology Company / Environmental Risk Assessment; G. Douglas, J. Hardenstine, S. Rouhani, NewFields Environmental Forensics; D. Kong, Chevron Energy Technology Company; W. Gala, Chevron Energy Technology Company / HES

Site investigations require the collection and analysis of representative environmental samples to delineate impacts, risk, and remediation options. When samples are removed from the environment, concentrations of semi-volatile polycyclic aromatic hydrocarbons (PAHs) begin to change due to various processes such as evaporation, adsorption, photo and microbial degradation. Preservation techniques are used to minimize these changes between collection and analysis. The most common techniques are refrigeration, freezing, and acidification. Regulatory agencies have developed holding time requirements of 14 days for PAH in soil/sediment samples stored at < 6°C. The technical basis for these requirements is not well defined yet failing to meet these criteria may deem the analytical results not valid. This study examined the effectiveness of using chemical preservatives for sediment PAH samples to defensibly extend the prescribed holding time requirements in the absence of refrigeration. Sediment samples collected at three (3) separate sites impacted with petrogenic and pyrogenic PAHs were analyzed as preserved (sodium azide) and unpreserved samples at defined time intervals up to 60 days. Statistical analysis of the data demonstrated no degradation of PAHs in the sediment samples preserved with sodium azide for up to 60 days at ambient or 4°C. Sodium azide preservation provides a useful technique to ensure sediment sample integrity in situations where maintaining holding temperature below 6°C during transport to the laboratory may be uncertain, e.g., during sample collection in remote locations.

MP282 Comparison of various digestion and extraction methods for the determination of heavy metals from soils polluted by electronic waste

A. Adebayo A., FUPRE / Environmental Manag Toxicology; O. Osibanjo, Basel Convention Coordinating Center for Training for West Africa Sub Region, Univ of Ibadan, Nigeria / Dept of Chemistry Univ of Ibadan Nigeria; D.V. Perez, Embrapa Soils, Rio de Janeiro, Brazil; J.M. Godoy, Pontifícia Univ Católica do Rio de Janeiro, Brazil / Dept of Chemistry

It is very essential to assess various digestion methods to accurately determine elemental concentrations in soils. In this present study, various digestion and extraction procedures were evaluated in order to assess the degree of contamination with heavy metals in soils polluted by electronic waste from Alaba International market, Lagos State, Nigeria.Total acid dissolution, aqua regia digestion, DTPA dissolution and 2M HNO3 extraction procedures were applied to samples.Ba, Cd, Cr, Cu, Ni, Pb, Sn, Zn and V were determined by inductive coupled plasma optical emission spectrometry (ICP-OES).A comparison of total acid dissolution including hydrofluoric acid (HF) treatment and aqua regia soluble fraction was done to estimate the applicability of aqua regia digestion in analysis of total metal concentrations in soils. The amount of Zn, Cu, Pb, Ni, Cd, Cr, V, Ba and Sn extracted by the four extraction methods showed a linear positive correlations which are statistically significant. Correlation coefficients between total metal concentrations and aqua regia contents revealed very strong positive correlations which are statistically significant (r values for Zn, Pb, Cd, Cr, Ni,V, Sn, Ba and Cu are 0.946, 0.973, 0.938, 0.901, 0.997, 0.956, 0.843, 0.982 and 0.930, respectively. These results showed that total metal contents, 2M HNO3 and DTPA can be useful preliminary indicator of areas where the risks of metal deficiency are high.

MP283 Concentration of Polycyclic Aromatic Hydrocarbons (PAHs) and Polychlorinated Biphenyls (PCBs) in urban and semi-urban soils in Havana

A. Escobar Medina, D.S. Pacheco, CENSA; I. Hilber, Agroscope ART; R. Faure Garcia, Y. López, CENSA; N. Bartolomé, Agroscope ISS / Analytical Chemistry Natural Resources Environmental Protection in Agriculture; O. Fonseca, CENSA; T. Bucheli, Agroscope ART / Environmental Analytics Natural Resources and Agriculture

Havana is the capital of the Republic of Cuba, with a population of more than 2 million citizens. In the last years more than one million tourists visited the city per year and with that also the traffic increased. Moreover, some industry is situated in the capital. Alongside with high human activities contaminants are emitted such as polycyclic aromatic hydrocarbons (PAHs) formed by incomplete combustion and polychlorinated biphenyls (PCBs). The main objectives of this study was to evaluate the level of these contaminants in the Havana province. Therefore, a soil monitoring was performed by the national center of animal and plant health (CENSA) in Cuba in collaboration with Agroscope ISS, Switzerland. The project was funded by the Swiss National Science Foundation and should also strengthen the analytical capacity of the CENSA laboratory. This will, in combination with the creation of a soil archive, increase the information flow between science represented by CENSA and the government represented by the ministry of science, technology and environment (CITMA) from Cuba. Soils were sampled at 12 agricultural sites, 1 industrial spot and at 7 parks in the Havana province. Concentrations of the sum of the 16 USEPA PAHs ranged from 0.04 to 71 mg Kg-1(dry weight, dw). The median of the agricultural soils was 0.1 mg Kg-1dw and the one of the 7 parks 1.9 mg Kg-1dw. The main source of pollution is pyrogenic with a predominance of diesel combustion produced by cars as an analysis of molecular PAH markers revealed. The sum of seven PCB congeners showed concentrations between 3 and 109 ug Kg-1dw. Different soil uses such as industrial, agricultural, or recreation had no significant influence on the PCB concentrations (p-value = 0.08). Some sites exceeded the trigger value of Switzerland for PAHs of 20 mg Kg-1dw according to that an eventual risk for human, animal and plant health needs to be assessed. As Cuba, up to now lacks environmental contaminant regulations this study serves as a basis to establish regulatory concentrations for organic contaminants. A long-term prospective is to extend the monitoring to other provinces and to the whole island to create a soil monitoring network. In parallel, the analytical laboratory capacity of CENSA was strengthened. Different extraction methods and chromatographic conditions were tested and the laboratory participated in a round robin to check the precision, accuracy and reliability of the results.

MP284 Determination of heavy metals in soils by microwave-assisted digestion and inductive coupled plasma optical emission spectrometry

A. Adebayo A., FUPRE / Environmental Manag Toxicology; D.V. Perez, Embrapa Soils, Rio de Janeiro, Brazil

The analysis of the total concentration and the leachable fraction by aqua regia digestion of six heavy metals (Cd, Cr, Cu, Ni, Pb and Zn) in soils was determined by microwave digestion technique combined with the flame atomic absorption and inductive coupled plasma optical emission spectrometry. The acid mixture of HF-HCL-HNO_3 (1:3:1) was utilized to achieve total digestion of soils; the tests carried out provide evidence that the extraction of heavy metals from soils by the microwave-irradiated closed vessel system is a viable alternative to the traditional heating systems. The experimental study was conducted using two BCR standard reference materials BCR 141R and BCR 701 standard reference material. Maximum recovery, precision and accuracy established the excellent performance of the methods used.

MP285 Development of a simultaneous analytical method for agricultural chemicals in tap water using LC/MS/MS

N. Kobayashi, National Inst of Health Sciences; T. Tsukamoto, H. Horiike, Shimadzu Corporation; R. Kubota, Y. Ikarashi, National Inst of Health Sciences

In order to ensure the safety of drinking water, many agricultural chemicals are monitored by many of water suppliers in Japan. However, analytical methods for agricultural chemicals in tap water are complicated. Therefore, much labor and cost is required to apply these methods. We have developed a simultaneous analysis method of 140 agricultural chemicals which are the "Complimentary Items" in tap water in the Japanese Waterworks Act, by liquid chromatography – tandem mass spectrometry (LC/MS/MS). Further, we evaluated the validity of the analytical method based on the results of the recovery tests of these agricultural chemicals added in tap-water at two concentrations (i.e., between 1/100 and 1/10 of the "desired value" and lower than 1/100 of the "desired values"). Limit of quantitation, repeatability precision, accuracy (recovery), and reproducibility precision (precision between laboratories) of each agricultural chemical were assessed based on the criteria in the guideline for validation of testing method in drinking water, which has been released by the Ministry of Health, Labour and Welfare. Regarding the 105 agricultural chemicals, the quantification limits were lower than 1/100 of the desired values of each agricultural chemical, and the accuracy (recovery) and repeatability satisfied the criteria of the above guideline. Regarding other 12 agricultural chemicals, the quantification limits were lower than 1/10 of the desired values of each agricultural chemical, and the accuracy (recovery) and repeatability also satisfied the criteria. Therefore, we judged that the simultaneous analytical method we have developed in the present study was applicable to the analysis of 117 agricultural chemicals in drinking water. In order to expand this LC/MS/MS simultaneous analysis method as a standard analytical method of drinking water, we will conduct the validity test of the analytical method among other examination organizations.

MP286 Development of Analytical Methodology UAE-HS-SPME for Organochlorine Pesticides Analysis in Water using Eva Passive Sampler's by GC-MS/MS

D.M. Cardenas, Departamento de Analisis Instrumental/Facultad de Farmacia, Universidad de Concepcion; F. Tucca, Facultad de Ciencias Ambientales/Centro EULA, Universidad de Concepción / Sistemas Acuáticos; C. Mardones, Departamento de Analisis Instrumental/ Facultad de Farmacia Universidad de Concepcion; R.O. Barra, Universidad de concepcion / Aquatic systems

Passive sampling is a method used for the monitoring of a wide range of xenobiotic compounds in environmental, such as pesticides. Organochlorine pesticides (OCPs) are highly toxic compounds and they are found in very low concentrations in the environment. Passive sampling emerges as a tool able to detect analytes in environmental samples. In order to improve the sensitivity and selectivity, we show an extraction method for passive sampling using a coupled analytical methodology between ultrasound assisted extractions (UAE)-headspace solid phase microextraction (HS-SPME). Analytical methodology UAE and HS-SPME were optimized by univariate analysis and central composite design, respectively. Analyses were performed using gas chromatography–mass spectrometric (GC-MS/MS) in the Multiple Reaction Monitoring (MRM) mode. The optimized methodology was able to obtain detections limits 0.322 – 0.516 µg L^{-1}, acceptable repeatability with a relative standard deviation less than 20% (n= 4) and recovery percentage >60%. External standard calibration was employed for the quantification, where linear ranges (from 1.0 to 5.0 µg L^{-1}) with r^2 values between 0.9902 to 0.9961 were observed. Finally, coupling the UAE, HS-SPME and GC-MS/MS suggest a methodology for the analysis of twenty organochlorine pesticides detected by passive sampler devices and it applied for their calibration in situ with total analysis time four hours and detection limits less than 0.5 µg L^{-1}. Acknowledgements: CRHIAM/ Conicyt/Fondap N° 15130015; Fondecyt N° 1140466 project

MP287 Effect of acid pretreatment on anaerobic biodegradation of rice straw

M. Kim, B. Kim, Seoul National Univ; K. Nam, Seoul National Univ / Dept of Civil and Environmental Engineering; Y. Choi, Seoul National Univ / Dept of Civil and Environmental Engineering

Our study focused on both treating immense organic wastes (i.e., agricultural waste, sludge from WWTP) and obtaining useful energy resources like methane gas. Vegetable biomass such as rice straw is consist of non-biodegradable lignin, merely biodegradable cellulose and hemicellulose. Physical (i.e., grinding, heating, boiling), chemical (i.e., acid, base), and biological (i.e., microbe, fungi) pretreatment can be used to enhance hydrolysis efficiency and to extract available/useful carbon sources. Hemicellulose are known be degraded by acid pretreatment which has a relatively short reaction time and high sugar production yield. This study analyzed biologically producible methane gas and verify the acid pretreatment efficiency on anaerobic biodegradation using biochemical methane potential (BMP) test. Acid pretreatment was conducted using 2% H_2SO_4 with 1:10 (solid:liquid) ratio and autoclaved (121?, 60 min) for accerelating hydrolysis process. Four types of substrates were used for the experiment, which are (1)untreated rice straw, and acid-pretreated rice straw in phase of (2)solid, (3)liquid, and (4)solid/liquid phase. The produced methane amount using liquid phase was expected to be significantly higher than other substrates since the carbon sources in liquid phase are mainly short sugar chains, while carbon sources in solid phase are mainly lignin, cellulose, hemicellulose and some sugars. However the methane produced amount was similar between liquid phase of acid-pretreated rice straw (434 mL CH_4/g TC) and untreated rice straw (solid phase, 430 mL CH_4/g TC) indicating that the methane production reaction in liquid phase was inhibited due to the residual salts. Acid pretreatment using strong acid might have significantly reduced bioavailable fraction of rice straw, therefore different conditions of acid pretreatment will be applied in order to verify the optimal condition of acid pretreatment in anaerobic biodegradation.

MP288 Enantiomerization of Metalaxyl in South Carolina Soils

C. Rollerson, Clemson Univ / Environmental Engineering and Earth Sciences; C.M. Lee, Clemson Univ / Environmental Engineering and Earth Sciences Dept

Many pesticides on the market today are chiral, which means that they contain two enantiomers. Enantiomers are molecules that are mirror images but are non-superimposable. These pesticides are usually sold as a racemic mixture, which contains equal amounts of both enantiomers; however, typically only one enantiomer is toxic to the target pest. In an effort to decrease the mass of pesticides in the environment, manufacturers could market only the most effective enantiomer of the pesticide. However, if the single enantiomer is unstable in the environment (undergoes enantiomerization), it defeats the purpose of producing a single enantiomer formula. Little research has been conducted to determine how pesticides undergo enantiomerization in the environment, especially in soil systems. Metalaxyl is a systemic fungicide used in various crops that is marketed as a single enantiomer, metalaxyl-M (97% R-(-)-metaxyl and 3% S-(+)-metaxyl). Soil was collected near Lake Hartwell in Anderson, SC, and was analyzed for its mineral composition, pH, and organic matter content. Racemic metalaxyl and metalaxyl-M were exposed to the soil to study the change in enantiomeric fraction. The change in enantiomeric fractions in the presence of the soil was determined via HPLC. Preliminary data for metalaxyl in contact with individual minerals (e.g., calcite) showed a slight, but statistically significant change, in the enantiomer fraction. Similar behavior is expected for metaxyl in contact with the soil. In conclusion, by examining the effects of different types of soils and conditions (e.g., pH) on the rate of enantiomerization, more sustainable pesticides can be developed and manufactured. It may also help determine enantioselective degradation and the degradation products of these compounds, which can also be beneficial to toxicology studies and risk assessment.

MP289 Environmental Fate Studies with 14C-POEA

M. Kurtzweil, M. Shepard, Monsanto Company

Tallow amine polyethoxylate, commonly referred to as POEA (polyoxyethylene alkyl amine), is a nonionic surfactant contained in many glyphosate-based formulations that improves uptake and efficacy of the active ingredient, thereby reducing the amount needed for effective weed control. Four regulatory-guideline environmental fate studies were initiated in 2012 to obtain data for potential use in ecological risk assessments for formulations containing POEA and include: hydrolysis, aerobic aquatic degradation, adsorption/desorption, and aerobic soil degradation. ^{14}C-Labeled POEA was synthesized for use in the studies to aid in analysis of the surfactant, to assess mineralization to CO_2, and to allow for mass balance determinations. POEA was found to be chemically stable under abiotic hydrolysis conditions. POEA dissipated rapidly from the water column of natural water-sediment systems under aerobic conditions through a combination of metabolism and adsorption to sediment, with a DT_{50} of 2-3 hours. The rate of dissipation of POEA from the water column is consistent with rates reported in other water-sediment studies. Results from the adsorption/desorption study showed that POEA was strongly sorbed to soils and that sorption primarily correlated with increasing organic carbon. Based on the calculated adsorption coefficients, POEA is considered hardly mobile in soil according to the FAO mobility classification. Dissipation in both soil and sediment involved a combination of metabolism and binding. The DT_{50}s for POEA in the aerobic soil study ranged from 20 to 166 days with rates slowing as the percent organic carbon of the soils increased. Dissipation of POEA in the aerobic aquatic sediments was relatively slow and approximately 17-18% of the applied dose was still extractable at the end of the 100-day study in both systems. Based on results of the studies, along with predicted environmental concentrations and available toxicity data, acute and chronic risk to organisms in the water column and in the sediment/soil are considered to be low due to rapid dissipation/degradation of POEA and limited bioavailability.

MP290 Environmental Screening of Water Samples Utilizing Ion Mobility Enable High Resolution Mass Spectrometry

K.J. Rosnack, Waters Corporation / Food Env Business Operations; G. Cleland, L. Mullin, A. Ladak, Waters Corporation

Companies and environmental regulatory authorities are under pressure to develop screening methods capable of detecting a broad spectrum of environmental contaminants in a single analytical run. Many are turning to High Resolution Mass Spectrometry (HRMS) as part of the solution for obvious reasons since modern non-targeted, data independent, analyses offer a high level of selectivity through the acquisition of full spectra with accurate mass and isotopic information for both precursor and product ions in a single run. Following standards analysis, local lake and tap water samples were collected and extracted for PFASs. Data was acquired using alternating high and low collision energy states across the full analytical mass range, such that product ions were also generated. Ion mobility separations were performed simultaneous allowing the data be aligned by retention time and drift time giving extra selectivity. Multiple chromatographic and ionization techniques were used on a single platform to cover a wide range of compound classes. With a focus on perfluorinated compounds in water samples, information rich datasets were collected using data independent acquisition of both high and low energy simultaneously with ion mobility separation. The same instrument was operated in this mode coupled with a variety of chromatographic techniques and ionizing methods (including ESI and API). By utilizing the different chromatographic and ionization techniques the range of compounds covered can be expanded. Using a fully integrated scientific information system, which performs data processing via Apex 3D peak picking and componentization, a target list of compounds was screened against. In order to identify target compounds against a library mass error, isotopic fidelity and fragment matching was used. A unique measurement that is made via the mobility separation collisional cross section (CCS) giving an extra point of confirmation for known compounds. The mobility separation also allowed the spectral clean up in data allowing identification to be performed with more confidence. The same data was then used to isolate non-targeted compounds by using an array of comparison and discovery tools without the need to reprocess. Identification of these significant compounds of interest is also addressed by discussing elucidating techniques, such as a novel batch elucidation tool, available within the integrated scientific information system.

MP291 Evaluating PCB Congener Water Sample Contamination from Sampling Equipment

D. Williston, C. Greyell, King County / Dept of Natural Resources and Parks; J.H. Stern, Dept of Natural Resources and Parks

This study evaluates the potential for sampling equipment to cause contamination in water samples analyzed for low level polychlorinated biphenyls (PCB). Equipment blank samples collected for previous County studies suggest that autosampler equipment may be contributing select PCB congeners to water samples at concentrations high enough to affect total PCBs results. Two sampling methods were used to collect surface water samples from the Green River in King County, Washington to better understand specific PCB congener contamination from autosampler equipment and evaluate the potential bias to Green River surface water samples collected in previous King County studies. Concurrent samples, one with an autosampler and one using hand-composite grab method, were collected at two locations under both baseflow and storm conditions. In addition, the study evaluates which piece(s) of the sampling equipment may contribute PCBs to the equipment blank contamination. Equipment samples included laboratory water that had passed through one of three types of sample tubing (silicone, Teflon®, and sampling splitting tubing) as well as equipment blank laboratory source water to evaluate potential PCB contamination from these materials. All samples were analyzed for PCB congeners using Method 1668c. The results indicate a very high bias in total PCBs in Green River water samples collected by the autosampler from PCB congeners 47, 51 and 68; on average they contributed 90% of the total PCBs in the samples collected with autosampler compared to 4% in hand-composite grabs. These same three congeners were detected in relatively high concentrations in Versilic SPX-50 silicone tubing equipment samples but not in the platinum-cured silicone tubing equipment samples. The Teflon® and sample splitting tubing showed very low detections of these congeners. The data from this study will be used to better understand the magnitude of equipment contamination bias and possible data correction approaches to total PCB congener results collected with autosamplers from previous County Green River studies as well as what modifications to sampling methods should be made for future water sampling efforts for PCB congeners.

MP292 Identification of Metabolites in Soil and Water-Sediment Studies Conducted with 14C-POEA

M. Kurtzweil, M. Shepard, Monsanto Company

Tallow amine polyethoxylate, commonly referred to as POEA (polyoxyethylene alkyl amine), is a nonionic surfactant contained in many glyphosate-based formulations that improves uptake and efficacy of the active ingredient, thereby reducing the amount needed for effective weed control. In addition to assessment of the dissipation rates of ^{14}C-POEA in soil and water-sediment degradation studies initiated in 2012, metabolites were identified in soil as well as in water and sediment. Metabolism was extensive as evidenced by the formation of $^{14}CO_2$ in both studies; ranging from 12 to 47% in the aerobic soil study and 10 to 15% in the aerobic aquatic study. Metabolism in the aerobic soil study was complex where four main classes of metabolites were identified by LC-MS and confirmed using a derivatization approach. All of the metabolites result from oxidative processes. The classes of metabolites consisted of tertiary amines containing both polyoxyethylene groups on nitrogen and terminally carboxylated aliphatic chains, secondary bis-polyoxyethylene amines and their corresponding mono- and di-carboxylate analogs, primary mono-polyoxyethylene amines and their corresponding carboxylated analogs, and di-carboxylated versions of polyethylene glycol. Metabolism in the aerobic aquatic study was not as complex as in the aerobic soil study as only tertiary amine metabolites containing both polyoxyethylene groups on nitrogen and terminally carboxylated aliphatic chains were identified as well as secondary bis-polyoxyethylene amine metabolites. This presentation will focus on discussion of the techniques used to identify metabolites in the aerobic soil and aerobic aquatic studies as well as the proposed pathways for metabolism of POEA in the two studies.

MP293 Implications of chronic carbon black exposure on the development of type 2 diabetes mellitus

K. Baker, West Texas A&M Univ / Life Earth and Environmental Science

Type 2 diabetes mellitus is one of the most frequently diagnosed diseases in the modern world. Often, high fat diets and sedentary lifestyles are considered the cause of type 2 diabetes; however, recent studies have associated chronic exposure to particulate matter less than or equal to 2.5 micrometers in diameter with the development of key aspects of metabolic syndromes that eventually develop into type 2 diabetes. While pm2.5 has been studied extensively, the individual components it can be composed of have not, one of which being carbon black. Carbon black has been associated with cardiovascular disease and has also been shown to have some of the same metabolic syndrome aspects as pm2.5 such as disruption of AMPK pathways, gluconeogenesis, and cardiovascular functionality. The purpose of this study is to assess the impact of chronic exposure to carbon black particulates on human health related to type 2 diabetes mellitus through analysis of biochemical endpoints such as interleukin 6, glucose sensitivity, and liver accumulation. Study portions include an epidemiological study analyzing the diagnosis rates of type 2 diabetes mellitus in specific geographical zones with high levels of carbon black, air particle studies from varying regions to analyze the particle type and structure, and a full body chronic inhalation mouse study utilizing the particle types identified during the air particle studies through assessment of key biological endpoints associated with metabolic syndrome and development of type 2 diabetes mellitus.

MP294 Importance of Data Quality Management for Risk Assessment

C. Julias, CDM Smith

Data quality management (DQM) is the most critical part of an investigation and should be applied to every stages of the investigation, especially a remedial investigation and feasibility study at a Superfund site. Starting from investigation planning, sample collection and analysis, to data reporting and evaluation, DQM should be rigorously, thoroughly, and diligently implemented in every steps to ensure the data used for evaluation, especially for risk assessment, are complete, accurate, and precise. The quality of environmental data is important in assessing risks to human health and the environment when exposed to contaminants and, consequently, making risk management decisions. Poor data quality provided to data users, especially risk assessors, will result in costly and unnecessary resampling, worst yet making wrong remedial actions. Environmental data management software, such as Scribe and Environmental Quality Information System (EQuIS™), are used to plan, track, and document sample collection and analysis. In addition, EQuIS™ also provides automation for electronic data deliverable checks and submissions. Subsequently, using these software will minimize errors and efforts and, thus, reduce cost. However, there are also some issues and challenges when using these software that users should be aware. Using these software coupling with effective DQM will ensure the quality of data collected and analyzed at a contaminated site, especially at a Superfund site. Thus, a technically sound and legally defensible risk management decision can be made.

MP295 Interaction of BDE-47 and its Metabolite 6-OH-BDE-47 with the Human ABC Efflux Transporters P-gp and BCRP: Implications for Human Exposure Assessment

S. Marchitti, USEPA ORD; C.S. Mazur, C. Dillingham, S. Rawat, USEPA; A. Sharma, J. Zastre, UGA; J. Kenneke, USEPA

ATP binding cassette (ABC) transporters, including P-glycoprotein (P-gp; MDR1) and breast cancer resistance protein (BCRP) are membrane bound proteins that mediate the cellular efflux of xenobiotics as an important defense against chemical toxins. Exposure to various environmental chemicals including brominated flame retardants, such as polybrominated diphenyl ethers (PBDEs), can result in changes in transporter gene expression; however, little information exists on how PBDEs and their metabolites interact with ABC transporters. The purpose of this study was to assess the interaction of BDE-47 and its hydroxylated metabolite 6-OH-BDE-47 with P-gp and BCRP using MDR1- and BCRP-expressing membrane vesicles and stably transfected NIH-3T3-MDR1 and MDCK-BCRP cell lines. In P-gp membranes, the parent compound BDE-47 had no measurable effect on P-gp activity; however, 6-OH-BDE-47 was a potent P-gp inhibitor (IC_{50} = 11.7 µM). In BCRP membranes, BDE-47 inhibited BCRP activity; however, 6-OH-BDE-47 was a stronger inhibitor [IC_{50} = 45.9 µM (BDE-47) vs. IC_{50} = 9.4 µM (6-OH-BDE-47)]. ATP-dependent transport of BDE-47 and 6-OH-BDE-47 was not detected, suggesting that neither compounds are substrates of P-gp or BCRP. Intracellular concentrations of known P-gp and BCRP substrates [(^{3}H)-paclitaxel and (^{3}H)-prazosin, respectively] were significantly higher (indicating less efflux) in both NIH-3T3-MDR1 and MDCK-BCRP cells in the presence of 6-OH-BDE-47, but not BDE-47. Collectively, our results indicate that the BDE-47 metabolite 6-OH-BDE-47 is an inhibitor of both P-gp and BCRP efflux activity. These findings suggest that some of the effects previously attributed to BDE-47 in biological systems may, in fact, be due to 6-OH-BDE-47. Implications for xenobiotic efflux and considerations for human exposure and risk assessment are discussed.

MP296 Legacy and current use pesticides: environmental relevance to wildlife reservationssy

P.M. Ondarza, Universidad Nacional de Mar del Plata / Depto Ciencias Marinas; P.G. Costa, Lababoratório de Microcontaminantes Orgânicos e Ecotoxicologia Aquática, Univ Federal do Río Grande / Escola de quimica e alimentos; L. Scenna, Laboratorio de Ecotoxicología y Contaminación Ambiental, Instituto de Investigaciones Marinas y Costeras, CONICET-Universidad Nacional de Mar del Plata, Mar del Plata; K. Miglioranza, Laboratorio de Ecotoxicología y Contaminación Ambiental, Instituto de Investigaciones Marinas y Costeras, CONICET-Universidad Nacional de Mar del Plata / Laboratorio de Ecotoxicología y Contaminación Ambiental IIMyC FCEN

Agricultural practices and wildlife reservations are sometime located very close and the impact of pesticide applied are of great concern to those ecosystems mainly on sensitive species. The southern area of the Atlantic Forest is located in Misiones province, in the northwestern of Argentina. Misiones has more than 50% of its surface covered by national and international reservations, such as the Iguazú Falls (7 Wonders of Nature) and Yabotí MAB-UNESCO Reserve. Current-use and banned pesticides were measured in streamwater, suspended particulate matter (SPM) and bottom sediments (BS) in Acaraguá and Ramón rivers. These rivers are mainly used for direct consumption and domestic use by population. Samples were collected from upper, middle and lower sectors in each river, which run along agricultural lands passing through natural reservations. Endosulfans (a-, b- and sulfate), chlorothalonil, chlorpyrifos and trifularin were determined by GC-ECD. Pesticides more frequently detected were endosulfan and chlorpyrifos in water, SPM and BS, with high levels in streamwater (10-1700 ng/L) and the low in BS (0.2-1.3 ng/g dry wt). Chlorothalonil and trifluralin were only found in streamwater of Acaraguá (average 0.1 and 0.3 ng/L) and Ramón (average 10.4 and 0.5 ng/L) rivers. The a-/b-endosulfan ratios ranged from 3 to 10, showing a fresh application despite it was banned in 2013. Levels of endosulfan and chlorpyrifos in water were higher than the national limits for freshwater biota protection ≤7 ng/L a- + b-endosulfan and ≤6 ng/L for chlorpyrifos. Moreover, the abundant precipitation in this area (>2000 mm/year) enhanced the availability of both pesticides, facilitated by its relative hydrophilicity. Therefore, endosulfan and chlorpyrifos occurrence deserve more attention, and monitoring programs are recommended in order to diminish their incorporation to aquatic biota and, consequently to human. This study reveals the impact of agricultural use on wildlife reservations, which would be vulnerable to runoff of current and legacy pesticides. Studies involving atmospheric transport of these contaminants are now developing in our laboratory in order to understand the pesticide dynamics in these environments.

MP298 Predictive Modelling of Trace Metals Concentrations

K. Newman, Univ of Saskatchewan; M. Evans, Environment and Climate Change Canada; M. Davies, Hatfield Consultants; D. de Boer, Univ of Saskatchewan

The input of trace metals from oil sands mining operations has led to a growing concern about water quality in the Athabasca River watershed of Alberta, Canada. These metals are derived from a variety of sources including those associated with oil sands mining, e.g., airborne releases from combustion, the bitumen upgraders, and wind-blown dust. Ground water, surface water overflow, and bank erosion are additional sources of metals to rivers and lakes in the oil sands area. These metals may, on occasion, exceed CCME water quality guidelines for the protection of aquatic life. Detection of trends in metal concentrations (and causal factors) can be challenging due the complexity of rivers resulting in spatial and temporal variability in metal concentrations, and interactions between different tributary sources such as groundwater, overland flow, and precipitation. Using data collected by the Regional Aquatics Monitoring Program (RAMP) over 1999-2014, we develop a method to predict trace metal concentrations in water using proxies including DOC (dissolved organic carbon), alkalinity, and TSS (total suspended solids). The efficacy of this model is demonstrated for the Athabasca River, the Clearwater River, and the east and west bank tributaries. In doing so, we characterize their unique chemical features, improving our understanding of the variability of metal concentrations in the oil sands area as a whole. This allows for improved investigations of temporal and spatial variations in metal concentrations and other aspects of the water chemistry within the watershed including how they vary with proximity to oil sands developments. Moreover, these predictive models provide an alternative method (to simple considerations of concentration) for investigating trends in trace metal concentrations by the inclusion of easily measured influencing variables. Additionally, our methods could be generalized to other watersheds.

MP299 Preliminary results of organochlorine pesticides in the atmospheric aerosol around Mexico using passive samplers

G. Arias Loaiza, UNAM, Ciencias de la Atmosfera / Centro de Ciencias de la Atmosfera; E. Beristain-Montiel, Universidad Nacional Autonoma de Mexico; S. Gómez-Arroyo, O. Arnador-Munoz, Universidad Nacional Autonoma de Mexico / Centro de Ciencias de la Atmosfera

The transport, persistence, bioaccumulation and biomagnification of organochlorine pesticides (OP) have made them of special interest; they also exhibit carcinogenic, mutagenic and toxic properties. OP in remote areas can be collected by passive samplers. In our study, we employed polyurethane foam (PUF) disk as sorbent in exposition through 90 days on 2014 (n=8) and 2015 (n=20) in five sites around México Country. Sampling sites are part of the Network of Atmospheric Observatories (RUOA) from Universidad Nacional Autonoma de Mexico. OP were extracted from the sampling media using dichloromethane in a system that consists of a homemade glass cell carrying PUF sample, it is coupling to reflux and immersed in an ultrasonic bath with time, potency and temperature control. The extraction variables were evaluated previously using a factorial design (2^3) obtaining the best conditions (50 °C, 40 % and 40 min, twice). Alpha-endosulfan was found in all sites, except at the east of the country (Los Tuxtlas, protected natural area 530 m.a.s.l.). Other OP in minor concentration was 4,4'-DDE. Nowadays, we are analyzing 60 samples; we will show their seasonal and spatial trend of the found OP.

MP300 Quality assessment of selected borehole water samples around selected sewage sites and industrial effluent discharge points

E. Nwaichi, The Univ of Nottingham; E. Essien, O. Akinmoladun, Univ of Port Harcourt

This study assessed the quality of selected borehole water samples located around sewage sites and industrial effluent discharge points. Water samples were collected from sewage sites located at Iwofe, Eleme, Choba, Rumuomasi, Trans-Amadi and Industrial Effluent discharge points at Gbaran, Forcados and Bonny in Rivers state Nigeria. Two locations adopted as Control were located at Eneka and Elelenwo all in the metropolis of Rivers state Nigeria. Results indicated that for borehole samples around sewage sites: Conductivity, Temperature, Total Dissolved Solids, Total Suspended Solids were significantly low ($p< 0.05$) and were within the permissible limits of WHO and NSDWQ at all locations except for Total Suspended Solids, Nitrates, Total Coliform, Dissolved Oxygen, Fecal Count at Trans-Amadi were significantly higher while colour at all locations were within the limits. The pH value was below that recommended by WHO and NSDWQ (6.5-8.5), thus indicating that the water from all the locations which is also a characteristic of the Niger Delta region, irrespective of distance between boreholes and septic tanks, was acidic. Copper, Zinc, Chromium and Nickel were significantly low and within the permissible limits of WHO and NSDWQ at all locations ($p>0.05$). Mean concentration of Iron was higher in Trans Amadi due possibly to corroded pipes. Microbiological parameters were significantly high indicating the presence of Fecal Count and Total coliforms at all locations except in Eneka and Elelenwo. Parameters investigated for water samples located around Industrial effluent discharge points were within WHO and NSDWQ permissible limits, higher Turbidity was observed in relation to Conductivity at Gbaran and Forcados due to the presence of dissolved gases in the groundwater. While Chemical Parameters: pH, Chloride and Total Hardness were within the WHO and NSDWQ limits at all the location except for Dissolved Oxygen, Biochemical Oxygen Demand and Nitrates that are significantly different ($p>0.05$) and higher at Bonny, Gbaran and Forcados. Heavy Metals such as Copper, Zinc, Chromium and Nickel were significantly low and within the permissible limits of WHO and NSDWQ at all locations. Iron was significantly high at Gbaran compared to Forcados. Total Coliforms and Fecal count were present in the water samples from Gbaran, Forcados and Bonny indicating the presence of disease causing microorganisms.TPH and PAH of the water samples were lower than the WHO/NSDWQ permissible limits in all the locations studied. Generally, some of the parameters studied fell within WHO and NSDWQ permissible limits while some parameters exceeded the recommended limits for drinking water in some locations. It is therefore important that conscious effort and measures be made to reduce the introduction of contaminants into the environment as these find their way into the ground water and eventually the food chain.

MP301 Safety evaluation and bioactivity of extracts of selected plant species used to treat sexually transmitted diseases in southern Africa

S. Adebayo, Univ of Pretoria / Biomedical Sciences; P. Mamba, Univ of Pretoria / Plant Science; E. Tshikalange, Univ of Pretoria / Pant Science

Background: Sexually transmitted diseases (STD's) have a major impact on sexual and reproductive health worldwide. Each year, the World Health Organization (WHO) estimates 448 million new cases of curable STD's are diagnosed. As the emergence of drug resistance in STD's related micro-organisms and potential side effects demands the discovery of newer drugs, the exploration of newer anti-microbial substances from natural sources may serve as promising alternatives. Despite the implied potential and long history of use, the hazards associated with the consumption of plant extracts are rarely investigated. Some plant species are known to produce poisonous chemical that could impact negatively on the health of consumers. In this study, twelve medicinal plants used traditionally in the treatment of sexually transmitted diseases are investigated for bioactivity and safe use. Methods: Ethanol plant extracts and three isolated flavonoids were evaluated for their anti-microbial activities against selected pathogens associated with STDs (one fungi and three bacteria). To determined anti-inflammatory activities of the extracts and compounds, the inhibitory effect was measured on the pro-inflammatory enzyme, 15-lipoxygenase. The extracts and compounds were also investigated for their anti-HIV activity against recombinant HIV-1 enzyme using non-radioactive HIV-RT colorimetric assay, as well as cytotoxicity in vero monkey kidney cell lines in vitro. Results: Acacia karoo and Rhoicissus tridentata extracts indicated good antimicrobial activity with MIC values ranging between 0.4 and 3.1 mg/mL. Extracts of Jasminum fluminense, Solanum tomentosum and flavonoid 2 and 3 had good

anti-inflammatory activity with IC_{50} less than positive control quercetin (IC_{50} = 48.86 µg/mL). Acacia karoo and flavonoid 3 exhibited moderate HIV RT inhibition activity of 66.8 and 63.7% respectively. Rhoicissus tridentata and Terminalia sericea had the best RT inhibition activity (75.7 and 100%) compared to that of the positive control doxorubicin (96.5%) at 100 µg/mL. The extracts had IC_{50} values ranging between 70.83-133.3 µg/mL, compared to actinomycin D (IC_{50} = 0.009 µg/mL) positive control. Conclusion: The observed activities may lead to new multi-target drug against sexually transmitted diseases. The tested extracts had low cytotoxicity on vero kidney cell lines, indicative of their relative safety.

MP302 Seasonal and spatial dynamic of current-use pesticides (CUPs) in an Argentinian watershed

D. Perez, Instituto de Investigaciones Marinas y Costeras CONICET/ UNMDP / Lab Ecotoxicologia; E. Okada, INTA Unidad Integrada Balcarce; M. Menone, Instituto de Investigaciones Marinas y Costeras CONICET/UNMDP / Lab de Ecotoxicologia; J. Costa, INTA Unidad Integrada Balcarce

The Argentinian Pampa region is the major agricultural zone, in which, the agricultural lands are strongly linked to surface waters. However, Argentina has not regulation for most of the current -used pesticides (CUPs) in surface water to protect the aquatic life. The objective of this work was to study the seasonal and spatial variations of CUPs in surface waters of “El Crespo” stream, and to determine the maximum levels reached to evaluate the possible impact on aquatic life. “El Crespo” stream is only influenced by farming activities, with intensive crop systems upstream (US) and extensive livestock production downstream (DS). It is an optimal site for pesticide monitoring studies since there are no urban or industrial inputs into the system. Water samples were collected monthly from October 2014 to October 2015 in the US and DS sites by triplicate using 1 L polypropylene bottles and stored at -20°C until analysis. The samples were analyzed using liquid chromatography coupled to a tandem mass spectrometer (UPLC-MS/MS). The most frequently detected residues (>40%) were glyphosate (GLY) and its metabolite amino methylphosphonic acid (AMPA), atrazine, acetochlor, metolachlor, 2,4-D, metsulfuron methyl, fluorocloridone, imidacloprid, tebuconazole and epoxiconazole, which are used in the crops cultivated in the area (i.e. soybean, potato, maize and wheat). Individual analysis showed that the herbicide GLY and its metabolite AMPA presented seasonal and spatial variations. The highest concentrations of GLY and AMPA were detected in US site during spring 2014 (2.09 ± 0.39 and 1.13 ± 0.56 µg/L, respectively) and in DS during summer 2015 (1.06 ± 1.02 and 0.20 ± 0.23µg/L). Comparing totalCUPs concentration between sites, a significant increase in UP site during spring 2014 (4.03 ± 0.43 µg/L) in relation to DS (1.54 ± 1.17 µg/L) was observed, may be due to pesticide applications during fallow and transport via surface runoff. Data generated in the present research could be used for evaluating the possible impact of pesticide mixtures on aquatic life and for regulation guidelines.

MP303 Seasonal and Spatial Variation of Persistent Organic Pollutants in Mexico City

E. Beristain-Montiel, Universidad Nacional Autonoma de Mexico / Especiación Química; G. Arias Loaiza, UNAM, Ciencias de la Atmosfera / Centro de Ciencias de la Atmosfera; O. Arnador-Munoz, Universidad Nacional Autonoma de Mexico / Centro de Ciencias de la Atmosfera; S.L. Gómez-Arroyo, Universidad Nacional Autonoma de Mexico

Persistent Organic Pollutants (POPs) are a group of halogenated synthetic compounds widely used in common applications as pesticides, dielectric fluids and flame retardants. A large number of compounds are prohibited or restricted by the Stockholm Convention due to their high toxicity, risk to human health and environmental pollution. A simple, fast and green methodology was developed to determine POPs in airborne particle matter using a micro scale cell and ultrasonic assisted extraction. POPs were obtained in an online extraction-filtration-evaporation system and analyzed by gas chromatography – mass spectrometry/negative chemical ionization. Application of this methodology allowed us to study temporal and spatial POPs trend in five urban sites in Metropolitan Area of Mexico City (MAMC) by collecting particles ≤ 2.5 µm ($PM_{2.5}$) in 2013 and PM_{10} durin 2014. Concentrations of POPs between 0.1 and 6.9 pg m^{-3} were founded in all sampling period. BDE-99 (pentabromodiphenyl ether), endosulfan and endosulfan isomers were found in all sites and seasons. Endrin aldehyde, dieldrin, DDE and other polybrominated diphenyl ethers (PBDEs) were also found but they were not uniformly distributed. Temporary homogeneous distribution of organochlorine pesticides sum was observed (Kruskal-Wallis, KW, p = 0.8). Polybrominated diphenyl ethers sum showed lower concentration in rainy season compared with warm and cold dry seasons (KW, p ≤ 0.02). Northeast and Southeast showed higher pesticides sum concentrations than Center, Northwest and Southwest of MAMC (KW, p ≤ 0.01). PBDEs sum was higher in Northeast respect to the rest of MAMC (KW, p ≤ 0.004). Spatial trends were explained by predominant wind trajectories while temporal variations were result of old emission and background concentrations. The presence of DDT, endrin, HCH and endosulfanan derivatives showed evidence of old emission or long range transport. Results showed evidence of POPs contamination in MAMC and for our knowledge this is the first time that POPs were determine in airborne particle matter in urban sites from Mexico.

MP304 Selenium Analysis in Surface Water using EPA Method SW7742

R. Zajac, K. Teplitsky, H. Ohlendorf, CH2M

This field study, conducted at the New River in eastern North Carolina, compared results from two different analytical methods for the measurement of selenium concentrations in brackish surface water. Environmental Protection Agency (EPA) methods SW6010 and 6020 are common analytical methods for selenium analysis. The use of these methods in brackish water has a higher detection limit, and can cause elevated results of selenium due to the high salt content of the brackish water. EPA method SW7742, with borohydride digestion of the sample followed by graphite furnace atomic absorption (GFAA), provides a detection limit of less than 1 microgram per liter (µg/L) and is more suited for brackish water. Surface water samples were collected at either low or high tide in 2012, 2013, and 2014 and analyzed using methods SW6010/6020. Concentrations ranged from 9 to 180 µg/L. Those results seemed questionable because there are no known site-related sources of selenium discharge to the New River in this vicinity. Therefore, additional surface water samples were collected at low and high tide in 2016 and analyzed using method SW7742. Concentrations were between 0.2 and 0.4 µg/L. Based on comparison of the results, Method SW7742 is the more appropriate method to use when conducting selenium analysis in brackish water.

MP305 Structural Elucidation and Environmental Risk Assessment of Candesartan Ozonation Products

M. Diehle, RWTH Aachen Univ; W. Gebhardt, V. Linnemann, RWTH Aachen Univ / Inst of Environmental Engineering

Candesartan belongs to the class of angiotensin II receptor antagonists which are used for the treatment of hypertension. During the last years, its release into wastewater due to human excretion has considerably increased caused by a steady growth of its prescription rate. Candesartan is only partly eliminated during conventional wastewater treatment und thus enters the receiving waters. It has been detected in surface water up to 1,100 ng/l. The use of advanced wastewater treatment technologies such as ozonation is currently tested to eliminate trace organic substances which are not sufficiently removed during biological wastewater treatment. During ozonation, trace organic compounds are usually not completely mineralized but transformed into oxidized products. The molecular structure of these transformation products is mostly unknown and it is unclear whether they induce an environmental risk. Here, we applied laboratory-scale ozone treatment to pure candesartan solutions in order to identify possible transformation products. LC-MS measurements including software-assisted peak detection were conducted after the ozonated samples had been enriched by means of solid phase extraction. LC-MS^n experiments were carried out to tentatively identify the transformation products' molecular structures. To assess their environmental behavior in silico calculations for logP and biodegradability were performed. Additionally, the acute luminescent bacteria test using Vibrio fischeri was used for toxicity testing of the samples before and after ozonation. A wide variety of transformation products could be detected. Most of them showed lower retention times compared to candesartan. Compounds with higher as well as with lower molecular weights than candesartan were detected. The poster presents a selection of transformation products for which a molecular structure could be proposed and the hereof calculated lopP and biodegradability values. The logP values and the lower retention times indicate an increased polarity compared to candesartan. Thus, the transformation products possess a lower bioaccumulation potential as well as a decreased tendency to adsorb onto sediments and particles when released into surface water. Biodegradability calculations result in a slight up to a distinct increase of degradability under aerobic conditions. First results of toxicity testing show no toxic effect for the initial solution as well as for the ozonated samples.

MP306 The Biogeochemistry and Long-Range Atmospheric Contamination of Antarctic Glacial Cryoconites

A. Mass, D. McKnight, Univ of Colorado at Boulder / Inst of Arctic and Alpine Research

The condensation of gases in cold environments and the semivolatile nature of many persistent organic pollutants (POPs) lead to a temperature-driven global distillation process in which atmospheric contaminants are deposited and accumulate in the cryosphere. This poleward transport leads to multiple environmental concerns including halocarbon-driven ozone degradation, contamination of glacial headwaters, and the biomagnification of lipophilic pesticides in Arctic food chains. Although long-term monitoring programs in the Arctic examine the transport and environmental fate of pollutants in the Northern hemisphere, there is a significant lack of comparable monitoring in Antarctica and the distribution of semivolatile contamination in the Southern hemisphere is far less understood. This study analyzed glacial cryoconite meltwater collected over two austral summer seasons (November- February) in the McMurdo Dry Valleys of Antarctica in order to characterize the seasonally variable biogeochemistry of glacial meltwater, identify long-range atmospheric contaminant deposition on Antarctic glacial surfaces, and examine the effect of cryoconite water chemistry on the fate of persistent organic pollutants. Preliminary identification of low-level organochlorine pesticides in cryoconite water may broaden the database of contaminant studies available to model semivolatile distillation in the Southern hemisphere.

MP307 Use of Radon to Determine Site-Specific Attenuation between Subslab Soil Gas and Indoor Air for a Vapor Intrusion Evaluation of VOCs

J.A. Kountzman, Black & Veatch / Federal Services Division

Vapor partitioning or attenuation refers to the reduction in volatile chemical concentrations that occurs during vapor migration in the subsurface, coupled with the dilution that can occur when the vapors enter a building and mix with indoor air. The aggregate effect of these physical and chemical attenuation mechanisms can be quantified through the use of a vapor intrusion (VI) attenuation factor (AF), which is defined as the ratio of the indoor air concentration arising from vapor intrusion to the soil gas concentration at the source or a depth of interest in the vapor migration route. Because of the presence of occupied buildings directly above a groundwater plume contaminated with VOCs, a multiple line of evidence indoor air study was conducted in support of a Superfund site investigation. Paired subslab soil gas and indoor air samples were collected from an occupied residence and office building during three sampling events (summer, fall and winter). Samples were analyzed for radon and a targeted set of VOCs (cis-1,2-dichloroethene, tetrachloroethene, trichloroethene, and vinyl chloride). Site-specific AFs were developed for subslab soil gas to indoor air using the measured radon and VOC results from the paired samples. Radon was consistently detected in both subslab soil gas and indoor air compared to several of the targeted VOCs which were less frequently detected. As a result, radon provided a good surrogate for estimation of a site-specific attenuation factor for the VOCs (radon allowed for development of AFs for the two structures even when VOCs were not detected). Site specific AFs for the residence and office building using radon and the VOCs were compared to EPA default AFs. While the attenuation factor developed for the residence was very consistent with EPA's default value (and the attenuation factors reported in the USEPA national database), the attenuation factor developed for the office building was significantly lower. Building construction features as well as heating and ventilation systems likely account for the difference in the observed AFs. Recommendations for incorporating site-specific AFs in VI risk assessments are presented and discussed.

Integrated Environmental Assessment and Management – Poster Only

MP309 A Tier II Plant Exposure Estimation Tool

E. Donovan, USEPA; K.V. Garber, USEPA / Office of Pesticide Programs Environmental Fate and Effects Division; C. Peck, A. Blankinship, USEPA

The United States Environmental Protection Agency's (EPA) Office of Pesticide Programs Environmental Fate and Effects Division (EFED) is developing a replacement for the TerrPlant model, which is used to estimate pesticide exposures to plants inhabiting terrestrial and wetland habitats. Conceptually, this model considers pesticide transport via spray drift and runoff from treated areas into and onto adjacent non-target habitats. The new model, Audrey III, makes use of existing models currently employed for estimating exposure by EPA, including AgDRIFT, the Pesticide Root Zone Model (PRZM5), and the Variable Volume Water Model (VVWM). In Audrey III, the terrestrial exposure model is focused on a conceptual Terrestrial Plant Exposure Zone (T-PEZ), whose width is determined by the distance from the edge of field traveled by overland sheet flow and whose depth is determined by the plant root zone. Within the T-PEZ, exposure is estimated separately for loading of pesticide entrained in runoff and sorbed to eroded sediment, and pesticide deposited directly onto foliage by spray drift. For areas outside of the T-PEZ, exposure is estimated for pesticide transported via spray drift only. A separate wetland conceptual model in Audrey III is based on a conceptual Wetland Plant Exposure Zone (W-PEZ), and assumes the same surface area dimensions used for the "Standard Pond" in PRZM5 (10 ha field and 1 ha body of water) although different dimensions for depth are assumed. Similar to the T-PEZ, concentrations are estimated based on loadings from runoff, eroded sediment, and spray drift; however, the W-PEZ is modeled as two completely mixed compartments (variable volume water column and benthos) linked together via mass-transfer. The aquatic exposure model is also based on pesticide loading from runoff, erosion, and spray drift to a relevant aquatic plant habitat. Potential applications of Audrey III in risk assessment will be presented.

MP310 An all-in-one ecological risk assessment (ERA) tool: AIST-MeRAM

B. Lin, National Inst of Advanced Industrial Science / Research Inst of Science for Safety and Sustainability; Y. Meng, Beijing Normal Univ / Academy of Disaster Reduction and Emergency Management; W. Naito, AIST Tsukuba West / RISS; M. Kamo, Advanced Industrial Science and Technology

Ecological risk assessment (ERA) of chemicals is a complicated procedure that requires enormous time and labor in collection and assessment of the hazard data and a high level of expertise in interpreting the risk. Furthermore, new assessment methodologies have been increasingly developed, making the shift from traditional impact assessment at the organism level to more ecologically relevant assessments such as "species sensitivity distribution (SSD)" or "population-level effect modeling". For these reasons, ERA of chemicals is considered "something difficult or impossible for those with little assessment experience and cumbersome or complicated for practitioners". AIST-MeRAM released on December

2014, is an all-in-one risk assessment English version tool that embedded with all the necessary data, the scheme of Chemical Substance Control Law (CSCL) of Japan, and the ERA methodologies from simple hazard quotients to more complicated modellings such as SSD and population-level assessment approach. Visit to webpage of http://en-meram.aist-riss.jp/ for the tool download and the detailed information.

MP312 Comprehensive Three Method Sampling Program for Refining Exposure Estimates and Pinpointing Sources of Lead in a Site along a Large Western US River

K.L. Tobiason, Windward Environmental; N. Judd, Windward Environmental, LLC / Senior Risk Assessor; J. Toll, Windward Environmental LLC

Elevated lead concentrations have been identified in near-shore sediments and upland soils on a site situated on a large river in the western United States with a history of mining operations. Following a removal action near a former tailings impoundment and mill operation, a comprehensive sampling program was completed to gain a deeper understanding of the horizontal and vertical extent of lead concentrations in the area for use in evaluating risk to human health and ecological receptors associated with near-shore sediment and soil. The sampling was also designed to determine if lead concentrations could be attributed to local sources that have the potential to contribute to contamination on beaches along the river. This comprehensive program combined three different sampling methods used in conjunction with one another to better characterize lead concentrations: incremental composite sampling (ICS), portable X-ray fluorescence (XRF), and coring. Composite sampling following ICS methodology was used to obtain results representing the concentration of lead for each of the 16 decision units (DUs) in the study. We evaluated results from all DUs to understand the horizontal distribution of lead over the areas sampled. The portable XRF analyzer was used to obtain lead concentrations in sieved and dried sediment and soil samples collected from between four to thirteen discrete locations within each DU. XRF results were used to both evaluate the horizontal distribution of lead within DUs and to guide the field-based decision on where to conduct coring. Confirmatory analysis of a subset of XRF samples validated use of the XRF results. Core samples were collected from three different depths to understand the vertical distribution of lead at locations of interest within each DU. Our evaluation of results from the three types of samples collected in this study indicate that XRF was effective in identifying locations of interest (based on higher lead concentrations) for core sampling. In addition, we used site-specific data to adjust lead concentrations for bioavailability to be more representative of human health exposure. Taken together, these methods provide comprehensive lead exposure information and information about horizontal and vertical extent of lead.

MP313 Cooperative Approaches & Simplified Methodologies for Rapid Assessment: Natural Resource Damage Assessment; Human Health & Ecological Risk Assessment

T. Ambrose, NewFields Environmental / Sediment Management Marine Sciences

Environmental assessments of oil and hazardous materials often involve “Natural Resource Damages” and “Environmental Risk”, which often encompass complex data analysis, allocation, and decision making. As a result, trustees, potential response parties (PRPs), and other decision makers are faced with lingering schedules and elevated costs. In addition, these assessments are typically performed as distinct efforts and at different time frames throughout the project remediation, even though they generally employ the same data and similar analysis. Most importantly, the valuable natural resources that have been damaged and the associated environmental risks, are delayed for restoration and resolution, as they await allocation and settlement funds. As a result, the overall benefits to the resources and parties involved do not justify or outweigh the significant associated costs. However, cooperative approaches with simplified methodologies and rapid assessment tools have been developed to address complex environmental data issues, thus expediting a cooperative and simplified process. For example, natural resource damage assessment employed in the early stages of remedial design can be coordinated with risk assessment to synchronize the needs for data collection and monitoring. This avoids unnecessary resampling or duplicate data gathering, and fulfills both process requirements with a cooperative well-designed investigation and restoration design that achieves a faster resolution of the entire site’s liability. This presentation identifies and describes the available rapid assessment tools and cooperative approaches that are provided by NewFields to facilitate this expedited process. These tools allow clients and decision makers access to the most timely and valuable information to arrive at overall conclusions of natural resource damages and potential environmental risks at facilities. Thus, site management occurs faster and natural resources are restored sooner for ecological and human reuse, which is the critical common goal. Uncertainties are present within any simulation of the environment, however, cooperative simplified assessment approaches provide overwhelming schedule and budget reductions that achieve restoration sooner, thus trumping the greatest benefit for all entities.

MP314 Development of inter-species correlation estimation (ICE) based species sensitivity distribution (SSD) models for use in hazard assessment

J. Brill, The Procter & Gamble Co. / Environmental Stewardship and Sustainability; S.E. Belanger, The Procter & Gamble Company / Central Product Safety Dept

Web-ICE (Web-based Inter-species Correlation Estimation) is an internet-based modeling platform developed by USEPA to relate acute toxicity of a chemical for one species to that of another. ICE allows the user to input an acute toxicity value for a surrogate species and predict the effect value for many other species, thus potentially filling in data gaps for a variety of environmental assessment purposes. ICE has been used to explore relatively straightforward species to species relationships, generalized Species Sensitivity Distributions, and make predictions of safe concentrations for endangered or threatened species exposed to chemicals. With the recent publication of ICE models for algal species (Brill et al. 2016) a full array of potential models for algae, invertebrates and fish for aquatic hazard assessments are available. Development of SSDs is particularly interesting and herein we described an assessment of SSDs based on acute toxicity for a number of well-studied industrial chemicals which possess databases large enough to make comparisons of ICE model SSDs with true SSDs. We seeded ICE models with traditional algal, Daphnia, and fish toxicity data from industrial chemical databases to generate full SSDs and probe their utility, taxonomic drivers, and the potential influences of empirical test species choices on SSD outputs for use in hazard assessments. This poster presents newly developed ICE-based SSDs and will compare ICE predicted SSDs to empirical SSDs using multiple seeding options. The ability to use ICE as an extrapolation technique for risk assessment greatly enhances our overall dependence on animal tests as well as presents another mechanism to reduce uncertainty factors applied to minimal data sets.

MP315 Effluent Water Quality from Seven Wastewater Treatment Plants in Savannah, Georgia, USA

K.S. Sajwan, T. Newsome, Savannah State Univ / Dept of Marine and Environmental Sciences; K. Ballou, Savannah State Univ; B.G. Loganathan, Murray State Univ / Dept of Chemistry Watershed Studies Inst

The city of Savannah is located on the southeast corner of the State of Georgia, USA. Metropolitan Savannah and its suburbs all together have a population of over 450,000. There are seven wastewater treatment plants (Crossroads, Georgetown, President Street, Garden City, Tybee, Wilshire, and Richmond Hill) in Savannah which serve the daily domestic wastewater treatment needs of this population. Savannah’s storm water drainage systems are very well connected with the wastewater lines. All these plants have the capacity to accommodate additional storm run off during high rainfall events. Recently, there has been a push to recycle the treated sludge and treated water from these facilities for irrigation to lawns, gardens and/or golf courses. However, there have also been some serious concerns for reusing both treated sludge and treated water that may contain heavy loads of nutrients and other toxic metals. The main objective of this study was to evaluate the variations in the pH, salinity, dissolved oxygen, NO_3-N, and elemental levels of effluent water from seven wastewater treatment plants in Savannah, Georgia. Effluent waters were collected from seven wastewater treatment plants in Savannah, Georgia and analyzed for pH, salinity, dissolved oxygen, NO_3-N and various elements. The result of this study indicated that, all these treatment plants effluent water varied in pH, salinity, NO_3-N, and elemental composition. It is a matter of great concern that, despite stringent environmental regulations, there has been no improvement in wastewater quality for this time period. Therefore, careful consideration must be given in reusing the effluent waters for land application to avoid human exposure via plant uptake and subsequent consumption of agricultural products.

MP316 Environmental effects monitoring protocol development: three Brazilian river estuary case studies

T. Furley, APLYSIA Environmental Research and Solutions; P. Pavione, Aplysia Inst; K. Costa, UFES; C. Peronico, IFES; F. Barreto, UFES; T. Basilo, M. Paes, IFES; J. Parrott, Environment and Climate Change Canada; M. Hewitt, Environment and Climate Change Canada / National Water Research Inst; K.R. Munkittrick, COSIA; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate Aquatic Contaminants Research Division

The Brazilian Program for Assessment of Water Quality (PNQA) has not yet established a standardized methodology for environmental effects monitoring, making it difficult to compare the results from different water bodies. Recent movements have shown the importance of integrating physical, chemical, and biological results for environmental health studies. Some countries like Canada, United States, Sweden, Finland, New Zealand and Chile have already adopted these parameters in environmental monitoring programs, even in some of their regulations. In Canada this type of monitoring was implemented in the mid-90s, as part of the federal program of Environmental Effects Monitoring (EEM). This EEM program is used as a scientific feedback tool to determine if the current regulations are sufficiently protective of local receiving environments. The present study aimed at validating and adapting the Canadian EEM program, in a pilot project in Brazilian estuarine ecosystems referred to as the Fish Guide Project. The EEM approach was used to assess the health of three estuaries of Espirito Santo State: the Benevente, Jucu and Santa Maria da Vitoria rivers. Three sampling points were selected in each river along a hypothesized contamination gradient. Fish and benthos studies were conducted during three sampling periods in 2014 and 2015 in different seasons (dry and wet). In parallel, water and sediment chemical parameters were analyzed. Three different fish species were chosen as bioindicators, Genidens genidens, Ophioscion punctatissius and Eleotris pisoni, with November representing their reproductive season. The fish index (GSI, HIS and K) and benthos community structure results showed that the greatest environmental effects were observed in sampling points located in the region next to the sewage discharge, reflecting the results of chemical analyses of water, sediment, and fish filets. The greatest environmental effects have been observed in the Jucu River and the best environmental conditions were found at the Benevente River. From this study it was possible to evaluate the health status of the 3 Brazilian estuaries and to publish the Brazilian environmental effects monitoring protocol in December 2015. Adopting this protocol is expected to maximize the effectiveness of environmental monitoring studies while reducing time and cost.

MP317 EPA's National Reassessment of Contaminants in Fish from US Rivers

L. Stahl, J. Wathen, USEPA / Office of Water Office of Science and Technology; T. Kincaid, USEPA / Office of Research and Development; B.D. Snyder, Tetra Tech, Inc; H.B. McCarty, CSC Government Solutions LLC, a CSRA Company; T. Cohen, Tetra Tech / Center for Ecological Sciences

Multiple EPA offices collaborated to conduct a reassessment of fish contamination in U.S. rivers as part of the Agency's 2013-14 National Rivers and Streams Assessment (NRSA). This is the first national assessment of contamination in river fish that will generate probability-based data for analysis of trends in fish contaminant levels when compared to fillet concentration results from the 2008-09 NRSA. In 2013 and 2014, field teams collected one fish composite sample per site from a statistically representative subset of 361 river locations (5^{th} order or greater), 224 sites of which were assessed during the 2008-09 NRSA. The composite samples consisted of up to five similarly sized adult fish of the same species that are commonly consumed by humans. Aliquots of fillet tissue from the composite samples were analyzed for mercury (361 composites) and 13 perfluorinated compounds (PFCs), including perfluoroctanesulfonic acid (PFOS) (352 composites). Fillet samples from the 224 sites that corresponded to locations sampled during the 2008-09 NRSA were also analyzed for the full complement of 209 PCB congeners. All 361 of the fillet samples contained detectable levels of mercury, and all fillet samples from the 224 previously sampled sites that were analyzed for PCBs contained one or more congeners. All but one fillet sample from the 352 composites contained PFCs and 349 of those fillet samples contained PFOS. The concentration ranges measured for mercury, total PCBs, and PFOS are 8.6-1,070 ng/g, 0.06-4,700 ng/g, and 0.16-9.9 ng/g, respectively. The 2013-14 NRSA fillet results indicate that 26% of the sampled population of rivers had fish with mercury tissue concentrations that exceeded EPA's 300 ppb fish tissue-based water quality criterion for methylmercury, 49% of the sampled population exceeded EPA's 12 ppb cancer human health screening value (SV) for PCBs, and 10% of the sampled population exceeded the Minnesota Department of Health 40 ppb human health SV for PFOS.

MP318 extreme weather events in the Río de la Plata: Threats and risks in coastal cities

M.N. Rodriguez Moreyra, F. Granja, M.E. Garcia, S.O. Demichelis, National Univ of Lanús / Environmental Laboratory, Urban Environmental Management, Dept of Productive Development and Technology

The flooding of the Río de la Plata are generated by the phenomenon of sudestada. It occurs at any time of the year, 90% of sudestadas take place between April and December although stronger (with higher gusts to 30 knots and usually with rainfall throughout the region) occur from March to October. It is characterized by persistent, regular Southeastern strong winds, relatively low temperatures and generally with rainfall of varying intensity, although sometimes it can occur without precipitation. In the case of sudestada with rainfall, it is generated by the combined effect of two systems, one high pressure (located on the Atlantic Ocean, off the coast of central Patagonia) that transports cold air maritime origin to the east of the province of Buenos Aires, south end of Coast and South Eastern Republic of Uruguay, and low pressure system (located on the Central and southern Mesopotamia and the western region of Uruguay) that brings warm, moist air over the region. When depression deepens, Southeast wind circulation industry producing the sudestada intensifies. In this work records extreme events of floods in the coast of the Río de la Plata between 1900-2000 in Quilmes, Berazategui, Ensenada, Berisso and Magdalena, area with large percentage of territory in floodrisk . It is known that in recent years, the average sea level on the coast of Argentina and River Plate have increased considerably according our records. Among the causes of the increase are the increased rainfall and rised water flows contribution of Uruguay and Parana Rivers. The causes of extreme flood events in the selected coastal strip are: rainfall (57.1% of cases), rains with overflowing streams (28.6%), rain with wind (11.4%) and promotion webs (2.9%). In the event of floods between 1987 and 2007 on the coast of Río de la Plata there was a large amount of flooded areas with a total of 15,318 evacuees, at least a total of 16 dead, with flooding March 1988 more evacuations occurred (8500 people). This event features across the coastal strip as evacuees exceeded 55% of total evacuations in the period in Quilmes; for Berazategui, 90.1%; for the game of Ensenada, 32.8%; and Berisso, the proportion was much lower, reaching barely 3.2% of total cases. We conclude that in the Risk Management of extreme weather events, must be addressed actions to reduce vulnerability and exposure of populations and increase the resilience of cities to cope with extreme weather events.

MP319 Filing a Biotechnology Submission under Toxic Substances Control Act (TSCA) and Environmental Hazard Analysis

A. Muneer, USEPA

Have you created an intergeneric microorganism species and thought about using it for commercial or research purposes? Did you know that the US Environmental Protection Agency has an application process in which you can do that? Come learn what the TSCA Biotechnology Program is about, including Microbial Commercial Activity Notice (MCAN), TSCA Experimental Release Application (TERA), and Tier I and Tier II exemptions, and Biotechnology Test Market Exemption Applications (TMEAs) while learning about what environmental hazards intergeneric microorganisms pose.

MP320 Hazard assessment of the water-soluble fraction from a petroleum-based lubricating oil in aquatic organisms

Z. Currie, Univ of Saskatchewan / Toxicology Centre; L. McPhee, Univ of Saskatchewan Toxicology Centre / Toxicology Centre; D. Tkatchuk, Univ of Saskatchewan / Toxicology Centre; K.E. Bresee, Intrinsik Environmental Sciences; C. Semper, Trans Canada; S. Siciliano, Univ of Saskatchewan / Toxicology Group and Dept of Soil Science; N.S. Hogan, Univ of Saskatchewan / Toxicology Centre

Oil and gas transport depends on vast pipeline networks and many compressor stations, where automated actuator valves pressurize and control the flow of the oil and gas. These valve actuators use hydraulic fluid as a lubricant, and leakage of the fluids has caused soil staining around the valves. Direct toxicity risks of this lubricating oil to aquatic organisms from groundwater infiltration as well as spring runoff are uncertain. Therefore, a hazard assessment of UNIVIS J13 lubricating oil was performed to evaluate the toxicity of the mixture to aquatic organisms. We assessed the acute toxicity and sub-lethal effects of pure lubricating oil UNIVIS J 13 in Vibrio fischeri, Daphnia magna, and embryo-larval stages of two amphibian species, Xenopus laevis and wood frog (Rana sylvatica). Aquatic organisms were exposed to a range of percentages (3, 6, 12, 25, 50, 100%) of 1:1 loadings of UNIVIS J 13 water accommodated fractions (WAF). Dose-response relationships were established and lethal loading 50 (LL_{50}) values were determined. The 5-minute LL_{50} in Vibrio fischeri was determined to be 33.4%, and the 48-h LL_{50} in Daphnia magna was determined to be 24%. For Xenopus laevis, there were no significant differences in mortality among treatment groups, but total length, tail length, and snout-vent length were significantly decreased in the 100%, 50%, and 25% WAF treatment groups. For wood frogs, there were no significant differences in mortality nor morphometric endpoints. In order to fully assess the hazard of UNIVIS J13 to a wide range of aquatic organisms, future work aims to evaluate the acute toxicity of UNIVIS J13 WAF in the aquatic plant Lemna minor. However, the toxicity data gained from this study thus far indicates that 1:1 loadings of UNIVIS J13 water accommodated fractions pose de minimis risk to aquatic organisms.

MP321 Health risk assessment of metal induced inhalation exposure to PM2.5 in Korea

I. Kim, Gwangju Inst of Science and Technology / School of Earth Sciences and Environmental Engineering; K. Park, Gwangju Inst of Science and Technology / School of Environmental Science and Engineering; S. Kim, Gwangju Inst of Science and Technology

There is a growing interest in the particulate matter, especially PM2.5 (< 2.5μm) in Korea. Annual average PM2.5 concentration from 2006 to 2011 in Seoul was 27μg/m^3 that is higher level than annual standard of WHO (10μg/m^3), USA (15μg/m^3) and even Korea (25μg/m^3). Since PM2.5 is small enough to be inhaled, the continuous high level PM2.5 is a serious problem that threatens the public health. In this study, we evaluated the national level of carcinogenic metals (Cr(IV), As, Ni, Cd) in PM2.5 based on 55 literatures. The exposure parameters for Korean was established to reflect properly the inhalation exposure characteristics of Korean. The lifetime excess cancer risks (LECR) of four metals was calculated following probabilistic approach. The uncertainty and sensitivity of LECR were characterized by Monte Carlo simulation (Crystal ball, Oracle). Of the four metals, the LECR of Cr(IV) and As exceeded the negligible ($< 10^{-6}$) risk but ranged in the acceptable risk (10^{-6}-10^{-4}). The LECR of Ni and Cd were negligible level. Sensitivity analysis showed the metal concentration is a dominant parameter that influence the LECR. Even though the LECR of single metals are not threat, it is necessary to consider the potential risk of metals in terms of the mixture. This study will suggest not only the national risk level of metallic PM2.5 in Korea but also the probabilistic approach to assess the risk of single and mixture compounds.

MP322 Integrated evaluation of air pollution effects: in vitro toxic and genotoxic properties and early biological effects in buccal cells of children

E. Ceretti, Univ of Brescia / Dep of Medical and Surgical Specialties Radiological Sciences and Public Health; G.C. Viola, Univ of Brescia Italy / Dept of Medical and Surgical Specialties Radiological Science and Public Health; G. Mazzoleni, Univ of Brescia / Dept of Clinical and Experimental Sciences; C. Zani, Univ of Brescia Italy / Dept of Medical and Surgical Specialties Radiological Science and Public Health; S. Levorato, Univ of Perugia Italy / Dept of Pharmaceutical Sciences; A. Carducci, Univ of Pisa, Italy / Dept of Biology; F. Bagordo, Univ of Salento, Italy / Dept of Biological and Environmental Science and Technology; S. Bonetta, Univ of Torino, Italy / Dept of Public Health and Pediatrics; D. Feretti, Univ of Brescia Italy / Dept of Medical and Surgical Specialties Radiological Science and Public Health; T. Salvatori, Univ of Perugia, Italy / Dept of Pharmaceutical Sciences; M. Verani, Univ of Pisa, Italy / Dept of Biology; F. Serio, Univ of Salento, Italy / Dept of Biological and Environmental Science and Technology; E. Carraro, Univ of Torino, Italy / Dept of Public Health and Pediatrics; S. Vannini, Univ of Perugia, Italy / Dept of Pharmaceutical Sciences; S. Bonizzoni, Brescia Municipality; P. Colombi, Centro Servizi Multisettoriale e Tecnologico CSMT Gestione S.c.a.r.l.; U. Gelatti, Univ of Brescia Italy / Dept of Medical and Surgical Specialties Radiological Science and Public Health

Air pollution is a global problem. The IARC classified air pollution and particulate matter as carcinogenic to human. Children are a high-risk group in terms of the health effects of air pollution, and early exposure during childhood can increase the risk of developing chronic diseases in adulthood. The MAPEC_LIFE (Monitoring Air Pollution Effects on Children for supporting public health policy) is a project founded by EU Life+ Programme (LIFE12 ENV/IT/000614) which intends to evaluate the associations between air quality and early biological effects in children and propose a model for estimating the global risk of early biological effects due to air pollutants and other factors in children. The study was carried out on 6-8-year-old children living in 5 Italian towns with different levels of air pollutants. Micronucleus frequency was investigated in buccal cells of children. To evaluate child exposure to urban air pollutants, PM0.5 samples were collected for 72h in the school areas using a high-volume air sampler. PM0.5extracts were chemically analyzed for PAH and nitroPAH content and for toxic and genotoxic properties. MTT and NR citotoxicity assays on A549 cells, comet and micronucleus tests on A549 cells, and Ames test on Salmonella strains TA100, TA98, TA98NR and YG1021 were performed. Data on urban air quality during the study period were obtained from the Regional Agency for Environmental Protection. Levels of main pollutants were, as expected, higher in the North of Italy. All PM0.5 extracts showed a mutagenic effect on TA98 and YG1021 strains, suggesting the presence of nitroaromatic compounds, results confirmed by chemical analysis. No genotoxic or oxidative effect of PM0.5 extracts was observed using comet and micronucleus tests. A light cytotoxic activity was detected for all the PM0.5 extracts, except for Brescia sample. Micronucleus frequency in buccal cells of the 1089 recruited children was higher in Brescia (0.06/100 cells) than in any other towns (from 0.03 to 0.05/100 cells). The results showed that, even if all PM0.5 extracts induced mutagenic effect on bacterial cells, they had no genotoxic and only light toxic effects on human cells. Results about micronucleus frequency in children suggested that, in addition to air pollution exposure, some other factors, related to lifestyle or further exposures, may influence micronucleus frequency and cellular response to air pollutants.

MP323 Large Scale Habitat Creation and the Risk Management of the Everglade Snail Kite (Rostrhamus sociabilis); Copper Bioaccumulation

J.M. Allen, Formation Environmental; M.C. Lewis, Formation Environmental LLC; B. Westmark, Environmental Consulting and Technology, Inc.; R. Kukleski, R. Taylor, South Florida Water Mgmt District

As part of the ongoing Everglades restoration, former agricultural lands are commonly converted into aquatic and semi-aquatic habitats for water quality improvement and large-scale habitat creation. The conversion of former agricultural areas into aquatic and semi-aquatic habitats creates the potential for mobilization of agrochemicals applied during the active farming of the land. Of particular concern in south Florida is the accumulation of copper, which is widely used as a fungicide in citrus agriculture, into the Florida apple snail. The apple snail is the primary food source for the federally endangered Everglade snail kite and has been shown to rapidly accumulate copper to concentrations of potential concern for feeding snail kites. The SFWMD has completed a series of bioaccumulation tests intended to provide a set of soil/sediment benchmarks that are protective of the Everglade snail kite that can be used as remediation goals during water resource project construction. Initial studies, completed in 2014, exposed juvenile apple snails to sandy soils collected from various locations across south Florida containing copper concentrations between 35 and 120 mg/kg in a series of small (8 ft. by 15 ft.) mesocosm cells. As part of the initial study, a set of threshold tissue concentrations (TSCs) protective of the snail kite were also calculated. The results indicated that concentrations of copper in sandy soils up to 120 mg/kg may be acceptable to leave in place prior to flooding of former citrus groves. Subsequent studies have assessed the difference in copper desorption and bioaccumulation between sandy soils and soils containing much higher levels of organic carbon and have proposed higher benchmarks in areas with highly organic soils (i.e. > 20% OC). The SFWMD is currently conducting a third phase of studies aimed at reducing uncertainties in the original studies and providing additional, more focused data by assessing bioaccumulation within functional water resource project areas that contain sediment copper concentrations at or near the proposed soil benchmarks. The results of the studies will be used by the Interagency Copper Science Review Panel (ICRSP) stakeholders to develop better risk management strategies and balance risks to the Everglade snail kite with the benefits of large-scale habitat creation as part of the restoration of the Everglades.

MP324 National Endangered Species Assessment of Malathion: Problem Formulation and Step 1 Review

S. Teed, Intrinsik Environment Sciences Inc.; R.L. Breton, Intrinsik Environmental Sciences, Inc.; C. Greer, Intrinsik Environmental Sciences (US), Inc. / Biology; K.L. Hill, Intrinsik / Dept of Biology; L. Padilla, Stone Environmental, Inc.; M.F. Winchell, Stone Environmental, Inc. / Environmental Systems Modeling; P. Whatling, FMC Corporation / Senior Manager of Regulatory Science; N. Pai, K. Budreski, T.L. Estes, Stone Environmental, Inc.

National endangered species assessments (NESA) are currently underway for three case study pesticides (e.g. chlorpyrifos, malathion, diazinon). The Environmental Protection Agency (EPA) and the Fish and Wildlife Service (FWS) (the Agencies) have released their preliminary biological evaluations (BE) for the three organophosphates and the 60-day comment period has past. The BEs have been informative and provided insight into how the Agencies are approaching the malathion evaluation. We have been conducting an aquatic and terrestrial NESA building upon our refined ecological risk assessment for malathion re-registration under FIFRA. We have completed a conservative screening-level risk assessment (Step 1) and are well into the refined assessment (Step 2). We are conducting these analyses for entire receptor groups, focal species as surrogates, and where appropriate specific listed species. Selected approaches are described and key considerations in data quality and multiple lines of evidence are discussed to provide support and context to the risk conclusions. This presentation provides an update to this process and highlights some of the differences in our approach relative to the Agencies BEs.

MP325 Perfluorinated compounds in surface water and sediments of Diep and Plankenburg rivers in Western Cape South Africa

B.O. Fagbayigbo, Cape Peninsula Univ of Technology / Environmental health and occupational studies; B. Opeolu, Cape Peninsula Univ of Technology / Faculty of Applied Sciences; O. Fatoki, B.J. Ximba, Cape Peninsula Univ of Technology / Chemistry

In this study, seasonal variation and distribution of nine perfluorinated compounds (PFCs) in surface water and sediments of Diep and Plankenburg Rivers in Western Cape, South Africa were assessed. Nine PFCs were extracted from water and sediments samples using solid phase extraction (SPE). Thereafter, the concentrations of the PFCs were determined using Ultra performance liquid chromatography coupled with quadrupole time of flight (UPLC/QTOF). Levels of PFCs in sediments were higher than in water samples from corresponding sampling points. Priority compounds (PFOS and PFOA) were detected in all samples, with concentrations ranging between (71.05 -1090.92 ng/L) for PFOS, and (6.67 – 2144 ng/L) for PFOA in surface water. The levels in sediment ranged between 0.50 and 248.14 ng/g dw, for PFOS and 9.70 and 156.8 ng/g dw, for PFOA. The maximum values for the partitioning/distribution coefficient (log K_{OC}) were 1.311 and 1.316 respectively for PFOS and PFOA. Elevated levels of PFCs were detected in surface water and sediment samples in summer months relative to levels detected during winter. Levels of PFOS and PFOA in surface water were higher than recommended threshold limits (200 and 400 ng/L) for PFOS and PFOA respectively for surface water. These values may be attributed to the presence of informal settlements and industrial facilities in the vicinity of the sampling locations. Anthropogenic activities seem to be a major source of input of PFCs into the aquatic ecosystem, although this present study could not verify this. Keyword: PFOS, PFOA, Surface-water, Sediment, Season, UP/LC-QTOF.

MP326 Potential Human Toxicity of Petroleum Biodegradation Metabolites in Groundwater Samples from Fuel Release Sites

A. Tiwary, Chevron / HES; R.I. Magaw, Chevron ETC; D.A. Zemo, Zemo & Associates; R.E. Mohler, Chevron ETC / PAD; K. O'Reilly, Exponent / Environmental and Earth Science; S. Ahn, Exponent, Inc. / Environmental and Earth Science; C. Espino Devine, Chevron ETC

Petroleum hydrocarbons biodegrade in the environment and are converted to polar (non-hydrocarbon) metabolites. These metabolites are extracted from groundwater samples and quantified as Total Petroleum Hydrocarbons (TPH) unless a silica gel cleanup (SGC) step is applied to the sample extract prior to the TPH analysis. The polar metabolites can be separated from the non-polar hydrocarbons by incorporating the SGC step; however, some regulatory agencies are hesitant to adopt this method, citing the unknown nature and toxicity of these complex mixtures. Non-targeted GCxGC-MS analyses of groundwater samples from historic fuel release sites have tentatively identified over 1700 unique polar metabolites representing many distinct structural classes of chemicals including acids/esters, alcohols, phenols, ketones, and aldehydes. The potential chronic toxicity of these metabolites to human receptors has been investigated. Evaluation of potential chronic human toxicity of the metabolites was initially assessed by reviewing available agency-derived Reference Doses (RfDs) for individual potential metabolites, and then developing an RfD-based toxicity ranking system for each structural class of potential metabolites. This ranking system was applied to all metabolites identified in each groundwater sample. Results show that the vast majority of the metabolites are in structural classes that are ranked "Low" toxicity to humans (RfDs≥0.1 mg/kg/day). In addition, upgradient (representing local background conditions) and downgradient groundwater samples were collected from representative biodegrading fuel release sites and submitted to a commercial laboratory to screen for genotoxicity using the in vitro gamma-H2AX assay, and for estrogenic effects using the in vitro Estrogen Receptor Transcriptional Activation (ERTA) assay. Results of these screening assays indicate that the metabolite mixtures do not appear to have the potential to cause significant genotoxic or estrogenic effects. Overall, the complex mixtures of polar metabolites identified in groundwater are unlikely to present a significant risk to human health.

MP327 Regional distribution of ecological risks of pesticides in Japan – Integrated analysis of environmental model and species sensitivity distribution

T. Nagai, National Inst for Agro-Environmental Sciences; S. Yachi, Inst for Agro-Environmental Sciences, NARO

We analyzed regional distribution of ecological risks of 67 pesticides (commonly used in Japanese paddy fields) in 350 sites of Japanese river water. Region-specific environmental models and species sensitivity distribution (SSD) were integrated to quantify ecological risks in each site. Environmental model used in this study consists of environmental scenario (property of river basin) and environmental dynamics from paddy field to river. The predicted environmental concentrations (PEC) in river water was calculated considering pesticide mass discharge through surface runoff and seepage using physico-chemical parameters (soil adsorption constant and half-life in water) and paddy field lysimeter test data. To predict region-specific PEC, the important region-specific parameters of environmental scenario, which are river flow, paddy rice cropped area, and pesticide usage ratio in the basin, were organized at 350 river sites in Japan. The calculated region-specific PECs were validated by comparing with measured concentrations in a river. Differences between measured and predicted concentrations were within 10-folds for all but one pesticide. The SSDs of the 67 pesticides were also analyzed based on acute toxicity data. To do so, ecotoxicity database was constructed by collecting acute toxicity data for freshwater organisms. The magnitude of ecological risk was quantified as the index of potentially affected fraction (PAF) by jointing SSD and the regional distribution of PEC. Finally, we developed the database of PECs and PAFs and the Google map based visualization tool of the data at the 350 sites in Japan. Several techniques for filling the gaps of fate and effect data were also developed.

MP328 Ring test to improve the OECD 306 marine biodegradation screening test

A. Ott, T. Martin, Newcastle Univ; G. Whale, Shell Health / Shell Health; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; B. Rowles, Cefas / OCNS; M. Galay-Burgos, ECETOC; R. Davenport, Newcastle Univ

Recent ECETOC workshops have recommended a series of modifications and enhancements to existing OECD biodegradation screening tests, to deliver more robust methods for assessing persistence. Specific enhancements investigated included increased test durations and investigating the impact of biomass density and diversity on the probability of observing biodegradation. These proposed steps were designed to minimise the high variability and poor reliability previously reported in OECD biodegradation screening tests, such as the OECD 306 marine biodegradation test, whilst increasing the ecological relevance of such studies. The Cefic-LRi funded Eco11 project investigated and validated these enhancements. As a follow up in 2015, the UK Centre for Environment, Fisheries and Aquaculture Science (Cefas) hosted an international workshop on the OECD 306 test in Lowestoft. One of the outcomes from the workshop was an agreement between the chemical industry, regulators and academia that there was too much variability in existing marine biodegradation screening tests and that there was a need to develop a revised method and initiate a ring test of an improved OECD 306 test. This ring test project commenced in January 2016, funded by Cefic-LRi. Laboratories from North America, Japan and Europe, regulators, industry and academia are involved. The ring test aims to validate the use of increased biomass densities and an extended test duration to obtain a more environmentally relevant OECD 306 screening test. Seawater concentration by tangential flow filtration will increase the likelihood of including specific degraders, whilst longer test durations will allow us to investigate previously reported long lag phases in marine systems. A summary of the ring test protocol together with preliminary test results and the status of the experimental work will be presented.

MP329 Risk Reduction Assessment as a means of Quantifying Benefits of a Potential Dredged Material Containment Facility

M.C. Ciarlo, EA Engineering, Science, and Technology; C. Cheatwood, M. Powell, EA Engineering, Science, and Technology, Inc. PBC; P.A. Derrick, EA Engineering, Science and Technology, Inc. PBC / WNRE; F. Barranco, EA Engineering, Science, and Technology, Inc. PBC

As part of due diligence for planning a potential Dredged Material Containment Facility (DMCF), the Maryland Port Administration (MPA) considered Coke Point, a peninsula on the Patapsco River in Baltimore Harbor, Maryland. Preliminary concepts for the DMCF included configurations that would utilize or cover near-shore areas within the Patapsco River. The Patapsco River is a highly urbanized estuary subject to chemical inputs from a wide variety of sources, including legacy pollution, urban runoff, industrial discharges, and known disposal sites. Planning studies found that sediments contain elevated concentrations of metals, polycyclic aromatic hydrocarbons, and polychlorinated biphenyls. One of the potential benefits of a DMCF which extends into the river is that it may cover over areas of elevated concentrations and thus reduce risks to people, wildlife, fish, and crabs from legacy pollutants. Therefore, risk assessment and management studies were performed to quantify the beneficial risk reduction associated with the DMCF to help inform project planning and coordination. A human health and ecological risk assessment was performed for the area offshore of Coke Point that quantified risks from chemicals detected in sediment, water, fish, and crabs. Human health risk assessment focused on recreational and commercial uses, and drew from field studies of bioaccumulation into important fisheries species. Ecological risk assessment focused on the potential for impacts to fish, crabs, and wildlife. Special focus was given to differentiating risks due to chemicals associated with possible sources at Coke Point from risks associated with more widespread urban inputs. Risk assessment results were used to map areas producing the highest risk. Spatial analyses were used to quantify the potential risk-reduction benefits of the project and the possible need for risk management actions. Risk reduction was predicted for numerous potential DMCF design concepts, and potential benefits were incorporated into feasibility studies for the project.

MP330 RiskChallenge: A simulation of the risk assessment process for humans and ecological receptors

R.G. Stahl, E.I. DuPont de Nemours and Company / Corp Remediation; T.S. Bingman, DuPont / Corporate Remediation

RiskChallenge is an innovative simulation that demonstrates the principles and practices of human and ecological risk assessment and the challenges of resource-limited, multi-stakeholder decision-making. It gives participants an opportunity to apply their risk assessment skills to realistic, hypothetical scenarios, such as those involving contaminated sites and new chemicals. The steps in the risk simulation follow, but do not mimic exactly, those which might be present in various national regulatory programs in the US or elsewhere. The studies and data that participants can purchase for the risk assessment are based the experience of the simulation developers, or from publicly available reports. As a member of a team of stakeholders, participants formulate the problem, assess the exposure and effects data, characterize the risk(s), and make a risk management recommendation. Finite funding and time are given to gather the data needed for the analysis. After the simulation, management recommendations, approaches, frustrations, and uncertainties are shared with other teams. The simulation provides valuable, hands-on experience in the human health and ecological risk assessment process. There are no winners or losers. The goal is simply to increase interest and understanding in risk assessment that will facilitate its use in environmental decision-making across public and private sectors. The simulation is designed to be balanced, objective, and realistic, so it is valuable and entertaining to virtually all stakeholders. While geared toward individuals with environmental backgrounds, virtually anyone can participate. Once tested and validated, this simulation will be donated to SETAC for scientific outreach and education.

MP331 Storm wave modeling (sudestada) – coastal flood risk

C. Haspert, S.O. Demichelis, M.E. Garcia, Univ of Lanús / Environmental Laboratory / Urban Environmental Management / Dept of Productive Development and Technology National,

The metropolitan area of Buenos Aires is the most densely populated area of the Argentina republic, a large area of this region is below 5m elevation, vulnerable to flooding during storm surges passage (sudestadas) considered. Coastal areas and cities located in them, are threatened by a wide variety of climate-related hazards. The Argentina coast of Río de la Plata and in particular, the metropolitan area of Buenos Aires, do not escape this situation, becoming increasingly vulnerable because of climate change. The overall objective of this work is the mathematical modeling of a wave of storm using the open source model Delft3d in the Río de la Plata, to assess the risk of coastal flooding. For execution digitized nautical charts for the depths of the study area, which then interpolated triangularly were assigned to the nodes of the grid computing, built by the RFGRID And QuickIN model modules. And also from the tidal constituents obtained for the study site, the model was calibrated with data from the National Hydrographic Service tide predicted for different coastal points of interest. The adjusted model calibration and was then used to simulate a remarkable sudestada occurred in the month of May 2000, using season winds aeroparque city of Buenos Aires and waves on the ocean edge of deep water obtained from the database IFREMER for that date. It was obtained from the modeling, the levels and wave height along stations located control over the Argentina coast. It is observed that the amplitude of the wave is amplified as it propagates storm into the Río de la Plata, due to the decrease in width and depth. The peak levels for the climatic conditions were used to map flood irrigation on a site of interest. The methodology is applicable to future scenarios within the context of climate change.

MP332 Synergistic Induction of Metal-Responsive and Oxidative Stress Gene Biomarkers in Placental JEG-3 Cells by environmental Arsenic & Cadmium Mixtures

O. Adebambo, NC State Univ / Biological Sciences; P.D. Ray, Univ of North Carolina at Chapel Hill / Envronmental Science Engineering; D. Shea, North Carolina State Univ; R.C. Fry, Univ of North Carolina at Chapel Hill / Environmental Science and Engineering

Exposure to elevated levels of the toxic metals inorganic arsenic (iAs) and cadmium (Cd) represents a major global health problem. These metals often occur as mixtures in the environment, creating the potential for interactive or synergistic biological effects different from those observed in single exposure conditions. In the present study, environmental mixtures collected using a passive sampling device from two waste sites in China, and identical mixtures prepared in the lab were tested for toxicogenomic response in placental JEG-3 cells. These cells serve as a model for evaluating cellular responses to exposures during pregnancy. One of the mixtures was predominated by iAs and one by Cd. The gene biomarkers heme oxygenase 1 (HO-1) andmetallothioneinisoforms (MT1F and MT1G) previously shown to be preferentially induced by exposure to either iAs or Cd, and metal transporter genes aquaporin-9 AQP9 and ATPase, beta polypeptide ATP7B were measured in order to evaluate the effects from the metals mixtures using dose and time course experiments. There was a significant increase in the mRNA expression levels of HO-1, MT1F and MT1G in mixture-treated cells compared to the iAs or Cd only-treated cells. Notably, the genomic responses were observed at concentrations significantly lower than levels found at the environmental collection sites. These data demonstrate that metal mixtures increase the expression of gene biomarkers in placental JEG-3 cells in a synergistic manner. Taken together, the data suggest that toxic metals that co-occur may induce detrimental health effects that are currently underestimated when analyzed as single metals.

MP333 Utilization of CBEDMS to dynamically evaluate contribution to receptor relative risk to support the allocation of remediation costs

C. Peterson, EHS Support LLC; N. Goulding, EHS Support, Inc.; C. Hankley, EHS Support; T. Biksey, EHS Support LLC / Director Risk Assessment; G. Long, EHS Support, Inc.

Relative risk ratios were calculated for constituents of concern (COCs) to apportion remedial costs for potentially responsible party (PRP) to address unacceptable risks associated with non-aqueous phase liquid (NAPL) contaminated sediments. The ratios estimate the potential risk to human and ecological health based on source-specific COCs including polynuclear aromatic hydrocarbons (PAHs), copper, lead, and polychlorinated biphenyls (PCBs). Apportionment was also based on the estimated COC mass, the volumes of affected sediment, and the spatial distribution of PRP-specific COCs. The goals identified in the Feasibility Study included reduction of: PAH-specific cancer risks during recreational activities; PCB exposure to fish and shellfish; benthic ecological risk from exposure to COCs; and, risks to herbivorous birds from exposure to dietary PAHs. Approximately 900,000 records of historical data were compiled from sources including portable document format (PDF) and electronic tables and databases to a cloud-based enterprise database management system (CBEDMS). Records included spatial, analytical, and lithological information; human and ecological toxicity values; and, molecular weights. Human and ecological COC- and location-specific relative risk ratios for multiple sediment lithologies were calculated using COC concentrations and site-specific preliminary remediation goals (PRGs). Integrated with a geographic information system (GIS), the CBEDMS generated uniform and reproducible total results for multiple PAH and PCB datasets (e.g., individual, alkylated, and total PAHs, individual and total PCBs); determined lithologic interfaces for estimation of COC-specific relative risks for vertical profiling of impacts; estimated mass of each COC by location; and calculated risk-driver-specific sediment volumes to be remediated. The CBEDMS allowed for dynamic evaluation of the spatial distribution of COCs and NAPL in sediments, relative risks to human and ecological health, and masses of COCs and volumes of sediment for each risk driver to inform the risk manager in an iterative approach. This enabled the apportionment of remedial costs by identifying PRP contribution to unacceptable levels of risks. This methodology supported a scalable, flexible, and defensible position in the allocation of remedial costs and can be applied to remediation sites from small, multiple party projects to complex Superfund projects and natural resource damage assessments (NRDA).

MP334 Whole Stream Metabolism in Agriculture Drainage Systems

J.L. Farris, Arkansas State Univ / Univ Distinguished Professor; O. Iseyemi, Arkansas State Univ / Environmental Science; M. Moore, USDA-ARS National Sedimentation Laboratory / Water Quality and Ecology; S. Choi, Arkansas State Univ

Agricultural drainage systems influence stream metabolism and productivity by channeling nutrients and other resources from terrestrial ecosystems into aquatic systems. Monitoring ecosystem function in smaller catchments may be more cost effective and practical than measuring the whole ecosystem. This study investigated stream metabolism within replicated experimental agricultural drainage systems during a simulated storm runoff event. Eight vegetated drainage ditches of two types (conventional and controlled with weirs) with contrasting vegetation management strategies have been studied. Four vegetated ditches (two of each type) were mowed with clippings remained in the system, while vegetation in the remaining four ditches was left unmanaged. Results indicated ditches with weirs had significantly ($p < 0.001$) higher gross primary production (GPP) (2.83 ± 0.31 g O_2 m^{-2} d^{-1}) compared with conventional ditches with no weirs (0.60 ± 0.23 g O_2 m^{-2} d^{-1}). The presence of additional vegetation in this system may have contributed to its higher GPP, rather than the presence of autotrophic biomass (algae), because mean chlorophyll a was comparable between ditch treatments. This demonstrates the ability of weirs to play a role in enhancing soil inundation which supports denser autotroph biomass. Community respiration (CR) was significantly ($p = 0.04$) higher in mowed ditches ($- 0.98 \pm 0.39$ g O_2 m^{-2} d^{-1}) than in unmowed ditches ($- 0.20 \pm 0.06$ g O_2 m^{-2} d^{-1}). The higher CR could be attributed to vegetation clippings left in ditches after mowing, which may have increased available organic matter to the system, thus fueling additional heterotrophic microbial respiration. Overall, all ditches were net autotrophic, having positive net-ecosystem production (NEP), and a ratio of GPP: CR >1.0. This study is among the first to demonstrate that agricultural drainage ditches are good representation of streams draining agricultural catchments in assessing whole stream metabolism and function.

Alternative Approaches to Animal Testing for Ecotoxicity Assessments

TP001 A mass spectrometry based metabolomics study of fluoxetine exposure in developing zebrafish embryos

P. Mishra, National Univ of Singapore; B.C. Kelly, Barry C Kelly / Civil Environmental Engineering

Aquatic organisms are continuously exposed to a host of pharmaceutically active compounds (PhACs) in the natural water reservoirs leading to inadvertent effects. It is crucial to detect the induced toxicological insult in the early stages, despite there being no morphological changes. Detection of early stage disruptions at the molecular level and profiling of differential metabolites can aid risk assessment endeavours. Fluoxetine is one such PhAC which has potential endocrine disrupting properties and has been detected in aquatic environment worldwide including in Singapore. In the present study in vitro toxicity experiments using embryonic zebrafish were conducted to assess metabolomic changes associated with exposure to a cascade of fluoxetine concentrations. An untargeted metabolomics approach was adopted to furnish the whole body tissue metabolites of zebrafish embryo. The exposure commenced at 2hours post fertilization (hpf) and continued until 96hpf. Larvae were then snap frozen to quench metabolism and arrest enzymatic activity, followed by extraction using a solvent mixture of acetonitrile: isopropanol: water (3:3:2; v/v/v) . The extracted metabolites were subsequently analysed using mass spectrometry (GC-MS). A total of 35 metabolites were positively identified against the Fiehn library database. Multivariate analysis tools (PCA, OPLS-DA) were used to identify metabolites that were differentially regulated with increasing fluoxetine concentration. Hierarchical clustering analysis was applied to the mined data and metabolite classes such as amino acids and lipids were found to be perturbed. Integration of multivariate and univariate analysis revealed significant dysregulation of 11 metabolites. Impediment of the energy and amino acid metabolism could have serious implications for normal and healthy embryo development.

TP002 A mass spectrometry based metabolomics study of triclosan exposure in developing zebrafish embryos

J. Fu, National Univ of Singapore; B.C. Kelly, Barry C Kelly / Civil Environmental Engineering

Triclosan (TCS), used as an antibacterial and antifungal agent, is ubiquitously detected in the natural environment. Increasing studies provided strong evidence of its potential for acting as an endocrine-disrupting chemical (EDC), involving both estrogenic and antiestrogenic effects as reported. It is vital to detect its toxicological impact in the early stage organisms, in terms of molecular level and metabolites profiling, despite no morphological effects was detected when organisms were exposed to TCS in environmental-related concentration. In the present study, in vitro toxicity experiments using zebrafish embryos were conducted to assess metabolomics changes with exposure to a wide range of TCS concentration. Exposure is to be carried out at 2 hpf and terminated at 96 hpf. Larvae were then snap frozen, followed by extraction using a solvent mixture of acetonitrile: isopropanol: water (3:3:2; v/v/v). Subsequently, samples were analyzed with gas chromatography mass spectrometry (GC-MS) to identify the metabolites based on Fiehn library database. As a result, a total of 35 metabolites were positively identified. Multivariate analysis (PCA, OPLS-DA) and univariate analysis (One-way ANOVA) were employed to identify significant dysregulation in metabolites and 11 metabolites showed significant differences due to TCS exposure. This outcome may suggest the biological mechanisms have been effected, including impaired energy production, lipid metabolism and increasing oxidative stress.

TP003 Comparison of human and fish estrogen receptor ligand binding domain-mediated response to estrogenic compounds

F. Lambert, M. Tagmount, Univ of Florida / Center for Environmental and Human Toxicology; C. Vulpe, Univ of Florida, Gainesville / Physiological Science

Endocrine disrupting chemicals (EDCs) are compounds that perturb hormonally regulated processes. Xenoestrogens, or estrogen mimics, are a class of EDC that have the potential to cause reproductive dysfunction; they mediate their effects by binding estrogen receptors (ER), causing changes in transcriptional activation. These chemicals enter the aquatic environment through land run-off and water treatment effluents, making their effects on fish populations a concern. However, current in vitro screening assays for xenoestrogens are commonly based on human estrogen receptors, which differ from teleost fish ERs in their amino acid sequences, number of subtypes, and subtype functions. These differences suggest that current assays may not accurately indicate the potential risk posed to fish. In this study, we focus on the role of the ligand-binding domain (LBD) in the ER-mediated response to estrogenic compounds. We utilize transactivation assays to compare ER LBD sensitivities between human and teleost ER subtypes. The hinge (D), LBD (E), and N-terminus (F) region of each ER subtype from human (hERα-def and hERβ-def), zebrafish (zERα-def, zERβ1-def, and zERβ2-def), and rainbow trout (rtERα-def, rtERβ1-def, and rtERβ2-def) are expressed as fusion proteins with a GAL4 DNA binding domain. GAL4-ERdef fusion proteins are used in transactivation assays, conducted in HEK293 cells, to compare the ER LBD-mediated response to a selection of natural and synthetic estrogenic compounds. Focusing on the LBD region of the ER is a targeted approach intended to pin-point differences in ER-mediated responses between species. Overall, this study provides insight regarding the use of fish-based in vitro assays as a means to assess the potential risk of EDCs to aquatic organisms.

TP004 Making the fathead minnow fish embryo toxicity test feasible: Spawning strategies to optimize embryo production

J. Krzykwa, Texas Christian Univ; K. Roush, J.A. Malmquist, M.K. Sellin Jeffries, Texas Christian Univ / Dept of Biology

With the passage of REACH legislation, and its strong push for using alternative toxicity testing methods that improve animal welfare, there has been interest in expanding the fish embryo toxicity (FET) test. In the US, efforts to modify the existing FET test protocol have paved the way for a fathead minnow FET test, the teleost model species typically used for acute toxicity assessments in the US. Previous studies have shown that the fathead minnow FET is similar in its predictive ability to the larval growth and survival test indicating that the FET test may be a viable replacement. However, procuring eggs at an early enough developmental stage (≤32 cell) and in sufficient quantity (>170 embryos/test replicate) to initiate a FET test has been a challenge. For the fathead minnow FET test to be a viable toxicity testing method, a spawning strategy that allows for adequate egg production must be developed. With this in mind, we sought to determine which male:female spawning ratios would optimize egg production and also examined the impact of collection time on the number of ≤32 cell embryos harvested. Specifically, this study compared breeding ratios (1m:4f, 1m:8f, 2m:4f, 2m:8f) and egg collection times (2, 4, and 8h after "sunrise") to determine which combination produced the largest number of ≤32 cell stage embryos. Initial results suggest that breeding colonies containing a single male optimize total egg production and that spawning windows of ≤2h allow for the collection of appropriately staged embryos. Implementation of the spawning methods identified in this study will allow fathead minnow embryo FET tests to be a more feasible option for chemical and effluent acute toxicity assessments. Further studies looking into breeding structure availability, light cycles, and alternative ratios could assist with perfecting breeding methods for the purpose of the fathead minnow FET test.

TP005 Use of surface mucus as a biomarker for endocrine disruption in an estuarine fish

A. Yammine, Louisiana State Univ AgCenter; A. Haukenes, Univ of Arkansas at Pine Bluff; C. Green, Louisiana State Univ AgCenter

Reproductive investment and endocrine health are normally assessed using assays which typically rely on blood collection, which is often lethal to small fishes. Surface mucus collection offers a less invasive methodology to determine concentration of 11-ketotestosterone (11-KT) and vitellogenin (VTG). This project seeks to (1) validate and confirm the use of mucal swabs as an effective and non-lethal alternative to determine concentrations of 11-KT and VTG of Fundulus grandis through comparative assays of blood plasma, and (2) use this minimally invasive method to evaluate potential endocrine disruptions in F. grandis undergoing chronic exposure to a water accommodated fraction (WAF) of crude oil, and (3) assess potential differences in endocrine disruption at the population level based on exposure history. Mucus and plasma samples were collected from male and female F. grandis. Both 11-KT and VTG showed significant positive relationships between their concentrations in the plasma and mucus. Four different populations of F. grandis with different exposure histories were exposed to WAF for 60 days, and post-WAF conditions for 40 days. Assessment of mucosal 11-KT concentrations showed that endocrine disruption was observed in many populations throughout time with a severe decline 40 days post-WAF. Changes in concentrations of 11-KT and VTG where significant with the linear relationship of time, treatment and population. Exposure history also had a significant effect on 11-KT concentrations; exposed reference site males had a decrease in 11-KT concentrations, while concentrations of 11-KT of exposed males from contaminated sites increase. Exposed females showed near null concentrations of mucosal VTG when exposed to WAF regardless of exposure history. These data demonstrate the utility of mucus sampling as a less invasive tool to assess endocrine disruption in fish exposed to polyaromatic hydrocarbons in laboratory and field settings.

TP006 Development of a fish liver microtissue model to characterize the toxicity of aromatic hydrocarbons and nanoparticle-based dispersants

A. Rodd, Brown Univ / Pathology Laboratory Medicine; R. Hurt, Brown Univ / School of Engineering; A. Kane, Brown Univ / Pathology Laboratory Medicine

Engineered nanoparticles can assemble at water-oil interfaces to stabilize oil droplets into an emulsion, and are under development for use as dispersants following oil spills. This project focuses on the potential impacts of environmental exposures to these nanoparticles on aquatic organisms. Using a fish liver cell line, PLHC-1, in a three-dimensional (3D), scaffold-free microtissue model, we are examining the environmental impacts of co-exposure to polycyclic aromatic hydrocarbons and surface-engineered carbon black as a model nanoparticle dispersant. 3D cultures can provide the benefits of tissue-like cell-cell interactions and the opportunity for longer term cultures, but also present challenges associated with imaging, maintaining viability, and adapting two dimensional assays to 3D systems. For this novel fish liver microtissue model, assays to determine the toxicity of aromatic hydrocarbons and nanoparticles, including biomarkers of stress and xenobiotic metabolism, were optimized in monolayer and then adapted for use in 3D with toxicants. To characterize the fish liver spheroids, changes in histology, differentiation, and response to toxicants were measured during long term cultures of spheroids. This model is applicable for testing real-world contaminant mixtures, and is being developed as a sensitive screening assay for low-level chronic or cumulative exposures. This research is supported by NIEHS Training Grant T32 ES07272, NIEHS Superfund Research Program P42 ES013660, the Institute at Brown for Environment & Society, and the generous support of Donna McGraw Weiss '89 and Jason Weiss.

TP007 Development of an In Vitro Chicken Gonad and Liver Slice Culture to Study the Effects of Endocrine Disrupting Chemicals

K. Mittal, J. Brandenburg, McGill Univ / Dept of Natural Resource Sciences; N. Basu, McGill Univ / Dept of Environmental Health Sciences

Exposure to Endocrine Disrupting Chemicals (EDCs) can have adverse effects on the hypothalamic-pituitary-gonadal-liver (HPGL) axis. Disruptions in this pathway can cause changes in reproductive physiology, neuroendocrinology and metabolism leading to population level impacts. Field- and whole-organismal studies have shown that EDCs adversely affect avian species such as chickens, quails and bald eagles. While offering compelling evidence of harm, organismal studies involve sacrificing a large number of animals, are time consuming and expensive. In recent years there has been great interest in developing in vitro systems to study biologically relevant disturbances in interconnected pathways composed of complex biochemical interactions and small molecules that control communication between cells. Among the various in vitro approaches being explored, tissue explants show great promise. For example, explants from neonatal rats and embryonic chicken retina had superior histology, showed remarkable retention of architecture and were more similar to freshly isolated tissue than 2-D cell culture. Given the promise of tissue explants as an alternative in vitro model, the objective of this study is to establish an in vitro slice culture of gonadal and liver tissue from day 19 chicken embryos. Optimal methods included slicing gonads and liver in chilled phosphate buffer and culturing for 24 hours at 37°C and 5% CO_2. Gonads were treated with pregnant mare serum gonadotropin (PMSG – 0, 2.5, 5, 10IU), and mRNA expression of genes involved in steroid biosynthesis viz. 17β-hydroxysteroid dehydrogenase (17β-HSD) and aromatase (CYP19A1) were analyzed. Liver slices were treated with 17β-Estradiol (E2 – 0, 0.1, 1.0, 10, 100, 1000nM) and vitellogenin (VTGII) mRNA expression was analyzed to assess functionality of the cultures. Gonads dosed with PMSG did not show any changes in 17β-HSD and CYP19A1 expression. Liver slices dosed with E2 at 0.1 and 1.0nM showed a 5 ± 1.7- and 8 ± 2.1-fold increase in VTGII expression. However this dose response did not extend through to the 10, 100 and 1000nM treatments. Studies to optimize the assays are ongoing following which the cultures will be dosed with EDCs of interest. Understanding the effects of contaminants on the HPG-L axis is important in determining the detrimental effects that EDCs have on humans and wildlife at organismal levels, and this in vitro model could serve as a valuable screening tool to study these interactions.

TP008 Characterization of gene expression in lake trout, northern pike and rainbow trout following exposure to EE2, fluoxetine and HBCD in vitro

B.K. Eisner, Univ of Saskatchewan / Toxicology Dept; S. Beitel, Univ of Saskatchewan – Toxicology Centre / Dept of Chemical and Environmental Engineering; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

Large numbers of chemicals are discharged into aquatic ecosystems as a result of human activities. While some of these compounds have been widely studied and adverse effects on fishes have been identified, there is an increasing number of emerging contaminants (ECs), including pharmaceuticals and personal care products (PPCPs) or brominated flame retardants (BFRs), for which little or no toxicity data regarding aquatic organisms is available. Many of these ECs, such as 17α-ethynylestradiol (EE2), a potent estrogen agonist used in oral contraceptives, fluoxetine, a common antidepressant, and hexabromocyclododecane (HBCD) a widely used BFR, may pose significant risks to aquatic ecosystems due to their prevalence in the environment.Specifically, large quantities of these chemicals have been identified in municipal wastewater effluents (MWWEs). Widespread use of ECs has raised concerns regarding their possible risks to the environment, particularly to native species of cultural, recreational and commercial importance to Canadians, including lake trout (Salvelinus namaycush) and northern pike (Esox lucius). While extensive data are available on model laboratory species, such as rainbow trout (Oncorhynchus mykiss),little is known of the effects of these ECs to species in northern ecosystems, and as such, there are approaches needed that allow to assess potential effects to such species. However, there is increasing concern with regard to live animal testing, particularly with regard to endangered or wild species, and therefore, alternative testing methods, such as in vitro tissue explant assays, are needed. Following an in vitro tissue explant assay in which lake trout, northern pike and rainbow trout livers were exposed to serial concentrations of EE2, fluoxetine or HBCD, transcript abundance of select genes was measured in these species and a species-specific response was characterized. With exposure to EE2, fluoxetine or HBCD, no response was observed in expression of genes related to endocrine disruption or oxidative stress in any species tested and, therefore, these species are relatively more tolerant to these chemicals than other species previously tested.

TP009 Sampling Season, a Factor Influencing Prevalence of Gonadal Intersex and Molecular Biomarkers in Smallmouth Bass

A. Abdelmoneim, Purdue Univ / Forestry and Natural Resources; D. Deegan, Elkhart/South Bend Aquatic Community Monitoring Program; J. Gao, Purdue Univ / Dept of Forestry and Natural Resources; M.S. Sepulveda, Purdue Univ / Dept of Forestry and Natural Resources and School of Health Sciences

Over the past decade, studies have shown that exposure to estrogenic chemicals can cause gonadal intersex in fish. Smallmouth bass (Micropterus dolomieu) males appear to be highly susceptible to developing this condition in the form of testicular oocytes with cases reported in various areas across the U.S. The main objective of this study is to identify molecular biomarkers of gonadal intersex in smallmouth bass. First, we studied the prevalence and severity of gonadal intersex in smallmouth bass sampled from the St. Joseph River, an impacted river in northern Indiana, at several sites, seasons and years. Our results showed variable prevalence and severity of gonadal intersex, ranging from 0% to 100% and score 1 to 4, respectively. Over the different years tested, the prevalence and severity of gonadal intersex was always significantly higher in spring (spawning season) when compared to the prevalence in summer (post-spawning) of the same year. Next, we quantified molecular biomarkers of intersex in smallmouth bass by studying the differential expression of gonadal genes involved in sex differentiation (esr1, esr2, foxl2, vtg, cyp19a, cyp1a, star, lhr and fshr). Hepatic vitellogenin (vtg) transcript levels were significantly higher in males with gonadal intersex compared to normal males, but only in the spring. Finally, we investigated the levels of VTG plasma protein in males with and without gonadal intersex using Western blot analysis. Our results confirmed our earlier findings by showing detectable levels of VTG in males with gonadal intersex that also had high levels of vtg transcript expression. Overall, our results show that the prevalence and intensity of intersex is highest during spring, and that VTG is a successful biomarker of gonadal intersex only during the spawning season.

TP010 Perfusion based Lab-on-a-Chip technology for automated toxicity testing with the marine amphipod Allorchestes compressa

R. Cartlidge, RMIT; D. Nugegoda, D. Wlodkowic, RMIT Univ / School of Applied Sciences

Amphipods have gained popularity as excellent bioindicators. They are important links in numerous food chains and have localized behavior that can be used to assess sediment toxicity and water quality. Bioassays performed with amphipods, however, largely still use static conditions in large test volumes, require manual manipulation of samples, and employ mortality as the major test criterion, since sublethal tests including behavioural tests are time and labour intensive and can be subject to 'Observer bias'. This work describes design and validation of a miniaturized, continuous perfusion based Lab-on-a-Chip technology for automated sub-lethal behavioural toxicity tests using the native Australian marine amphipod Allorchestes compressa. An automation module with a high-resolution USB camera, user-friendly fluidic interconnects and miniaturized 3D-printed interface was developed. To evaluate performance of the new chip-based system, median lethal concentrations (LC_{50}) of a panel of reference toxicants obtained on this system were compared with those from tests using conventional static protocols, and were not significantly different. Automated behavioral tests were then conducted by perfusing toxicants through the chip-based device to dynamically assess the effect of toxicants on selected locomotory parameters. Results showed that the system was able to detect changes in the swimming behavior of A.compressa at toxicant concentrations that did not induce mortality in test populations. For the majority of chemical stressors tested, behavioral sub-lethal changes occurred early and in a concentration- and exposure time-dependent manner and could be recorded with no observer input. We postulate that integrated Lab-on-a-Chip systems can enable new avenues for "Early Warning" biomonitoring systems that can automate the use of sensitive behavioral indices to rapidly detect presence of toxicants in aquifers.

TP011 Effect of Petroleum Refinery Effluent on Haematological and Biochemical Characteristics of Juvenile African Catfish (Clarias gariepinus)

E.U. Ezeji, Federal Univ of Technology / Biotechnology; C.E. Okwuchi, Federal Univ of Technology / Biological Science

Effect of Petroleum refinery effluent on hematological and biochemical characteristics of juvenile African catfish was investigated. Twenty five juvenile African catfish with the average weight of 3.0 kg were subjected to four graded sub-lethal concentrations (0.002, 0.006, 0.01 and 0.016 mg/l) of petroleum refinery effluent and water (control) for fourteen days. A significant reduction ($p< 0.05$) was observed in haemoglobin concentration (Hb), pack cell volume (PCV), red blood cell (RBC) and white blood cell (WBC) counts compared with the control. Reduction in Mean corpuscular volume (MCV) and Mean corpuscular heamoglobin concentration (MCHC) were however not significant ($p>0.05$). Result of the biochemical studies shows significant ($p< 0.05$) increases in the activities of Aspartate aminotransferase (AST) and Alanine aminotransferase (ALT) in the samples exposed to petroleum refinery effluent, suggestive of hepatic cellular damage. Protein concentration was significantly ($p< 0.05$) lowered in the samples exposed to the effluent while the reduction in albumin was not significant ($p< 0.05$). This study has shown that alterations in the levels of haematological and biochemical parameters of African catfish can be used as an indication of potential hazards of petroleum refinery effluent on aquatic biota.

TP012 A call for consistency: What is the most appropriate form of euthanasia for fish

D.M. Saunders, Univ of Saskatchewan / Toxicology; J.E. Naile, Shell Oil Company / Ecosystems Research Division; J. Hughes, USGS / Columbia Environmental Research Center; D. Lyon, Shell Oil Co. / Shell Health Risk Science Team; C.L. Meyer, Shell Oil Company / Ecotoxicology

Shell has a global animal testing policy and associated guidelines which are reviewed by an external committee and updated regularly to guarantee 'best practices' for the humane use of animals. In 2014 Shell used roughly 82,000 fish for product or whole effluent toxicity testing, which is the largest category of vertebrate animal testing conducted by or on Shell's behalf. Shell's guidelines include a discussion of the euthanasia of laboratory animals. In the Shell animal testing guidelines, euthanasia means, literally, an easy or good death and in practical terms, this means that the animal should be killed causing minimal pain or distress. The guidelines reference the American Veterinary Medical Association (AVMA) Guidelines on Euthanasia, and the Newcastle Consensus of 2006 on carbon dioxide euthanasia. However, no specific method of euthanasia for fish is recommended in the Shell guidelines. To remain at the forefront of humane fish handling practices, these guidelines and the referenced documents were reviewed with the objective of identifying a method of euthanasia specifically for fish. Two common methods of euthanasia were reviewed: 1) CO_2-saturated water and 2) buffered tricaine methanesulfonate (MS-222). Use of CO_2 with terrestrial animals can cause rapid asphyxiation and the AVMA guidelines supports its use for the humane euthanasia of both terrestrial and aquatic animals, though little information actually exists supporting this position for fish. Further, other organizations such as the Canadian Council for Animal Care (CCAC) strongly advocate against the use of CO_2 for euthanasia of fish. The CCAC presents that the addition of CO_2 to water forms carbonic acid which can alter the pH of the aquatic environment causing undue suffering for the fish. Indeed, the AMVA guidelines warn that CO_2 might cause pain due to formation of carbonic acid on the respiratory and ocular membrane of terrestrial animals, though they do not extend this consideration to an aquatic environment. The use of the anesthetic, MS-222, was also reviewed as it is currently a prominent method of euthanasia. Both the AVMA and CCAC guidelines suggest the use of an overdose of MS-222 for humane euthanasia, though recent studies suggest it might be aversive to fish. Following an extensive review of best practices and literature representing state of the science, we proposed the discontinued use of CO_2 and the use of MS-222 as the prominent method of euthanasia for Shell testing.

TP013 Use of the RT-gill W1 Cell Assay for Predicting Fish Acute Toxicity – In vitro to In vivo Comparison for Fragrance Molecules

G. Sanders, Givaudan International SA / Regulatory Affairs and Product Safety; A. Natsch, H. Laue, Givaudan Schweiz AG / Fragrances S T; T. Haupt, Givaudan Schweiz AG / Biosciences In vitro Toxicology

Considerable effort has been invested in recent years in the development and validation of testing methods aimed at fulfilling the principles of the 3Rs (Reduction, Refinement and Replacement of animal tests), while maintaining a high degree of scientific reliability. Regulatory relevance is also a major consideration in the development, validation and implementation of alternative testing techniques. The OECD Test Guideline 236, Fish Embryo Acute Toxicity Test, was adopted in 2013 offering an alternative to the OECD 203. Tanneberger et al. (2013) proposed a further simplification step through the use of a fish gill cell line assay as a means of predicting acute toxicity. This approach has been applied in our research laboratories with the Rainbow Trout gill cell line RTgill-W1 for 40 fragrance molecules, with wide ranging physico-chemical properties, and broadly differing intrinsic toxicity as determined from reliable in vivo studies. The findings of this benchmarking study reveal a strong correlation ($r^2 = 0.93$) between the In vivo LC50 values, based on fish mortality, and the In vitro EC50 values based on cell cytotoxicity for the fragrance molecules tested. Furthermore, the overall extrapolation illustrates a median under-/over-prediction from In vitro EC50 values to In vivo LC50 values of a factor of 1.68 which is well within the variability associated with the OECD 203 test guideline when the effects of inter-species and inter-laboratory variation are accounted for. This assay clearly offers a simple, accurate and reliable alternative to In vivo fish acute toxicity testing for chemicals presumably acting mainly by narcotic mode of action. This study provides validation of the assay on an independent set of chemicals not tested before and indicates that fragrance chemistry clearly is within the applicability domain of the assay. The assay protocol is currently being evaluated in an international inter-laboratory ring test, required as a pre-requisite for adoption as a draft OECD test guideline.

TP014 Construction and curation of a large ecotoxicological dataset for the EcoTTC

A. Beasley, Dow / Product Sustainability Consultant Toxicology and Environmental Research Consulting; M.G. Barron, USEPA / Gulf Ecology Division; S.E. Belanger, The Procter & Gamble Company / Central Product Safety Dept; J. Brill, The Procter & Gamble Co. / Environmental Stewardship and Sustainability; D. DeZwart, DdZ-Ecotox; M.R. Embry, ILSI Health & Environmental Sciences Inst; B. Farr, ILSI Health and Environmental Sciences Inst (HESI) / Health and Environmental Sciences Inst HESI; M. Halder, A. Kienzler, European Commission – Joint Research Centre / DG Joint Research Centre IHCP EURL ECVAM; T.J. Norberg-King, USEPA / NHEERL/Mid-Continent Ecology Division; H. Sanderson, Aarhus Univ / Environmental Science; R.M. Sternberg, USEPA / Environmental Fate and Effects Division; P.W. Wilson, Sanofi US, Inc. / Health Safety and Environment

The Ecological Threshold for Toxicological Concern, or ecoTTC, has been proposed as a natural next step to the well-known human safety TTC concept. The ecoTTC is particularly suited for use as an early screening tool in the risk assessment process, in situations where chemical hazard data is poor, or when an appropriate QSAR is unavailable. EcoTTCs are developed using statistical distributions of Predicted No-Observed Effect Concentrations (PNECs) to reflect the breadth and depth of the ecotoxicological dataset beneath. Therefore, the diversity and quality of the underlying dataset is crucial to the future utility of the ecoTTC. A database consisting of approximately 110,000 unique ecotoxicological records has been created based on recent assessments of published data and international chemical management programs. Stepwise data selection strategies, query systems and curation techniques are applied to ensure a transparent, methodical process towards a final dataset on which to found development of ecoTTCs. Reference-sourced toxicity data is associated with physical chemistry data and taxonomic information for the tested chemical. The resulting dataset contains information on 6200 unique CAS numbers for 1900 species in three trophic groups for use in ecoTTC development and associated metadata mining. This presentation does not necessarily reflect the views or the policies of the USEPA or the European Commission.

TP015 Small-Scale Microcosm Assay to Assess the Environmental Fate and Ecotoxicity of Nanomaterials in Aquatic Systems

S.L. Harper, Oregon State Univ / EMT; F. Wu, Oregon State Univ / Chemical, Biological and Environmental Engineering; B.J. Harper, Oregon State Univ / Dept of Environmental and Molecular Toxicology

With the ever-growing diversity of nanomaterials in commerce, it is impractical to utilize current testing paradigms to evaluate each material for its potential environmental impacts. Given the immediate need to quickly and cost-effectively screen nanomaterials for ecotoxicity, data-rich assays that are rapid, biologically representative, easily implemented, and readily amenable to inter-laboratory standardization are of significant value to the scientific community. The goal of this research was to establish a novel, ecologically relevant, small-scaled freshwater microcosm assay for simulating realistic exposure scenarios and understanding community response to nanomaterials. Microcosms comprised of algae (Chlamydomonas reinhardtii), bacteria (Escherichia coli), predatory invertebrates (Daphnia magna), and developing vertebrates (Danio rerio) were used to evaluate biological and ecological responses to nanomaterial. Two commercially available ZnO NPs were evaluated in each of the single organisms in addition to community exposures. Our results showed that engineered ZnO NPs can elicit differential toxicity among test organisms at 0.01 and 1 mg L^{-1}, and overall, less toxicity was observed for each species when exposed as a community. Next, a series of 70 nm AgNPs [polyethylene glycol (PEG), silica (Si), or aminated silica-coated AgNP (Ami-Si) at 0, 0.1, 1, and 5 mg L^{-1}] were used to investigate the relative influence of surface charge, composition, dissolution and organismal uptake on toxicity. We found that PEG-AgNPs had the highest overall toxicity followed by Si-AgNPs, and lastly Ami-Si-AgNPs. Increasing species complexity in this study also reduced the toxicity to algae and bacteria. Our findings indicate that surface functionalization plays an important role in determining dissolution, uptake and toxicity of AgNPs. Increasing trophic complexity in both experiments decreased organismal susceptibility under the same NP exposure concentrations, likely due to changes in bioavailability. Thus, single-species tests provide conservative estimates of environmental impacts, as exposures may be mitigated in more realistic multi-species scenarios. Rapid testing strategies, such as the nanocosm assay, will enable researchers to meet both current and future testing needs, as well as rapidly improve our understanding of risk from environmentally-relevant exposure to nanomaterials.

TP016 Using D. magna as an alternative to fish toxicity mitigation testing for cationic substances

E. Salinas, BASF SE / Experimental Ecotoxicology; J. Bozich, Univ of Wisconsin, Milwaukee / SFS; D. Smith, Wilfrid Laurier Univ / Chemistry; R. Lukas, BASF SE

Cationic polymers (CPs) are polyelectrolyte chemicals used widely in industrial applications (e.g. water clarification) and as a functional component of various "down-the-drain" household products. CPs generally have a low environmental concern due to the presence of organic carbon (OC) in surface water that greatly reduces their bioavailability, even at low mg/L levels. To better understand CP toxicity under environmental exposure scenarios, USEPA recommends establishing baseline acute fish toxicity in clean water and conducting at least 2 additional acute fish toxicity tests at higher total OC (TOC) levels to evaluate the mitigation potential. Daphnia acute toxicity tests are also required as part of the baseline aquatic ecotoxicity dataset and are a suitable alternative to assess mitigation, fitting easily into established regulatory frameworks. Clean water used for baseline toxicity tests should have TOC < 2 mg/L, but guidelines allow any water, ranging from defined artificial water to natural surface water, as long as general criteria are met. Subtle water chemistry variations within the clean water criteria are believed to have little influence on the toxicity outcome. To better understand variation in clean water studies, we explored the impact of ppb additions of TOC in artificial water with different hardness on CP toxicity. We used CPs of varying molecular weights and cationic charge density in Daphnia acute toxicity tests. Our results indicate that ppb levels of TOC produced strong CP toxicity mitigation. In addition, water hardness was an important co-mitigating parameter for the toxicity of all polymers tested. These results suggest that clean water variations of TOC and water hardness affect baseline CP toxicity and should be considered in environmental exposure scenarios. We recommend measures to enhance the reliability of baseline toxicity tests with cationic polymers while representing an environmentally realistic worst case exposure.

TP017 Are alternative strategies actually faster, cheaper and more efficient than traditional methods?

K. Mittal, McGill Univ / Dept of Natural Resource Sciences; D.E. Crump, Environment and Climate Change Canada; J. Head, McGill Univ / Natural Resource Sciences; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre; G. Hickey, McGill Univ; N.S. Hogan, Univ of Saskatchewan / Toxicology Centre; S. Maguire, McGill Univ; N. Basu, McGill Univ / Dept of Environmental Health Sciences

Chemical contamination is considered to be one of the planet's greatest threats (~100,000 chemicals are currently registered in commerce). Animal based toxicity testing methods are not feasible with respect to number of animals used, money and time spent. Hence, typically, high risk classes of chemicals undergo rigorous toxicity testing. As a result, either chemicals that are unknowingly highly toxic might be in widespread use or, obtaining regulatory approval for emerging chemicals might get delayed. Seminal reports over the last decade have pushed for a paradigm shift in toxicology, with more emphasis on mechanistic, screening platforms to prioritize chemicals for in vivo testing. Several alternative methods have been developed for toxicological purposes that are professed to be faster, cheaper and use fewer animals than traditional in vivo models. The purpose of this study was to perform a bibliometric search to identify and review papers covering the following five crucial areas when comparing alternativeto in vivo methods, viz. A) cost of testing (toxic* AND alternat* AND economic* AND benefit*), B) time needed for testing ("in vitro" OR screen*) AND ("short-term" OR time OR ((high OR increase*) AND throughput)) AND toxic*, C) number of animals needed ("in vivo" AND toxic* AND "animal testing" AND number*), D) predictability of alternative methods (("in vitro" OR "high throughput" OR alternat*) AND screen* AND "in vivo" AND predict*) and E) regulatory acceptance of data from alternative methods ((alternat* OR "in vitro") AND toxic* AND "risk assessment"). In general, a search for ("in vitro" AND "toxic* AND screen*) found 3,467 publications between 2007 and 2016 as compared to 1,094 between 1997 and 2006. A few empirical examples were found in support of the five areas of inquiry. For example, custom designed qPCR arrays can yield screening level information in ~3 weeks compared to ~6 months ordinarily needed for standard tests. 'omics based technologies are estimated to yield 25-fold cost savings. Regulatory testing (ex. Pulp and Paper Mill) uses animals to test all substances, while the compliance rate is ~97%. Results from screening assays for estrogenic and androgenic activity predicted in vivo responses with high accuracy, however thyroid related effects could not be predicted accurately. However, taken together, there are few studies that have empirically examined the notion that alternative methods are faster, cheaper and more efficient.

TP018 Evaluation of toxic effects of detergent in embryos and adult zebrafish (Danio rerio)

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos

In ecotoxicological studies, the zebrafish has been used as a test organism for assessing the effects of chemical compounds mainly. In toxicity tests, has been used to embryos of this species because its response comparable to the sensitivity of adult organisms. In Mexico, the use of these organisms is not stipulated in the legislation, despite being an alternative to replace fish bioassays. The aim of this study was to determine the toxic effect of two surfactants: LAS and Triton X and 5 products (Extram, Ace, Ariel, Foca and Roma) in embryos and adult zebrafish Danio rerio to compare their sensitivity. Static bioassays were conducted with a duration of 48 and 96 hours, embryos and adult fishes were exposed to 5 concentrations of toxic (12 replicas), plus a control without toxic. LC_{50} was determined and a comparison of the LC_{50} obtained to test are made to detect if the responses of embryos and adult fish are different. The toxicity of surfactants was (high to low toxicity): TX > LAS. And products: Extram > Ariel > Roma > Ace > Foca. Comparison of LC_{50} indicated no significant differences in the effects of detergents between embryos and adults in tests with Ace, Foca and Roma products. But if observed differences in the response of adults and embryos exposed to surfactant and the detergent Ariel. The embryos were more sensitive to these products. The results indicate that tests with zebrafish embryos are a useful tool in monitoring studies. Because wastewater discharges in the Valley of Mexico contain high concentrations of detergents (0.5-100 ppm) and their final destination is the aquatic systems, for this reason it is important to continue research to detect responses that indicate the possible adverse effect on fish by the action of different the discharges and tensors to prevent irreversible deterioration of the populations in the medium and long term.

TP019 Testing toxicity of graphene oxide in zebrafish embryos

F. J Hernández, Somaprobes; A. Alday, BioBide; A. Muriana, BBD BioPhenix S.L. / RD; C. Quevedo, BioBide

Due to their unique physiochemical properties, two dimensional graphene oxide (GO)-based materials have attracted considerable attention both in research community and industry. With the more application of this nanomaterial in the production of goods used in our daily life, it is increasingly released into the environment. However, the health risks associated with environmental exposure to GO are largely unknown, particularly with respect to embryogenesis. Zebrafish embryos are an alternative model for the evaluation of developmental toxicity of chemicals during early life stage with the characteristics of small-scale, high throughput and easy observations. In preliminary experiments, 4 hours-post fertilization (hpf) zebrafish were treated with 8 concentrations of GO (water dispersion): 0.1, 0.3, 1, 3, 10, 30, 100 and 300 mg/L. A hole in the chorion was performed with a thin needle to prevent toxicity induction by hypoxia due to graphene adhesion to the chorion. Embryos were analyzed daily until 4 days post-fertilization (dpf) and not toxicity manifestations or lethality were observed at any of the concentrations tested. To guarantee the uptake of graphene, a second experiment in which graphene was injected was carried out. Two concentrations were selected, 3 mg/L, the concentration from which aggregation of graphene was clearly detected in the first experiment and one lower concentration, 1 mg/L. Toxicity manifestations were not detected in this case either. To further ensure that the absence of effect is not due to the absence of GO uptake, a smaller particle size preparation of GO will be also tested. Additional behavior test will be also performed, besides the morphology evaluation, to detect possible toxicities.

Lab Data, Hazard, Risk and Regulation of Endocrine Active Chemicals – So What? The Big Picture from Little Pieces

TP020 Neonatal exposure to bisphenol analogues disrupted genital development in male mice

H. Tan, M. Widelka, Southern Illinois Univ Carbondale / Cooperative Wildlife Research Laboratory and Dept of Zoology; S. Wang, Z. Zheng, Southern Illinois Univ Carbondale / Dept of Physiology; D. Chen, Southern Illinois Univ Carbondale / Cooperative Wildlife Research Laboratory and Dept of Zoology

The public concern and governmental regulations on bisphenol A (BPA) have stimulated the development and production of alternative substances to replace BPA in a myriad of applications. A total of 16 bisphenol analogues that are structurally similar to BPA have already been used in the manufacture of polycarbondate plastics and epoxy resins, as well as other industrial applications. Given the endocrine disrupting activities of BPA and potentially other analogues, the present study investigated and compared the effects of neonatal exposure to BPA, BPB, BPE, and BPS on the genital development in male mice. Pups were injected subcutaneously on the right shoulder in the mornings of days P0.5, P2, P4, and P6, resulting a dose level of 50 µg/g body weight/day. Mice were sacrificed at the weaning day (P21) and were evaluated for four parameters, including anogenital distance, glans penis length, glans penis morphology, and testis weight. The results demonstrated that BPA, BPB, or BPE significantly shortened glans penis length, while BPS didn't. No difference in penis length was observed between any two treatments of BPA, BPB, and BPE. Testis weight and anogenital distance were also significantly affected by all four bisphenols. Testis weights in BPA treatments were significantly lower than those in BPE or BPS groups, but no difference was observed between BPA and BPB treatments. These results suggested that bisphenol analogues other than BPA may possess similar endocrine disrupting effects compared to BPA. This raised the concern if some of these analogues can be used as safe replacements of BPA.

TP021 Triclosan exposure delays development, alters sphingomyelin, and perturbs expression of genes

C.M. Mansfield, Clemson Univ / Environmental Toxicology; N. Sengupta, Clemson Univ / Dept of Biological Sciences; C. Saski, Clemson Univ / Dept of Genetics and Biochemistry; W.S. Baldwin, Clemson Univ / Biological Sciences

Triclosan, a widely used bactericidal chemical used in consumer products, perturbs lipid metabolism and represses development in Daphnia magna under resource limited conditions. Triclosan is a known inhibitor of HR96 inhibitor, an ortholog of the xenobiotic-sensing nuclear receptors CAR/PXR found in mammals that control the regulation of phase I-III detoxification. HR96 has also been shown to regulate sphingolipid metabolism. Previous research in our group demonstrated the capacity of triclosan to increase sphingomyelin concentrations in D. magna associated with repressed development. Repression of sphingomyelin metabolism could be responsible for delaying development in neonates under low energy diets; thus increasing survival at the expense of reproductive development. RNA-sequencing was performed to determine changes in gene expression caused by 48-h exposure to 0.25 µM triclosan. Up-regulated genes include glutathione-s-transferases (GSTs), cytochrome P450s (CYPs), beta-mannosidase and mannose binding proteins. Examples of down regulated genes include cuticular proteins, carbohydrate sulfotransferases, glucose dehydrogenase, bile salt activated lipases, and ABC transporters. QPCR confirmation is currently underway as is further bioinformatic analysis of the pathways altered. In addition, the physiological and RNA-seq data generated indicates triclosan induces detoxification pathways, perturbs molting and growth, and alters energy metabolism, specifically lipid/sphingomyelin metabolism. Future research will work to associate specific pathways to perturbed development from a neonate to an adult. Overall, our research provides potential mechanisms as to why triclosan's toxicity is much worse than anticipated when exposure occurs in less than ideal environmental conditions.

TP022 Field and laboratory approaches to understanding testicular oocytes and gonadal development in smallmouth bass in relation to exposure to EACs

S. Kadlec, Univ of Minnesota – Duluth / Integrated Biosciences; R.D. Johnson, USEPA / ORD NHEERL Mid-Continent Ecology Division; D.R. Mount, USEPA / ORD NHEERL Mid-Continent Ecology Division Duluth; P. Schoff, Univ of Minnesota Duluth / Natural Resources Research Inst

In previous work we reported smallmouth bass populations in Northeastern Minnesota rivers and lakes with testicular oocyte (TOs) prevalence ranging from 7 to 59%, which is consistent with reports from other U.S. river systems. While it is often presumed that TOs are associated with exposure to endocrine active compounds (EACs), our analysis suggested only a weak relationship. To better understand gonadal development in smallmouth bass and how it might be influenced by exogenous estrogens, we conducted two laboratory exposures using 17-α-ethinyl estradiol (EE2). In experiment 1, smallmouth bass fry were exposed to 2 or 10 ng/L EE2 for 90 d beginning at swim-up, then reared for an additional 90 days in clean water. Treatment and control groups were subsampled intermittently for histological evaluation of gonadal development. In fish exposed to 2 ng/L EE2, 100% developed ovaries by day 63. The ovaries continued to develop even after cessation of EE2 exposure. In experiment 2, smallmouth bass fry were exposed to 0.11, 0.33, 1.0, or 3.0 ng/L EE2 for 100 days, and evaluated for gonadal development at days 90 and 120. In the group exposed to 3 ng/L EE2, 100% of fish developed ovaries, while all groups exposed to lower concentrations showed a roughly 50:50 female-to-presumed male sex ratio. No TOs were observed in any fish exposed to concentrations of EE2 lower than that which caused presumptive sex reversal. This result suggests that wild smallmouth bass TOs may not be caused by juvenile exposure to estrogenic compounds.

TP023 Steroidogenic genes in male mummichog exposed to model androgen 5α-dihydrotestosterone or 17α-methyltestosterone; an in vitro investigation

R. Rutherford, Wilfrid Laurier Univ / Biology; A.L. Lister, Wilfrid Laurier Univ / Dept of Biology; D. MacLatchy, Wilfrid Laurier Univ / Biology

Elucidating key events in adverse outcome pathways (AOP) is integral to strengthening biological links across multiple levels of organization. Current research has identified decreased plasma sex steroid hormones in mummichog, an estuarine killifish, after exposure to androgenic compounds, in conjunction with decreased egg size and reduction of plasma vitellogenin. However, the molecular cause is currently unknown. Potential impacts on the steroidogenic pathway in mummichog were assessed by exposing testis tissue in vitro to control (solvent only), 10^{-3}, 10^{-6} and 10^{-9} M of the non-aromatizable androgen 5α-dihydrotestosterone (DHT) and the aromatizable androgen 17α-methyltestosterone (MT) for 6, 12, 18 and 24 hours. A 24-hour preliminary in vitro (without androgen) was conducted to ensure RNA and gene expression integrity were maintained. There was no significant difference in RNA integrity across the 24-hour in vitro at 18^{O}C. RNA integrity from snap-frozen and in vitro tissue was also compared and no differences detected. A suite of genes including steroidogenic acute regulatory protein, 11β-hydroxysteroid

dehydrogenase and cytochrome P450 17A1 were analyzed for altered expression over 24 hours in the preliminary in vitro, with no difference in expression detected. Genes were normalized to β-actin. Comparison of aromatizable and non-aromatizable model androgen responses will increase knowledge of potential differences in androgen impact due to androgen classification and support AOP development.

TP024 Mixture effects of the analgesics dipyrone and acetaminophen in the catfish Rhamdia quelen

H. Silva de Assis, UFPR / Pharmacology; I.C. Guiloski, Univ Federal do Paraná / Farmacologia; L.d. Fernandes, UFPR / Pharmacology

Pharmaceuticals such as acetaminophen and dipyrone are prescribed in human medicine and have the potential to contaminate water and sediments via inputs from sewage treatment plants. Their impacts on humans and ecosystems are emerging issues in environmental health. Some pharmaceuticals can act as endocrine disruptors by changing gonads morphology and /or hormone levels in fish, for example. This study aimed to assess whether mixture of acetaminophen and dipyrone cause endocrine disruption by the expression of brain aromatase, testosterone and estradiol levels and oxidative stress in gonads of commercial fish Rhamdia quelen. Males and females were exposed separately to environmental concentrations of acetaminophen (2.5 µg/L), dipyrone (5 µg/L) and mixture (2.5 µg/L of acetaminophen + 5 µg/L of dipyrone) in a semi-static bioassay. These concentrations were used in previous studies. After 21 days of exposure, the animals were anesthetized and the blood was taken to hormone analyses. The hypothalamus was collected for the aromatase expression. The biochemical biomarkers as superoxide dismutase (SOD), glutathione peroxidase (GPx), glutathione S-transferase (GST), reduced glutathione (GSH) and lipoperoxidation (LPO) were analyzed in the gonads. In testis, GST activity was reduced by the pharmaceuticals mixture. Dipyrone also caused reduction in SOD and GST activities. No changes were observed in the GPx, GSH and LPO. Differing from males there was an increase of the SOD activity in the ovaries of animals exposed to the single drugs and to the mixture. The mixture caused LPO in female gonads, but no changes were observed in the GST, GPx and GSH. Estradiol and testosterone levels in males and females were not different from control. Brain aromatase expression in females was reduced by acetaminophen, dipyrone and the mixture. In males, aromatase expression was unchanged.The results demonstrated that the mixture of these two pharmaceuticals caused oxidative stress in female gonads and reduction of brain aromatase expression, suggesting an endocrine disruptor effect in females. The results also showed different responses in antioxidant system of males and females.

TP025 Toxicity and Thyroid Disrupting Effects of Halogenated Mixtures on Zebrafish Embryos

A. Godfrey, A. Abdelmoneim, Purdue Univ / Forestry and Natural Resources; M.S. Sepulveda, Purdue Univ / Dept of Forestry and Natural Resources and School of Health Sciences

Numerous halogens act as endocrine disrupting chemicals (EDCs) that can alter thyroid function. Members of this group include perfluorinated chemicals, commonly used in Teflon and food packaging, and flame retardants, used in a wide array of products such as clothing and electronics. Exposure of organisms to these EDCs can negatively affect growth and development. Therefore, there is a need to develop next generation, less toxic chemicals. The objective of this study is to further test these potential "safer" alternatives, singly and in mixtures. We used zebrafish embryos as our model organism due to its high structural and functional homology to humans and its suitability for early development studies. Three well known hazardous endocrine disruptors, perfluorooctanoic acid (PFOA), tris (1,3-dichloro-2-propyl) phosphate (TDCPP) and tetrabromobisphenal A (TBBPA), and two next generation chemicals, 9,10-Dihydro-9-oxa-10-phosphaphenanthrene 10-oxide (DOPO) and perfluorobutyric acid (PFBA), were tested both singly and in mixtures. First, we identified their LC50s under 96 hour exposures using zebrafish embryos. Next, we estimated their LC50 values in tertiary mixtures to identify any potential mixture effects. Our findings suggest that all mixtures tested display a partial addition effect; however, the next generation chemicals were less toxic in mixtures than their toxic counterpart. Finally, we are using an established pathway between thyroid disruption and swim bladder dysfunction to identify any thyroid disrupting effects caused by our chemicals of concern. We quantified changes in the surface area of the swim bladder as well as changes in expression levels of genes involved in thyroid dysregulation as a result of single and mixture exposures. Our preliminary findings from exposures to a mixture of PFOA, TDCPP and TBBPA showed reductions in swim bladder surface area, suggesting possible detrimental effects on the thyroid function during early development.

TP026 Molecular Signaling Pathways Elicited by 17-α-Ethinylestradiol in Intersex and Sex-reversed Japanese Medaka

A. Abdelmoneim, Purdue Univ / Forestry and Natural Resources; M.S. Sepulveda, Purdue Univ / Dept of Forestry and Natural Resources and School of Health Sciences

Water bodies receive effluents from waste water treatment plants, holding numerous endocrine disrupting chemicals. Fish exposure to these chemicals, particularly during sexual differentiation, can cause abnormal changes on gonadal development. 17-α-ethinylestradiol (EE2) is a well-studied synthetic estrogen agonist used in oral contraceptive formulations and commonly found in sewage effluents. Fish exposure to EE2 is known to elicit concentration dependent changes in gonads, ranging from the development of gonadal intersex to complete sex reversal. These gonadal changes have been well-studied in Japanese medaka, a laboratory fish model with genetic sex determination. The objective of this study is to understand the molecular signaling pathways involved in the development of gonadal intersex and sex reversal as a result of EE2 exposure. We exposed 9 dpf (days post fertilization) medaka larvae to 0, 20 and 200 ng/L EE2 for 30 days. These concentrations and length of exposure were chosen to elicit intersex and complete sex reversal, respectively. After 12 days of exposure and by the end of the sex differentiation period, male larvae were collected for next-generation sequencing (RNA-Seq) using Illumina HiSeq2500. The remaining males were exposed until 39 dpf then reared under controlled conditions until 90 dpf for histological analysis to validate the effects of these exposure regimes on gonadal development. RNA-Seq data analysis was performed using Tophat and Cufflinks to identify differentially expressed genes between different groups. Our findings suggest that exposure to EE2 induce direct (steroid hormone receptor-mediated) and compensatory changes to the hypothalamus–pituitary–gonadal–liver axis in a concentration-dependent manner. Results on the differentially expressed genes in intersex and completely sex-reversed males will increase our understanding on the molecular changes associated with the development of these gonadal abnormalities after EE2 exposure.

TP027 Effects of EACs in the Environment: Effectiveness of Freshwater and Saltwater Pond Remediation on Reducing Impact in Bermuda

D.J. Fort, M. Mathis, C. Fort, H. Fort, Fort Environmental Laboratories Inc; J. Bacon, Bermuda Zoological Society

Indications of endocrine disruption and reproductive impairment in cane toads, killifish, and, diamondback terrapins in freshwater and marine ponds in Bermuda have prompted efforts to remediate polyaromatic hydrocarbons (PAH) and oxygenated PAHs (OPAH) within the pond sediments. A modified Tier 1 EDSP 21-day Fish Short-Term Reproduction Assay (FSTRA) was used to evaluate the effects of sediment exposure from freshwater and saltwater ponds in Bermuda on reproductive fecundity and endocrine function in fathead minnow (Pimephales promelas) and killifish (Fundulus heteroclitus), as well as, the effectiveness of remediation strategies. Baseline modified FSTRA assessment showed decreased reproductive fecundity, lower male body weight, and altered endocrinological measures of reproductive status were observed in both species. Higher plasma T levels in female minnows and 11-KT levels in both male and female minnows and female killifish exposed to freshwater and marine sediments, respectively. Decreased female E2 and VTG levels and gonadal CYP 19 (aromatase) activity were also found in sediment exposed females from both species. No effect on female 3/17-HSD activity was found in either species. Solar powered, diffuse, small bubble aeration was installed within one freshwater, and subsequently, in one saltwater pond. PAH, OPAH, and anaerobic degradation product levels were monitored over the course of 1.5 years and post-remediation modified FSTRA was used to assess remediation status of the freshwater pond. Reproductive performance and endocrine endpoints were similar to control sediment levels indicative of successful remediation. PAH, OPAH, and anaerobic degradation product levels are being monitored in the saltwater pond. Modified FSTRA will be used similarly to assess remediation success.

TP028 Cadmium and BPA in vivo exposures alter endocrine related genes in the freshwater snail Physa acuta. New biomarker genes in a new model organism

M. Morales, P. Martinez-Paz, UNED; P. Sanchez-Arguello, INIA – National Inst for Agricultural and Food Research and Technology / Environment; G. Morcillo, UNED; J. Martinez-Guitarte, Universidad Nacional de Educación a Distancia / Fisica Matematica y de Fluidos

The freshwater snail Physa acuta is a sensitive organism to xenobiotics and appropriate for aquatic toxicity testing in environmental studies. There is scarce genomic information on P. acuta so in this work we identify several genes related with the hormonal system to evaluate the effects of Cadmium (Cd) and Bisphenol A (BPA), pollutants frequently found in aquatic environments. Endocrine-disrupting chemicals (EDCs) can affect the synthesis or secretion of hormones and alter their endogenous functions. We have selected two compounds with known endocrine-disrupting activity in vertebrates to analyze their potential effect on the Gastropoda endocrine system. The transcriptional activity of the endocrine related genes estrogen receptor (ER), estrogen-related receptor (ERR), and retinoid X receptor (RXR) were analyzed in P. acuta exposed to Cd and BPA. Real time reverse transcriptase-polymerase chain reaction (qRT-PCR) analysis showed that Cd and BPA presence altered the expression pattern of ER, ERR, and RXR mRNAs, suggesting a putative mode of action that could explain the endocrine disruptor activity of these xenobiotic at a molecular level on Gastropoda. These data provide, for the first time, information about the effects of Cd and BPA on the endocrine system of Gastropoda and suggest that ER, ERR and RxR genes could be a potential biomarkers of exposure to compounds with activity as endocrine disruptors. Acknowledgements: Funded by CTM-2015-64913-R from the Ciencias y Tecnologías Medioambientales program (SPAIN).

TP029 Advantages and Challenges for Determining Mode of Action of Industrial Chemicals: A Case Study with Alkylphenol and Alkylphenol Ethoxylates

K.K. Coady, The Dow Chemical Company / Toxicology Environmental Research and Consulting; J. Klapacz, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; C.A. Staples, Assessment Technologies, Inc.; B. Losey, RegNet Environmental Services

Determining the mode of action for environmental contaminants is increasingly important in the field of environmental toxicology for several reasons including, but not limited to: 1) potential future use of predictive toxicity methodologies which are based on molecular initiating events and modes of toxic action, 2) refining the assessment of the hazards of environmental mixtures in the environment, and 3) consideration of proposals for hazard based approaches to regulating chemicals based on perceived mode of action. While the mode of action of pharmaceuticals and pesticide active chemistries may be relatively straight-forward based on their design for efficacy with a selection toward minimizing non-target effects, industrial chemicals present unique challenges. This case study will examine Alkylphenols (APs) and low mole alkylphenol ethoxylates (APEs), which are environmental degradants of the higher mole APEs used as detergents, emulsifiers, wetting agents and dispersing agents in industrial chemical formulations. AP and low mole APE are known to have weak estrogenic activity; however, this is not the only or even the primary mode of action that is linked to adverse effects in environmental species Several lines of evidence will be presented that can be used to elucidate the mode of action of these and other industrial chemicals. High through-put toxicity screening, acute to chronic ratios, weight of evidence evaluations based on chronic toxicity data from various taxa (i.e. mammalian, fish, invertebrate and plant), and "omic" data will be used to make the case that for many industrial chemicals, a "lead" toxic mode of action may be hard to identify. Recommendations for determining modes of action for industrial chemicals and implications for regulatory aspects will be discussed.

TP030 Screening, Prioritizing, and Classifying EDCs: A comparison of international efforts to identify endocrine disrupting chemicals

J. Boucher, ETH Zurich; Z. Wang, Swiss Federal Inst of Technology / Inst for Chemical and Bioengeneering; K. Hungerbuehler, M. Scheringer, ETH Zurich / Inst for Chemical and Bioengineering

To date, a wide variety of organizations across multiple sectors around the world have published reports and communications proposing lists of chemicals that they have labeled as endocrine disrupting chemicals (EDCs) or suggested as potential EDCs. For example, government agencies from multiple countries have established their own priority chemical lists, screening programs, and/or knowledge bases to assist with ongoing research and pending management measures. Some industry bodies have also reviewed the topic and published their own lists for self-regulation within the respective sector. The intended purpose, selection criteria used to create these lists, and details included differ considerably among them. In this study, we have reviewed and consolidated in total over fifteen existing lists in the public domain. In particular, we aim to step back and gain an overview of the global efforts being made to identify and classify EDCs and to establish which chemicals have received the most consensus and evidence for being EDCs or should be prioritized for assessment in the foreseeable future. From the evaluation, we noted that while many lists have already been heavily developed and publicized, others are planned or currently in early development stages. Clarity of the selection criteria was also found to be varied, with some lists discussing the exact methodology used and others citing some form of expert consultation or not disclosing clear criteria. Multi-stakeholder consultation (through government, business, and/or community input) also occurred during the development of some, especially those that have direct regulatory impacts. Other differentiating factors include whether a list is static or changeable, homogenous or further sub-classified, and EDC-focused or more universal. Our comparison demonstrates that significant resources have been and are being invested into identifying and understanding EDCs, as reflected by the number and diversity of these lists. Simultaneously, it also highlights inconsistencies in methods being used, the lack of input from developing and transition countries, and the need for further clarification of the meaning and purposes of the lists.

Birds as Indicators of Environmental Change: Molecular to Population Effects of Contaminant Exposure and other Stressors

TP031 Levels of legacy and emerging organohalogenated compounds in Northern goshawk and White-tailed eagle nestlings from different latitudes in Europe

N. Briels, M.E. Løseth, L.N. Torgersen, Norwegian Univ of Science and Technology / Biology; I. Eulaers, Univ of Antwerp / Biology; T. Nygård, T.V. Johnsen, J. Bustnes, Norwegian Inst for Nature Research NINA; P. Gómez-Ramírez, Univ of Murcia / Sociosanitary Sciences; J. Martínez, Univ of Murcia / Ecology and Hydrology; G. Malarvannan, G. Poma, A. Covaci, Univ of Antwerp / Toxicological Center; V.L. Jaspers, Norwegian Univ of Science and Technology / Biology

Since the ban of several organohalogenated compounds (OHCs), industries have produced unrestricted alternatives that are also emerging in the environment, including birds. To assess to which degree these compounds are present in birds of prey, nestlings of Northern goshawk (NG; Accipiter gentilis) and White-tailed eagle (WTE; Haliaeetus albicilla) were investigated for exposure to legacy and emerging OHCs. Birds were sampled over a latitudinal gradient in Spain (NG: Murcia at 38°N) and in different locations in Norway (NG: Trøndelag at 63°N, Troms at 70°N; WTE: Smøla at 63°N, Steigen at 67°N). Blood and body feathers were taken as non-destructive sampling methods. Polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), dichlorodiphenyltrichloroethane and metabolites (DDXs), chlordanes (CHLs), hexachlorobenzene (HCB) and hexachlorohexanes (HCHs), together with emerging compounds, such as novel brominated flame retardants (NBFRs), dechlorane plus (DP) and phosphorus flame retardants (PFRs), were analysed using gas chromatography-mass spectrometry. The total OHC load in feathers of NG was twice as high in the northernmost location Troms (280 [181-518] ng g^{-1} dw) as in Trøndelag (93 [52-165] ng g^{-1} dw) and Murcia (103 [55-198] ng g^{-1} dw). This pattern differed in plasma, as Trøndelag had the highest OHC load (11 [1.8-40] ng mL^{-1}), followed by Troms (7.6 [1.4-35] ng mL^{-1}) and Murcia (3.2 [1.2-21] ng mL^{-1}). In WTE, birds from Steigen had the highest OHC load in both matrices, with plasma concentrations twice as high as in Smøla (11 [6.3-115] and 4.1 [1.8-15] ng mL^{-1}, resp.). In both species, PFRs were by far the major contributors to the total OHC load in feathers (36-84%). Other major contaminant groups were DDXs and PCBs (or HCHs in Murcia). The most dominant compounds of each group found in feathers of both species were tris(1-chloro-2-isopropyl)phosphate, p,p'-DDE, CB153, BDE47, oxychlordane (OxC) and β- and γ-HCH. In plasma, DDX and PCBs were the main contaminant groups (≥95% of the total OHC load) and CB153, CB180, p,p'-DDE, OxC, BDE99, BDE47 and β-HCH were the dominating compounds. PFRs in plasma were only detected in WTE from Steigen. In general, feather concentrations exceeded those in plasma, especially PFRs. This could be due to accumulation in feathers during feather growth or external contamination. Also, fewer compounds were detected in Spain than in Norway, suggesting further investigation of geographical exposure patterns.

TP032 Assessing Cholinesterase (ChE) activity in the Humboldt penguin (Spheniscus humboldti) from Punta San Juan de Marcona, Ica, Peru

W.C. Flores, Universidad Peruana Cayetano Heredia / Proyecto Punta San Juan Centro para la Sostenibilidad Ambiental; E. Serrano, Universitat Autònoma de Barcelona / Servei dEcopatologia de Fauna Salvatge SEFaS; M. Adkesson, Chicago Zoological Society / Brookfield Zoo; S. Cárdenas, Universidad Peruana Cayetano Heredia / Programa Punta San Juan; M. Cardeña, Universidad Peruana Cayetano Heredia / Proyecto Punta San Juan Centro para la Sostenibilidad Ambiental; J. Alava, Inst for the Oceans and Fisheries, Univ of British Columbia / School of Resource and Environmental Management

The use of current used pesticides with associated misuse and overuse in operational applications have resulted in the contamination of land, freshwater and coastal areas of the Pacific coast of South America. The toxic effects and persistence of these compounds in the marine environment are scarcely known in Peru. Exposure to organophosphorus (OP) and carbamates (CB) can inhibit the function of acetylcholinesterase (AChE), the enzyme responsible for neurotransmission, causing mortality or lethal effects in organisms. With the aim to determine baseline information on the normal activity of cholinesterase (ChE) in free-ranging Humboldt penguins (Spheniscus humboldti), we assessed ChE activity levels and whether body condition and sex of individuals are factors influencing ChE in penguins. Blood samples were collected from 17 males and 18 adult females in 4 areas of the Reserve Punta San Juan in Ica, Peru. Sampled penguins were considered clinically healthy. Samples were centrifuged and serum collected for biochemical analysis. We used generalized linear mixed models to explore the influence of sex, body condition and sampling location on the values of ChE. Body weight was included as a covariate, and the area as a random factor. The enzymatic activity was expressed in units (U) per L of serum (i.e. 1 U is a µmol of substrate hydrolyzed per minute). Mean concentrations of ChE ranged from 1248 ± 264 U/L (1.25 ± 0.3 U/mL) to 1413 ± 196 U/L (1.40 ± 0.2 U/mL), with a minimum concentration of 618 U/L (0.60 U/mL). Males had lower cholinesterase levels relative to those detected in females. However, the relationship between body weight and ChE should be interpreted with caution. While the association of ChE activity found in our penguins to ChE inhibiting pesticides or anti-cholinesterase compounds is scarcely understood due to the lack of background values and thresholds related to pesticides applications or chemical assaults in the region, our study reveals the first baseline that can be used as reference for ChE activity as a potential biomarker in Humboldt penguins as well as for wildlife and ecotoxicological risk-assessment. The range of ChE activity found here may be considered as basal levels for non-exposed penguins or penguins relatively exposed to low levels of pesticides (OP or CB) from unidentified local sources, highlighting the use of this seabird species as a sentinel to monitor the state of the health of the coastal-marine ecosystem along the Peruvian coast.

TP033 Useful biomarkers in sentinel European starlings (Sturnus vulgaris) exposed to vehicle exhaust emissions

M.A. North, Univ of Calgary / Ecosystem & Public Health; S. Bertazzon, Univ of Calgary / Geography; G.G. Kaplan, Univ of Calgary / Medicine; D.W. Kinniburgh, Alberta Centre for Toxicology / Physiology and Pharmacology; J.E. Smits, Univ of Calgary / Ecosystem and Public Health

The health effects of air pollutants have been established in common laboratory species for many individual compounds, and at excessive (unnatural) concentrations. Epidemiological studies are identifying relationships between inflammatory disease syndromes in humans and air pollutants such as oxides of nitrogen and sulphur, and fine (respirable) particulate matter. There is very little information available on the effects of realistic pollutant mixtures on wildlife, particularly from experimental exposures. Wild-caught, adult European starlings (Sturnus vulgaris) were divided into two groups of approximately 30 birds each to study the effects of vehicle emissions on wild passerines. Experimental and reference groups were housed and managed under the same conditions, controlling for the effects of vehicle noise, lighting and temperatures. The experimental group was exposed to vehicle exhaust diluted to simulate maximum ambient urban air concentrations, vented through their enclosure for five hours per day for one month. Body condition (using scaled mass index), cell- and antibody-mediated immune responses, and hormonal responses were assessed as non-lethal indicators of toxicologic effects, whereas hepatic detoxification enzymes (EROD), measures of oxidative stress (TBARS, GSH) and the histopathology of selected tissues provide insight into other possible biomarkers. Early results indicate a significantly reduced response to the PHA skin test of cell mediated immunity. Other responses in the contaminant exposed birds compared to the controls will be presented based on these hormonal and toxicological biomarkers. As well, we describe the experimental setup, and provide recommendations for future studies of exposure to air pollutants.

TP034 The Use of Homing Pigeons as a Biomonitor for Atmospheric POPs in Guangzhou, China

Y. Pei, Jinan Univ; R.S. Halbrook, Richard S. Halbrook / Zoology Cooperative Wildlife Research Laboratory; J. You, Jinan Univ / School of Environment

With the worsening air quality in China, it is essential to monitor the contaminants of concern in the atmosphere, especially in the megacities. Traditional atmospheric monitoring, such as using passive air samplers provides the concentration data in gaseous phase and particulate phase, but lacks the consideration about bioavailability, not to mention assessing toxicity risk of long-time exposure. Instead, biomonitoring with homing pigeons raised in urban area could be served as a suitable biomonitor of air pollution in cities. First, the homing ability makes homing pigeons live in their birth places during lifetime and keep exposing in air in the target area. Second, every homing pigeon has a foot ring recording its birth information, and usually they can live more than ten years. Last, more than 80,000 homing pigeon lofts are registered in China, spreading almost all cities in 34 provinces. In this research, 29 homing pigeons in Guangzhou urban area were collected and grouped to 1-, 5-, 10-year age groups. After necropsy, histopathological assessment was conducted for lung and liver. Concentrations of a variety of persistent organic pollutants (POPs), including polycyclic aromatic hydrocarbons (PAHs), organochlorine pesticides (OCPs), polychlorinated biphenyl (PCBs) and halogenated flame retardants (HFRs) in lung, liver and fat tissues were measured. In addition, drinking water and three types of pigeon food were sampled. There was a positive correlation between contaminant concentrations and the age of pigeons. Except of few PAHs, no other target POPs were detected in pigeon food and water, indicating these POPs were likely accumulated in the organisms through respiration. Within the same age group, concentrations of HFRs in lung tissue were significantly higher than those in liver tissue, verifying the respiration was the dominant route of exposure rather than diet. For the homing pigeons with high PAH concentrations in lung tissue, pathological responses were also observed. Female homing pigeons in the 5 and 10 year groups have significantly lower POPs concentrations in fat tissue than the males, probably because the POPs were reduced from the females by laying eggs. Compared with atmospheric monitoring data, biomonitioring data using homing pigeons provides a reference for assessing the respiration exposure risk of POPs to the residents in study area.

TP035 Effects of PCB 126, PCB 77 and Two Environmentally Relevant PCB Mixtures on the Gonadotropin Releasing Hormone System in Hatchling Japanese Quail

K.D. Dean, Stratus Consulting Inc. / Dept of Animal and Avian Sciences; M. Ottinger, Univ of Houston / Dept of Animal and Avian Sciences

Gonadotropin releasing hormone-I (GnRH-I) is a key component of reproductive function of vertebrates, with birds being no exception. Stimulation of GnRH-I producing neurons causes release of GnRH-I into the hypophyseal portal system followed by stimulation of the release of follicle stimulating hormone (FSH) or luteinizing hormone (LH) from the anterior pituitary. During non-breeding periods the hypothalamic-pitiuitary-gonadal axis (HPG) is relatively quiescent, but is stimulated by seasonal changes in daylength leading to activation of reproductive function. Adequate function of the HPG axis is at hatch is particularly important in precocial species such as the Japanese quail (Coturnix coturnix japonica) as it ensures appropriate sexual development and growth for reproduction. The purpose of this study was to determine if embryonic exposure to PCB 126, PCB 77 and two environmentally relevant PCB mixtures affected the development of the HPG axis and if there were detectable effects in hatchlings that could potentially relate to impaired reproductive function in adults. Fertile eggs from Japanese quail (n=30/group) were injected with the PCBs prior to incubation. The concentrations injected resulted in dose response curves in all treatments, except for PCB 77 injected eggs. Birds were sampled at hatch, brains were dissected rapidly and frozen over dry ice to retain the integrity of the brain shape for accurate hypothalamic punches to be performed. Hypothalamic GnRH-I was measured using an EIA specific for GnRH-I, the active form in avian species. As in previous studies, hypothalamic GnRH-I was sexually dimorphic. Response to the PCBs was non-linear, and followed an inverted U response, suggesting that embryonic survival at higher doses was also a factor in the response and the more sensitive embryos did not survive. These results point to potential actions of PCBs on hypothalamic systems that may be independent of thyroid system impacts of the PCBs. This work was supported by the U.S. Fish and Wildlife and the Hudson River Natural Resource Trustees. The conclusions and opinions presented here are those of the authors and do not represent the official position of any of the funding agencies, the Hudson River Trustees, or the United States of America.

TP036 Effects of PCB77 on development of the Bursa of Fabricius at hatch in the tree swallow (Tachycineta bicolor)

M. Ottinger, Univ of Houston / Dept of Animal and Avian Sciences; K.D. Dean, Stratus Consulting Inc. / Dept of Animal and Avian Sciences

The Bursa of Fabricius of hatchling birds is an important component of the immune system for production and maturation of B-cells. Sex hormones such as estrogens and androgens play an important role in bursa development, as can endocrine disrupting compounds. The purpose of this study was to determine if embryonic exposure to PCB 77, a dioxin-like PCB, would cause anatomical changes in the bursa of hatchling male or female tree swallows. Fertile tree swallow eggs at approximately embryonic day 2.5 were injected with 2.0uL of PCB 77 and placed back in the nest to develop. Eggs remained in place until two days prior to hatch, then were transferred to the laboratory. Control eggs were treated identically. All eggs were checked for development twice before removal to the laboratory. Samples were collected within four hours of hatch and fixed in neutral buffered formalin, then stained with hematoxylin. There were changes in bursa, follicle and lumen size associated with treatment. This work was supported by the U.S. Fish and Wildlife and the Hudson River Natural Resource Trustees. The conclusions and opinions presented here are those of the authors and do not represent the official position of any of the funding agencies, the Hudson River Trustees, or the United States of America.

TP037 Tree swallow chromosomal damage across the Great Lakes: An application of a multi-level model to ecotoxicology

R.A. Erickson, USGS – UMESC / Upper Midwest Environmental Sciences Center; T.W. Custer, C.M. Custer, USGS / Upper Midwest Environmental Sciences Center; K. Aagaard, USGS / Upper Midwest Environmental Sciences Center; E. Oziolor, Baylor Univ / Environmental Science; E. Bigorgne-Vizade, ANSES / Unit of Chemical Substances Risk assessment Dept; C.W. Matson, Baylor Univ / Environmental Science

Tree swallows (Tachycineta bicolor) may serve as a bioindicator because toxicants accumulate in the species. These toxicants also hold the potential to adversely affect the tree swallow and may potentially damage DNA. Chromosomal or DNA damage can be measured by examining genome size coefficients of variation (DNA CV) using flow cytometric techniques. We sought to examine the amount of chromosomal damage within tree swallows across the Great Lakes and we collected nestlings from 69 sites in the Great Lakes basin. These sites included multiple sites within 27 Areas of Concern (AOCs) and 9 nearby non-AOC sites. Our data contained multiple levels of information and accounting for this information required considering the hierarchical nature of the data. Specifically, we developed a multi-level (or hierarchical) model to account for the variability and covariates within replicates, within nestling, within nest box, within site, and within AOC/meta-site. This model also allowed us to account for pseudo-replication. Using the multi-level model, we were able to estimate the DNA CV values at different levels of inference. We specifically found that some sites had greater chromosomal damage than our reference sites. We also found important covariates at different levels within the model. In addition to our specific results, we also discuss how multi-level models may be used to address other situations found in ecotoxicology.

TP038 Concentrations and spatial patterns of organic contaminants in tree swallows at US and Binational Great Lakes Areas of Concern (AOCs), 2010-2015

C.M. Custer, T.W. Custer, P.M. Dummer, USGS / Upper Midwest Environmental Sciences Center; D. Goldberg, J. Franson, USGS / National Wildlife Health Center

Tree swallows (Tachycineta bicolor) were sampled across the Great Lakes basin in 2010-2015 to provide a system-wide assessment of current exposure to organic contaminants as part of the Great Lakes Restoration Initiative (GLRI). These results provide information identified as critical by regulators to assess the ‘Bird or Animal Deformity or Reproductive Problems’ Beneficial Use Impairment (BUI). Eggs were collected from 69 sites across all five Great Lakes, including 27 Areas of Concern (AOCs), some with multiple sites, and ten sites not listed as an AOC. Concentrations of organic contaminants in eggs were quantified and compared to background and reproductive effect thresholds. At approximately 30% of AOCs, tree swallow eggs had geometric mean total polychlorinated biphenyls (PCBs) concentrations at or below average background concentrations (0.34 mg/g wet wt.). Mean concentrations at 78% of AOCs were below the mean at the most contaminated non-AOC location (1.30 mg/g wet wt.). The AOC with the highest level of PCBs in eggs was Waukegan Harbor, IL (geometric mean = 7.30 mg/g wet wt.) followed by Lower Green Bay and Fox River, WI (2.6 mg/g wet wt.) and Kalamazoo (2.2 mg/g wet wt.). Exposure to polybrominated diphenyl ethers (PBDEs) was minimal, and only 3 of 27 AOCs and one non-AOC had geometric mean concentrations that exceeded background for tree swallows (96 ng/g wet wt.). Concentrations of both PCBs and PBDEs were 10 to >20 times below the lower limit for hatching effects. In contrast, geometric mean concentrations of dioxin and furan (PCDD-F) toxic equivalents (TEQs) at Saginaw River and Bay AOC (242 pg/g wet wt.) and Midland, MI (475 pg/g wet wt.), a non-AOC site upstream, exceeded the lower limit for hatching effects (181 pg/g wet wt. PCDD-F TEQs). All other sites had geometric mean concentrations of PCDD-F TEQs below background levels (87 pg/g wet wt. PCDD-F TEQs). Other organic contaminants, including p,p'-dichlorodiphenyldichloroethylene (DDE), mirex, heptachlor, and chlordane, were at or below background concentrations, or did not differ between AOCs and non-AOCS. With some exceptions, both at the site or individual sample level, there seems to be only minimal exposure (at or below background) to the organic contaminants measured in the Great Lakes Basin.

TP039 Transcriptomics, contaminants, and other biomarkers in tree swallow (Tachycineta bicolor) nestlings from the Great Lakes

C. Tseng, Baylor Univ / Environmental Science; C.M. Custer, T.W. Custer, USGS / Upper Midwest Environmental Sciences Center; N.K. Karouna-Renier, S.L. Schultz, USGS-Patuxent Wildlife Research Center / Beltsville Lab; E. Oziolor, Baylor Univ / Environmental Science; E. Bigorgne-Vizade, ANSES / Unit of Chemical Substances Risk assessment Dept; C.W. Matson, Baylor Univ / Environmental Science

Polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), dioxins, and a variety of pesticides and other contaminants of emerging concern are significant issues in the Great Lakes Areas of Concern (AOC). Tree swallow (Tachycineta bicolor) nestlings were collected from 27 AOCs and nine nearby non-AOC sites, with multiple sites on each of the five Great Lakes, from 2010 to 2015. Contaminant analyses and biomarkers were examined in all nestlings collected. In birds, hepatic cytochrome P450 1A4 (cyp1a4) and cytochrome P450 1A5 (cyp1a5) gene expression have been shown to be good indicators of an induced aryl hydrocarbon receptor (AHR) pathway, whose ligands include dioxins, PAHs, and PCBs. Additionally, their expression is generally proportional to the commonly utilized surrogate for AHR induction, ethoxyresorufin-O-deethylase (EROD) activity. Among our samples, we observed population-specific differences in the strength of the correlation between AHR pathway induction and PCB and PAH concentrations, particularly at Waukegan Harbor, IL. Unlike other PCB-contaminated AOCs, we found that EROD activity was only moderately induced at Waukegan Harbor, despite mean nestling PCB concentrations of 6 ppm and high total PAHs in stomach contents. Additionally, transcriptomic analysis was performed for a subset of samples, including nestlings from Manistique River, MI, River Raisin, MI, Saginaw River, MI, Waukegan Harbor, and four other non-AOC sites. RNA-Seq library construction and sequencing used Illumina chemistries. The de novo transcriptome was assembled using the Trinity platform, followed by RSEM for expression estimation and EdgeR for differential expression analysis. Transcriptomic analysis indicated that cyp1a4 and cyp1a5 expression at Waukegan Harbor was only about one third of that observed at River Raisin, although the PCB concentrations from Waukegan Harbor were three fold higher than those from River Raisin. Other population differences in gene expression, and their correlations with other biomarkers and environmental chemistry will also be discussed.

TP040 Transcriptome profiling of American kestrels exposed in ovo to two persistent organic pollutants -SCCPs and TBBPA-BDBPE

N.K. Karouna-Renier, USGS Patuxent Wildlife Research Center / Beltsville Lab; B. Yee, Johns Hopkins Univ; P.F. Henry, USGS / Patuxent Wildlife Research Center; D.T. Sprague, USGS Patuxent Wildlife Research Center; R.S. Cornman, USGS Fort Collins Science Center; K.J. Fernie, Environment & Climate Change Canada / Ecotoxicology and Wildlife Health

The increased use of alternative flame retardants and related products and their reported persistence in the environment have resulted in greater bioaccumulation in wildlife located near point sources and in more remote locations. However, few data are available on the potential adverse effects of these compounds in the exposed animals. Here we report on an investigation into genomic effects of two such persistent organic pollutants (POPs) – short-chain chlorinated paraffins (SCCPs) andtetrabromobisphenol A bis[2,3-dibromopropyl ether] (TBBPA-BDBPE; CAS 21850-44-2) – on a predatory bird species, the American kestrel(Falco sparverius). SCCPs are emerging POPs identified by the Stockholm Convention and by the U.S. Environmental Protection Agency as chemicals of concern due to potential long-term risks from exposure. These highly resistant additive chemicals are used in metal lubricants and coolants in metal cutting, and as plasticizers and flame retardants in plastics and paints. Similarly, TBBPA-BDBPE, a derivative of TBBPA,is an additive flame retardant that is used in a wide range of plastic products, resins, textiles, paints, and household electronics. Although TBBPA-BDBPE was introduced as a possible replacement for decabromodiphenyl ether (decaBDE), it may be as persistent and has similar environmental transport mechanisms. In this study, RNA-Seq analysis was performed to identify differentially expressed genes in American kestrels exposed in ovo to environmentally relevant concentrations of SCCPs and TBBPA-BDBPE. Our goal was not only to identify dysregulated genes, but also to gain a better understanding of kestrel genomics. A transcriptome was constructed de-novo and benchmarked, obtaining 25,000 annotated isoforms pertaining to nearly 17,000 unique genes. Differential expression analysis of SCCP-exposed males and females together, identified significant changes in 673 genes (adjusted p-value < 0.05), with 3 genes exceeding log2 fold changes. In TBBPA-treated hatchlings, 4 genes exceeded a log2 fold change over vehicle control birds. Analyses of differential expression by sex for each compound, increased the number of genes exceeding log2 fold change, suggesting significant differences in the responses of male and female American kestrels to both of these POPs.

TP041 Identifying adverse effects on neuroanatomy of hatchling American kestrels exposed to two novel brominated flame retardants

M.F. Guigueno, McGill Univ / Dept of Natural Resource Sciences; N.K. Karouna-Renier, USGS Patuxent Wildlife Research Center / Beltsville Lab; P.F. Henry, USGS / Patuxent Wildlife Research Center; J. Head, McGill Univ / Natural Resource Sciences; L.E. Peters, Stantec Consulting; V. Palace, IISD-Experimental Lakes Area; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; K.J. Fernie, Environment & Climate Change Canada / Ecotoxicology and Wildlife Health

Each year, new chemicals are introduced to the market. The Canadian federal government's Chemicals Management Plan (CMP) has identified priority chemicals, including multiple flame retardants, for risk assessment and management. Techniques for assessing these chemicals have generally not considered their potential impacts on the brain. Some flame retardants accumulate in the brain, and the brain is known to be sensitive to physiological perturbations including contamination. We used an established technique, neuroanatomy, in a novel context, ecotoxicology. We exposed American kestrels (Falco sparverius), key top predators of terrestrial ecosystems, in ovo to one of two commonly used brominated flame retardants (BFR): 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (EHTBB also abbreviated as TBB; CAS 183658-27-7), or bis(2-ethylhexyl)-2,3,4,5-tetrabromophthalate (TBPH; CAS 26040-51-8). Controls received vehicle (safflower oil) only. We sectioned 40-µm slices throughout the brain of hatchling kestrels using a cryostat, followed by Nissl staining to label all the cells and delineate targeted brain regions. We measured the volumes of the hippocampus and the telencephalon in the left and right hemispheres. The hippocampus, a region in the telencephalon, plays a crucial role in spatial memory and navigation in birds, and dysfunction in the hippocampus could affect their survival and reproduction. BFR are especially likely to impact the hippocampus because of their known effects on thyroid hormones that influence hippocampus development and neurogenesis, and on sex steroids for which the avian hippocampus expresses androgen and estrogen receptors. In addition to determining whether hippocampus volume relative to the telencephalon is affected by BFR exposure, we determined whether whole telencephalon volume and symmetry between the hemispheres were affected. This project links chemical exposure with potential neurological effects in birds. These changes could have an impact on behaviour at the individual level, and ultimately, affect populations.

TP042 Mercury concentrations in Double-crested Cormorant chicks across Canada

R. Lavoie, Royal Military College of Canada / Biology; L. Campbell, Saint Marys Univ / Dept of Environmental Science

Spatial patterns of mercury (Hg) have been found in freshwater ecosystems across Canada for many taxa including fish and birds. Hg biomagnifies in aquatic food chains and can reach high concentrations in fish-eating birds. However, it is often hard to sample a representative population size of adult birds to monitor concentrations of contaminants over a large spatial scale. Moreover, adult birds can migrate and can show a contaminant profile that may not be entirely representative of local resources of the monitored ecosystems. The aim of this study were (1) to develop a model to estimate Hg concentrations in breeding adults by using chicks as proxy and (2) to determine if there was a spatial pattern of Hg in piscivorous birds. Double-crested Cormorant (Phalacrocorax auritus) chick feathers were sampled at 19 sites across Canada (n = 5 chicks / site). Adult tissues (freshly grown feathers and blood) were sampled at five of those locations to establish correlations between tissues and age classes. We found a good correlation of Hg concentrations between adults and chicks and between adult tissues. We developed a model to estimate Hg concentrations in adults across Canada using chicks as proxy. We found an increase in Hg concentrations with latitude, but not with longitude. Our study shows that chicks can be a suitable proxy for monitoring mercury concentrations in adult fish-eating birds. Future work will include an analysis of birds across North America.

TP043 Determining Baseline Mercury Concentrations in Seabird Eggs in Lake Melville, Labrador, Canada Before Flooding of the Muskrat Falls Hydroelectric Dam

N.M. Burgess, Environment & Climate Change Canada / Science and Technology Branch

Nalcor Energy is currently constructing the Muskrat Falls hydroelectric dam on the Churchill River in Labrador, Canada. Flooding of the reservoir is expected in 2017-18. At the environmental assessment hearings which preceded the project, concerns were raised by the Nunatsiavut Government and the Government of Canada about downstream increases in aquatic methylmercury in Lake Melville, as a result of dam construction. Nalcor Energy discounted these concerns. This project began in 2013, to determine the baseline mercury concentrations in the eggs of marine birds breeding in Lake Melville, prior to flooding of the Muskrat Falls reservoir. We collected eggs of ring-billed gulls (Larus delawarensis) and common terns (Sterna hirundo) on islands in western Lake Melville in 2013-15. These eggs were analysed individually for total mercury, and in 2015 for stable carbon and nitrogen isotopes ($\delta^{13}C$ and $\delta^{15}N$, respectively). We found no differences in mean egg mercury concentrations among islands or among years for either ring-billed gulls or common terns. The geometric mean of egg mercury concentrations in common tern eggs (0.92 µg/g, dry wt.) was significantly greater than in ring-billed gull eggs (0.77 µg/g), while the variance in mercury concentrations was greater in the gull eggs. In eggs collected in 2015, $\delta^{15}N$ was analysed to investigate the trophic patterns of the gulls and terns. Comparing $\delta^{15}N$ data (mean ± SD) between ring-billed gull eggs (10.5 ± 1.3‰) and common tern eggs (12.5 ± 0.5‰) indicated that the gulls foraged over a wider trophic range, and on average at a lower trophic level than the terns. Mercury concentrations in the gull eggs were unrelated to either $\delta^{13}C$ or $\delta^{15}N$. However, in the common tern eggs, both $\delta^{13}C$ and $\delta^{15}N$ were negatively associated with mercury concentrations. Current mercury levels in the Lake Melville gull and tern eggs pose little risk of adverse effects on reproduction. This study provides baseline data prior to the flooding of the Muskrat Falls reservoir, which we will use to assess the amount and duration of subsequent mercury increases after flooding.

TP044 Methylmercury Effects on Bird Reproduction: Critical Review and Identification of Toxicity Reference Values

P.C. Fuchsman, M.H. Henning, L. Brown, M.J. Bock, Ramboll Environ; V.S. Magar, Ramboll Environ US Corporation, Chicago, IL

Effects of Hg on birds have been studied extensively and with increasing frequency in recent years. We conducted a comprehensive review of MeHg effects on bird reproduction, evaluating laboratory and field studies in which observed effects could be attributed primarily to Hg. Our review focused on exposures via diet and maternal transfer in which observed effects (or lack thereof) were reported relative to Hg concentrations in diet, eggs, or adult blood. Applicable data were identified for 25 species. From this data set, we identified ranges of toxicity reference values (TRVs) suitable for risk assessment applications. Typical ranges of Hg effect thresholds are approximately 0.2 to 1.5 mg/kg in diet, 0.08 to >0.3 mg/kg-day on a dose basis, 0.6 to 2.6 mg/kg in eggs, and 1.7 to >6.7 mg/kg in parental blood (all concentrations on a wet weight basis). For Hg in avian blood, this review represents the first broad compilation of relevant toxicity data. For dietary exposures, the current data support TRVs that are higher than older, commonly used TRVs. The older diet-based TRVs incorporate conservative assumptions and uncertainty factors that are no longer justified, although they generally were appropriate when originally derived, due to past data limitations. The egg-based TRVs identified from this review are more similar to other previously derived TRVs but have been updated to incorporate new information from recent studies. While important research needs remain, a key recommendation is that species not yet tested for MeHg toxicity should be evaluated using toxicity data from tested species with similar body weights.

TP045 Elucidating Biomarkers of Developmental Toxicity Associated with Pharmaceutical Pollutants

J. Meadows, East Carolina Univ / Pharmacology and Toxicology; E. Hvastkovs, East Carolina Univ / Dept of Chemistry; J.C. DeWitt, East Carolina Univ / Pharmacology and Toxicology

Pharmaceutical pollutants are emerging contaminants of concern as low concentrations of therapeutic drugs are detected in a variety of water sources around the world. Few published studies address the toxicity of these compounds from chronic exposures at concentrations well below therapeutic doses. Even less is known about how these pollutants effect susceptible populations, such as the developing embryo. Many pharmaceutical agents found in water sources are endocrine disruptors, which can disrupt the hypothalamus-pituitary-adrenal axis, or stress axis. Early life stress in the form of environmental contaminants can have profound effects on both development and regulation of body functions later in life. Therefore the focus of this research is on phenotypic anchors associated with the stress axis in an avian model. Fertilized chicken eggs were injected with 0.0001, 0.00001, or 0.000001 mg/mL in DMSO of fluoxetine, fenofibrate, or norethisterone, which represent different pharmaceutical classes that have been detected most abundantly in recent water sampling studies. Upon hatching, collected endpoints included open-field activity as a general marker of arousal and body and organ weights as markers of developmental toxicity. Pre-hatching mortality indicated thatfor eggs that did not hatch, most embryos stopped developing within the first week of incubation, a period characterized by rapid energy utilization for organogenesis. Open-field activity suggested that fluoxetine and norethisterone decreased the arousal of hatchlings at all doses, as compared to the control. No significant changes in organ weights were observed, although there was wide variability in the weights of spleens and bursas of hatchlings exposed to various concentrations of fenofribrate and norethisterone. These phenotypic changes indicate that exposure to pharmaceutical pollutants at environmental concentrations can impact the development and behavior of chickens. Future analysis will include plasma corticosterone levels and brain and liver glucocorticoid receptor concentrations to anchor developmental indicators with changes to the stress axis.

TP046 Competitive Binding of Persistent Organic Pollutants to the Thyroid Hormone Transport Protein Transthyretin in Glaucous Gull (Larus hyperboreus)

. Mortensen, NTNU Univ / Dept of Biology; G. Gabrielsen, Norwegian Polar Research Inst; E.S. Heimstad, NILU – Norwegian Inst for Air Research; I. Sylte, Univ of Tromso; B. Jenssen, Norwegian Univ of Science and Technology / Biology

The glaucous gull (Larus hyperboreus) is one of the largest avian top predators in the Arctic. High levels of persistent organic pollutants (POPs) and their metabolites have been detected in the glaucous gull. Several studies indicate that these high levels can contribute to detrimental effects, and one possible mechanism is that chemicals interfere with the endocrine system. Thyroid hormones (THs) are important for thermogenesis, reproduction, growth and differentiation, and are transported in the circulation system of glaucous gull mainly bound to the transport proteins globulin, albumin and transthyretin (TTR). The present study used molecular modeling to construct homology models of TTR in glaucous gull and docked several well-known and emerging POPs in the models to predict binding affinities of POPs to the TH binding site in glaucous gull TTR. The models predicted that a large group of structurally diverse compounds would bind to glaucous gull TTR, mostly halogenated compounds but also not halogenated compounds. Among the predicted TTR binders were polybrominated diphenyl ethers (PBDEs), polychlorinated biphenyls (PCBs) and their metabolites, different brominated, chlorinated and phosphorus flame retardants, perfluorinated compounds (PFCs) and other emerging compounds. The presence of functional groups in the compounds were predicted to increase the binding affinity, and if the functional groups were ionized the binding affinity was predicted to further increase. However, the presence of functional groups were not required for the compounds to bind to TTR. The models also predicted that brominated analogues had higher affinity to TTR than the corresponding chlorinated analogues. Several of the brominated compounds, PFCs and THs had comparable binding affinity to TTR. Many of the compounds have been found in the glaucous gull or in the Arctic environment and organisms. The results indicated that competitive binding of multiple POPs with THs for TTR in glaucous gull can potentially disrupt the circulation of THs and possibly affect the TH homeostasis and TH-dependent functions.

Existing and Emerging Contaminants in Changing Arctic Environments

TP047 Accumulation of PBDEs of in Stranded Harp (Pagophilus groenlandicus) and Hooded Seals (Cystophora cristata) from the Northeastern United States

B. Soulen, J. Gnau, Univ of North Texas; B. Venables, Univ of North Texas / Biology; D.W. Johnston, Duke Univ Nicholas School of the Environment / Duke Marine Lab; A.P. Roberts, Univ of North Texas / Dept of Biological Sciences Inst of Applied Science

Polybrominated diphenyl ethers (PBDEs) are highly lipophilic components of brominated flame retardants that are environmentally persistent and bioaccumulate. PBDEs are effectively taken up from the gastrointestinal tract and accumulate mainly in fat depots (blubber) and liver tissues. Species inhabiting Arctic and sub-Arctic regions, such as seals, can have upwards of 30% of their body mass composed of blubber. When those blubber stores are mobilized for energy, they are simultaneously releasing stored toxicants into circulation causing them to be more bioavailable. Most studies looking at accumulation of PBDEs in seals have focused on harbor and grey seals with few looking at harp and hooded seals. In this study, we analyzed accumulation of PBDEs in seal blubber from 22 stranded harp and 9 stranded hooded seals sampled along the northeast coast of the U.S. (1999-2010) and determined the PBDE congener fingerprint for each individual. PBDEs were extracted from blubber sub-samples using gel permeation chromatography and analyzed using GC-MS. The five most environmentally relevant PBDEs were targeted: BDE-47, -99, -100, -153, and -154. Total PBDE concentrations were calculated for each individual using the relative response factors determined from a calibration curve generated using certified reference materials. The congener fingerprint (concentrations and % totals for each congener) was determined for each individual. Preliminary results show ?PBDEs in both species ranging from 65.15- 149.74 ng/g lw. BDE-47 is the most abundant congener found in all samples comprising upwards of 50% of the total PBDES present. The results of this study will aid in understanding the effects of PBDEs on harp and hooded seals being that both of these species are reliant on blubber stores during all life stages.

TP048 Temporal and spatial trends of polychlorinated naphthalenes (PCNs) in ringed seals from the Canadian Arctic

M. Houde, Environment and Climate Change Canada / St Lawrence Center; X. Wang, Environment and Climate Change Canada / Aquatic Contaminants Research Division; S.H. Ferguson, Fisheries and Oceans Canada; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division

The ringed seal is the most abundant Arctic pinniped with a circumpolar distribution and has been a key biomonitoring animal for examining spatial and temporal trends of persistent organic pollutants (POPs) in the Arctic since the 1970s. Polychlorinated naphthalenes are widespread environmental contaminants that have been reported in air samples and marine mammal tissues from the Arctic although spatial and temporal data are much more limited compared to most POPs. While intentional production and use of PCNs stopped in the 1970/80s they remain in old products such as capacitor fluids, engine oil additives, and electrical insulators. Current PCN emissions are mainly as by-products of combustion such as waste incineration and coke production from coal. The main objective of this research was to investigate the presence and the temporal trends of PCN in ringed seals from the across the Canadian Arctic. Ringed seal blubber samples were collected by hunters in the communities of Sachs Harbour, Resolute Bay, Arviat and Nain between 2011 and 2015 and analyzed for 68 (out of 75) PCNs by GC-HRMS. Geometric mean concentrations of ΣPCNs ranged from 0.50 to 5.6 ng/g l.w. across the 4 sampling locations, with the highest levels recorded in seals from Sachs Harbour and Resolute Bay in 2011 and 2012. Tetra- and pentachloro-PCN congeners predominated, representing 89-94% of ΣPCN. Mean concentrations declined from 2012 to 2014 except at Nain, Labrador. These mean concentrations are about ten-times higher than for the same locations sampled over the period 2000-2010. The previous PCN data were determined by low-resolution mass spectrometry and were based on fewer congeners which may explain the lowest levels reported. Polychlorinated naphthalenes are more prominent contaminants in Canadian Arctic seals than previously determined based on new results using improved analytical techniques.

TP049 Metal accumulation and histopathological changes in Arctic hares (Lepus arcticus) inhabiting a Deactivated Lead-Zinc Mine in the Canadian High Arctic

S. Amuno, Nunavut Impact Review Board; S. Niyogi, Univ of Saskatchewan

The current study was undertaken to determine post-mining baseline accumulation of selected trace metals, and histopathological alterations in free-living Arctic hares (Lepus arcticus) inhabiting the vicinity of a deactivated lead-Zinc mine located in the North Baffin Island of the Canadian high Arctic. Trace metal analysis included measurement of arsenic, cadmium, iron, lead and zinc in hepatic and renal tissues and soil, and histopathological assessment involved evaluation and scoring the severity of metal-induced hepatic and renal lesions. In general, metal burden in hepatic and renal tissues of hares collected from the vicinity of the mine did not differ markedly relative to that in hares collected from the reference area. Nonetheless, a higher accumulation pattern of cadmium and lead in the hepatic tissues of hares was recorded in the mine area relative to the reference area, although no corresponding hepatic lesions were observed in animals collected from the mine area. Surface soils near the mine area contained significantly higher levels of trace metals (Zinc> Manganese>Lead>Cadmium>Arsenic) compared to that in the reference area. Moreover, soil cadmium levels were found to exhibit a strong correlation with the cadmium burden in renal tissues of hares. Generally, both mine-impacted and reference animals showed similar but varying severities of hepatic and renal lesions at the sublethal level, notably vascular congestion, occasional large hepatocyte nuclei, binucleate hepatocytes, yellow-brown pigmentation in the cytoplasm of hepatocytes, and clustering of hepatocytes. Only hares collected from the mine area with relatively higher tissue burden of lead showed renal edema, and hemorrahage of the capsular surface. This study represents the first assessment of metal-induced histopathological alterations in Arctic hares inhabiting a historical mining area in the high Arctic.

TP050 Climate Change, contaminants, ecotoxicology: interactions in Arctic seabirds at their southern range limits

K. Elliott, McGill Univ / Dept of Natural Resource Sciences; J. Head, McGill Univ / Natural Resource Sciences; R.J. Letcher, B. Braune, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; K.J. Fernie, Environment & Climate Change Canada / Ecotoxicology and Wildlife Health

Effects of contaminants on Arctic wildlife are occurring against a backdrop of rapid climate change. Contaminants can cause endocrine disruption and associated impacts on reproduction. Because the endocrine system plays a critical role in allowing animals to respond to environmental stress, endocrine disruption could limit the plasticity of wildlife to respond to climate change. In 2016, we examined how the ability of seabirds to respond to changing ice conditions is impacted by a suite of selected legacy and emerging contaminants. We studied thick-billed murres at their southern range limit, where climate change is strongly impacting seabird health. When ice breaks up earlier, adults must fly further and so expend more energy but ultimately gain less food, and young murres grow more slowly. Hormone systems are likely involved in this phenomenon as high levels of stress hormones (corticosterone) and potentially thermoregulatory hormones (thyroid hormones) impel individuals to increase energy expenditure, fly farther and find alternative prey sources. We expected that high levels of contamination would disrupt hormone regulation, decoupling the relationship between hormones and energy expenditure in seabirds. We anticipated that chemical disruption of that relationship may explain why some individuals appear unable to alter their foraging behavior in response to changing ice conditions.

TP051 Organophosphate flame retardants and plasticizers in the High Arctic: Deposition and Transport in Lake Hazen

A.O. De Silva, Environment and Climate Change Canada; K. St Pierre, V. St.Louis, Univ of Alberta / Biological Sciences; C. Spencer, Environment and Climate Change Canada; I. Lehnherr, Univ of Toronto; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Use of organophosphate esters (OPEs) as plasticizers and flame retardants has increased substantially since the restrictions on polybrominated diphenyl ether (PBDE) flame retardants in the early 2000s. OPEs were thought to be a more suitable alternative with lower persistence and decreased bioaccumulation potential. The long range transport potential of OPEs is uncertain. The modeled atmospheric half-life is very short (< 1 day) which would render them unlikely candidates for long range transport. However it has been hypothesized that OPEs adsorb to aerosols, making them less available to oxidation and increase their potential to be transported over long ranges to non-source regions. We chose the Lake Hazen watershed (82 °N) in Quttinirpaaq National Park on northern Ellesmere Island, Canada to investigate the presence of OPEs and the impact of watershed processes on their loadings. At 540 km^2, Lake Hazen is the tenth largest Arctic lake and the world's largest lake north of the Arctic Circle. Sampling over the 260 m water column of Lake Hazen demonstrated an OPE profile dominated by tris(2-butoxyethyl)phosphate (TBEP, 0.89-8.4 ng/L), followed by chlorinated OPEs: tris(2-chloroisopropyl)phosphate (TCPP, 0.55 – 2.2 ng/L), tris(1,3-dichloroisopropyl) phosphate (TDCPP, 0.13-1.4 ng/L), tris(2-chloroethyl)phosphate (TCEP, 0.085 – 2.1 ng/L). These concentrations are an order of magnitude lower than OPEs in the Great Lakes: 12±2.1 ng/L TCPP, 4.0±1.0 ng/L TDCPP, 1.5 ±0.2 ng/L TCEP, and 75±39 ng/L TBEP. OPEs were detected in the glacier-fed rivers flowing into Lake Hazen as well as the major outflow, the Ruggles River. Concentrations of TCPP, TDCPP, triphenylphosphate (TPP), and TBEP were 2 – 10 x higher in the Turnabout River compared to the Ruggles River. This suggests that the glacier-fed rivers are an important source of OPEs into Lake Hazen. Temporal sampling was conducted to evaluate snowmelt inputs and the role of ice cover on OPEs in Lake Hazen. These results demonstrate the long range transport potential of OPEs and their water-borne mobility in the dissolved phase leading to a consistent presence in the Lake Hazen watershed.

TP052 Long range transport of organophosphate flame retardants and plasticizers: deposition in a High Arctic ice cap

A.O. De Silva, Environment and Climate Change Canada; C. Young, Memorial Univ / Dept of Chemistry; C. Spencer, Environment and Climate Change Canada; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A. Criscitiello, Univ of Calgary; M. SHARP, Univ of Alberta; C. COOK, Environment and Climate Change Canada; H. PICKARD, Memorial Univ of Newfoundland

Organophosphate esters (OPEs) have been used as alternatives to brominated flame retardants, plasticizers, and anti-foaming agents for several decades globally. Applications in varied industries including furniture, textiles, electronics, building materials, vehicle and petroleum industries and typically they are incorporated as additives as opposed to chemically bonded to the substrate. This has led to questions regarding environmental fate and transport. There have been increasing reports of detection in indoor and outdoor air, sediment, water, wastewater, and biota. Hypotheses regarding the long range transport potential of OPEs have emerged based on detection in precipitation and air in remote locations as well as monitoring in oceans. These observations are surprising since OPEs are not expected to meet persistence or physical property criteria for long range transport.The purpose of this research was to evaluate the long range transport potential of OPEs by examining their profile in the high Arctic. To this end, we selected an ice cap located on the uninhabited Devon Island spanning 55,000 km^2 in the Canadian Arctic archipelago. It is at extreme northern latitude, 75 °N and the highest point of the ice cap itself where sampling occurred is at an elevation of 2200 m. Here, we obtained a longer ice core with a bottom depth dating 1979 in order to perform a robust and continuous time series spanning several decades. OPEs were detected in every annual layer of ice from 2014 to 1979.In the most recent year analyzed, 2015, the predominant analyte was TCPP (49%), followed by TnBP (14%), TCEP (9.6%), TPP (9.0%), TBEP (7.3%), TEP (5.8%), TDCPP (3.7%). Together these six analytes comprised 98% of the total OPE concentration.Many of the OPEs were correlated with each other ($p< 0.05$). The strongest correlation was TCEP with TnBP (Spearman correlation coefficient R_S 0.90. The annual deposition rate was used to calculate flux in ng/cm^2 so that temporal trends in deposition could be evaluated. The data indicated increasing deposition of most OPEs since the 1990s. The majority of the analytes displayed doubling times of between 3 and 6 years. The doubling time for the chlorinated OPEs, TCEP and TDCPP, were much longer (14 and 21 y, respectively) suggesting that emissions of these compounds may be tapering. This is interesting given that TCEP and TDCPP were replacement flame retardants for polybrominated diphenyl ethers (PBDEs).

TP053 Transport and bioaccumulation of perfluorinated Compounds in an Arctic lake catchment influenced by permafrost disturbance and climate change

A. Cabrerizo, A. DeSilva, Environment and Climate Change Canada / Aquatic Contaminants Research Division; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; C. Spencer, Environment and Climate Change Canada / Aquatic Contaminants Research Division; S. Lamoureux, Queens Univ / Geography; M. Lafrenière, Queens Univ / Dept of Geography and Planning

Although perfluorinated alkyl substances (PFAS) and their precursors differ from the legacy persistent organic pollutants (POPs) in the way they bioaccumulate and bind to proteins, they are globally distributed and found in biota from remote areas, such as the Arctic. The goal of this study was to investigate whether global warming, which is affecting Arctic lakes and their catchments, may impact the transport and bioaccumulation of PFAS. The study was conducted at the Cape Bounty Arctic Watershed Observatory on Melville Island (74°55′ N, 109°35′ W), where two adjacent, geologically similar watersheds with two lakes (West and East) are currently undergoing climate-driven changes. PFAS concentrations (C4-C16 PFCAs, C4-C10 PFSA) were determined in archived Arctic char muscle samples (N=190) collected annually from 2008- 2015. Lake and river water and soil samples collected in 2015 (n=50) around the lakes and watersheds were also analysed for PFAS. Although the two paired watersheds and lakes are adjacent, ongoing studies have revealed significant permafrost disturbances affecting the West Lake watershed which has resulted in high turbidity combined with elevated POC and DOC in comparison to East Lake. Preliminary results show the presence of PFAS in all environmental matrices selected, with levels up to 0.7 ng/L for PFBA in lake water and river, although no statistically significant differences were observed between lakes. Preliminary results for ∑PFCAs and ∑PFSAs in char show slightly higher concentrations in West Lake. Body condition factors (CF) were calculated to assess the health of Arctic char in both lakes from 2008-2015 and results show that CF in West Lake char have declined significantly at a rate of 4.5% per year, while increasing 3.3% per year in char from East Lake. Condition factors between 0.7-1 are typical in char of other Arctic Lakes, while < 0.6 for char of West Lake, implies a low food supply and could explain the slightly higher concentration of PFAS detected in Arctic char from West Lake. In the same way, $\delta^{13}C$ in char muscle was consistently more depleted in East Lake than West Lake suggesting that carbon in West Lake arctic char is more of terrestrial origin. Our preliminary results suggest greater inputs of PFASs in West Lake which may be due to mobilization of previous atmospherically deposited PFCAs and PFSAs during the accelerated permafrost disturbances in the West Lake catchment.

TP054 PCBs in the Arctic atmosphere: Determining important driving forces using a global atmospheric transport model

C. Friedman, Maine Maritime Academy / Ocean Studies; N.E. Selin, MIT

We present a spatially and temporally resolved global atmospheric polychlorinated biphenyl (PCB) model, driven by meteorological data. The model is skilled at simulating mean atmospheric PCB concentrations and seasonal cycles in the Northern Hemisphere midlatitudes and mean Arctic concentrations. The model does not, however, capture the observed Arctic summer maximum in atmospheric PCBs. Using sensitivity simulations to assess processes within, outside, or transport to the Arctic, we examine the relative influence of climate- and emissions-driven processes on Arctic concentrations and their effect on improving the simulated Arctic seasonal cycle. We find evidence that processes occurring outside the Arctic have a greater influence on Arctic atmospheric PCB levels than processes that occur within the Arctic. Our simulations suggest that re-emissions from sea ice melting or from the Arctic Ocean during summer would have to be unrealistically high in order to capture observed temporal trends of PCBs in the Arctic atmosphere. We conclude that mid-latitude processes are likely to have a greater effect on the Arctic under global change scenarios than re-emissions within the Arctic.

TP055 Community based seawater monitoring for organic contaminants and mercury in the Canadian Arctic

J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A. De Silva, D.C. Muir, Environment and Climate Change Canada; R. Lohmann, Univ of Rhode Island / Graduate School of Oceanography; I. Lehnherr, Univ of Toronto; C. Spencer, Dept of Environment and Climate Change; A. Gleason, Environment and Climate Change Canada; X. Wang, Environment and Climate Change Canada / Aquatic Contaminants Research Division; P. Amarualik Sr, Resolute, Nunavut

In Arctic marine ecosystems numerous emerging and legacy organic contaminants and methylmercury (MeHg) are bioaccumulated from seawater to lower food web organisms and may reach elevated levels in top predators, such as seals and polar bears, as well as humans consuming them as part of a traditional diet. To date, most contaminant measurements in Arctic seawater have been ship-based and are therefore limited to open water conditions and have therefore not examined seasonal variability, including effects of ice cover and snow/ice melt. We have established a community based seawater monitoring program to examine contaminants with varying physical/chemical properties including perfluorinated alkyl substances (PFASs), brominated flame retardants (BFRs) current use pesticides (CUPs), organophosporus triesters (OPEs), and MeHg. Sampling is being carried out in May under ice and in August in open water conditions in Barrow Strait/Lancaster Sound near Resolute, Nunavut where there are modern laboratory facilities. Collections are being carried out using “active” methods (Niskin samplers at 5 depths of the ~100 m water column and large volume sampling through a XAD resin column/ filter) and “passive” methods (polyethylene membranes (PEs) deployed for ~5 weeks). All analyses were carried out in clean laboratories at the Canada Centre for inland Waters in Burlington, ON and Lohmann lab at University of Rhode Island. Analyses of PFASs show that PFOS concentrations have declined steadily since 2008 and are now non-detect (< 1 pg/L). However, PFOA concentrations are higher in 2011-2015 than in 2005-2010 and are associated with partial ice cover and meltwater inputs. OPEs analyses showed lower levels of 9 OPEs (< 0.01-1.5 ng/L) compared to ship-based sampling in the Arctic (14-36 ng/L) (Jantunen 2014). Seawater MeHg concentrations were comparable to those reported for 2004-05 (range ~20-100 pg/L) and were higher in surface waters in May than in August, likely due to losses in the open water season via photodegradation. Results for BFRs and CUPs will also be presented, including comparison of polybrominated diphenyl ethers (PBDEs; a class of flame retardant) using “passive” and “active” methods. Overall, results to date highlight the need to include examination of temporal trends that consider seasonal variability in sampling designs and monitoring programs.

TP056 Investigation of Mercury Toxicity in Landlocked Arctic char in High Arctic Lakes

B.D. Barst, McGill Univ / Dept of Natural Resource Sciences; P.E. Drevnick, Univ of Michigan School of Natural Resources Environment / Biological Station; M. Rosabal, Université de Québec à Montreal / Departement des sciences biologiques; P. Campbell, Université du Québec, INRS / INRS Eau Terre Environnement; J. Hadrava, McGill Univ / Dept of Natural Resource Sciences; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; G. Köck, Inst for Interdisciplinary Mountain Studies; N. Basu, McGill Univ / Dept of Environmental Health Sciences

In the Canadian Arctic, mercury (Hg) concentrations in the tissues of non-anadromous (“landlocked”) Arctic char are elevated with ~30% of the sampled populations exceeding toxicity thresholds. In 2011, 2012, and 2015 we collected tissues (liver, muscle, brain) from Arctic char (n=167) from four lakes (Small, North, 9-Mile, and Amituk) on Cornwallis Island, Nunavut. The lakes sampled span a gradient of Hg contamination, allowing for the comparison of biological endpoints in char with low Hg concentrations to char with high Hg concentrations. The objectives of this research were to (1) measure total Hg and Hg speciation in Arctic char livers, brains and subcellular components, (2) determine correlations between Hg concentrations and biomarkers of oxidative stress in livers and brains, and (3) assess potential histological changes in livers and brains in relation to Hg exposure. Results thus far show a wide range in total Hg concentrations in Arctic char among lakes (0.05 to 2.5 parts-per-million wet weight in muscle), with about 31 % of individuals exceeding a toxicity threshold of 0.5 parts-per-million wet weight. Methylmercury was the predominate form of total Hg in liver (~80 %), where concentrations were two to three times higher than in muscle (to a maximum concentration of 6.5 parts-per-million wet weight). Total Hg was predominately found in the sensitive subcellular pools (mitochondria, microsomes and lysosomes, and heat-denatured proteins, including enzymes) of low- and high-Hg char, suggesting that increasing Hg exposure does not result in an activation of detoxification mechanisms in the liver. As a result, a significant fraction of Hg may exit the liver and reach the brain, as concentrations in the two organs were similar. To determine if Hg concentrations affect Arctic char, we measured several biomarkers of oxidative stress. Results indicate a positive correlation between total Hg and levels of lipid peroxidation in the livers of Arctic char. This link may explain histological changes in the livers of fish from the most contaminated lake. This research goes beyond documenting Hg concentrations in fish and will provide critical knowledge concerning fish health status.

TP057 Selenium and mercury levels in sub-Arctic versus Arctic prey fish in eastern Canadian Arctic marine ecosystems

S. Pedro, Univ of Connecticut / Natural Resources and the Environment; A.T. Fisk, Univ of Windsor / Great Lakes Inst for Environmental Research; S.H. Ferguson, Fisheries and Oceans Canada; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; N. Hussey, S. Kessel, Univ of Windsor / Great Lakes Inst for Environmental Research; M.A. McKinney, Univ of Connecticut / Natural Resources and the Environment

Indirect effects of climate change in the Arctic include altered predator-prey relationships due to shifting habitat ranges of prey fish species. Studies on predator diets suggest that sub-Arctic prey species, such as capelin (Mallotus villosus) and sand lance (Ammodytes spp.), are replacing Arctic cod (Boreogadus saida) as the main prey item, far mostly within the low to mid-Arctic regions. These invaders may have different contaminant levels than similar trophic position residents due to seasonal migrations from the sub-Arctic into Arctic marine systems. Within Arctic marine food webs, mercury (Hg) levels have been increasing in some biota in recent decades. Current levels may put some top predators at risk of adverse biological effects. We previously found from samples collected in 2012-2014 that sub-Arctic invaders actually tended to have lower Hg levels than Arctic resident prey fish. Nonetheless, as selenium (Se) may offer protective effects against Hg toxicity, it has been suggested that Se levels and Se:Hg molar ratios should be considered in evaluating the risks from Hg exposures. We determined the Se levels in muscle tissues of various species of Arctic and sub-Arctic prey fish and the possible contribution of Se as a protective nutrient by calculating the Se-to-Hg molar ratios. We collected Arctic fish and invertebrates (sculpin (Scorpaeniformes), northern shrimp (Pandalus borealis), amphipods (Amphipoda) and Arctic cod) and sub-Arctic fish species (sand lance and capelin) from three differentially-invaded regions in the eastern Canadian Arctic. There were no significant differences in Se levels and Se:Hg molar ratios within species from different regions. All species had similar Se levels, except for sand lance with twice as much Se (1.1 ± 0.2 µg/g) compared to other species ($p < 0.001$). Se levels are generally regulated in body tissues, and thus the differences may be more likely related to species-specific regulation on internal Se levels relative to variation in environmental exposures to Se. There were significant differences in Se/Hg molar ratios among species ($p< 0.001$), except between capelin-sand lance and sculpin-northern shrimp. The highest ratios were found in sand lance (122 ± 15) and the lowest in northern shrimp (6.9 ± 0.4). Nonetheless, the Se/Hg molar ratios were above one for every fish, suggesting protective levels of Se against Hg toxicity for consumption of both Arctic and sub-Arctic forage fish by piscivorous predators.

TP059 Assessment of coliform and faecal coliform bacteria in lake water samples collected from Larsemann Hills area over East Antarctica

A. Chauhan, A. Ranjan, T. Jindal, Amity Univ / Amity Inst of Environmental Toxicology Safety and Management AIETSM

Antarctica is the largest pristine wilderness in the world. Nevertheless, Antarctic waters are being polluted due to anthroprogenic activities caused by various research activities. In Antarctica, coliforms are generated by two sources: local vertebrate populations and human activities. The Larsemann Hills is an ice-free area of approximately 50 km2, located halfway between the Vestfold Hills and the Amery Ice Shelf on the south-eastern coast of Prydz Bay, Princess Elizabeth Land, East Antarctica (69º30′S, 76º19′58″E). The ice-free area consists of two major peninsulas (Stornes and Brooknes), four minor peninsulas, and approximately 130 islands. The Larsemann Hills area contains more than 150 lakes at different Islands and Peninsulas. There are four stations in the area including Bharati Indian Research Station which is located between Thala Fjord & Quilty bay, east of Stornes Peninsula in Antarctica at 69° 24.41' S, 76° 11.72' E approximately at 35 m above sea level.Coliform bacteria are not pathogens themselves, but their presence indicates the possibility of finding pathogens. In contrast, fecal coliform bacteria such as Escherichia coli are found in feces, and their presence in drinking water indicates fecal contamination. E. coli can also be a pathogen itself, so if E. coli is found in water there is a good chance that other pathogens are present. In the present study, eleven lake water samples were analyzed to study coliform and fecal coliform bacteria. Out of six lake water samples collected during 34th Indian Scientific Expedition to Antarctica (ISEA) four samples were found to be contaminated with coliform bacteria, however, Faecal coliform were absent when tested with selective media. MPN coliform were found to be present in two samples (Brookness peninsula (69°22'49.5"S, 76°17'21.2"E) and Mcloed Island (69°22'04.69"S, 76°09' 00.79"E) out of five samples collected during 35th ISEA. Faceal coliform were absent in all samples. Presence of MPN coliform indicates that the degree of pollution and sanitary quality of lake water. Coliform contaminations are found in the lakes which are in the vicinity of those areas which are regularly accessible (L-3, L-1D, L-7A, Murk water). and However, there are other factors which may lead to coliform contamination such as migration of microbes through birds and transport of food items from ship to research station.

Arctic Spill Science – Fate, Effects and Response

TP060 Quantifying the effect of biodegradation on oil toxicity using the PETROTOX model

J.E. Naile, Shell Oil Company / Ecosystems Research Division; D.M. Saunders, Univ of Saskatchewan / Toxicology; G. Whale, Shell Health / Shell Health; V. Broje, Shell Projects and Technology / Spill Response Specialist Environmental Scientis; M.G. Smit, Shell Global Solutions Int.

Although rare, the accidental release of crude oil during processes such as extraction or transport does sometimes occur, and to effectively and properly respond to these incidents, one must understand the oil's fate and effects in the environment. Knowing the rate and extent of biodegradation of spilled oil is critical to fully understand its fate and potential effects in the environment. Many degradation studies simply use the non-descript measurement of total petroleum hydrocarbons (TPH) to model degradation, which can be useful in understanding what is happening overall, but can misrepresent the toxicological consequences of this degradation. Individual hydrocarbon components which make up petroleum substances have specific and different physiochemical properties which cause them to behave differently in the environment, both in terms of toxicity and degradation. The spreadsheet PETROTOX model developed by Concawe calculates the toxicity of complex petroleum products to aquatic organisms using the substance's detailed chemical composition. This three-phase model simulates the distribution of each structure in the water, air, or oil-phase, then calculates toxicity based on the predicted aqueous concentrations, using the target lipid model, assuming additivity. To simulate expected water concentrations following effective dispersion, relatively small amounts (15ppm) of oil were mixed with water in closed respirometer flasks. To allow for thorough toxicological comparisons of the oil at various stages of weathering, detailed chemical analysis (GC-FID) was performed at four time points (0, 5, 10, 28 days) over the course of 28 days. The present study evaluates differences in toxicity and degradation of crude oil as it weathers over time.

TP062 Effects of oil spill responses on key Arctic zooplankton species

K.U. Toxværd, Cowi A/S / Water and Nature; P. Hansen, M. Pančic, E. Koehler, Technical Univ of Denmark; J. Søreide, M. Hatlebakk, The Univ Centre in Svalbard; H. Eide, UiT The Arctic Univ of Norway; C. Lacroix, S. LeFloch, CEDRE; T. Nielsen, DTU Aqua / Technical Univ of Denmark; M. Hjorth, Cowi AS

Increased shipping and oil and gas activities in the Arctic increase the risk of an oil spill. Oil compounds can have toxic impact on Arctic marine ecosystems, but impacts from response technologies on ice associated ecology have not been studied extensively. The copepod Calanus glacialis is a key species in the Arctic marine ecosystem. It plays a central role in energy transfer between primary producers and higher trophic levels of the Arctic food chain. It is therefore relevant to study potential consequences of an oil spill on this ecological important species. As a part of a large joint industry initiative (www.arcticresponsetechnology.org) a first of its kind mesocosm experiment was executed in an Arctic fjord of the Island of Svalbard. Effects of natural attenuation of the oil, in-situ burning and chemical dispersion were studied on grazing, egg production and hatching of the Arctic copepod Calanus glacialis. Eight mesocosms with open top and bottom were deployed in the sea ice in Van Mijenfjorden, Svalbard, in February 2015. Two replicates were used for all treatments. After application, surface ice was allowed to re-establish. Water was collected from the top 2 cm water column in March and just before sea ice break up in May, and was used in two 14-day incubation experiments with C. glacialis collected in Isfjorden. Copepods were fed during the experiment and eggs and pellets were quantified daily. Egg hatching was determined in the beginning and end of the experiment. There was no significant effect of the oil spill treatments on average cumulated specific pellet production or egg hatching success. However in May, the average cumulated specific egg production was significantly higher in the oil-dispersant mixture treatment compared to the control from day 2 (+ 169 %) until the end of the experiment (+ 41 %). To correlate observed effects and toxicity, and to examine potential pollutant transfer, the chemical content of incubation water, exposed females and produced eggs was further analysed for chemical residue. These results will be presented on the SETAC 2016 conference.

TP063 Long-term resilience in polar cod exposed to dispersed oil and burned oil residue

M. Frantzen, Akvaplan-niva AS; J. Nahrgang, Univ of Tromsø / Arctic and Marine Biology; S. LeFloch, CEDRE; L.A. Camus, Akvaplan-niva

Scientifically sound information on the efficiency of oil spill response (OSR) actions to reduce environmental impacts is essential for net environmental benefit analysis. The use of chemical dispersants as an OSR is debated, as dispersants are known to significantly increase the oil concentration in the water column for a restricted time. In situ burning of spilled oil may be an alternative OSR to dispersant. However, after successful in situ burning of spilled oil, approximately 10% of the oil slick will remain in the environment as burned oil residue. The main aim of the present study was to assess potential long-term effects on polar cod (Boreogadus saida), an Arctic key species, after an acute exposure to dispersed crude oil or in situ burned oil residue. Wild caught polar cod (N=240) were individually tagged prior to being exposed for 48 hours to clean seawater (control), an environmentally realistic concentration of either mechanically dispersed oil, chemically dispersed oil or burned oil residue (N=60 per treatment). At the end of the exposure period all fish were transferred to a common rearing tank in order to study potential long-term effects on survival, growth (specific growth rate, condition factor) and reproductive investment (gonadosomatic index, gonadal histology) throughout a six months resilience period. The preliminary results show that the total hydrocarbon concentration in the water of the MDO and CDO treatment was 10-20 ppm. Dispersed oil induced a transient short-term reduction in SGR in the first week post-exposure. Over the course of the first 4-month post-exposure, the SGR In the MDO And CDO was compensated and no significant differences between exposure treatments and controls were observed at the following time points. Furthermore, no treatment-dependent mortality has been identified. Histological analyses for reproduction impairment analyses are ongoing. Ultimately, the produced data will be used in the development of the Net Environmental Benefit Analysis (NEBA) tool and in population effect modeling.

TP064 Matrix models for Arctic Calanus species: using experimental toxicity data for oil components to assess population level effects

R. Jak, P. de Vries, J. Tamis, IMARES Wageningen UR; M. Hjorth, Cowi AS; S. Falk-Petersen, Akvaplan-niva; L. Hemerik, Biometris Wageningen UR

When assessing population level effects of oil spills, data are required on both the life history parameters of species and toxicity end-points. We constructed age-structured matrix models for Arctic copepods to predict the impact of potential oil spills at the population level. Two matrix models were defined, representing the Arctic shelf species Calanus glacialis, spawning in waters all around the Arctic shelf and C. hyperboreus, the Arctic oceanic species connected to deep-sea, with a 2x2 and a 4x4 matrix model, respectively, which refer to a 2-year and a 4-year life-cycle. The post-breeding models included egg production and mortality rates as life-history parameters. Relevant Arctic conditions were taken into account by defining a winter diapause period, where no mortality is assumed to take place. Toxicity information on exposure to oil and oil-components was collected for Calanus species. It appeared that the life-history parameter with the highest elasticity in the model was the adult survival, meaning that changes therein have most impact on the output, i.e. population size. This is because the adult class produces offspring. Published data on mortality rates in field and laboratory studies appeared too high to maintain viable populations. Therefore, we modified these parameter values such that modeled populations became viable. Adequate toxicity information on oil and oil components for Calanus species appeared to be scarce, and we therefore selected pyrene as a model compound. However, reported end points for pyrene were not directly applicable in the matrix model, and we developed new approaches to derive a dose-response relationship from the available data. Based on the generic matrix models, simulation models using day-to-day calculation steps were developed to test the effects of various oil spill scenarios at the population level, taking into account a range of exposure concentrations and exposure durations. The results show that the calculated population effects are very different, when based on different types of effect concentrations (NOEC, LOEC and LC_{50}). We argue that simple matrix models are very useful to assess the potential impacts of oil spills at the ecological relevant population level, but that scarcity of information limits an accurate quantitative assessment. A more realistic estimate of natural survival rates and the toxic effects thereupon will allow for a better assessment of population level consequences of an oil spill.

TP065 Produced water exposure causes cardiac toxicity in early life stages of cold-water fish

B. Hansen, D.F. Krause, SINTEF Materials and Chemistry / Environmental Technology; D. Altin, BioTrix; K.C. Hellstrøm, SINTEF Materials and Chemistry / Environmental Technology; R. Nepstad, SINTEF Materials and Chemistry / Monitoring and Modelling; M.U. Rønsberg, T. Nordtug, T. Størseth, SINTEF Materials and Chemistry / Environmental Technology

Emissions of produced water (PW) to the marine environment in the North Atlantic and Barents Sea are regulated with the overall aim of producing no harmful environmental effects. PW contains variable amounts of polycyclic aromatic hydrocarbons (PAHs), which have the potential to cause severe developmental alterations during the embryonic stage in fish. In the present study, we exposed Atlantic cod (Gadus morhua) and haddock (Melanogrammus aeglefinus) to PW during embryonic development. These species are widely distributed in the North Atlantic, as far north as the western coast of Svalbard. We exposed embryos of both species to three concentrations of produced water for 4 days during organogenesis in an attempt to survey the possibility of PW to cause cardiac toxicity and associated developmental effects on larvae. Thereafter we transferred them to clean seawater where they developed until hatching. No significant effects were observed for survival and hatching success compared to controls. Concentration-dependent bradycardia (reduced heart rate) was observed during both embryonic and larvae stages for both species. Craniofacial and spinal deformations as well as yolk sac oedemas were observed in larvae treated with high PW concentrations during embryogenesis. There is a need to identify the PW components that are causing the observed effects, and if concentrations of these components can exceed the effect threshold in actual PW discharges.

TP066 Effects of produced water components on growth, development and reproduction in Arctic pelagic copepods

I. Salaberria, NTNU Univ / Biology; I.B. Øverjordet, SINTEF Materials and Chemistry / Applied Environmental Biology and Chemistry; B. Hansen, SINTEF Materials and Chemistry / Environmental Technology; T. Nielsen, DTU Aqua / Technical Univ of Denmark; D. Altin, BioTrix; T. Nordtug, SINTEF Materials and Chemistry / Environmental Technology; A.J. Olsen, NTNU / Dept of Biology

Increasing ice cap melting is opening up new areas in the Arcticto human activities such as oil exploration. Oil drilling involves the release of large quantities of hydrocarbons into the marine environment, notably as produced water and oil droplets. The PWC-Arctic project endeavors to assess the potential environmental impact of oil exploration in the High North by quantifying the uptake and excretion kinetics of produced water components and oil droplets and their effects on growth, development and reproduction of the Arctic copepods Calanus glacialis and C. hyperboreus. These calanoids are key zooplankton species with high lipid content which makes them prone to uptake of lipophilic oil components. Particular focus is on bioaccumulation kinetics, oil component transfer, effects on metabolism, growth, fertility and fecundity of various development stages. Experimental findings include slower excretion of heavier polyaromatic hydrocarbons (PAHs) from copepodid C5 C. glacialis than predicted by a single compartment model while physiological effects of exposure appear to be transitory. The parameterized data collected in this project will provide direct input to numerical models aimed at predicting the impact of produced water on the marine environment in the Arctic.

TP067 Uptake and elimination kinetics for polycyclic aromatic hydrocarbons in Arctic lipid rich copepods

I.B. Øverjordet, SINTEF Materials and Chemistry / Applied Environmental Biology and Chemistry; R. Nepstad, SINTEF Materials and Chemistry / Monitoring and Modelling; I. Salaberria, NTNU Univ / Biology; B. Hansen, T. Nordtug, SINTEF Materials and Chemistry / Environmental Technology; D. Altin, BioTrix; K. Sandoval, P.R. Gardinali, Florida International Univ / Chemistry Biochemistry and SERC; A.J. Olsen, NTNU / Dept of Biology

Oil exploration and production has recently moved further north towards the Arctic, increasing the potential for exposure of Arctic organisms to polycyclic aromatic hydrocarbons (PAHs) during regular production as constituents of produced water (PW) and from accidental oil spills. Hence, understanding the toxicokinetics of PAHs in Arctic species is increasingly important for environmental risk assessments of regular discharges and damage assessment following accidental spills. The calanoid copepods Calanus finmarchicus, C. glacialis and C. hyperboreus are the dominating zooplankton species in the North Atlantic Ocean and the Barents Sea. They store excess energy by accumulating large volumes of lipids during their late development stages before molting into adults. Previous studies have shown that exposure to lipophilic water pollutants such as PAHs results in an accumulation of these components in Calanus species. Traditionally the uptake and depuration kinetics are modelled using one-compartment toxicokinetics. However, previous experimental data on C. finmarchicus strongly indicate that elimination of PAHs is much slower than expected based on calculations by state-of-the-art one-compartment toxicokinetic models such as OMEGA. In the present study, the lipid rich developmental stage copepodite V (CV) of the Arctic Calanus was exposed to a filtered dispersion of alkane oil spiked with 11 PAHs for 120 h at 1 °C. The log Kow of the PAHs ranged between 3.3 for naphthalene and 5.78 for chrysene. A 120 h depuration period in clean seawater followed the exposure period, and samples for body burden analyses were taken at regular intervals during both the exposure and the depuration periods. Models developed to fit to the uptake data were used to predict depuration kinetics for individual compounds. Several of the PAHs, especially the heavier fluoranthene, pyrene and chrysene, showed approximately 100 % retention after the 120 h depuration period, substantial deviations from the predictions by the one-compartment models. The slow depuration of PAHs in lipid rich Arctic copepods demonstrated in this experiment indicates that stored PW components may be more available for transfer to progeny, as well as having a higher potential for transfer to higher trophic levels than previously anticipated.

Use of Freshwater Mollusk Toxicity Data for Improved Conservation of Water and Sediment Quality

TP068 Investigating the impacts of water quality on freshwater mussels

S. Choy, USFWS / Ecological Services; E.N. Buttermore, Dept of Biology; J. Moore, US Fish and Wildlife Service / Interior

Freshwater mussels (family: Unionidae) are amongst the most endangered organisms in North America, with over 70% of native unionid species listed as endangered, threatened, or as a species of special concern. Pollution is cited as one of the major factors in the decline of unionids. Recent laboratory toxicity tests indicate that freshwater mussels, particularly in the juvenile life-stage, are amongst the most sensitive aquatic organisms to ammonia. In addition, studies have also shown that concentrations of ammonia can be elevated in pore water (i.e. the interstitial water between particles of sediment) relative to overlying surface water. With juvenile mussels constantly being exposed to pore water via direct contact and pedal feeding, resource managers may be missing a key piece of information by focusing only on concentrations of contaminants in surface water. In 2013 and 2014, U.S. Fish and Wildlife Service biologists collected pore water and overlying surface water at sites in Michigan, Wisconsin and Minnesota to examine any potential correlations between surface water quality and pore water quality, and water quality and mussel abundance. The overarching objectives of the project were to aid decision-making and provide resource managers with additional data and tools (e.g., by enhancing a Mussel Threats Geospatial Database) with respect to mussel reintroduction and restoration efforts. We will present a summary of our methods, results, conclusions and any relevant recommendations that may contribute to future management and conservation of freshwater mussels.

TP069 Acute and chronic toxicity of aluminum to a unionid mussel (fatmucket, Lampsilis siliquoidea) and an amphipod (Hyalella azteca)

C.D. Ivey, USGS – CERC / Aquatic Toxicology; E.L. Brunson, Columbia Environmental Research Center USGS / Aquatic Toxicology; D. Cleveland, Columbia Environmental Research Center USGS / Analytical Chemistry; N. Wang, USGS / Columbia Environmental Research Center; D.M. Eignor, USEPA / Office of Water

The U.S. Environmental Protection Agency (USEPA) is updating the ambient water quality criteria (WQC) for aluminum (Al). Recent studies have indicated that freshwater mussels are sensitive to some metals (e.g., copper and nickel), ammonia, and major ions (e.g., chloride, potassium, and sulfate). However, little is known about the sensitivity of mussels to Al. Previous studies have demonstrated that Al toxicity to aquatic organisms is influenced by hardness and pH. A pH of 6 favors the presence of all Al hydroxide species and maximizes their solubility, presenting a worst-case condition. The objective of this study was to evaluate acute and chronic toxicity of total Al to a unionid mussel (fatmucket, Lampsilis siliquoidea) and a commonly tested benthic invertebrate (amphipod, Hyalella azteca) at pH 6 in diluted well water (hardness 100 mg/L as $CaCO_3$). The amphipod was one of the most sensitive species in the USEPA chronic Al dataset. The acute (4-day) and chronic (28-day) exposures with mussels and amphipods were conducted in a proportional flow-through diluter with a pH controller to maintain a constant pH of 6.0. Both species survived >95% in all treatments over the acute exposures. Acute EC50 of >6200 µg total Al/L for the mussel and amphipod was greater than the EC50s for other species in the USEPA dataset. Control survival was 100% for mussels and 95% for amphipods at the end of chronic exposures. Chronic EC20s based on dry weight was 163 µg total Al/L for the mussel and 409 µg total Al/L for the amphipod. For both species, the EC20s for biomass were slightly (< 4 to 6%) higher than the EC20s for dry weight. Results indicate that the mussel was more sensitive than the amphipod in the chronic Al exposures. When including the mussel data in the USEPA chronic Al dataset, the mussel would be the fourth most sensitive species with the amphipod being the fifth most sensitive species.

TP070 Acute and chronic toxicity of nickel or zinc to a mussel (Lampsilis siliquoidea) and an amphipod (Hyalella azteca) in water-only exposures

J.L. Kunz, USGS / Columbia Environmental Reserach Center; N. Wang, USGS / Columbia Environmental Research Center; D. Cleveland, USGS / Columbia Environmental Research Center; C. Bauer, USEPA / Region V; E. Hammer, USEPA

The USEPA is reviewing the protectiveness of its national ambient water quality criteria (WQC) for nickel and zinc. Previous studies have indicated that freshwater mussels and the amphipod Hyalella azteca are sensitive to nickel and zinc in acute or chronic exposures. However, survival, growth, or reproduction of the tested organisms may not have been optimal in these previous studies. The methods for conducting chronic toxicity tests with mussels and H. azteca have been recently refined, resulting in improved control growth for the mussels and amphipods, improved reproduction for amphipods, and the ability to conduct longer-term (12-week) tests with mussels. The objectives of this study were to evaluate acute and chronic toxicity of nickel or zinc to the mussel Lampsilis siliquoidea and amphipod H. azteca in water-only exposures, and to evaluate the influence of test duration on the toxicity of nickel and zinc to mussels in chronic exposures. Results from both acute and chronic tests reinforced the sensitivity of L. siliquoidea and H azteca to nickel and zinc. In particular, the acute 50% effect concentration [EC50] of L. siliquoidea exposed to nickel was less than half of the final acute value of 940 µg/L in the current WQC at a hardness of 100 mg/L. Similarly, the chronic EC20s for H azteca were >4-fold lower than the chronic WQC of 52 µg/L for nickel and >2-fold lower than chronic WQC of 120 µg/L for zinc. Chronic EC20 for L. siliquoidea was >3-fold lower than the chronic WQC for zinc. Refined chronic test conditions did not appear to change the 42-day sensitivity of H. azteca to either zinc or nickel, relative to previous studies. Increasing the duration of exposures from 4 to 12 weeks with L. siliquoidea did not change EC20s for nickel but decreased the EC20s for zinc by about 50%. The results indicated that refined chronic test conditions did not substantially change the sensitivity of L. siliquoidea or H. azteca to nickel or zinc; however, including the toxicity data from this study in a revision to the WQC would likely lower the WQC for nickel and zinc.

TP071 Maternal metal transfer in the introduced apple snail Pomacea sp. and consequences for their use in pollution biomonitoring

S. Banerjee, Univ OF LOUISIANA AT LAFAYETTE / Biology; P.L. Klerks, Univ OF LOUISIANA AT LAFAYETTE / Dept of Biology

Two species of the apple snail, Pomacea maculata and P. canaliculata, have recently been introduced in Louisiana marshes. The spread of these invasive species is bound to have a variety of ecological consequences. However, their presence can have a beneficial consequence as well if Pomacea snails can serve as biomonitors for metals such as Pb, Cd and Cu in their environment. One issue that may influence their usefulness in biomonitoring is the maternal transfer of metals. Such transfer would facilitate biomonitoring; it is generally much easier to find the snails' eggs than the snails themselves, as the brightly colored egg clutches are laid above the water level. Insight into the maternal metal transfer will also assist with assessing the ecotoxicological consequences of metal pollution in freshwater environments. The maternal transfer could have effects on the developing young, as has been observed in least killifish studies in our lab. Moreover, maternal transfer of metals can serve as a means of metal elimination, as was seen in previous studies with the crustacean Daphnia magna. To our best knowledge, the occurrence and consequences of metal transfer in apple snails have not been studied. We are currently conducting laboratory experiments to determine effects of long-term, chronic exposure on the reproductive success of Pomacea exposed to metal concentrations. Subsequent work will then address the metal transfer and the consequences on reproductive endpoints such as clutch size, hatching time and hatching success. Exposures of adult Pomacea snails to Pb, Cd or Cu are being conducted with snails collected from the drainage ditches of Patterson, LA. These exposed snails are then transferred to clean water and allowed to lay eggs. One subset of each egg clutch will be analyzed for metal levels while the remainder is allowed to hatch while being monitored for toxicity effects.

TP072 Metal accumulation and biomarkers in a Neotropical freshwater clam for monitoring water bodies at coal mining areas: a case study in Southern Brazil

L.F. Oliveira, M.T. Cabral, Univ Estadual de Londrina / Ciencias Fisiologicas; C.D. Vieira, W.E. Risso, Univ Estadual de Londrina / Departamento de Ciências Fisiológicas; C.B. Martinez, Univ Estadual de Londrina / Ciencias Fisiologicas

Coal mining is one of the highest potentially impactful industry activities and can cause several alterations in the environment, representing an example of a source of metal mixtures in the environment. In this context, the present study focused on the investigation of metal bioaccumulation and sub-lethal effects promoted in the Neotropical bivalve Anodontites trapesialis, after 96 h of confinement in a stream located near a coal mining, aiming to evaluate the efficiency of a set of end-points as tools for monitoring these areas. Bivalves were maintained in cages for 96 h at two sites located upstream (Up1 and Up2) and two sites downstream (Dw1 and Dw2) from the mining area. At each experimental site physical and chemical variables were measured in the water, and samples of water and sediment were collected for metal determination. Mantle, gills, digestive gland, muscle (foot) and hemolymph were collected for metal (Al, Fe, Mn and Zn) bioaccumulation analyses. The following biomarkers were measured in the gills, mantle and digestive gland of the bivalves: total antioxidant capacity, lipid peroxidation, protein carbonylation, glutathione S-transferase activity, metallothionein content and acetylcholinesterase activity. The results showed the influence of coal mining area on the stream water as alterations in some physical and chemical variables were observed at the two sites located downstream. The bioaccumulation of Fe and Al occurred in gills and hemolymph of animals caged at downstream sites. As expected, A. trapesialis caged at Dw sites showed more alterations in the biomarkers analyzed, however animals from Dw1 and Dw2 showed a different pattern in those alterations. In the gills, the occurrence of oxidative damage (lipid peroxidation and protein carbonylation) was observed only in animals caged at Dw2, in spite of the similar metal bioaccumulation in this tissue in animals caged at both Dw sites. In the mantle, lipid peroxidation was demonstrated only in A. trapesialis caged at Dw1, while MT content and TAC alterations were observed in bivalves from Dw2. In the digestive gland no alterations were observed in the biomarkers analyzed. Thus, the Al and Fe accumulation and oxidative damages in A. trapesialis tissues could be efficient tools for monitoring the environment quality of these particular mine.

Measuring and Estimating Bioavailability: Linking Exposures to Effects for Improved Ecological Risk Assessment

TP073 Measuring bioavailable mercury in process wastewater and ambient water: not all mercury is the same

R.J. Reash, American Electric Power

Regulating bioavailable forms of trace elements is being accepted by a growing number of water resource agencies. In the US, a significant event to promote regulating bioavailable forms of trace elements was the issuance of USEPA's dissolved metals policy (1993). For bioaccumulative trace elements (Hg, Se), the goal of minimizing bioacculation potential is to regulate the most bioavailable species. Despite extensive knowledge on the biogeochemistry and bioaccumulation potential of Hg, most resource agencies regulate total Hg in wastewater samples, with no consideration given to known bioavailable forms (MeHg and inorganic reactive Hg). This study provided preliminary results of Hg speciation in wastewater, ambient, and mixing zone samples. Effluent samples were collected from treated FGD (flue gas desulfurization) wastewater (at four coal-fired power plants) and ambient Ohio River samples. Samples were analyzed for total Hg, dissolved Hg, MeHg, and acid-soluble inorganic Hg. For wastewater samples, the proportion of total Hg as bioavailable Hg ranged from 27 to 100% (median = 32%). For ambient samples, levels of total Hg were low (all less than 3 ng/L), so estimates of bioavailable Hg had considerable uncertainty. Concentrations of total Hg and MeHg in fish tissue samples using fish collected near the four power plants were low (< 0.3 mg/kg wet wt.), thus the Hg discharged from power plant wastewaters had seemingly minimal bioaccumlation potential. The regulation of bioavailable forms of total Hg could prevent the imposition of costly source controls, and is supported by scientific understanding of Hg cycling and fate.

TP074 Quantitative AOP-based predictions for two aromatase inhibitors – evaluating the influence of bioaccumulation on prediction accuracy

S. Poole, G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; B.R. Blackwell, ORISE / National Health and Environmental Effects Research Laboratory; J.E. Cavallin, USEPA / USEPA Mid-Continent Ecology Division; W. Cheng, ORISE / USEPA Integrated Systems Toxicology Division; D. Feifarek, USEPA / National Health and Environmental Effects Research Laboratory; K.M. Jensen, M. Kahl, E.C. Randolph, USEPA / National Health and Environmental Effects Research Laboratory; R. Milsk, ORISE; T. Saari, USEPA / ORD, NHEERL; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory

The adverse outcome pathway (AOP) framework can be used to support the use of mechanistic toxicology data as a basis for risk assessment. For certain risk contexts this includes defining quantitative linkages between the molecular initiating event (MIE) and subsequent key events (KEs) within an AOP. One AOP for which strong, quantitative linkages have been established is aromatase inhibition leading to reproductive dysfunction in fish. A series of computational models have been linked to develop a quantitative AOP (Q-AOP). A measure of aromatase inhibition is used as the model input to estimate circulating plasma estradiol (E2) concentration and resultant circulating plasma vitellogenin (VTG) concentration. To evaluate model predictions, two aromatase inhibitors, letrozole and epoxiconazole, were selected based on their relative aromatase inhibition potency in USEPA ToxCast assays. Reproductively mature female fathead minnows (Pimephales promelas) were exposed to varying concentrations of either letrozole (0, 0.5, 7.5, 25, 75, 250 µg/L) or epoxiconazole (0, 8, 25, 80, 250, 800 µg/L) in 24h flow through exposures. One additional consideration for model predictions was bioaccumulation of exposure chemicals and resultant circulating plasma concentration. To identify this, plasma from exposed minnows was extracted by supported liquid extraction (SLE) and concentrations of letrozole or epoxiconazole determined by LC-MS/MS. Plasma bioaccumulation factors (BAF_{plasma}) varied across concentration ranges with lower exposure concentrations leading to greater bioaccumulation. Letrozole (logP = 2.22) BAF_{plasma} ranged 0.173-0.25, indicating rapid metabolism or excretion of the compound, while epoxiconazole (logP = 3.44) BAF_{plasma} ranged 34.4-66.9. Exposure tank concentrations and calculated plasma concentrations were used as model inputs. Model estimates using both inputs will be compared with experimental measurements to highlight potential refinement of Q-AOP predictions. The contents of this abstract neither constitute nor necessarily reflect USEPA policy.

TP075 Bioavailability prediction of estrogenic contaminants in marine sediments

D.M. Santos, São Paulo State Univ- Inst of Chemistry / Analytical Chemistry; M. Williams, CSIRO / Land and Water; M. Marchi, Unesp-Inst of Chemistry / Analytical Chemistry; R.S. Kookana, CSIRO / Land and Water

The frequent input of organic contaminants in marine environment through industrial and urban effluents can be responsible for a pseudo-equilibrium state between aqueous phase and sediments that can directly affect the bioavailability of these compounds in the system. In this work, we have invstigated chemical methods: "E"value and extraction agents as butanol and β-HPCD, to predict the bioavailability of triclosan (TCS), bisphenol A (BPA) and 17α ethynylestradiol (EE2) in marine sediments in a 60-day experiment followed by aqueous phase analysis by GC-MS/MS after solvent exchange and derivatization procedure. The bioavailability study based on "E" value model involves isotopic exchangeability of these compounds and shows lower percentages (< 20%) for all compounds individually and observed in different periods of interaction. For TCS this exchangeability occurs until 7 days of experiment. After this period, TCS shows be strongly complexed with the matrix. This was also evident when data for butanol and β-HPCD were accessed, with an extraction of 80% just on the first days of experiment. For BPA and EE2, the fraction considered exchangeable was lower (< 13%) and the extraction intensity was slightly higher for butanol treatment. According with these results the bioavailability order considering the tested sediment was: TCS>BPA>EE2 although TCS was bioaccessible just in the first days of interaction. In this way, obtained results can be important to help the comprehension of the complex behaviour pathways of these contaminants in marine environment, being an useful precursor test for bioassays and contributing for estimate the risk assessment in this system.

TP076 Building improved in vitro exposure assessment capability: Towards the development and implementation of enhanced QIVIVE tools

T. Gouin, Unilever / Safety and Environmental Assurance Centre; J.A. Arnot, ARC Arnot Research & Consulting / Adjunct Professor Dept of Physical Environmental ScienceDept of Pharmacology and Toxicology; M.R. Embry, ILSI Health & Environmental Sciences Inst

Recently the NRC published a series of reports outlining a strategy for conducting risk assessment in the 21st century, a key emphasis of which is working towards an improved mechanistic understanding of toxicity pathways. Due to the large numbers of chemicals used in commerce, however, substantive challenges exist associated with testing all endpoints and chemicals in an efficient and inexpensive. To address this challenge, recent activity aimed at assessing the effects of a large number of chemicals screened through a suite of in vitro assays, and commonly referred to as high throughput screening, has gained increasing interest. The underlying hypothesis is that toxicological response is driven by interactions between chemicals and biomolecular targets. The goal of high throughput screening is, thus, to focus on a multiple target matrix approach, rather than a single target. The matrix contains an expanded number of potential targets, whose chemical interactions may be characterized by in silico models, biochemical assays, cell-based in vitro assays, and nonmammalian animal models. Data derived from high throughput in vitro screening can thus provide guidance in assessing potential toxicological hazards relevant to both HRA and ERA. Combining high throughput in vitro data with mechanistic insight regarding exposure dose in vivo, however, is proving to represent a substantive challenge. Nonetheless, it has long been understood that chemical toxicity arises from an interaction between a chemical and a site of action that leads to perturbation of a biological function. This is best assessed based on a dose-response relationship, where the dose/concentration delivered to the organism via respiration, diet, intravenous, or dermal, is used as a surrogate for the concentration at the site of toxicological action. Consequently, it is important to emphasize that it is ‘the dose that makes the poison”. In this presentation a number of key challenges associated with ensuring accurate translation of data between in vitro and in vivo systems are highlighted.

Systems Modeling Approaches for Ecotoxicology to Link Molecular Responses to Ecosystem Effects

TP077 Development of a Mathematical Model for Fecundity in Mummichog (Fundulus heteroclitus)

R. Downing, Arizona State Univ West Campus; B. Clark, D.E. Nacci, D. Champlin, USEPA / Atlantic Ecology Division; T. Bosker, Univ of Leiden; K.H. Watanabe, Arizona State Univ West Campus / School of Mathematical and Natural Sciences; J. Nishimura, Arizona State Univ West Campus

Ranging from the Atlantic coast of Florida to the Maritime Provinces of Canada, the mummichog or Atlantic killifish (Fundulus heteroclitus) is an important model organism for understanding the effects of pollutants in estuarine and marine ecosystems. In particular, the toxicological effects of stressors on fecundity are central to understanding ecological impacts. We developed a mathematical model to predict mummichog fecundity based on a model developed for fathead minnows (Pimephales promelas). In the fathead minnow model, the concentration of a fish egg yolk precursor protein, vitellogenin (VTG) is a key driver and important predictor of oocyte growth and spawning events. However unlike fathead minnows, mummichogs exhibit non-overlapping cycles of oogenesis, which is associated classically with the lunar cycle. We adapted the fathead minnow model to mummichogby fitting empirical spawning data (clutch sizes and spawning intervals) from mummichog in paired mating experiments and from the literature. We then evaluated the model by predicting independent data that included group spawning design experiments. Preliminary results suggest that the modeling assumptions used for fathead minnows may need to be revisited to improve the mummichog fecundity model. Factors that may be important include: female size, variation of the proportion of non-spawning mature females through the reproductive season, and the strength of lunar periodicity displayed by populations within the species range, where Northern-most populations exhibit low periodicity. We are also evaluating the effects of social interactions (group size) on spawning success. By considering how models can accommodate variation in fish species reproductive strategies, we can more easily develop other fish species-specific fecundity models to predict the ecological impacts of stressors.

Challenges in Testing and Monitoring of Micro- and Nano-Plastic Effects and Environmental Distribution

TP078 Development of analytical procedure for microplastic analysis in biological tissues: application to Mytilus edulis from the Atlantic coast

N. Phuong, Univ of Nantes; A. Zalouk-Vergnoux, L. Poirier, A. Kamari, Univeristé de Nantes / MMS; J. Rouxel, R. Sussarellu, IFREMER; F. Akcha, IFREMER / Laboratory of Ecotoxicology; A. Chatel, Université Catholique de lOuest / Sciences Environnement; C. Mouneyrac, Université Catholique de lOuest / UNAM Université Nantes Angers Le Mans Mer Molécules Santé MMS; F. Lagarde, Inst of molecules and materials of Le Mans / Inst of Materials and Molecules of Le Mans IMMM UMR CNRS

Since the middle of the last century, several million tons of plastics have been produced. Whilst the societal benefits of plastic are far-reaching, this valuable commodity is the subject of increasing environmental concern as 10% of produced plastics is estimated to end up in the ocean. Once in the environment, macro debris undergo mechanical, chemical and biological actions. All these degradation processes lead to their fragmentation into microplastics (MPs) which accumulate in the environment. Many different procedures were used for MP quantification and characterization in environmental and biological samples. However, no simple protocol allowing the routine monitoring of MPs is nowadays available. The aim of this study was to develop a preparation procedure to finally apply it for the monitoring of MP in mussels (Mytilus edulis) from the Atlantic coast (Pays de la Loire, France). The digestion, filtration and analysis steps were optimized comparing different solvents (HNO_3 (65%), H_2O_2 (30%), NaOH (30%), HNO_3/HCl (37%) (3:1, v/v), HNO_3/H_2O_2 (3:1, v/v), HNO_3/$HClO_4$ (70%) (4:1, v/v)), filters (cellulose nitrate (5 µm and 12 µm), polycarbonate (0.2 µm), aluminum oxide filter (2 µm), fiberglass and cellulose acetate (1.2 µm)) and analysis modes (reflection, transmission) using µFTIR. Finally, a simple protocol minimizing the time-consuming operations and the sources of errors was validated with spiked samples and presented 70 to 100% of recovery depending of the MP nature (polyethylene, polypropylene, polyvinyl chloride). In a second part, this protocol was applied to wild and cultivated mussels collected at three sites on the Atlantic coast. The results showed few MP of acrylonitrile butadiene styrene (ABS) by individuals. The seasonal and intersite variabilities were discussed.

TP079 Extraction and Analysis of 10-500 µm Sized Microplastic in Wastewater

M. Simon, N.v. Alst, Aalborg Univ; D.A. Stephansen, Aalborg Univ / Civil Engineering; J. Vollertsen, Aalborg Univ

Wastewater is an important source of microplastic. However, rather few studies exist on microplastic in raw and treated wastewater especially when it comes to small sizes. In this work we present a method for sample preparation of raw wastewater and treated wastewater and the following analysis using a micro-FTIR imaging system with a focal plane array detector (FPA). For analysis of particles below 80 µm we use transmission of IR through a sample while larger particles are analyzed by reflection. For each identified particle its size, form and material is determined. The focus point of this presentation is the methodology of sample preparation, pitfalls and possibilities as well as lessons to be learned on sample preparation for subsequent micro-FTIR imaging. Wastewater is a challenging matrix for analyzing microplastic particles, which is further complicated by the small size range targeted. The sample preparation and analysis hence is extensive. For raw wastewater, 1 L of sample is pre-treated by wet-sieving on a 500 µm sieve. Due to the strong adherence of plastic particles to other particles, a surfactant is added prior to sieving. A sub-sample is treated with cellulase, upon which the sample is oxidized by adding hydrogen peroxide and a catalyst. The initial enzymatic breakdown of cellulose is required because cellulose fibers (from toilet paper) otherwise limit FTIR analysis as they tend to coat the plastic particles. The oxidized samples are wet sieved into 80-500 µm and ≤80 µm intervals. The particles are removed from the sieves and gathered into demineralized water by ultrasonic treatment and filtered separately through a 10 µm stainless steel mesh. Particles are then collected in ethanol. A sub-sample of the ethanol is transferred to a transmission window (≤80 µm particles) or a reflection window (80-500 µm particles). For treated wastewater, varying sample volumes are collected as the content of suspended matter differs much between treatment plants. Known amounts of wastewater are filtered on-site onto 10 µm stainless steel filters until they clog. Filters are then treated enzymatic and oxidative. The recovery rate of the method is tested with 100 µm polystyrene beads and found to be around 80%. Additionally, the results from a field study is presented where 10 of the largest Danish wastewater treatment plants have been sampled and the efficiency of the treatment plants to remove microplastic particles in the size range of 10-500 µm evaluated.

TP080 Extraction, Identification and Quantification of 10-500 µm Microplastics in Soils and Road Dust Using Micro-FTIR Imaging

N.v. Alst, M. Simon, Aalborg Univ; D.A. Stephansen, Aalborg Univ / Civil Engineering; J. Vollertsen, Aalborg Univ

The occurrence of microplastic in agricultural soils is poorly known. This study focuses on the occurrence of microplastic in the size range 10-500 µm in soils that received wastewater sludge as fertilizer. It presents the method of sample preparation and presents data from a field study, but centers on the identification of microplastic using micro-FTIR imaging in terms of the methodology, pitfalls and possibilities of this technology. In the first step of analysis for soil and road dust, a sample is suspended into a surfactant solution, slightly agitated and wet sieved into 4 size fractions of 10-40, 40-80, 80-200 and 200-500 µm. Each sample is transferred to a straight glass funnel with stopcock, for gravimetrical separation of the inorganic fraction and a 1.7 g/cm3 zinc chloride ($ZnCl_2$) solution is added. The sample is agitated for approximately 20 minutes by aeration from below. The aeration is turned off, and organic material sticking to the side of the glass is flushed into the bulk liquid with $ZnCl_2$ solution. The column is left to stand for 2 hours, and approx. 200 mL of the top liquid column is drained through a side port. The $ZnCl_2$ solution is resupplied and the floatation sequence is repeated twice. The mixed liquid obtained from the separation is filtered over a 10 µm steel filter, which is then oxidized in H_2O_2 enhanced by a catalyst. The oxidized sample is again filtered over a 10 µm steel filter, and the particles suspended in ethanol. For particles ≤80 µm, a subsample of the ethanol is deposited on an IR transmission window mounted in compression with a clear aperture of 10 mm. For particles >80 µm, a subsample is transferred to an IR reflective MirrIR microscope slide on which a steel washer is mounted, also restricting the area to a diameter of 10 mm. The sample amount is chosen so the window is suitably populated for micro-FTIR analysis. The ethanol is evaporated and the sample analyzed using an Agilent micro-FTIR Imaging system, which is equipped with a 128x128 pixel Mercury Cadmium Telluride (MCT) Focal Plane Array (FPA) microscope detector. Particles ≤80 µm are analyzed in transmission mode with a 25x or 15x objective, and particles >80 µm analyzed by reflection using a 4x objective. With the 128x128 MCT FPA detector, this gives individual pixel sizes of 3.3x3.3, 5.5x5.5 and 20.1x20.1 µm and a field of view of 422x422, 704x704 and 2640x2640 µm respectively. For all identified particles its size, form and material are recorded.

TP081 How we may get it wrong using standard test guidelines to test for effects of plastic particles

A. Palmqvist, Roskilde Univ / Dept of Science and Environment; F. Khan, K. Syberg, Roskilde Univ / Dept of Science and Environment

Plastics have become ubiquitous and seemingly unavoidable contaminants in the environment. A major part of it, at least when measured as abundance rather than mass, is in the form of micro- and probably nano-plastic particles. Whereas larger sized plastic litter has obvious impacts on e.g., exposed reptiles, birds and mammals, particles on the nano- to micro scale is likely to affect smaller sized animals that play important ecological roles for example by forming the basis of food-webs or contributing to the degradation of organic matter and cycling of nutrients. As such it is necessary that we explore the hazard of nano- and micro-sized plastic particles to organisms inhabiting all types of environments. Ecological effects of chemicals is typically tested under controlled conditions in the laboratory, in order to avoid or be able to consider confounding factors, using tests as prescribed by standard test guidelines (e.g., OECD, US-EPA). Such tests are optimized for testing chemicals in solution, and in many cases to test for chemicals that may be directly taken up from the surrounding medium over external surfaces (e.g., skin and gills). Few standard tests are suitable to test for effects of contaminants that exert their effect through ingestion of the contaminant. For contaminants on particulate form ingestion is precisely a likely prerequisite for exerting and detecting maximum effects. In this presentation we will provide examples from both aquatic and terrestrial tests highlighting how exposure conditions prescribed by standard test guidelines may give a false impression of the inherent hazard of small scale plastic particles. We will also provide some suggestions on how to overcome some of these obstacles with manageable adjustments of standard tests.

TP082 Pristine Micro- and Nano-Plastics Readily Form Microorg-Agglomerations in a Lab-Simulated Marine Environment

S. Summers, Heriot Watt Univ / School of Life Sciences; M. al-sid-cheikh, Plymouth Univ; A. Catarino, T. Henry, Heriot-Watt Univ / School of Life Sciences; S.J. Rowland, Plymouth Univ; R.C. Thompson, Plymouth Univ / School of Marine Science and Engineering; T. Gutierrez, Heriot Watt Univ / School of Life Sciences

Researchers have shown that small sized (nano- / micro-) plastic fragments are present throughout the oceans, yet their ultimate fate is still unclear. Numerous laboratory studies, conducted with pristine plastic particles, have investigated their effects on marine organisms; however, the environmental relevance of such experiments are in debate. In the natural marine environment, microorganisms and exopolymeric substances (EPS) are associated with plastics and this association may alter the behaviour and effects of plastic particles. The flocculation of plastic particles, EPS and microorganisms (termed here microorg-agglomerates [MAGs]) should be investigated in order to improve our understanding of the behaviour and effects of plastics in the marine environment. To address this in the present study, MAGs were created in vitro using pristine polystyrene particles which were then incubated with natural seawater on roller tables; a range of plastic sizes was employed (50 nm – 10 mm) in separate experiments. Additionally, the mechanisms of MAG cohesion were examined using several microscopy techniques and the microbial community assessed using MiSeq sequencing. The behaviour of plastic fragments in an aquatic environment is partly dependent on size. Smaller particles have a greater colloidal stability, suggesting that they remain in suspension, separate from other plastic pieces. However, our research shows that plastics ≥50 nm flocculate to form MAGs up to 1 mm in size within 7 days, under laboratory conditions. In addition to plastics, MAGs were shown to comprise of particulate matter and a rich community of microorganisms found entrained within an amorphous matrix of EPS, which acts as a cohesive agent bonding the MAGs. The presence of EPS and particulate matter within MAGs may alter the buoyant density of these agglomerates, influencing their sinking velocity and position in the water column. Our findings reveal that plastics can form into micro- and millimetre-scale MAGs, potentially influencing their fate. In addition, the formation of MAGs may result in a modification of the behaviour of plastics as their buoyancy and colloidal stability is altered. Changes in the rich microbial community associated with plastic agglomerates may also play an important role in influencing the fate of chemical pollutants sorbed onto or incorporated into the plastics, in the uptake of pathogens by consumers, and more broadly upon their impacts to higher trophic levels.

Leveraging Technologies Between Mammalian and Ecological Toxicology to Advance Risk Assessment

TP083 Dose-level selection and exposure refinement in mammalian toxicology

N. Burden, NC3Rs

The benefits of incorporating exposure considerations within the safety assessment process are being increasingly recognised. This includes improving understanding of internal exposures and increasing the human relevance of doses that are used in mandatory animal toxicity studies. Toxicokinetic (TK) analyses are already a routine component of the safety assessment of pharmaceutical candidates. Exposure data for chemicals is currently largely limited to estimations and measurements of applied external concentrations. There are therefore opportunities to increase the use of TK data to inform the design and utility of toxicity studies for agrochemical and industrial chemicals. Such data could be used to inform dose selection for subsequent toxicity studies and ensure they are relevant to predicted human internal exposure levels. This would obviate the need for the traditional maximum tolerated dose approach, and the dosing of unnecessarily high test concentrations which result in development of toxicities in animals that bear no real-life relevance. Effects observed when high doses are tested often trigger further toxicity studies and investigations into mode of action which may not be necessary. The advent of sophisticated microsampling techniques also brings advantages, as circulating blood levels can be correlated to observed toxicities within the same animal. This can not only increase understanding of dose-response relationships but also decreases the need for groups of satellite animals dosed solely for TK analyses. This type of exposure-driven approach is applicable to both human health and environmental safety assessments, and supports the generation of data that is directly applicable for making risk, rather than purely hazard-based, assessment decisions.

TP084 Adverse outcome pathway as a unifying collaborative framework to tackle challenging ecological problems: a case study using behavior in larval fish

C.A. Murphy, Michigan State Univ / Fisheries and Wildlife; M.J. Carvan, Univ of Wisconsin-Milwaukee / School of Freshwater Sciences; N. Vinas, Midsouth Regional Chapter / Inst for Genomics Biocomputing and Biotechnology; M. Jones, Oak Ridge Natinoal Lab / Environmental Sciences Division

The concepts behind adverse outcome pathways (AOPs) are not necessarily new, but the coordination of a general framework, terminology, and resources is a recent development in the past decade. We found these qualities of the AOP to be an effective collaborative platform to unite multidisciplinary scientists to focus on challenging ecological problems, to form hypotheses and direct research. In our work, we focus on behavior, which is a challenging endpoint to incorporate into ecological risk assessment because it is difficult to infer how subtle changes in behavior translate to ecological metrics (such as population abundance trajectories), and it is often difficult to setup appropriate behavioral assays in the laboratory (especially for species not typically maintained in the lab). But behavior of organisms, if measured appropriately in laboratory assays, can provide much integrated insight into the physiological status of the individual, with implications for key demographic parameters such as individual survival and growth rates. We use the AOP framework to unite several different technologies and approaches: behavioral assays, gene expression, metabolomics, individual based models, and risk analyses to predict the effect of contaminants across levels of biological organization and infer population responses to quantify risk of exposure to certain chemicals. By using the AOP framework in a systematic way, we collect data on multiple species and facilitate cross-species comparisons. We also collaborate with other agencies and institutions that do similar work on different species – which assists our cross-species comparisons. Our aim is to determine what information can be collected on model species that will be informative for behavioral impairments and population responses on other species. We also wish to determine if molecular information can substitute for behavior assays related to foraging success and learning, as such assays are labor intensive and challenging to do on non-model species and molecular level information is relatively easier to collect. The AOP framework has been immensely helpful for organizing, focusing and propelling this research forward.

TP085 Mammalian toxicokinetics and alternative approaches to toxicity testing

A. Lowit, USEPA / Office of Pesticide Programs

Toxicokinetic information has great value in dose selection, evaluation adverse outcome pathways, cross-taxa evaluation/extrapolation, lifestage susceptibility, and reducing or replacing in vivo animal toxicity studies. This presentation will provide a discussion of the importance and value of having in vivo and in vitro toxicokinetic information in assessing risk to pesticides. Case study examples will be used to elucidate the principles of using toxicokinetic information in helping to assess toxicity testing and risk assessment. The talk will describe the use of in vitro toxicokinetic studies to compare across species and to assess variability. Finally, the presentation will highlight progress being made on by the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) and the NIEHS under the National Toxicology Program Interagency Center for the Evaluation of Alternative Toxicological Methods (NICEATM) in the area of developing alternative approaches for acute toxicity.

TP086 Global probabilistic environmental hazard assessment of antihistamines

L.A. Kristofco, Baylor Univ / Dept of Environmental Science; B.W. Brooks, Baylor Univ / Dept of Environmental Science

Global population concentration is increasingly occurring in megacities, where access to medicines is increasing more rapidly than waste management infrastructure is implemented. Antihistamines (AHs) represent a common class of pharmaceuticals, and have been shown to make their way through the sewage treatment process. As streams and many aquatic systems are increasingly dominated or dependent on effluent discharge of differential quality, chronic low dose exposures to non-target species must be considered. However, hazard and risks of AHs to non-target species are poorly understood. Here, we present a global assessment of AHs in surface waters and effluents. Antihistaminergic active pharmaceutical ingredients (APIs) were identified, literature occurrence and ecotoxicology data on the identified APIs was collated, therapeutic hazard values (THVs) for each API were calculated, and environmental exposure distributions (EEDs) of the APIs were compared to ecotoxicity thresholds, drug specific and cumulative THVs to estimate hazards in surface waters and effluents. 60 unique AH APIs were identified using the DrugBank and MaPPFAST databases. Literature searches on the occurrence of the identified AHs in environmental matrices was completed and, after consolidation returned < 100 unique occurrence publications in environmental matrices in Asia-Pacific, Latin America, Europe, and North America. However, the majority of surface water (63%) and effluent (85%) observations were from Europe and North America, which highlights relatively limited information from many regions, including developing countries and rapidly urbanizing areas in Africa, Latin America and Asia. Less than 10% of all observations were for estuarine or marine ecosystems, though the majority of human populations reside close to coastal ecosystems. Though diphenhydramine was most commonly reported, cimetidine, cinnarizine, loratadine, and ranitidine represented other frequently detected AHs. EED 5th and 95th centiles for all AHs in surface water, influent and effluent were 2, 6, and 5 ng/L and 212, 4287, and 1308 ng/L, respectively. Though some ecotoxicology publications for antihistaminergic APIs were identified, few of these examined mixtures or mammalian read across predictions. This study identifies the utility of global assessments of AHs and other pharmaceuticals to identify regions where environmental monitoring, assessment and management efforts appear necessary.

TP087 From Zero to Validated Adverse Outcome Pathway (AOP) with Genomics Guiding the Way

K.A. Gust, M.S. Wilbanks, US Army Engineer Research and Development Center / Environmental Laboratory; D.R. Johnson, Conestoga-Rovers & Associates / Environmental Laboratory; Y. Deng, Rush Univ Medical Center / Senior Scientist; L. Burgoon, E.J. Perkins, US Army Engineer Research and Development Center / Environmental Laboratory

Genomics investigations served as the foundation for discovery of a critical adverse outcome pathway (AOP) with relevance to both ecological and human health. The work represents a suite of studies that established the molecular, mechanistic and systems-level impacts of the most abundantly distributed class of munitions contaminants, the nitrotoluenes. Historical toxicological investigations of nitrotoluenes identified lethargy, weight loss and muscle wasting as general adverse outcomes (AOs) of exposure. In order to identify the source(s) of these AOs, global-transcriptomics expression investigations of nitrotouene exposures were conducted to identify the genes and pathways affected. A recurring theme of inhibited expression for transcripts involved in lipid & systemic cellular-energy metabolism pathways were observed in multiple species including rats, mice, birds, and fish in response to various nitrotoluenes. Effects on these pathways were confirmed in proteomics and lipidomics investigations where lipid catabolism was impaired leading to fatty acid accumulation in the liver in conjunction with muscle wasting and overall weight loss. An additional recurring omics response to nitrotoluenes was significant enrichment of peroxisome proliferator-activated receptor (PPAR) signaling pathways where expression of component genes were strongly inhibited. PPARs represent key transcriptional regulators of pathways controlling systemic energy metabolism, where the PPARα isoform controls various facets of lipid transport and metabolism. We then tested the effects of nitrotoluenes on PPARα signaling in human in vitro nuclear receptor inhibition assays confirming that various nitrotoluene structures caused significant signaling inhibition. Given the knowledge above, we developed a hypothetical AOP establishing PPARα binding / inhibition as the molecular initiating event (MIE) for a series of key events leading the adverse outcome (AO) of overall starvation-like weight loss. The connection between impaired PPARα signaling and the AO was validated in PPARα knockout (K/O) mice where the PPARα K/O eliminated the AO resulting from nitrotoluene exposures. Computational docking assays support the putative MIE indicating probable binding of nitrotoluenes to the PPARα active site, a hypothesis presently being tested in PPARα competitive-binding assays. Overall, this work demonstrates the power of omics techniques for leading systems-level development of AOPs.

TP088 Extrapolation Strategies for Ecological Risk Assessment with Inhalation Risk Assessment for Cetaceans as an Example

A.B. Rosenstein, Environmental Risk Expertise; T.K. Collier, Independent Consultant / Oceans and Human Health Program

Scaling (also called the allometric approach) is a theoretical approach used to predict toxicity in species for which toxicity data are lacking – it incorporates various biological, anatomical and physiological differences between species. In mammals, this approach characterizes how patterns of size, anatomy, physiology, and lifespan can affect toxicological endpoints. However, for many mammalian species, knowledge of the exact anatomical and physiological values and their variation is limited or non-existent. An additional uncertainty is that the allometric approach does not take into account differences in metabolism between species. How do current wildlife toxicity extrapolation strategies incorporate scaling factors and how much does lack of data affect the end results? We will present a summary of extrapolation approaches that have been used in ecological risk assessments, and will discuss promising methods currently being developed to take into account metabolic, physiological, and other species differences. As a case study, we recently extrapolated laboratory animal inhalation toxic effect levels to marine mammals (cetaceans) by scaling, using body mass and lung volume. Other physiological and metabolic differences between terrestrial mammals and cetaceans, some of which exist because cetaceans live and feed in deep water versus on land, are not well understood. Examples include differences in: lung physiology and nasal filtration; toxicant uptake because of gas pressures at depth versus on land; and metabolism. These factors were not incorporated into the extrapolations we have conducted so far. We will address the following question: what was the potential effect on our final exposure and risk estimates of omitting these factors?

Developments and Barriers in the Use of Bioavailability for Contaminated Soil and Sediment Human Health Risk Assessments

TP089 Applying site specific adjustments for arsenic: Bioavailability, bioaccessibility, and regulations

Y. Lowney, Alloy, LLC / Health Sciences

The available literature establishes that the bioavailability of arsenic in soil is reduced relative to the soluble forms of arsenic that serve as the basis for the regulatory toxicity criterion (cancer slope factor). This includes studies conducted for soils from individual sites or broader efforts that include soils with several sources of arsenic and soil types. Investigations have also included both in vivo studies using different animals and in vitro methods. The USEPA has determined that this body of evidence supports a default assumption of a 60% RBA for arsenic in soils, to be used when site-specific analyses are not conducted. This presentation will describe the evidence and process of reduced bioavailability of arsenic from soils, and also describe existing and emerging efforts to develop less expensive, “in vitro” methods to estimate arsenic RBA on a site-specific basis. Similar to the in vivo work, the investigations to develop an in vitro method for arsenic have included soils from individual sites, several sites, and more recently, a meta-analysis of in vitro data across several studies. The focus of this discussion will be on the bioavailability of arsenic in soils to human receptors, and describe the incorporation of arsenic bioavailability considerations into the human health risk assessment process.

TP090 Assessing the In Vivo Oral Bioavailability of Polycyclic Aromatic Hydrocarbons from Soil: Approaches and Challenges

S. Roberts, Univ of Florida, Gainesville; Y. Lowney, Alloy, LLC / Health Sciences

The literature includes several animal models and experimental approaches for assessment of the oral bioavailability of polycyclic aromatic hydrocarbons (PAHs) from soil. Each of these models and approaches has limitations that often include critical untested assumptions and experimental compromises. The metabolism of PAHs, within the GI tract as well as the systemic circulation, and substantial biliary excretion, pose significant challenges in developing sound oral bioavailability assessment methods. While there is almost universal agreement that a simple, cost-effective, reliable in vitro oral bioavailability method will be the most practical way to obtain site-specific relative bioavailability information, validation of candidate in vitro methods requires in vivo data that are scientifically sound to serve as benchmarks. For in vivo estimation of oral bioavailability of PAHs, there are a variety of animal models to consider, as well as endpoints such as measurement of parent compound and/or metabolites in blood, urine, feces, and tissues. Each of these has a rationale, but also technical limitations. Recent studies incorporating a radiolabeled benzo(a)pyrene tracer in weathered soil have allowed evaluation of bioavailability assessment methods for PAH concentrations in soil down to 1 ppm or less, which is the range in which remediation decisions need to be made for many PAH-contaminated sites. These studies have also revealed potential problems in determining an orally bioavailable concentration of PAHs in soil when soil concentration data are derived using standard analytical extraction procedures (e.g., EPA Method 3550C). This presentation highlights the progress that has been made in developing a consensus in vivo model system for PAH oral bioavailability.

TP091 Bioaccessibility of Native Polycyclic Aromatic Hydrocarbons and Derivatives in a Fuel Soot Using an in vitro Gastrointestinal Model

J.J. Pignatello, Connecticut Agricultural Experiment Sta. / Environmental Sciences; Y. Zhang, McGill Univ / Dept of Civil Engineering; T. Shu, Peking Univ / Laboratory for Earth Surface Processes College of Urban and Environmental Sciences; B. Xing, Univ of Massachusetts – Amherst / Stockbridge School of Agriculture

Soot particles disperse in air and settle on soil and environmental surfaces. Gastrointestinal exposure to PAHs and PAH derivatives in soot can occur by ingestion of soil or environmental particles via hand-to-mouth activities (especially for children) and by swallowing expectorant containing inhaled atmospheric particles. We measured the apparent bioaccessibility (B_{app}) of eleven PAHs, one nitro-PAH and four oxo-PAH derivatives present in a fuel soot using an in vitro three-stage GI model. The model included silicone sheet as an absorptive sink in the small intestinal stage. The soot-borne contaminants were regarded to exist in either a labile or a nonlabile state. Silicone absorption was expected to promote soot desorption by steepening the concentration gradient across the soot-fluid interface, mimicking the effect of absorption by the small intestinal epithelium. Consistent with this expectation, silicone significantly increased B_{app} and reduced the labile fraction remaining on the soot residue after digestion. We also studied the effects of changing physiological conditions in the digestive tract associated with food ingestion. The B_{app} was independent of gastric pH and addition of dietary proteins and carbohydrates, but it increased with bile acids concentration, small intestinal pH (5.00–7.35), and addition of dietary lipids. Rising small intestinal pH increased B_{app} by favoring mass transfer from nonlabile state to labile state, from labile state to digestive fluid, and from digestive fluid to silicone sink. Under fed conditions, B_{app} increased with inclusion of lipids by favoring mass transfer from nonlabile state to labile state, and from labile state to bile acid/lipid micelles in the digestive fluid. The extrapolated maximum possible (limiting) bioaccessibility (B_{lim}) ranged from ~30 to ~65% among the PAHs and PAH derivatives. Evidently a large fraction of these contaminants in fuel soot cannot be mobilized, a result with implications for risk assessment. In addition, B_{lim} was independent of molecular size or K_{ow}, suggesting that a major determinant of bioaccessibility is not contaminant hydrophobicity, but the distribution of chemical between nonlabile and labile states in the original solid. Lastly, the results indicate significant variability in soot PAH bioaccessibility within the range of physiological conditions experienced by humans, and suggest that bioaccessibility will increase with co-consumption of food, especially food high in fat.

TP092 Design and Implementation of In vitro Dermal Absorption Studies of PAHs from Impacted Soils for Application in Human Health Risk Assessment

G. Hoeger, ARCADIS / IEST; B.H. Magee, ARCADIS; N.D. Forsberg, Arcadis US, Inc. / Environmental and Molecular Toxicology

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous in the environment from both natural and anthropogenic sources. Currently, seven of these PAH compounds are listed as probable human carcinogens with benzo(a)pyrene (BaP) serving as the surrogate compound for evaluating mechanisms of carcinogenicity and relative carcinogenic potency in humans. For the first time, the EPA is proposing a dermal cancer potency slope factor in the pending toxicity assessment for BaP (EPA, 2013). The preliminary dermal slope factor, which is based on occurrence of skin tumors at the site of contact in mice exposed to BaP in solvent, may drive future remediation decisions if approved as currently proposed. Since most human exposures to PAHs occur by contact with impacted soil rather than being dissolved in solvent, the proposed dermal slope factor is likely to overestimate the risk of skin tumors in humans. Reduced bioavailability of PAHs in soil compared to PAHs in solvent is documented in the literature. The source(s) of PAHs to the soil and sequestration of PAHs in the soil matrix over time is believed to account for reductions in their observed bioavailability. Numerous in vitro dermal bioavailability studies have been performed evaluating dermal absorption of PAHs from soil using static or flow-through diffusion cells consistent with Organization for Economic Cooperation and Development (OECD) guideline 428 for testing skin absorption of chemicals. Design of an in vitro dermal absorption study using diffusion cells should include the following elements: Skin model and preparation; Receiving fluid; Experimental design; Soil test article preparation; and Flux calculation. Considerations including human versus animal skin, PAH binding in the stratum corneum, metabolic activity of the skin, effects of receiving fluid, sample collection and frequency, study duration, sample preparation and dosing, and control experiments are examples of design elements that will be addressed. Data interpretation and calculations for application in human health risk assessment and establishment of risk-based cleanup goals will also be presented. A case study will be provided evaluating the dermal bioavailability of PAHs in soil impacted by clay target fragments at a skeet range site.

TP093 Predicting and reducing PAH dermal bioavailability from soils with different source materials

H. Xia, U. Ghosh, Univ of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering

Polycyclic aromatic hydrocarbons (PAHs) are released into soils within different sorption domains (e.g. soot, coal tar or NAPLs) that may alter their bioavailability. Black carbon, such as activated carbon and char have been shown to provide strong sorption domains for PAHs and greatly reduce the freely dissolved concentrations (C_W). Our previous study has discovered strong correlation between soil partitioning coefficients (K_d) and dermal flux simulated by in vitro uptake into pig skin, and that dermal uptake may be well predicted by C_W. The objectives of this study were to 1) investigate the effects of biochar amendment on PAH dermal bioavailability from soils, and 2) use diffusion models to explain and predict dermal uptake by humans from soils. In this study, a number of baseline soils were contaminated with different source materials (soot, coal tar and fuel oil) to achieve a range of PAH concentrations. A subset of the contaminated soils was then treated with 2% biochar to investigate the effect of carbon amendment on PAH dermal exposure from soils. The soil K_d and C_W were determined through aqueous partitioning experiments using polyoxymethylene passive samplers. And the dermal exposure was simulated using in vitro diffusion into pig skin. The soil amendment using 2% biochar was able to reduce PAH dermal uptake by nearly 40% to 90%, through reduction of C_W. However, the effect of biochar varied with different PAH sources: e.g. greater reduction was observed in solvent spiked than soot spiked soils. Strongly correlation between dermal flux and C_W was once again observed, but over a range of C_W across nearly 3 orders of magnitude. Steady state diffusion model derived from Fick's first law was initially used to predict dermal uptake using C_W andsteady statepermeability (Kp). However, the steady state model failed to give adequate prediction (of within 1 log unit deviation) due to the potential disequilibrium condition within skin. Therefore, a kinetic diffusion model derived from Fick's second law involving skin diffusivity (D) and skin/water partitioning coefficient ($K_{S/W}$) is being used to predict the dermal flux, which calls for accurate measurement of D and $K_{S/W}$. $K_{S/W}$ isbeing experimentally determined through skin/ water equilibrium test, and D will be extrapolated using a subset of experimental data (from solvent spiked soils). The kinetic model's performance will be evaluated for the various source materials against measured results.

Environmental Chemistry Perspectives from Around the Globe

TP094 A brief introduction to ChemTHEATRE, the platform to manage the monitoring data of chemicals in environment

K. Nakayama, Ehime Univ / Center for Marine Env Studies; T. Isobe, National Inst for Environmental Studies; S. Uno, Kagoshima Univ / Faculty of Fisheries; I.C. Handoh, Research Inst for Humanity and Nature; N. Ohno, Univ of Hyogo; T. Kunisue, Ehime Univ / Center for Marine Environmental Studies

A huge number of monitoring data on persistent organic pollutants (POPs), candidate POPs, pharmaceuticals and personal care products, and heavy metals in various environmental and biological specimens have been reported in scientific journals. However, almost all the valuable data set of the above chemicals are merely stored in simple electronic files, such as text and excel files, by each researcher, and hence they are poorly utilized for other scientists, e.g., to simulate the environmental behavior and fate, and to assess the risk. In the present study, we are developing a platform to deposit and visualize the monitoring data of chemicals in environment, named ChemTHEATRE (Chemical in the THEATRE: Tractable and Heuristic E-Archive for Traceability and Responsible-care Engagement). ChemTHEATRE stores chemical concentrations in environmental specimens with metadata of samples (sampling date and location, organism and its biometry, and so on) and of experimental methods (extraction method, used standards, instruments, etc). This platform enables us to visualize temporal and spatial distribution pattern of registered contaminants, and also to simulate their behavior and fate in the environment. Additionally, using this platform, you may directly reach the specific environmental specimens stored in the environmental specimen bank (es-BANK) at Ehime University, which allows us to obtain some additional data from the same samples, if necessary. At the first step of the platform development, we designed the database structure and registered the monitoring data of dioxins and other organochlorine compounds, brominated flame retardants, and organotin compounds in finless porpoises (Neophocaena phocaenoides) and skipjack tuna (Katsuwonus pelamis). Please visit ChemTHEATRE (http://www.chem-theatre.com/), free to access. We will also appreciate if you would kindly contribute to ChemTHEATRE to register your published monitoring data.

TP095 Effects of Pavement Type (asphalt vs. concrete) on Trace Metals in Road Dust

M. Fiala, Texas Southern Univ – Dept of Environmental Science and Technology / Dept of Environmental and Interdisciplinary Sciences; H. Hwang, Texas Southern Univ / Environmental Science

Operation of motor vehicles is a major source of environmental contaminants, especially in urban areas. Trace metals are released through abrasive wear between brake pads and rotors; tires and road surfaces. Oil and greases are released from improperly maintained vehicles, and asphalt pavement. To investigate the effects of pavement type on the release of contaminants into the environment, road dust samples were collected on concrete and asphalt sections of Highway 59 in Houston, Texas. Upon arrival at the laboratory, samples were sieved to 250-125 µm, 125-63 µm, and < 63 µm fractions and total environmental-available trace metals were quantified using ICP-MS. Trace metal concentrations increased with decreasing dust size, while trace metal mass decreased with decreasing size fraction. Although < 63 µm particles contained highest trace metal concentration, 250-125 µm particles contributed the greatest overall trace metal mass. Mass weighted average concentrations of < 250 µm size fraction for Co, Cd, Ni, Cu, Zn are 1.8 ppm, 3.1 ppm, 37.3 ppm, 104 ppm, and 185 ppm, respectively for concrete road dust and 2.7 ppm 4.2 ppm, 23.2 ppm, 64.4 ppm, and 265 ppm, respectively, for asphalt road dust. Trace metal concentrations are comparable to previous studies in Houston and other urban areas. The results indicate a significant difference may exist in Cu and Zn concentrations between asphalt and concrete pavement. Study results may be useful for determining road construction materials that contribute less contaminants to urban air and streams.

TP096 The seasonal trends of trace element behaviors in the bottom of Lake Koyama-ike, Japan

S. Murakami, M. Hosoda, Tottori Univ / Regional Science; T. Moriki, S. Horai, Tottori Univ

Lake Koyama-ike in Tottori in Japan is a lagoon at present, and it has been a freshwater lake for about 400 years. To improve the water quality, seawater introduction was started in 2012 and as a result the salinity of the lake water drastically changed in the year 2012. The salinity became 14-fold higher than that in 2011. In the present study, 18 trace element concentrations (Li, Al, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Ag, Cd, Sn, Sb, Ba, Pb) determined in sediment, pore-water and bottom water of Lake Koyama-ike in 2013, we compared the trace element levels in the samples between in June and in September. 15 element concentrations (Al, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Ag, Cd, Sn, Sb, Pb) in the sediment were higher in September than in June. It may show that the elution of elements from sediment decreases into bottom water and/or sedimentation and adsorption from water to sediment accelerate. We considered pore-water/ sediment ratio as the elution potential. The elution potential in June was higher than in September. It was reported that Fe and Mn tended to precipitate at pH exceed 8.0. pH values of the bottom water in all stations of Lake Koyama-ike in September were over 8.0. There were 9 elements (Al, Cr, Mn, Co, Ni, Cu, Zn, Cd, Sn) which showed positive correlations ($p < 0.05$) with Fe. From this result, it seemed that Fe and the 9 elements co-precipitated. Next, we assessed the toxicity of the trace elements in the sediment and the bottom water. In the risk assessment using sediment, As, Fe, Mn concentrations exceeded the levels which were concern of the organisms. In the toxicity assessment using the bottom water and pore-water, Zn concentration in the one station exceeded the level of influence on the reproductive function. To understand the bioavailability, therefore, continuous monitoring of the trace elements elution which elute easier from sediment into bottom water is important.

TP097 Relationship between temporal trend of trace element concentrations and grain size in the sediment of Lake Koyama-ike, Tottori

M. Sasaki, M. Hosoda, S. Murakami, Tottori Univ / Regional Science; T. Moriki, Tottori Univ; M. Nakamura, Japan Corbicula Reserch Inst; S. Horai, Tottori Univ

Lake Koyama-ike in Tottori in Japan is a lagoon at present, and it has been a fresh water lake for about 400 years. To improve the water quality, seawater introduction was started in 2012 and as a result the salinity of the lake water drastically changed in the year 2012. The salinity became 12-fold higher than that in 2011. In trace element concentrations in sediment, 7 elements (Cr, Co, Ni, Cu, As, Cd and Pb) significantly increased from 2011 to2013. There is a report that the concentrations of finer particle size are higher than coarse it. In the present study, Sediments of Lake Koyama-ike were separated into fraction of coarser than silt:CS (> 63 µm) and fraction of finer than silt:FS (?63 µm). 21 trace element concentrations of CS and FS were determined in Lake Koyama-ike. As a result of having compared trace element concentrations of FS with of CS, There were no elements showed significantly higher than FS in CS.

The elements showed significantly higher than CS in FS were Li, Mg, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Rb, Cd, Sn, Cs and Pb in 2011, and Li, Mg, Cr, Mn, Co, Ni, Cu, Zn, Se, Rb, Cs and Pb in 2013. The elements that common significantly higher than CS in FS in 2011 and 2013 were 12 elements (Li, Mg, Cr, Mn, Co, Ni, Cu, Zn, Se, Rb, Cs and Pb). The compositions of the grain size in 2011 and 2013 were 1.2 % in FS and 98.8 % in CS, and 2.4 % in FS and 97.6 % in CS, respectively. Thus, it found that FS fraction in 2013 was 1.2 % higher than in 2011. With regard to the reason why the total metal concentrations in 2011 increased in 2013, we estimated the contribution of the FS fraction to the changes of the trace element concentrations. The trace element which was the highest contribution was Mn 40.7%, following Mn, Fe was 22.1%, Zn was 19.2% and Cu was 19.0%. Contribution rates of Mn, Fe, Cu and Zn were relatively higher than of the others. Next, we investigated chemical forms of Fe and Mn with Eh-pH diagram. As showing in Fig.1, it was assumed that two species $Fe(OH)_3$ and $FeCO_3$ were dominant in the sediment. As showing in Fig.2, it was assumed that three species $MnCO_3$, Mn_3O_4 and MnOOH were dominant in the sediment. Therefore, it was guessed that it was easy environment to elute in Mn. In future study, chemical form analysis and elucidation of the mechanism of concentration changes are needed.

TP098 Risk assessment to lead exposure in Colombian Caribbean coast

F.M. Vergara, Cartagena Univ / Medicine School; B. Johnson-Restrepo, K. Martinez-Yanez, J. Zúñiga-De La Cruz, Univ of Cartagena / Grupo de Química y Medio Ambiente / Facultad de Ciencias Exactas y Naturales Universidad de Cartagena Sede San Pablo; Á. Fortich-Revollo, Univ of Cartagena / Grupo de Quimica y Medio Ambiente; M. Vallejo-Dorado, Univ of Cartagena / Grupo de Química y Medio Ambiente / Facultad de Ciencias Exactas y Naturales / Sede San Pablo

Workers are exposed to lead involuntarily through their contact with lead in their working environment. The work activities developed when cutting, handling and / or melt the metal represents a direct exposure. Many people earn their livelihood by carrying out labor activities in informal work places where they are highly exposed to metal contamination with a low protection and non-environmental health education. Therefore, there are adverse health implications of exposure to high level of Pb because its toxicity may result in damage to the central nervous system, developmental deficiency of red blood cells, cardiovascular system and may have a concomitant influence disorders human fertility in individuals. This research, workers (n = 258) between 18 and 80 years were examined in various trades with more than 5 years in office work involving lead exposure among which are welders, fishermen, repairers batteries, mechanical technician, carpenters , electricians, electronic technician and painters. For this study Pb concentration in blood was determine and using an atomic absorption spectrophotometer with graphite furnace (GF-AAS), Thermo Fisher Scientic iCE Series 3500. Diluting the blood sample in a mixture of Triton X-100, nitric acid, and ammonium hydrogen phosphate $(NH_4)_2HPO_4$ which was used as matrix modifier. Temperatures calcination and atomization optimized were 500Ԩ and 1600 ЂC respectively. Pb concentrations found vary according to labor activity in securities from not detectable (ND) to 72.80 mg /dL Pb. The average concentrations Ђ standard deviation (range) were recycling battery: 11.4 т 21.4 (ND- 72.8), fishermen 11.0 т 11.5 (0.25- 40.8), electricians: 11.37 т 17.8 (1.2 – 51.3), mechanical technician: 10.6 т 4.62 (ND – 59.0), electronic technician: 3.96 т 5.6 (ND – 7.91), painter 3.8 т 4.2 painter (ND – 11.7), welder: 3.7 т 7.3 (ND – 41.2), carpenter: 2.45 т 0, 95 (1.38 – 3.53) and control: 0.83 т 0.90 (ND Ђ_ 2.61). Establishing as a safe level value of 5 mg/dL in adult blood. Recycling battery, fishermen and welders proved trades increased risk to lead exposure, presented greater number of individuals sampled with values> 5 mg / dL. TP099 Protein expression of gastropod Stramonita haemastoma exposed to antifouling biocide TBT

L.R. Diniz, São Paulo State Univ- Inst of Chemistry / Química Analitica; L.T. Cappelini, Univ Federal de São Paulo – UNIFESP; B. Padovan, Instituto de Quimíca de São Carlos / Departamento de Quimica e Fisica Molecular; J.V. Alberice, Instituto de Química de São Carlos – IQSC – USP / Instituto de Química de São Carlos IQSC USP; P.d. Eugênio, Instituto de Química de São Carlos – IQSC – USP; I.B. Castro, Univ Federal de São Paulo / Instituto do Mar; E.M. Vieira, Univ of São Paulo / Departamento de Quimica e Fisica Molecular

Tributyltin (TBT), triphenyltin (TPhT) and other organotins derivatives were widely used as a biocide in antifouling paints in the early 60's to improve efficiency and the mobility of ships. These compounds are known to accumulate along the food chain, acting as an endocrine disruptor in marine organisms, with toxic and adverse effects in many tissues, including vascular system. Due to the formation of a dimorphism of male sex organs (penis and vas deferens) in females, the Stramonita haemastoma is considered as a bioindicator for Tributyltin (TBT). The TBT is considered to be the most toxic substance ever introduced into the marine environment. The proteomics analysis reflects the alteration of protein expression by environmental adaptations, providing a useful framework for the development of new tools for biomonitoring related types of contaminants. The purpose of this study is to determine the changes in protein expression in mollusc gastropod S. haemastoma exposed to tributyltin (TBT). The organisms were collected from Santos estuarine system. The Santos estuarine system are located in the São Paulo State, Southeastern Brazil. This area comprises a major industrial complex, as well as the largest port of Latin America (Porto of Santos). Currently, both harbour and industrial activities combined with the urban contribution represent the main sources of contaminants for coastal and marine ecosystems. Proteins were extracted using phenol / methanol, quantified by Bradford method and fractionated by OFFGEL using strips with pH range from 3 to 10. The method consists into flow protein solutions under a pH gradient gel immobilized through an electric field applied perpendicular to the direction of the flow. Then, the samples were analyzed by SDS – PAGE and identified by nano LC-MS. It is expected to find different proteins between different animals (males, females and hiposex animals).

TP100 Residues of Organochlorine Pesticides: Contamination of Surface Waters in Armenia

A. Aleksandryan, Ministry of Nature Protection of the Republic of Armenia / Head of Hazardous Substances Waste Policy Division; Y. Bunyatyan, A. Khachatryan, Waste Research Center State Non-Commercial Organization

In modern scientific literature, great attention is devoted to integral indicators such as the sum of concentrations of HCH isomers and the sum of concentrations of DDT isomers and metabolites, because their Maximum Allowable Concentrations (MACs) were set considering the amount of the mixtures. In order to determine the degree of pollution in some rivers and reservoirs of theRepublic ofArmenia by persistent organochlorine pesticides water sampling was done. 26 water samples were analyzed and 390 findings obtained. Determination of organochlorine pesticides was carried out by gas chromatography on Shimadzu chromatograph with electron capture detector and a glass capillary column 30 m × 0.32 mm × 0.25 µm (Equity??- 5). As follows from results obtained, water samples contained: DDT (100% samples), Heptachlor (96% samples), HCH isomers (81% samples), Hexachlorbenzene (35% samples), and Aldrin (4% samples). Dieldrin, Endrin, and Mirex were not revealed in analyzed samples. The residual amounts of above-mentioned pesticides varied in the range of: – Aldrin: 0-0.011 µkg/L (MAC = 2 µkg/L); – Hexachlorbenzene: 0.004-0.026 µkg/L (MAC = µkg/L; – HCH (sum of isomers concentrations): 0-0.251 µkg/L (MAC = 2 µkg/L); – Heptachlor: 0.016-0.339 µkg/L (MAC = 50 µkg/L); – DDT (sum of isomers concentrations and metabolites concentrations): 0.108- 2.917 µkg/L (MAC = 2 µkg/L). Levels of Aldrin, HCH, and Heptachlor did not cause any concerns, as they were below the MACs. DDT concentration levels (isomers and metabolites) were dangerously close to MAC, while in some cases (5% samples) the reveled DDT concentrations (isomers and metabolites) exceeded MACs. Undoubtedly, the appearance of pesticides in water is the result of their leaching from the soil and, as a consequence, we might state that the content of these pesticides in soil is much higher. This fact was also confirmed by our previous studies. Identification of DDT metabolites (DDE and DDD) signifies to earlier application of DDT that had already metabolized, while the revealed DDT signifies to "fresh" application of DDT as such. Upon the analysis of study results the following was revealed: – there were no samples with only DDE and DDD residues; – samples with identified DDT, DDE and DDD made 18%; – samples with only DDT residues made 81%. This latter phenomenon indicates to "fresh" application of DDT despite its prohibition

TP101 Shining light on environmental contaminants in sensory organs of pilot whales

M. Korbas, Canadian Light Source / Science Division; K. Hoydal, Environment Agency / Research; M. Dam, Environmental Agency

Synchrotron X-ray fluorescence imaging (XFI) is a powerful non-destructive tool for visualizing the distribution of elements of interest in biological specimens down to the subcellular level. Any element (phosphorus and heavier), if concentrated enough, can be detected and the presence of other elements does not decrease its efficacy. The elemental distribution images are built by raster scanning a specimen in the X-ray micrometer-sized beam and collecting the excited X-ray fluorescence signal from each irradiated spot. The remarkably high elemental specificity of this technique lies in the fact, that X-ray fluorescence photons emitted by certain element will have a unique range of energies that cannot be mistaken with any of the other elements. XFI has been successfully applied to answer a broad spectrum of biological questions; however, its application in environmental toxicology is relatively novel. Here we present an application of XFI to investigate the lifetime exposure to various metals/metalloids including mercury in the sensory organs of pilot whales. Previous XFI studies using acutely exposed zebrafish larvae (e.g. Korbas et al. ACS Chem. Biol. 2013, 8: 2256-2263) identified eye and potentially the inner ear as the target sites for methylmercury accumulation. Mercury presence in the sensory cells will likely have detrimental effects on animal vision, hearing and olfaction, which in turn may cause abnormal behavior and decreased survival rate in the wild. The aim of this study was to probe the retina and inner ear from the long-finned pilot whales (Globicephala melas) for the presence of toxic metals and metalloids including mercury. The tissues were sampled from pilot whales from the Faroe Islands in connection with the traditional drive fishery. The acquired material was fixed in formalin, embedded in paraffin and sectioned at 10-micron thickness. Of two adjacent sections, one was stained with H&E to obtain a histological image, while the other, intended for synchrotron XFI was mounted on a metal-free plastic cover slip without any further processing. The 5-micron resolution elemental maps including Ca, Fe, Zn, As, Se and Hg were measured with XFI. To facilitate the identification of the target areas/cells, the elemental distribution maps were then compared with their respective histological images. This study should contribute to better understanding of the extent of wildlife risk associated with long-term contaminants exposure.

TP102 Urinary concentrations of phthalates metabolites in Brazilian children

B. Rocha, Univ of Sao Paulo – USP / Análises Clínicas Toxicológicas e Bromatológicas; A.G. Asimakopoulos, New York State Dept of Health; F. Barbosa Junior, Univ of São Paulo; K. Kannan, New York State Dept of Health / Wadsworth Center Dept of Health

Human exposure to phthalates have received considerable attention due to their ubiquitous occurrence and potential adverse health effects. Little is known on exposure of Brazilian population to phthalates. The aim of this study was to establish the baseline concentrations of phthalates metabolites in 300 Brazilian children. Twenty three phthalates metabolites were analyzed in 300 urine samples of 6-14 years old children from five regions in Brazil (southeast, south, central-west, northeast and north) by liquid chromatography-tandem mass spectrometry. Overall, 9 metabolites (mono-ethyl phthalate (mEP), mono-(2-ethyl-5-carboxypentyl) phthalate (mECPP), mono-(3-carboxypropyl) phthalate (mCPP), mono-[(2-carboxymethyl) hexyl] phthalate (mCMHP), mono-isobutyl phthalate (mIBP), mono-n-butyl phthalate (mBP), mono-(2-ethyl-5-hydroxyhexyl) phthalate (mEHHP), mono-(2-ethyl-5-oxohexyl) phthalate (mEOHP) and mono-methyl phthalate (mMP)) were found in at least 95% of the samples with the highest median concentrations of mEP (57.0 ng/mL), mECPP (52.8 ng/mL), mIBP (43.7 ng/mL) and mBP (41.3 ng/mL).

Fate and Effects of Metals: Aquatic Biological Perspectives

TP104 A Combined Laboratory and Field Analysis of the Sulphate Dependence of Selenium Bioaccumulation in Algae

J.L. Van Geest, Golder Associates Ltd; A. deBruyn, Golder Associates / Environmental Science; J.R. Elphick, B. Lo, Nautilus Environmental

Sulphate can reduce selenate uptake in algae and aquatic plants, which effectively decreases the amount of dietary selenium available to subsequent trophic levels. However, sulphate dependence is difficult to characterize in field datasets because aqueous sulphate and selenium concentrations often covary. We therefore combined laboratory and field studies to characterize the sulphate dependence of selenium bioaccumulation at the base of the aquatic food web in surface waters where aqueous sulphate and selenium concentrations are correlated. A laboratory study was conducted to model the effect of sulphate on selenium uptake kinetics and steady-state selenium bioaccumulation in algae under controlled conditions. Analysis of uptake kinetics confirmed that tests had achieved steady-state, allowed evaluation of whether the effect of sulphate occur via changes to selenium uptake, elimination, or both, and allowed growth dilution to be quantified so that test results could be more directly related to field data. These results were then combined with field data from coal-mining regions in British Columbia, Canada. This laboratory-to-field integration involved characterizing the combined effect of covarying aqueous selenium and sulphate concentrations, and accounting for differences in algal growth between laboratory cultures and natural streams. The resulting 'hybrid' bioaccumulation model integrated laboratory and field information to model how sulphate concentrations and sulphate:selenium ratios can influence selenium bioaccumulation at the base of aquatic food webs.

TP105 Acute and chronic toxicity of metal mixtures containing cobalt, copper, and nickel to Ceriodaphnia dubia and fathead minnows

B.A. Stubblefield, Oregon State Univ / Environmental and Molecular Toxicology; A.S. Cardwell, Oregon State Univ / Faculty Research Assistant

Historically laboratory-based acute and chronic toxicity studies have focused on testing the effects of a single toxicant to an organism. Although a reductionist approach suggests that the conduct and interpretation of single-compound toxicity tests would be the best approach for predicting toxic responses to metals in the environment, "real world" exposures typically consist of simultaneous exposure to multiple metals. Water quality-based regulatory approaches, e.g., USEPA's Ambient Water Quality Criteria and the EU's Predicted No Effect Concentrations, have been established for individual chemicals and do not directly consider potential interactive effects resulting from exposure to metal mixtures. Acute and chronic toxicity tests were conducted to develop an understanding of the toxicity of complex mixtures containing Co, Ni, and Cu. A toxic unit (TU)-based approach where acute or chronic concentrations (LC_{50}s or EC_{10}s) were identified for each metal singly (LC_{50} or EC_{10}s quantified as one TU), followed by exposure to binary and tertiary (Co/Cu/Ni) metal mixtures in equivalent ratios of TUs. Standardized

USEPA acute and chronic testing methodologies were used. Endpoints were assessed to determine whether the mixtures exhibited additive (no difference in toxicity as a mixture), less-than-additive (reduced toxicity as a mixture), or more-than-additive (increased toxicity as a mixture) effects. In acute tests with C. dubia, mixtures generally exhibited a less-than-additive effect, while in the fathead minnow acute test, additive or greater-than-additive effects were observed. In the chronic tests with C. dubia, results indicated either additive or less-than-additive interaction. In the chronic tests with the fathead minnow, with the exception of one of the Co/Ni mixtures (that exhibited a less-than-additive effect), all the mixtures' indicated an additive effect.

TP106 Assessment of mining affected boreal lake sediments as a source of multimetal exposure to the benthic fauna

J. Wallin, Univ of Jyvaskyla / The Dept of Biological and Environmental Science; A. Väisänen, Univ of Jyvaskyla / Dept of Chemistry; J.V. Kukkonen, Univ of Jyvaskyla / Biological and Environmental Science; J. Karjalainen, A.K. Karjalainen, Univ of Jyvaskyla / Dept of Biological and Environmental Science

Because advanced technology demands vast amounts of metals, there is a growing need for mining activities in many countries. Although mining operations have evolved technologically, metal mining activities have generally long term environmental impacts. In Finland, the soft water boreal lakes are sensitive to ion loading since the buffering capacity is usually low. We assessed ecotoxicological risks of two different mining sites in 11 mining-affected lentic locations and two reference lake sites in Finland, with hypolimnion and sediment field sampling, environmental quality standard comparisons and a chronic toxicity test using a laboratory reared freshwater Oligochaeta Lumbriculus variegatus. This sediment-dwelling blackworm species served as a good representative of the freshwater lake bottom fauna. The national environmental quality standards for water were not exceeded during our sampling time, except for soluble nickel and cadmium concentrations in two sampling sites. Metal concentrations in the sediments were generally greater close to the mining sites. Preliminary results indicate the inhibition of both growth and reproduction of L. variegatus exposed to field-sampled hypolimnion and sediment along the contamination gradient. Our study also brought out the challenges of assessing contaminated sediments together with hypoxic hypolimnion as they are. With our authentic approach the aim was to overcome limitations related to application of standardized biotests to field-collected samples in order to gain a precise case-specific assessment of ecotoxicological risks of the two different mining sites. We will also discuss pros and cons of methodologies besides results indicating deterioration of environmental quality of water bodies downstream the mining sites.

TP107 Bioaccumulation of Heavy Metals by Aquatic Organisms from Historic Mining Operations in Arkansas

J.R. McCauley, Arkansas State Univ / Ecotoxicology Research Facility; J.L. Bouldin, Arkansas State Univ / Biological Sciences

The Rush Mining District along the Buffalo River in Arkansas has a significant history of zinc and lead mining operations. The tails and spoils of these operations deposit heavy amounts of raw ore into streams. One element commonly found in the earth's crust that becomes a minor constituent of the deposition is cadmium. Periphyton samples from Rush Creek and Clabber Creek, two creeks within the Rush Mining District were measured for cadmium as well as two creeks with no history of mining, Spring Creek and Water Creek. Periphyton samples from Rush and Clabber Creek contained mean cadmium concentrations of 436.6±67.3 and 93.38±8.67 µg/kg, respectively. Spring Creek and Water Creek had a mean cadmium concentration of 40.49±3.40 µg/kg and 41.78±3.99 µg/kg within periphyton. The results indicate increased metal concentrations in algal communities from mined areas. As periphyton is the base of the aquatic food chain, it acts as a conduit for movement of cadmium in the food web. The ongoing project will include analysis of bioconcentration within invertebrates.

TP108 Comparison of Cu biouptake by Selenastrum capricornutum in the presence of organic matter from wastewater effluent and stormwater runoff

H. Luan, T. Vadas, Univ of Connecticut / Civil and Environmental Engineering

Urban streams receive Cu from both treated wastewater and stormwater runoff sources. Both sources have significant quantities of organic matter (OM) which is known to control Cu speciation and bioavailability. The purpose of this study was to experimentally assess and model Cu biouptake to the freshwater algae Selenastrum capricornutum, including both internalization and surface attachment, in the presence of different source and size fractions of OM. Dissolved OM was either left intact or separated into small (0-650 Da), medium (650 Da-50 kDa), or large (50 kDa-0.45 µm) size fractions using tangential flow filtration (TFF). Conditional stability constants of the OM were determined using competitive ligand exchange-solid phase extraction. Metal ligand concentrations were determined from Cu titrations. Conditional stability constants of the whole effluent OM were 0.5 to 1 log unit higher than those of stormwater OM for both hydrophilic and hydrophobic OM (Hydrophilic: Log $K_{Cu\text{-}eff\text{-}OMf}$ = 8.2±0.2, Log $K_{Cu\text{-}storm\text{-}OM}$ = 7.5±0.3; hydrophobic OM: Log $K_{Cu\text{-}eff\text{-}OM}$ = 8.9±0.4, Log $K_{Cu\text{-}storm\text{-}OM}$ = 7.9±0.1). The stability constants of the source OM were all higher than those of algae (Log $K_{M\text{-}total}$ = 6.3 and Log $K_{M\text{-}intra}$ = 6.8). Based on short-term uptake experiments, the results show there was 46% less total Cu uptake in the presence of effluent OM than stormwater OM, while intracellular Cu was about 25% less with effluent. This difference corresponded to the higher conditional stability constants measured for effluent OM than stormwater OM. We also found Cu mainly bound hydrophilic OM (80%) in effluent while it mainly bound hydrophobic OM (77%) in stormwater. Incorporating the conditional stability constants and metal ligand concentrations into an algal uptake model, the Cu uptake could be predicted. As for attachment to algal surfaces, stormwater OM promoted more accumulation of Cu on the algal surface, but this accounted for a small percentage of the total algal Cu content. Furthermore, there was a difference in Cu biouptake and stability constants between effluent and storm size fractions. For effluent OM, the Cu uptake and stability constants across size fractions were similar to the whole effluent. For stormwater OM the Cu stability constants were the lowest for the small size stormwater OM, resulting in more Cu uptake as stormwater OM size decreased. Differentiation between OM sources could lead to better predictions of metal uptake.

TP109 Comparison of fish mercury and selenium in fish otoliths and tissue, can we reconstruct the past?

M.J. Bock, Ramboll Environ; R.J. Reash, American Electric Power; J. Goodrich-Mahoney, EPRI / Environmental Dept; L. Friedrich, Stantec Consulting Ltd.; N.M. Halden, Univ of Manitoba / Dept of Geological Sciences

The composition of hard tissues is often used to reconstruct conditions in the past. For example tree rings and fish scales can be used to determine ages, growth rates, and other parameters. Fish otoliths grow throughout the life of a fish, with new material being deposited virtually continuously. The mineral matrix of otoliths contains various trace elements and, much like in muscle tissue, the concentrations of these elements is expected to respond to their concentrations in water. The goal of this work was to determine if otoliths could be used to estimate Hg and Se in muscle tissue. We measured Hg and Se in fish otoliths, tissues, and in surface water at seven locations in the Ohio River system. Trace elements in otoliths were measured using LA-ICP-MS, allowing very fine scale transects of metals concentrations and providing a time series of concentrations as the fish grows. It was assumed that the otolith concentrations measured in bone deposited during the last year of the fish's life would be most closely reflective of muscle tissue. There was a significant correlation between tissue and otolith Se, but the correlation was very weak for Hg. For Se, the correlation was significant for 3 of the 10 species with a sample size of 5 or more i.e., bluegill, small channel catfish and freshwater drum, with R^2 values of 0.60, 0.93, 0.71. Thus, for

many species there is also a high degree of variability in the relationship between tissue and otolith concentrations that makes directly relating the two difficult. We developed specie specific regression models that include a variety of water quality parameters in an attempt to account for confounding factors. The inputs tested in the model included various metals, pH, hardness, suspended solids, conductivity, and various nutrients. There was sufficient data to test the model for bluegills, channel catfish, hybrid striped bass, and sauger. For selenium, the best fit models included surface water selenium, and sulfate. For bluegill, channel catfish, hybrid striped bass and sauger the R^2 were 0.83, 0.70, 0.21 and 0.20. The results indicate that predictions of tissue Hg from otoliths is highly uncertain. However, for at least three species the results suggest that otoliths may be useful predicting tissue concentrations. By relating the date of deposition of otolith bone material to Se concentrations, it appears likely that for some fish species historical trends in tissue Se could be quantified and analyzed.

TP110 Comparisons of arsenate and arsenite interactions with periphyton with implications for trophic transfer

A.R. Lopez, North Carolina State Univ / Zoology Environmental Toxicology; D.B. Buchwalter, NC State Univ / Dept of Biological Science

Periphytic biofilms on benthic substrates are important food resources in aquatic ecosystems. These biofilms can also sit at the interface of oxic waters and hypoxic sediments, and as such can be exposed to trace elements in different oxidation states. Arsenic speciation is tied to environmental redox conditions and is also subject to biological alterations. In this study we compared the stability of aqueous arsenate and arsenite solutions under aerated and non-aerated conditions, both in the presence and absence of periphytic biofilms. In the absence of periphyton, As solutions that initially were predominantly arsenite (90% arsenite, 10% arsenate) were slowly oxidized over 7 days resulting in final solutions that were ~65% arsenite and 35% arsenate. Aeration did not strongly affect oxidation rates. In aerated arsenite solutions in the presence of periphyton, solution chemistry changed more dramatically, with rapid oxidation to arsenate and an increasing proportion of organic As forms forming over time. These changes were less dramatic under non-aerated conditions, suggesting that oxidation and methylation reactions were likely performed by organisms that require more oxic conditions. We also compared periphyton enrichment in periphyton exposed to AsV or AsIII (20 ug/L, static renewal, 7 days) and showed similar accumulation patterns of total As (101.3±26.7 mg kg-1 dw and 87.63±22.4 mg kg-1 dw, respectively). The accumulated final concentrations of arsenic in periphyton were 6281- and 6684-fold, higher than the aqueous concentrations they were exposed to. Mayfly (Maccaffertium sp.) larvae that were allowed to feed on AsV or AsIII treated periphyton were similar in their tissue concentrations (13.9 and 14.6 mg kg-1 dw, respectively), resulting in significant biodilution (approximately 10% of their dietary concentrations). The predominant form of As in both of the these biofilm treatments was AsV. Thus, periphyton is an important player in controlling the behavior, speciation and trophic transfer of As in aquatic food webs.

TP111 Dependence of Ecotoxicity of Zinc on Weight of Test Fishes: a Data Exploration and Modeling Based on Biotic Ligand Toxicity Model (BLM)

Y. Meng, Beijing Normal Univ / Academy of Disaster Reduction and Emergency Management; C. Lu, Beijing Normal Univ / Beijing Normal Univ Academy of Disaster Reduction and Emergency Managent

Ecotoxicity of certain chemical may be related to weight of the test organism, which will help interpret the variation in observed ecotoxicological effects and improve the ecological risk assessment. Driven by this motivation, the authors selected fatal effect data on fishes by zinc (Zn) to probe whether and how such a relationship exists. Fish test records for Zn in ECOTOXicology database (ECOTOX) were retrieved but only those were retained reporting both the life stage and weight of the organism, and the calcium (Ca^{2+}) concentration of the test solution. Finally a total of 258 data were extracted for adult fish tests with duration varying from 3.6 h to over 1000 h. The data exhibited a significant correlation between test fish wet weights and median lethal concentrations (LC50). The correlation coefficient was -0.23 ($p=2\times10^{-4}$) when all 258 data were used. When limiting the test duration no more than 120 h, the remaining 212 data exhibited a slightly weaker correlation with the correlation coefficient being -0.18 but still statistically significant (p=0.01). A Biotic Ligand Toxicity Model (BLM-TOX) was proposed to model the toxicological effect of Zn, accounting for the competition of Ca^{2+} and Zn^{2+} at gill uptake, and elimination or accumulative detoxification of Zn^{2+}. The BLM-TOX included three fundamental parameters, No Effect Concentration (NEC), Killing Rate (K_+), Eliminating and Accumulating Rate (K_{ga}). Nonetheless, the K_{ga} was further resolved into two parameters, the Maximum Eliminating and Accumulation Rate ($K_{ga,max}$) and a Compensatory Response Time (Beta). Under the BLM-TOX modeling scheme, three of the BLM-TOX parameters, NEC, K_+, $K_{ga,max}$ were considered possibly to be modulated by fish weight through certain linear models. With AIC as the model selector, the best BLM-TOX model was obtained: NEC=0,Beta=190.97 (1/h), K_+=0.12*log(W) (hl/mg), $K_{ga,max}$=47.08*log(W) (1/h) for the 258 dataset; NEC=0,Beta=15.48*log(W)+204.78 (1/h), K_+=0.076*log(W)+0.67 (hl/mg), $K_{ga,max}$=99.92*log(W)+12.65 (1/h) for the 212 dataset. The selected model seemed fitting the observed lethal concentrations (LCs) reasonably well, confirming the influence of test fish weight on the ecotoxicity. Such a step exploring the influence of test fish weight on ecotoxicity is expected to benefit the ecological risk assessment after further refinement and demonstration.

TP112 Development of a Draft Selenium Ambient Water Quality Criteria for the Protection of Aquatic-Dependent Wildlife

A. Jarvis, J.R. Beaman, K. Gallagher, USEPA / Office of Water

Selenium is found in aquatic ecosystems from the mining of metal ores and phosphates, fly ash from coal-fired power plants, and from leaching of agricultural soils (Presser et al. 2004). At low concentrations, selenium is an essential nutrient. However, selenium slightly above beneficial concentrations can be toxic for wildlife (Ohlendorf 2003). The bioaccumulation of selenium through the aquatic food web can place predatory organisms at risk. Avian species appear to be particularly sensitive to selenium exposure. Population level effects, such as malformations and reproductive impairments, have been observed at environmentally relevant concentrations in aquatic-dependent avian species (Ohlendorf et al. 1986; Hoffman et al. 1988). Therefore, to ensure that aquatic-dependent avian species are protected from exposure to selenium, USEPA is undertaking the task to develop a selenium criterion with the use of the latest scientific literature. The USEPA plans to derive a bird tissue criterion value by assessing food chain bioaccumulation with the use of updated models. Once finalized, this selenium criterion may be used by states and tribes as the basis for adopting water quality standards to protect aquatic-dependent wildlife.

TP113 Effect of pH and hardness on the toxicity of zinc, copper, cadmium, and Nickel to the freshwater diatom Navicula pelliculosa

T. Nagai, National Inst for Agro-Environmental Sciences

Metal effects on algal growth for species other than green algae have not often been investigated. Also, it has been widely known that metal toxicity is highly depending on water chemistry such as pH, hardness, and dissolved organic matter. Here, we investigated the effect of pH and hardness on the toxicity of zinc, copper, cadmium, and nickel to the freshwater diatom, Navicula pelliculosa. The values of pH and hardness of basic medium (modified OECD medium) were 7.0 and 47 mg/L (Ca:Mg ratio is almost 1:1 as molar concentration), respectively. The values of pH were varied to 4 different level: 7.0, 7.4, 7.8, and 8.2 (buffered by MOPS). Hardness were varied to 4 different concentration: 47, 77, 107, and 137 mg/L. Each toxicity test was conducted using 96-well microplates for 72 h, and the algal growth was monitored using a fluorescence microplate reader. Free ion activities in test solutions were calculated using chemical equilibrium speciation software WHAM6. The values of EC10 and

EC50 were determined by concentration-response analysis based on free ion activity. Effects of pH on the toxicity were substantial for copper and not so substantial for zinc, cadmium, and nickel. Effects of hardness on the toxicity were substantial for zinc and nickel and not so substantial for copper and cadmium. The metal bioavailability models were developed using above toxicity data. The model was based on independent effects among pH and hardness according to Deleebeeck et al. (2008, Sci Tot Environ 407, 1901). Model parameters were determined using above toxicity data. Comparisons between experimentally obtained and predicted EC50 and EC10 values showed fairly well agreement (almost all errors were within 2-factors).

TP114 Effects of dietary methylmercury on the dopaminergic system in adult fathead minnows and their offspring

K. Bridges, UNT / Dept of Biology Inst of Applied Science; B.J. Venables, T. Curran, Univ of North Texas / Biology; A.P. Roberts, Univ of North Texas / Dept of Biological Sciences Inst of Applied Science

Mercury (Hg) is a potent neurotoxin which can be globally transported once released into the atmosphere, contaminating even the most pristine aquatic ecosystems. Once deposition occurs, bacteria in the sediment can transform it into methylmercury (MeHg), an organic form capable of bioaccumulation and biomagnification in food webs. As a result, long-lived organisms at the top of the food web are at risk of exposure to MeHg through their diet, which can then be actively transferred from mother to offspring. Exposure during neurodevelopment can lead to serious, irreversible neurological dysfunction, associated with a variety of cognitive and motor abnormalities across species. At even low dietary concentrations associated with regular fish consumptions, exposure can lead to deficits in attention, and hyperactivity. Due to the abundance of confounding variables in human exposure studies, investigations using model organisms which focus on highly conserved biological systems are useful in revealing mechanisms of neurotoxicity. The present study uses one such model organism, Pimephales promelas, to propose a mechanism by which MeHg in the maternal diet may lead to hyperactive behaviors in offspring, and neurochemical changes in adult brain regions. Adult fatheads were exposed to a control diet (0.02 ppm Hg dry weight) or a low diet (0.72 ppm Hg dry weight) for 30 days. Adult brain tissue and embryos from each treatment were collected and analyzed for total Hg, dopamine (DA) concentrations, and monoamine oxidase (MAO) activity. Embryos from treated tanks displayed hyperactivity when compared with controls, as well as significant changes in DA concentrations, seen also in the telencephalon of adult brains. Exposure to MeHg also corresponded with a significant decrease in MAO activity in both eggs and brain tissue. These results suggest alterations to this highly conserved, and tightly regulated neurochemical pathway, due to Hg exposure, may lead to hyperactivity in offspring. Newly hatched larvae were also analyzed for differences in metabolites resulting from exposure to maternally transferred MeHg. Significant changes in abundances of metabolites associated with nervous system injury, and fatty acid metabolism were indicated. Collectively, these results suggest that current environmental exposure scenarios may have negative implications for development and survival of fish exposed to maternally transferred MeHg.

TP115 Effects of embryonic arsenic exposure on killifish's (Fundulus heteroclitus) behavior and nutrient uptake and availability

K. Sims, Clemson Univ ENTOX; L.J. Bain, Clemson Univ / Biological Sciences

Arsenic is found as a contaminant of drinking water, rice, and other crops. Epidemiological studies have shown that embryonic exposure to arsenic can cause changes in behavior and reductions in growth, but the mechanisms for these effects are not well understood. Thus, killifish were exposed to 0, 50, 200, and 800ppb arsenic as embryos, and after hatching, were reared in clean water for up to 78 weeks. Growth, assessed by condition factor, was significantly reduced in the 200 & 800ppb groups by 17-29%. The reduction in growth was correlated to changes in IGF1 and IGF1R transcript levels. Behavioral changes were also noticed during the grow-out period, including reduced response to food and huddling at the bottom. So, two different odorants were used to assess responses. No changes were seen with taurocholic acid, a bile salt that elicits a social response. However, introduction of an amino acid mixture, which initiates a feeding response, significantly reduced both the duration of response by 50%, and percent of fish responding by 42%. We hypothesize that embryonic exposure to arsenic impairs the fish's ability to sense odorants, leading to a reduction in weight, which is potentially caused by changes in IGF1 signaling pathways and/or reduced uptake of nutrients. Discoveries from this study can help raise awareness of the implications arsenic exposure can have on a growing fetus and potentially lead to more stringent regulations on the amount of arsenic allowed in food and water sources.

TP116 Evaluating the fate and effects of selenium in lab-cultured and field-collected biofilms

C. Rickwood, Natural Resources Canada; P. Huntsman-Mapila, Natural Resources Canada / Natural Resources Canada; C. Greer, National Research Council of Canada

A weight of evidence approach has been employed to better understand the biological, chemical and physical influences affecting selenium (Se) fate and effects in biofilms. Biofilms were cultured in-house over a period of 4 months under continual exposure to Se and compared to field-collected biofilms from an area known to have elevated Se in sediments. The techniques used included mini-peepers, Diffusive Gradients in Thin films (DGTs), mineralogical characterization, sequential extractions and microbial assessments to understand the various influences affecting Se fate. In addition, a number of exposure assessments were conducted with surface sediments (field) and biofilms (lab) to evaluate the trophic-transfer of Se to the benthic invertebrate Chironomus dilutus. The results from this study provide a better understanding behind the bioaccumulation of Se in biofilms, its potential effects on biofilm communities and the drivers behind Se mobilization.

TP117 Expression of metallothionein cDNA as a biomarker of environmental pollution in the wild mussel Mytella guyanensis in the Gulf of Guayaquil, Ecuador

A. Tirape Bajaña, ESPOL / Facultad de Ciencias de la Vida; P. Calle Delgado, O. Alvarado, Escuela Superior Politecnica del Litoral / Facultad de Ciencias de la Vida; J. Alava, Inst for the Oceans and Fisheries, Univ of British Columbia / School of Resource and Environmental Management

The potential use of a biomarker (metallothionein) in the digestive gland of wild mussels (Mytella sp.) for ecotoxicological assessment and biomonitoring of environmental pollution in the Guayaquil Gulf Estuary (Ecuador) was investigated. The synthesis of metallothionein is a specific response to elevated concentrations of inorganic pollutants. Metallothionein is a cytosolic protein found in a variety of tissues, playing an important role in the detoxification of metals and as a biomarker of exposure to heavy metal contamination. The objective of this study is to observe the methallothionein expression in this wild mussels species exposed to contaminated mercury sites. Two locations from Gulf of Guayaquil: Reserva de Producción Faunística Manglares El Salado (RPFMS) and Reserva Ecológica Manglares Churute (REMCH) were selected. While the RPFMS is extensively affected by anthropogenic pollution (urban-industrial development, agricultural monoculture and more recently shrimp pond aquaculture) with an average sediment total mercury concentration of 1.027 mg/kg dw. The REMCH is considered as a reference semi-pristine area exhibiting an average sediment total mercury concentration of 0.05 mg/kg dw. The average concentration in mussels collected at the RPFMS was 3.480 mg/kgdw, which exceeds the wet threshold (0.5 mg/kg) safety value used by many countries. The relative expression of metallothionein gene in mussels exposed to contaminated sites was detected for 100 copies of the housekeeping gene (Mitella sp.-β-actina) by qPCR. The results of this preliminary study suggest that toxicological gene expression of metallothionein may be a candidate biomarker and a tool for further biomonitoring mussel exposure to environmental inorganic pollutants in this tropical region.

TP118 Freshwater bivalve shells reveal the behavior of trace element concentrations in space and time

W.A. Shoults-Wilson, Illinois Wesleyan Univ / Biological Chemical and Physical Sciences; A. Fritts, Illinois Natural History Survey; J. Unrine, Univ of Kentucky / Plant and Soil Sciences; M. Fritts, A. Casper, Illinois Natural History Survey

Trace elements pose a challenge to our ability to understand their distribution in that they occur naturally. Trace elements may accumulate in a system due to geological and chemical factors other than pollution, or through indirect effects caused by human activities such as land use changes. In order to fully understand these effects, data sets across a large temporal and spatial range are required, however most modern pollution monitoring programs were only instituted in the 1970s or later. In this study, mussel shells from prehistoric, historic and modern collections were analyzed as proxies of trace metal accumulation in the Illinois River system. Shells were found to have almost no variation between species collected at the same site. Prehistoric shells consistently accumulated higher concentrations of Mn and Zn, but lower concentrations of As, Co, Cu and Ni. The elements Cd, Co, Cu and Ni were found to have increased over the past 120 years, while Mn decreased. One potentially confounding factor was that older populations of shells were significantly older and larger than larger collections. However, allometric relationships were not consistently significant and had little effect on temporal trends. In contrast, allometric relationships had a large effect on analysis of the spatial gradient along the Illinois River mainstem due to strong allometric effects at the uppermost and lowermost sites. Overall, modern shells indicated higher downstream concentrations of As, Co, Mn and Ni. Elements that varied spatially in no direction was Co, Cu, Ni and Zn. Large scales in the watershed and bivalve populations have clearly occurred over time. These changes are clearly expressed in the concentrations of elements such as Mn, which accumulates in higher concentrations in older shells. Other elements show clear elevation over a prehistoric baseline and vary in time and space, such as As, Co, Cu and Ni. Finally, another set of elements appears to be extremely conservative with little temporal or spatial differences. This set includes Fe and Cd, which while commonly associated with pollution appears in shells at extremely consistent concentrations. This study can serve as a model for future investigations into trace metal concentrations in bivalve shells and works towards a greater understanding of the manner in which they vary in both space and time.

TP119 Hepatic metal-binding complexes in cytosolic and mitochondrial fractions of field-collected eels (Anguilla rostrata) as determined by SEC-ICPMS

M. Rosabal, Université de Québec à Montreal / Departement des sciences biologiques; A. Caron, P. Couture, L. Hare, Université du Québec, INRS / Centre Eau Terre Environnement; P. Campbell, Université du Québec, INRS / INRS Eau Terre Environnement

American eel (Anguilla rostrata) populations inhabiting the Saint-Lawrence River (Canada) have severely declined over the last 30 years. Metal contamination, among other factors, may have contributed to this downward trend. In this context, measurements of subcellular metal-partitioning have revealed that although this species can detoxify metals (e.g., binding of metals to thermostable cytosolic proteins, metal incorporation into granule-like structures), indications of potential metal-induced toxicity were observed. Inappropriate binding of some metals to physiologically-sensitive target molecules (e.g., cytosolic enzymes) and organelles (e.g., mitochondria) can occur even in fish having low metal concentrations. To determine the molecular entities involved either in metal the detoxification response or targeted by these contaminants, we applied a hyphenated fractionation approach, based on size-exclusion chromatography coupled to inductively-coupled plasma mass spectrometry (SEC-ICPMS), to the cytosolic and mitochondrial fractions, where high metal concentrations were reported in livers of A. rostrata. In the whole liver cytosol, cadmium-containing complexes were found in the medium molecular-weight pool (MMW: 33 kDa – “1.3” kDa), where metallothionein-like proteins or peptides (MTLPs) are expected to appear. In contrast, thallium was consistently associated with low molecular ligands (LMW: < “1.3” kDa). The mitochondrial fraction was lysed with Triton 1% and centrifuged to remove the mitochondrial membranes. In the mitochondrial matrix, cadmium was also bound mainly to ligands of MMW (~9.5 kDa), suggesting the occurrence of MTLP ligands within the mitochondria. In contrast, Tl in the mitochondrial matrix was bound to ligands of both high molecular weight (HMW: > 620 kDa – 33 kDa) and LMW. These results provide important insights into the intracellular trafficking of metals in aquatic organisms chronically exposed to non-essential metals.

TP120 How long does it take for selenium to bioaccumulate in the diet and tissues of sturgeon?

W. Beckon, US Fish and Wildlife Services / Division of Environmental Contaminants

In trying to answer the question “how much is too much” with respect to selenium in the San Francisco Bay-Delta, attention rightly has been focused on the introduced Asian overbite clam that bioaccumulates selenium especially efficiently, and on the vulnerable sturgeon species that feed on this clam. In the Bay-Delta environment of fluctuating selenium and migrating sturgeon, to assess the risks of selenium to sensitive life stages of sturgeon, it is essential to understand the time delay between exposure to selenium in ambient water, and bioaccumulation of selenium in the tissues of the sturgeon species. Hitherto, estimating these lag times has been a matter of guesswork. Now, a statistical method has been demonstrated that enables us to provide more objective estimates. The method was developed using selenium monitoring data from the Grassland Bypass Project in the Kesterson area of the San Joaquin valley. The method can be used to infer estimated selenium bioaccumulation lag times of roughly 50-120 days for overbite clams, 178 days for white sturgeon, and 247 days for green sturgeon. Reliability of these estimates will be discussed along with implications for risk of selenium to sturgeon species.

TP121 Identifying Metabolomic and Transcriptomic Impacts of Heavy Metals in Zebrafish (Danio rerio)

S.S. Huang, SGS AXYS / Metabolomics; J. Benskin, Stockholm Univ / Environmental Science and Analytical Chemistry; N. Veldhoen, Univ of Victoria / Biochemistry and Microbiology; B. Chandramouli, SGS AXYS; H. Butler, SGS AXYS / Metabolomics; C.C. Helbing, Univ of Victoria / Dept of Biochemistry Microbiology; J. Cosgrove, SGS AXYS

Teleosts are valuable sentinel organisms for the aquatic environment as well as human health as they share a high degree of similarity in metabolic and physiological features with other vertebrates. As early life stages in fish have a reduced capacity to metabolize xenobiotics compared with that of mammals, embryonic or larval windows can be a sensitive toxicological model, particularly in addressing adverse effects of low-level chemical exposure. Compared with morphological assays, changes in mRNAs, proteins, and/or metabolite levels are sensitive and potential early indicators of systemic effects. As endogenous metabolite concentrations are determined by the organism’s biochemical processes, metabolomics is regarded as a comprehensive evaluation of biological response. Similarly, transcript levels can shed light on the transcriptional processes in the animal. In the present study, we evaluated the biological impacts of zebrafish larvae (Danio rerio) acutely exposed to environmentally relevant concentrations of heavy metals including, Cd, Cu, MeHg, and $AgNO_3$ using both metabolomics and transcriptomics. Quantitative measurements of 209 metabolites including amino acids, biogenic amines, glycerophospholipids, acylcarnitines, sphingolipids, fatty acids, bile acids, and ∑hexose from whole animals were performed by LC-/FI-MS/MS. Metabolomic profiles were distinguishable among chemicals. A strong concentration effect was observed in Cd and Cu exposed animals, where a general reduction in amino acids as well as docosahexaenoic acid was observed. In contrast, glycerophospholipids, sphingolipids, and ∑hexose, as well as GABA concentrations were significantly impacted in the $AgNO_3$ exposed animals but without a clear chemical concentration effect. Metabolite enrichment analysis in Cu and Cd exposed animals revealed affected pathways invovled in anti-oxidation protection such as selenoamino acid metabolism and glutathione synthesis, and in neuromodulation such as catecholamine biosynthesis. In addition, quantitative real-time PCR based transcriptomic analysis targeting 39 genes transcript presenting important developmental biomarkers will be performed. This combined method will provide the critical molecular level information needed to facilitate a systems biology approach in characterizing and evaluating potential biological impacts of heavy metal exposure in a teleost model.

TP122 Maternal transfer of metals in Steller sea lions (Eumetopias jubatus) from the Washington State coast

J. Aitken, Brooks Applied Labs / Speciation Group; E. Madonick, R. Gerads, Brooks Applied Labs / Business Development; A. Carter, Brooks Applied Labs; D. Lambourn, Washington Dept of Fish and Wildlife / Marine Mammal Investigations

Steller sea lion (Eumatopias jubatas) habitat extends throughout the perimeter of the Northern Pacific Ocean and is divided at 144ºW longitude. This species is distributed throughout Japan and Russia (the Eastern population) to the Aleutian Islands and California (the Western population). The population reduction in the Western stock and the population increase in the Eastern stock have been the basis of studies investigating intentional killing and entanglement, climate and dietary changes, disease, and contaminants as possible causes of this divergent pattern. Previous studies have evaluated metals concentrations in organ tissues that may cause neurological and other deleterious effects in Steller sea lion adults. Few studies have focused on the gestational transfer of metals between mothers and fetuses. Many metals are required for nutrition at low levels, and thus play a complex role in the metabolic processes of organisms. Due to maternal offloading, fetuses may endure more pronounced and problematic effects as a result of rapid biochemical integration of toxic contaminants during development. In the present study, metals concentrations were quantified in organs of four mother-fetus pairs located off of the Washington state coast to evaluate gestational transfer in the species. Samples were collected by the Washington Department of Fish and Wildlife – Marine Mammal Investigations Unit from deceased mammals by field researchers investigating other aspects of their life history. Comparisons of the mother's body mass and trace metal concentrations in her tissues will be evaluated. Further comparisons will be applied to her fetus. Metals of interest in this study include mercury, selenium, cadmium, and lead. To the best of our knowledge, this investigation will be the first to incorporate these metals in this context and will continue to expand on our knowledge of how metals are metabolized in Steller sea lions.

TP123 Metabolic and cardiovascular effects of dietary selenomethionine exposure in adult zebrafish (Danio rerio)

C. Pettem, Univ of Saskatchewan – Toxicology Centre / Toxicology; D.M. Janz, Univ of Saskatchewan / Toxicology Centre; L.P. Weber, Univ of Saskatchewan / Veterinary Biomedical Sciences

Selenium (Se) is an essential micronutrient involved in important metabolic functions for all vertebrate species. As Se is reported to have a narrow margin between deficiency and toxicity, there is growing concern surrounding the adverse effects of elevated Se exposure caused by anthropogenic activities. Oviparous vertebrate species, especially fish, are highly susceptible to elevated dietary Se exposure. Recent studies have reported that elevated dietary exposure of fish to selenomethionine (Se-Met), the primary form of Se in the diet, can alter metabolic capacity, energy homeostasis, swimming performance and cause a greater incidence of early life stage deformities and mortality. This study aims to further investigate mechanisms of Se-Met toxicity, particularly potential underlying cardiovascular implications of chronic exposure to environmentally relevant concentrations of dietary Se-Met in adult zebrafish (Danio rerio). Adult zebrafish were fed either control food or Se-Met spiked food (10.27 or 28.81µg Se/g, dry weight) for 90 days at 5% body weight per day. Following exposure, high resolution B-mode and Doppler ultrasound was used to characterize cardiac and vascular function. Chronic dietary exposure to Se-Met caused significant decreases in blood velocity through the atrioventricular (AV) valve, reduced stroke volume and cardiac output, and impaired ventricular diastolic filling. These effects may lead to further cardiovascular complications. Metabolic endpoints investigated included muscle glycogen and triglyceride stores, and fish fed with Se-Met spiked food had elevated energy stores, suggesting impaired energy homeostasis and metabolic dysfunction. Expression of mRNA genes of interest was quantified by use of Real-Time Quantitative Polymerase Chain Reaction (qRT-PCR) and current findings are being examined. The results of this study suggest that chronic exposure to dietary Se-Met can alter both cellular and physiological responses, and such consequences could threaten fitness and survivability of fish.

TP124 Metal-induced olfactory sensory neuron death and regeneration in zebrafish

E.Y. Ma, Univ of Washington / Dept of Biology; K. Heffern, Univ of Washington / Environmental and Occupational Health Sciences; E. Gallagher, Univ of Washington

Fish rely heavily on olfaction to maintain behaviors essential for survival, including predator detection and avoidance, prey selection, social behavior, imprinting, and homing. Environmental exposures to the metal ions copper (Cu) and cadmium (Cd) are known to cause olfactory toxicity with differential effects in olfactory neuron susceptibility and regeneration. In this study, zebrafish (Danio rerio) are used as a model system to study olfactory death and regeneration in teleosts. Confocal imaging in double-transgenic zebrafish larvae that differentially label ciliated and microvillous olfactory sensory neurons (OSNs) is used to image and analyze OSN changes following metal induced death and recovery. Following a 24-hour exposure to Cu at 5 days postfertilization, both ciliated and microvillous OSN populations exhibited cell injury and death in a dose-dependent manner. Recovery and regeneration of these OSN populations was observed at 24 and 48 hours after exposure. Cell proliferation assays using BrdU incorporation showed increased cell division following Cu-induced OSN death. Exposure to Cd also resulted in visible ORN death, albeit at higher concentrations relative to Cu exposures. Regeneration of OSNs was also observed 24 hours after Cd exposure. Assays for olfactory-driven behaviors were used to correlate the morphological changes observed through confocal imaging with behavioral endpoints. Our studies support the use of transgenic zebrafish to understand the mechanisms of olfactory injury and recovery that can occur in teleosts exposed to metals. Supported by NIEHS Superfund P42-04696.

TP125 Observed lower tissue residues of metals in Japanese dace collected from a metal contaminated river

Y. Iwasaki, Toyo Univ / Research Center for Life and Environmental Sciences; S. Furui, H. Tomiyama, D. Kitamura, Toyo Univ / Dept of Life Sciences; H. Tatsuta, Univ of the Ryukyus / Faculty of Agriculture; S. Kashiwada, Toyo Univ / Research Center for Life and Environmental Sciences

Heavy metal contamination is a major concern in freshwater environments. Accumulation (tissue residues) of metals in aquatic species has been well studied to evaluate the levels of the pollution and/or of the exposure of the studies organisms. The Watarase River, running in the northern Kanto region of Japan, had been severely polluted by heavy metals discharged from mining activities. Although the remarkable decrease in concentrations of metals including copper and zinc were observed, e.g., in 1960s, the concentrations notably in the upstream region are still higher than those in a reference river, the Omoi River. In the present study, toward understanding the biological responses of aquatic species to the current contamination, the metal accumulation (Cu, Zn, As, Pb, Cd, Fe) in muscle, liver, and gonad of Japanese dace, Tribolodon hakonensis (Cyprinidae) collected from two mid-stream sites in the Watarase and Omoi rivers, as well as those water and sediment concentrations, were investigated. Water and sediment concentrations at the site in the Watatase River were generally higher than those in the Omoi River. In contrast, interestingly, this trend was not necessarily observed for the metal accumulation in organs of Japanese dace. For instance, the amount of metals accumulated in liver of the dace in the Watarase River was often smaller. We will present detailed results on the metal accumulation and population genetic structure inferred from microsatellite genotyping, and discuss important implications for performing metal accumulation and toxicity studies.

TP126 Persistent lead contamination in an urban marsh: The legacy of lead shot

T.C. King-Heiden, Univ of Wisconsin – La Crosse / Biology; C. Belby, G. Gerrish, Univ of Wisconsin La Crosse

The La Crosse River Marsh (LRM) is a unique urban riparian marsh recognized for its high biodiversity in an urban setting. The La Crosse Gun Club operated a large trap shooting range at the LRM between 1932-1963, resulting in significant quantities of lead (Pb) shot being discharged into the marsh. Pb-contamination remains high as we have found Pb shot densities of >43,000 pellets/m^2, and surface sediments contain as high as 23,000 ppb Pb in some areas of the marsh. Using a combination of field and laboratory studies, we used a multi-disciplinary approach to survey and assess the impacts these contaminated sediments have on the marsh ecosystem. Water in the marsh contained concentrations within the range of concern for chronic toxicity. Pb from contaminated sediments is bioavailable, and Pb levels within duckweed, invertebrates, and some fish species correlate with the Pb found within sediments. Our laboratory toxicity assays suggest that sediments are minimally toxic to developing fish following acute exposure. Since the lead is not mobilizing system wide, we suggest any remediation efforts be focused in specific areas of high concentrations of the LRM, and that continued monitoring of the marsh is warranted.

TP127 Polymetal mixture from mining pollution alters functional traits and metabolomic profiles of freshwater clams (Musculium spp.)

J. Joyner-Matos, C. Brown, J. DeWitt, C. Higbee, W. Stevens, K. Magori, Eastern Washington Univ / Biology; C. Nezat, Eastern Washington Univ / Geology

A century of mining activity in the Coeur d'Alene, ID (CDA) region discharged an estimated 56 million metric tons of tailings into the CDA drainage. We are exploring whether freshwater clams (Musculium spp.) could serve as sentinels for the drainage. We collected clams (N=147) from an unimpacted site and exposed them (40 d) to water in equilibrium with lake sediment from the CDA drainage, with uncontaminated sand (control) or with a 50% sediment/sand mixture. Water in equilibrium with the 100% sediment treatment had 32 µg/L Cd, 411 µg/L Pb and 2,561 µg/L Zn. Functional traits were measured weekly and metabolomic samples collected at 24h, 48h, 72h, and weekly. Clams exposed to 100% sediment had the lowest survival ($p \leq 0.001$) and climbing ($p < 0.002$), maintained the largest brood sizes ($p = 0.002$) and extruded the fewest juveniles ($p < 0.05$). Of the functional traits, only juvenile extrusion followed a dose response pattern. We quantified 139 metabolites in a total of 35 samples from the control and 100% sediment treatments. Cystathionine and hydroxyproline tended to be lower in clams from the control conditions. Uridine, asparagine, aspartic acid, and 2-aminoadipate tended to be lower in sediment-exposed clams. These results indicate that metal exposure decreases clam activity, reproduction and survival and affects amino acid metabolism. A combination of functional traits and select metabolites may be effective biomarkers for metal exposure in these clams.

TP128 Responses of Calcifying Organisms to Ocean Acidification and Copper Exposure

G.K. Bielmyer-Fraser, Jacksonville Univ / Chemistry; P. Patel, Valdosta State Univ / Biology; M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology

Ocean acidification and land-based sources of pollution have both been linked to widespread declines of coral cover in coastal reef ecosystems. At the current rate of change, atmospheric CO_2 levels are predicted to increase to 1000 ppm by the end of this century. Though much attention has been focused on ocean acidification and to some extent metal pollution, only limited research has addressed combined exposure of both pollutants to coral reef organisms. In this study, two coral species, Acropora cervicornis and Pocillopora damicornis, and the sea urchin, Strongylocentrotus droebachiensis were exposed to two copper concentrations at two CO_2 levels (ambient and 1000 ppm) for 96 h. Cu accumulation and activities of the enzymes catalase, glutathione peroxidase, glutathione reductase, and carbonic anhydrase were measured. The results provide insight into mechanisms of both Cu and CO_2 toxicity to coral reef organisms and have implications for environmental exposure of multiple contaminants.

TP129 The effect of hydropeaking on energy stores and mercury concentrations in shoreline dwelling spottail shiner (Notropis hudsonius)

D. Green, Univ of Saskatchewan – Toxicology Centre / Toxicology; T. Jardine, Univ of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; D.M. Janz, Univ of Saskatchewan / Toxicology Centre

Hydroelectric reservoir construction induces chemical and physical changes that can affect downstream ecosystems. Methylmercury produced in reservoirs rapidly bioaccumulates in reservoir-impounded and downstream foodwebs, as evidenced by significant post-dam declines (1970 to 2013) in Hg concentrations ([Hg]) of commercial fishes (pike, walleye, sauger, and goldeye) from the Tobin Lake Reservoir and a downstream fishery. Further analyses reveal significantly delayed [Hg] decline from downstream walleye and goldeye populations relative to those in the reservoir ($p < 0.001$) despite low contemporary [Hg] in water. These latter effects could be related to stress imparted by daily dam-induced water fluctuations. Fish kills and strandings observed on low-pitched shorelines below the dam suggest that the irregular and highly variable shoreline manipulations imposed below this peaking hydro-electric facility may act as a chronic physical stressor, causing increased retention of [Hg] in downstream fish. Analyses of triglyceride and Hg concentrations in young of the year spottail shiner (Notropis hudsonius) collected from affected habitats reveal reduced energy accumulation in young of the year fishes ($p < 0.05$) and relatively greater [Hg] ($p < 0.05$) compared to upstream counterparts, suggesting that hydro-electric facilities may induce an energetic bottleneck that exacerbates [Hg] in downstream fishes. Analyses of glycogen depletion and cortisol induction in response to an acute physical stressor are currently underway to determine whether fish from affected habitats exhibit physiological signs of chronic stress.

TP130 The kinetics of selenium accumulation in laboratory algal cultures and implications for extrapolation to the field

A.M. deBruyn, J.L. Van Geest, Golder Associates Ltd; J.R. Elphick, B. Lo, Nautilus Environmental; C. Eickhoff, Nautilus Envirnomental / Ecotoxicology

Selenium accumulation in algae varies with many factors, including selenium species, algal species, and aqueous selenium and sulphate concentrations. Large differences in accumulation have also been observed between laboratory cultures and natural algal assemblages in the field. We used a kinetic analysis to explore how these factors could explain observed variability in bioaccumulation datasets. We measured selenium accumulation in the green alga Pseudokirchneriella subcapitata at a range of selenium and sulphate concentrations and modelled the effect of water chemistry on the uptake rate constant. We also measured algal growth and calculated the contribution of growth dilution to total elimination rate. We combined these data with published data on selenium uptake kinetics in other algal species and with field data characterizing selenium accumulation in natural algal assemblages. Our analysis suggests that growth can explain differences in selenium accumulation between lab and field, and could account for much of the observed variability in field data. The effect of sulphate, mediated by selenium:sulphate ratios and selenium speciation, may account for regional and habitat-related differences in bioaccumulation.

TP131 Trophic transfer of three-layered silver nanoparticles (Ag@gold@Ag) from the diatom Nitzschia palea to the snail Lymnaea stagnalis

D.E. Ponton, Univ of South Carolina / Center for Environmental NanoScience and Risk; S. Pourhoseini, R. Merrifield, Univ of South Carolina / Arnold School of Public Health; M.N. Croteau, USGS; J. Lead, Univ of South Carolina / Arnold School of Public Health; S.N. Luoma, Univ of California, Davis / John Muir Inst of the Environment

For silver nanoparticle (Ag NP) exposures, the role of the ions and particles in Ag bioaccumulation and toxicity has not been fully elucidated, with many reported studies suggesting that only Ag ions are taken up. Furthermore, very little is known about the influence of ions and particles for dietary uptake. Here we use an innovative tool, i.e., a three layered core-shell-shell Ag NPs (Ag@Au@Ag) to address the particle versus ion uptake question in feeding experiments with a freshwater invertebrate grazer. The Ag core of the NPs was prevented from dissolution by a gold (Au) layer, while the outer Ag layer coated with polyvinylpyrrolidone (PVP) could dissolve. Specifically, we exposed the pond snail Lymnaea stagnalis to diatoms mixed with increasing concentrations of Ag@Au@Ag NPs and measured Ag and Au uptake rates in the snail's soft tissues. Mass balance calculations of the Ag and Au allowed inferring food ingestion rates and assimilation efficiencies, which were used to estimate bioavailability. Comparisons of Ag/Au ratios in water, diatoms, snail's soft tissues and feces allowed determining whether Ag@Au@Ag NPs, Ag ions and/or Au are absorbed by the snails. Results so far suggest that nanosilver exposure from food might trigger important risks. Three layered core-shell-shell Ag NPs are novel tools to help understand these risks.

TP132 Use of Benthic Macroinvertebrate Field Collected Data in the Derivation of Site-Specific Standards for Iron in Circumneutral Waters

S. Skigen, R. Gensemer, GEI Consultants / Ecological Division; S.P. Canton, GEI Consultants, Inc. / Ecological Division

The field-based portion of this study was initiated in 2014. The purpose was to evaluate whether the existing concentrations of iron present in select, non-acid mine drainage stream segments in northwestern Colorado, even if they exceed the Table Value Standard of 1 mg Fe/L on the basis of total recoverable metal, are likely to pose a risk to aquatic organisms. Since 2014, on an annual basis, GEI has been collecting benthic macroinvertebrate samples from 17 – 25 sites concurrent with extensive water chemistry data in order to assess the health of aquatic communities and characterize the associated water chemistry profile. Additionally, a measurement of the potentially dissolved fraction and a sample collected using a 10 µm capsule filter has been analyzed to explore the use of alternative analytical methods. Sites selected consisted of locations characterized by high iron conditions matched with appropriate reference locations containing low iron, but similar habitat, flow, and total suspended solids concentrations. In order to properly partition the factors influencing the structure of the macroinvertebrate community, sites were targeted which worked to evaluate multiple variables including both disturbed and undisturbed locations within these watersheds, as well as segments with ephemeral and intermittent flow regimes. Based on data analyzed to-date we expect that a biologically relevant standard can be developed based on iron concentrations that are not associated with adverse impacts on benthic community structure when compared to nearby reference sites – potentially resulting in something akin to an ambient-based standard. Study objectives, design, and initial data evaluation will be presented.

TP133 Analysis of Se in pectoral fin rays of white sturgeon (Acipenser transmontanus) from San Francisco Bay as a non-lethal assessment technique

V. Palace, IISD-Experimental Lakes Area; L. Friedrich, Stantec Consulting Ltd.; J. Sun, San Francisco Estuary Inst; L.E. Peters, Stantec Consulting Ltd / Dept of Environment and Geography; P. Trowbridge, San Francisco Estuary Inst; Z. Jackson, US Fish and Wildlife Service; N. Halden, Univ of Manitoba; J. Hughes, USGS / Columbia Environmental Research Center

There is increasing pressure to develop alternative methods to assess the hazards posed by contaminants to wildlife while also reducing the number of lethal sampling events using wild animals. Opportunistic sampling was conducted to collect tissues from angler-harvested resident white sturgeon in San Francisco Bay, with the ultimate goal of developing a non-lethal method to assess exposure to inorganic contaminants. Specifically, this population of sturgeon is thought to be at risk to accumulate elevated concentrations of Selenium (Se) from their diet, which predominantly consists of overbite clams (Potamocorbula amurensis). Soft tissues (eg., muscle or egg/ovaries) are typically analyzed to determine Se exposure, but ongoing excretion, metabolism and tissue redistribution preclude resolving any temporal information from these analyses. Time resolved exposure can be determined using micro-chemical analysis of otoliths, but this requires lethal sampling. Pectoral fin rays also contain annual growth rings, but can be sampled non-lethally and require no special preservation for micro-chemical analysis. However, the relationship between trace elements in the bony matrix of otoliths and fin rays is not yet known. As part of a collaborative study, 27 and 22 adult white sturgeon were collected from San Francisco Bay in Feb 2015 and 2016, respectively. Selenium, as well as Zn, Sr, Hg, Pb and Ca (internal standard) were analyzed in annual growth zones of pectoral fin rays and otoliths from these fish using continuous LA-ICP-MS. Relationships between concentrations of Se in soft tissues (muscle and ovary), otoliths and pectoral fin rays will be presented. Fin rays may represent a relatively simple non-lethal tissue sample to establish temporal exposure to several elements in white sturgeon from San Francisco Bay.

TP134 Assessment of heavy metals concentration in fish tissues of selected fish species in Oguta Lake, Southeastern Nigeria

G.S. Adaka, Federal Univ of Technology / Dept of Fisheries and Technology; A. Nlewadim, Michael Okpara Univ of Agriculture, Umudike / Dept of Fisheries and Aquatic Resources Management

The study was carried out in Oguta Lake from January, 2012 to December, 2013 at five stations (Onu Utu, Okposha, Ogbe Hausa, Osemotor and Ede Ngwugwu) to study the concentration of heavy metals in fish tissues. The Lake is the largest natural freshwater lake in Imo State, Nigeria and originated from a natural depression. It is bounded between longitude 6° 41' – 6°50' East and latitude 5°41' – 5°44' North of the equator. Fish samples were collected twice per month using hook and line, gill net, cast net, bag net and local traps. A total of 1,989 fishes were used. The levels of heavy metals Copper (Cu), Lead (Pb), Cadmium (Cd), Arsenic (As) in three common edible fish species (Tilapia zillii, Citharinus citharus and Heterotis niloticus) were determined by air-acetylene flame Atomic Absorption Spectrophotometer after wet digestion of samples with 1:1 HNO_2, H_2O_2. The mean values of the heavy metals from the study shows; 0.67µg, 0.58µg, 0.64µg and 0.21µg for Cu, Pb, Cd, As respectively. The results obtained showed that the values of all the heavy metals in the fish samples were lower than the values recommended by WHO and the Food and Agricultural Organization of the United Nations and therefore safe for human consumption.

TP135 Bioaccumulation and trophic transfer dynamics of heavy metals in food web assemblage of intertidal mangrove ecosystem, Sungai Puloh, Malaysia

B. Udechukwu, A. ISMAIL, S.Z. ZULKIFLI, Universiti Putra Malaysia / Biology

In recent times, the ever increasing anthropogenic activities associated with industralization, population increase and urbanization in developing countries which leave chemical foot prints behind, pose risk to aquatic ecology. Among this chemical pollutants are heavymetals which are bioaccumulative, persistent, and toxic. this consequently impact aquatic organisms through bioaccumulation, trophic interactions, and dietary exposure. The aim of this research is to evaluate the heavy metals (Cu, Pb, Ni and Zn) and to assess their bioaccumulation patterns in surface sediment and some key ecological food chains in Sungai Puloh estuary. Also to characterize the trophic positions of samples: Periophthalmodon schloserri,Osteogeniosus militaris, Telescopium telescopium, Nerita lineata, Polymesoda coaxans,Penaus monodon,Uca annulipes, Dotilla myctiroides,and planktons in food web structure of Sungai Puloh. The direct aqua regia method was employed for metal estimation and metal concntrations (micro gram/g, dry weight)were determined by using an Air-acetelyne flame Atomic absorption flame Spectrophotometer, by Perkin- Elmer, and Isotope Ratio Mass spectrophotometer was used for stable isotopes ratio determination. The result revealed elevated Cu in P. mondon (47.19) and high levels of Pb (15.23, 16.86, 8.91) in catfish (O. militaris), U. annulipes, and D. myctiroides respectively. With the help of stable isotoe ratios of ^{13}C and ^{15}N analysis, two distinct food chains and four trophic positions were determined, with catfish occupying the highest trohic level. Using the catfish as a model for food web trophic system, the result showed that the carbon source for catfish (-17.30 per mill) is from the crabs (-17.39, -18.03) per mill for Ucan and Dotilla respectively with an enrichment of ^{13}C ratio values ~I per mill, complementing the idea that crab found in the stomach content is its staple food. It is arguable that the major source of Pb in catfish is from crabs and not from surface sediment since the biota sediment accumulation factor (BSAF: 0.2) recorded very low ration compared to that of the trophic tranfer factor (TTF:1.7). We concluded that heavy metal contamination in Sg. Puloh stems from the release of untreated or poorly / improperly treated effuluents into this mangrove ecosystem, and these metal contaminats are evidenced in the food chains of Sg. Puloh mangrove. The Pb in this study area pose some serious risk, and should be srictly monitored.

TP136 Determining Mercury Concentrations and Evaluating Two Biomarkers of Exposure in Two Popular Recreational Fishes in Hawaiian Waters

S.D. Shaw, B.A. Jensen, Hawaii Pacific Univ; C. Bryan, National Inst for Standards and Technology; K. Korsmeyer, Hawaii Pacific Univ

Mercury concentrations have been measured in Hawaiian commercial pelagic fishes and some bottomfish species, but have not been measured in many nearshore fish species targeted for recreation and food. Monitoring the commercial and local food fishes around the Hawaiian Islands is necessary to identify possible threats to the ocean environment and human health. Depending on the concentration and the chemical form, mercury exposure in fish can have lethal and sub-lethal effects including changes in behavior, reproduction, feeding, and tissue pathology. When assessing the risks of mercury exposure on aquatic ecosystems, molecular biomarkers are used to examine adverse effects. Metallothionein mRNA expression and protein levels increase in fish tissues through waterborne and dietary mercury exposure. Thioredoxin reductase mRNA expression levels have been shown to increase while protein activity was inhibited in fish tissues from waterborne mercury exposure. The purpose of this study was to measure mercury concentrations in two groups of nearshore fishes, trevallies, Caranx sp., and bonefishes, Albula virgata and Albula glossodonta, in order to provide baseline data for evaluating mercury exposure in these popular recreation fish. Trevally muscle and liver mercury concentrations ranged from 51.8 to 610.7 and 37.9 to 1501.2 ng/g wet mass, respectively. Bonefish muscle, liver and kidney mercury concentrations ranged from 93.3 to 937.8, 55.9 to 2390.4, and 92.4 to 5220.0 ng/g wet mass, respectively. In addition, thioredoxin reductase and metallothionein levels were measured as potential biomarkers of mercury exposure and initial assessment of fish physiological responses to mercury. Quantitative real-time PCR was used to measure mRNA expression levels and western blotting was used to measure protein levels to evaluate the potential use of these physiological responses as biomarkers of mercury exposure.

TP137 Embryonic-only arsenic exposure reduces growth and alters skeletal muscle development in killifish (Fundulus heteroclitus) one year later

D. Szymkowicz, Clemson Univ ENTOX / Environmental Toxicology; L.J. Bain, Clemson Univ / Biological Sciences

Arsenic is a contaminant of drinking water and crops in many parts of the world. Epidemiological studies have shown that arsenic has been linked to decreased birth weight, weight gain, and proper neuronal and skeletal muscle function. The goal of this study was to determine the effects of embryonic-only arsenic exposure on muscle growth and behavior in killifish up to one year after the exposure ends. Killifish embryos were exposed to 0, 50, 200 or 800ppb As^{III} from fertilization until hatching. Juvenile fish were reared in clean water and muscle samples were collected at 16, 28, 40 and 52 weeks of age. Feeding behavior was assessed at 28, 40 and 52 weeks of age. There were significant reductions in condition factors (CF) in the fish exposed to arsenic at 16 weeks (12-17%) and 28 weeks (12-15%). By 40 weeks, when the fish were able to be sexed, male fish had 13-15% reductions in CF at 40 weeks, while females had a 10-12% reduction at 52 weeks. Feeding behavior analysis showed quicker occupation of the top of tank in controls compared to arsenic-exposed fish, and consistently higher occupation of the bottom of the tank in the 200 and 800ppb fish. IGF-1 levels significantly correlate with condition factor in control fish, but this relationship dissipates as arsenic concentrations increased. Based on these results, arsenic is impairing growth and altering skeletal muscle development in killifish up to one year after an embryonic-only exposure. This could have implications in regards to arsenic exposure through maternal drinking water and fetal development.

TP138 Evaluation of the Effect of Cadmium (0.2mg/l) on Catfish (Claria garaiepinus)

M. Agboola, Dept of chemistry, Univ of Lagos / Chemistry

This study was designed to examine the effect of cadmium and Hibiscus sabdariffa calyx extract on cat fish (Clarias gariepinus). In this research work, four experimental set up were carried out and labeled group I, group ii, group iii, and group iv. Group I contains 30 liters of water and fish only (control group),group ii contains 30 liters of water, fish and cadmium only, group iii contains 30 liters of water, fish, cadmium and the extract, while group iv contains 30 liters of water, fish and extract only. From this study, exposure of 0.2mgl of $CdCl_2$ did not cause significant ($P > 0.05$) increase in the gill-body weight ratio relative to the cadmium free (control). Administration of $CdCl_2$ plus Hibiscus sabdariffa extract caused significant ($P< 0.05$) increase in the gill-cholesterol concentration and also the extract only caused insignificant ($P > 0.05$) increase in the gill concentration relative to the $CdCl_2$ plus Hibiscus sabdariffa extract free group. On administering both $CdCl_2$ and Hibiscus sabdariffa extract, they were found to produce gill-body weight ratio and gill-cholesterol concentration that are significantly ($P < 0.05$) different from the $CdCl_2$ plus Hibiscus sabdariffa extract free group. In this study, it was observed that Hibiscus sabdariffa calyx extract lowers cadmium induced high gill cholesterol. Also established, is the fact that gill cholesterol status can be used as index of cadmium-induced physiological stress in the catfish.

TP139 Mercury bioaccumulation in mangrove Mytella sp. as a bio-indicator of environmental pollution in the Guayaquil Gulf Estuary, Ecuador

P. Calle Delgado, Escuela Superior Politecnica del Litoral / Facultad de Ciencias de la Vida; A. Tirape Bajaña, ESPOL / Facultad de Ciencias de la Vida; O. Alvarado, Escuela Superior Politecnica del Litoral / Facultad de Ciencias de la Vida; J. Alava, Inst for the Oceans and Fisheries, Univ of British Columbia / School of Resource and Environmental Management

The Gulf of Guayaquil is the largest estuary along the Pacific coast of South America with a surface area of approximately 13,701 km^2 and coastal line of 230 km. The Gulf contains approximately 81% of the total area of Ecuadorian mangroves, encompassing about 150,000 hectares, and a highly productive ecoregion for artisanal and industrial fisheries. Two protected areas of the Gulf of Guayaquil, the Reserva de Producción Faunística Manglares El Salado (RPFMS) and Reserva Ecológica Manglares Churute (REMCH), were subject of this study. Both reserves differed in the degree of land use and urban development. The RPFMS is affected by anthropogenic impacts showing an average total mercury sediment concentration of 1.027 mg/kg dw, exceeding the Effects Range Medium (ERM) sediment quality guidelines for Hg (0.71mg/kg). The REMCH is considered as a control area with an average total mercury sediment concentration of 0.05 mg/kg dw. The aim of this study was to assess mercury bioaccumulation in the mangrove mussel Mytella sp. using the biota sediment accumulation factor (BSAF = the ratio between the mercury concentration in the mussels and the mercury concentration in the sediment) in both reserves as a monitoring approach for environmental risk assessment. Preliminary findings revealed an average mercury concentration of 4.896±0.76 mg/kg dw in mussels collected at the RPFMS, exceeding the wet threshold (0.5 mg/kg) safety value set by several countries. The BSAF for this specie was 5.34 ± 2.62 (kg/kg). Characterization of chemical pollutants and ecological risk assessments of anthropogenic activities in Ecuador are needed to establish proper environmental management strategies to mitigate and control anthropogenic pollution. Future directions are also required to understand the fate, transport and exposure in the environment of these contaminants.

Considering Water Scarcity for Environmental Decisions

TP140 USEPA's Life Cycle Assessment Research Center

J.C. Bare, USEPA / National Risk Management Research Laboratory; D.E. Meyer, United States Environmental Protection Agency / National Risk Management Research Laboratory; W. Ingwersen, USEPA; A. Henderson, B. Niblick, M. Gonzalez, USEPA / ORD

Recognizing Life Cycle Assessment (LCA) as one of the key tools which quantifies potential environmental impacts to support sustainable decision making within the Program and Regional Offices, the USEPA has developed the LCA Research Center (RC) to strategically coordinate ORD's LCA-related staff, fiscal assets, communication, and research projects. Building upon the existing and growing LCA and sustainability expertise, the LCA RC conducts research to advance LCA methodologies, tools, data, case studies, and training that can be used by internal and external stakeholders. The current research program will be presented along with technical points of contact for each project. The multi-million dollar transdisciplinary program includes data management, web-based tools and impact assessment research. Our current research portfolio includes: near-field exposure modeling integrated with LCA, water scarcity, nutrient loading, water treatment alternatives, sustainable materials management, and decision support research and tool development. In addition to this research, LCA RC members are currently active in SETAC NA LCA Advisory Groups (chair), the SETAC Global Advisory Group on Sustainability (co-chair), the SETAC LCA Global Coordinating Group, the UNEP-SETAC Life Cycle Initiative International Life Cycle Board, the Federal LCA Commons, and as advisors within various LCA standards. The core members of the LCA RC include experienced and developing LCA and sustainability experts who have developed workshops, special sessions, and presented numerous presentations, in addition to publishing over 20 peer-reviewed research manuscripts in the past 18 months.

TP141 What if Water Footprints were a Social Construct? Should they still be done?

C. Stahl, USEPA Region III; A. Henderson, USEPA / ORD

No single tool will be good for all situations but when practitioners understand first principles, it becomes possible to evaluate any tool against the need and determine whether there is a match. The principles for constructing a water footprint or any other type of index, whether for Life Cycle Analysis or something else, are the same. The people who make the choices about what parameters are included (or excluded) in the index determine the context, which is the key. In this presentation, learn how understanding the principles of index construction allows users (one kind of stakeholder) to examine and challenge their implicit assumptions about indices and their own index. Starting with a simple example of the EPA Hazard Ranking Score, learn why this calculation is not purely scientific. Utilizing critical thinking, learn why it is necessary to embrace our humanness but to do it appropriately. Learn also that when we are inclusive, transparent, learning-based, deliberate and methodical, it is possible to embrace our human qualities without giving in to arbitrariness or capriciousness. Building indices (or footprints) are social (i.e., values-laden) constructs and not scientific ones, even as scientific information is used. Therefore, it is not the tool or the index that determines whether decisions using them will be robust but the people who understand how to think critically and analytically about how they are used. Committing to a new way of thinking could be more difficult than committing to building new tools but it might be the real solution. Further, once the principles for index construction are understood, it is then possible to similarly apply them to environmental decision making. Come to this presentation and learn why.

TP142 Considering water quality in the impact assessment of water use in industry

C. Lin, P. Chiueh, National Taiwan Univ

Taiwan is an island country and depends on the electronics industry to create the booming economy. However, this industry not only requires large amounts of water, but also emits pollutants to water. And these activities deprive downstream water users, especially the agricultural sector, of enough and functional water. Even though the environmental impact assessment (EIA) has been implemented here, the trade-off between environment and economy is still not easy to be solved. The information provided by modeling the quantity of required water and the quality of emitted water is insufficient to support decision making. To identify the influence of industrial developments, an impact assessment model is needed. Therefore, based on life cycle assessment (LCA) framework and the withdrawal to availability (WTA) concept, this study developed a model which estimates the quantity and quality of water separately to represent water scarcity. And the model was applied to the case study which included several operating Science Parks in Taiwan. The result shows that the quality of water which cannot meet the requirement of downstream users would also result in water scarcity. Since high water scarcity relating to water quality does not stop water withdrawal by downstream sectors, hazards may rise by using low quality water. Thus, this model can clearly display the impact route of industrial activities and provide more information for further water resource management.

TP143 Characterisation model for green water scarcity footprint

P. Quinteiro, Univ of Aveiro / Dept of Environment and Planning; S. Rafael, M. Lopes, L. Arroja, Univ of Aveiro; A. Dias, Univ of Aveiro / CESAM Dept of Environment

Terrestrial ecosystems mostly rely on green water which itself depends on precipitation, soil physics, climate and land use. Green water refers to precipitation on land that does not runoff or recharges the groundwater but is stored in the soil or temporarily stays on the top of the soil or vegetation. The consumption of green water in land use activities, per se, does not necessarily lead to a reduction in surface water and groundwater or contributes to water scarcity. Indeed, the potential impacts on water availability depend clearly on local land-use production systems, and on the natural vegetation that is replaced by land-use production systems. This is an issue that has been poorly studied in life cycle assessment because the environmental mechanisms of green water consumption are not well understood. These mechanisms are: (1) potential disturbances of regional long-term availability of surface blue water (called as green water and soil interface) due to changes in green water use, and; (2) potential perturbations in the evaporation and transpiration that is recycled into the atmosphere, and then, in the rainfall that returns to the regional terrestrial ecosystem (called as green water and atmosphere interface), due to land use changes. This study is devoted to the development of indicators of green water scarcity at 30-arcmin global grid, considering these interfaces to evaluate the environmental impacts of net change in green water use, in life cycle impact assessment (LCA). The developed green water scarcity indicators are based on the quantification of the net change in evapotranspiration of the land-use production systems compared to the potential natural vegetation (reference situation), taking into account the share of the water evaporated or transpired through plants to the atmosphere that returns to the river basin, and the global annual environmental flow requirements (EFR). EFR quantify the water flow required to sustain positive functioning of the blue-water-dependent aquatic ecosystems services, including those required for human livelihoods and well-being. By this way, we evaluate how green water demand and availability can change blue water production. The presented LCIA method is useful for environmental decision-support in the production of rain feed agriculture and forestry, allowing to accounting for water scarcity in decision-maker's environmental calculations in a consistent and acceptable manner.

Water Management: Focusing on Issues Beyond Simply Capacity

TP144 Holistic regional management of multiple water quantity, quality and other stressors in Africa using PROBFLO

G.C. O'Brien, Univ of KwaZulu-Natal / School of Life Sciences; C. Dickens, International Water Management Inst

Best practice principles of Integrated Water Resource Management (IWRM) in Africa includes the need for robust holistic frameworks that address the risk associated with multiple stressors to social and ecological objectives on regional, trans-boundary scales. Recent rapid increases in water resource developments throughout Africa has resulted in widespread ecological impacts with associated socio-economic consequences. With regional regulators we have developed a regional IWRM Environmental flows framework that gives adequate consideration to non-flow stressors to describe the risk associated with sources in a holistic context. This regional scale ecological risk assessment approach incorporates Bayesian Networks to model the probable relationships between the flows and other driver variables, and socio-ecological indicators by assigning magnitudes and probabilities of adverse impacts of hazards to endpoints. In this paper we demonstrate the application of the PROBFLO approach in the Lesotho Highlands Water Project (Phase II) which includes the construction of the large Polihali Dam on the Senqu River, Lesotho and South Africa, and highlights from the Mara River application of PROBFLO as a part of the Water Allocation Plan for the Mara River Basin, Kenya and Tanzania. These case studies includes the establishment of Resource Quality Objectives for both case studies, the use of existing evidence, specialist solicitations and data generated through biophysical assessments to the study area. Outcomes included the establishment of a transparent, adaptable socio-ecological model to represent the risk relationships between sources, stressors, receptors and endpoints. A series of alterative management options and associated trade-offs were evaluated in the form of a range of scenarios with associated socio-ecological consequences. Scenarios were presented to stakeholders representing society who with the risk assessment outcomes contributed to the establishment of management plans for the use of the water resources. A range of mitigation measures were identified to minimise ecological consequences and monitoring. And adaptive management measures were designed to contribute to the implementation of the management plans. The PROBFLO approach has successfully allowed water resource use regulators to develop holistic plans to manage water quality, quality, habitat and other stressors on regional scales in Africa.

Advancing Sustainability in SETAC: Implementing the Berlin Declaration

TP146 A Rural Community's Pursuit of Sustainability

L. Kapustka, LK Consultancy

I live in rural southern Alberta, Canada next to a town of 2200 people, 3 km from another town of 2400 people, with surrounding isolated enclaves of ranchers, labourers, and artisans. The lures of the area are many including a vibrant community of artists and artisans; stunning vistas of the foothills vegetation and Canadian Rockies; an abundance of wildlife; wild fisheries, and more. Over the last 100 years, the region was shaped by ranching, logging, and development of the first major oil and gas formation in western Canada. Farming and gardening are prominent in the area and there is an active contingent of permaculture practitioners re-envisioning the ways crops are grown. This area, referred to as Diamond Valley, is described by some as being in the "blast zone" of Calgary, a multi-cultural city of 1.3 million that has grown explosively in the past two decades and looks to be continuing to extend into the countryside. Residents of the Diamond Valley have varied interests, including ordinary business types and elected officials who seek economic growth. But there are others who desiring the serenity that currently exists advocate consideration of no-growth options. Over the past few years, visioning meetings have been organized to attempt to define desired futures for the area. Lively discussions about these futures have emphasized the importance of personal and collective community wellbeing. From these, a number of initiatives have been proposed; some already being acted on. These include establishing shared walking and bike paths between communities, promoting smart water management/conservation, passing municipal bylaws allowing the raising of "urban hens" for personal egg production, and an energy co-op that will use proceeds to promote energy efficiency, renewable energy, and other initiatives designed to foster community engagement and community wellbeing. In this presentations, the local effort will be used to illustrate the importance of stakeholder engagement in shaping sustainability goals and activities. Comparisons will be made to comparable efforts in other communities that are making positive gains in the areas of sustainability and community wellbeing.

TP147 A US analysis of dairy, agriculture, and overall nutrient cycling to identify improvements in nutrient use efficiency

K. Veltman, Univ of Michigan / Dept of Environmental Health Sciences; A.D. Henderson, USEPA / Environmental Science; O. Jolliet, Univ of Michigan

Article 2 of the SETAC Berlin Declaration calls for promotion of resource-efficient economies. Nutrient efficiency is an area of concern for agriculture, and indeed larger economic systems. Analyses of global nitrogen flows have identified the potential for increased efficiency from livestock; dairy, specifically has an important role in nutrient cycling and delivery of nutrients to consumers. This project aims to create national-level nitrogen (N) and phosphorus (P) budgets for the US, assessing the role of dairy and other livestock production in national nutrient flows. Results show that the combined fertilizer and chemical industry is the major fixer of N2 from air, with an annual fixation of 9,350 kt N/ yr. Agriculture is the second largest sector, with an N2 fixation of 5,156 kt N/ yr for US. Agriculture is the largest source of reactive nitrogen emission to air, predominantly due to ammonia emissions of 3,047 kt N from fertilizer application to field crops. Many feedback loops exist in both the dairy food supply chain and the 'non-dairy' food supply chain. For example, 104 kt N is produced as a by-product at the crop-based food industry and fed to the national dairy herd. N-efficiencies range from 71% for the poultry processing industry to 95% for the dairy processing industry. In total 1,203 kt N in synthetic fertilizer is used to produce 445 kt N in milk and 1 kt N in meat (boneless equivalent, veal calves only). Thus, 37% of total N applied with synthetic fertilizer ends up in milk supplied to the processing industry. In terms of nutrient use efficiency (NUE), the dairy processing industry is the most efficient part of the dairy food supply chain with an efficiency of 97%. Retail has an NUE of 92%. The least efficient part of the dairy supply chain is the dairy herd, with only 21% of nitrogen fed to the herd recovered in milk and meat. The crop production stage and household stage have intermediate NUE of 78%. 'Hotspots' in the dairy food supply chain occur predominantly in the crop production stage and the 'dairy herd' (milk production) stage, suggesting that improvement should focus in particular, on reducing ammonia emissions in manure management systems and at fertilizer and manure application on the field.

Recent Advances and Trends in Poly- and Perfluoroalkyl Substances Research

TP148 Monitoring of long-range transport of perfluoroalkyl acids in precipitation from the Newfoundland and Labrador Boreal Ecosystem Latitudinal Transect

J. MacInnis, Memorial Univ / Chemistry; T. Vandenboer, Memorial Univ / Dept of Earth Sciences; S. Morran, Simon Fraser Univ / Dept of Biological Sciences; A.O. De Silva, Environment and Climate Change Canada; C. Young, Memorial Univ / Dept of Chemistry

Perfluoroalkyl acids (PFAAs) are recalcitrant compounds globally disseminated among abiotic and biotic media (1,2). Gas phase PFAAs can form in the atmosphere by oxidation of volatile precursors, such as fluorotelomer alcohols (3). PFAAs are volatile in the neutral form, but due to low pK_a values (4), they should be ionized under most environmental conditions. PFAAs have low volatility in the anionic state, so it is likely the condensed phase, including atmospheric particles, plays a role in long-range transport. Rain droplets are effective scavengers of particulate-bound and gaseous PFAAs in the atmosphere. The measurement of precipitation in remote locations can provide a PFAA atmospheric profile, which will enhance interpretations of long-range transport. In this work, precipitation was collected over two years along four Newfoundland and Labrador Boreal Ecosystem Latitudinal Transect (NL-BELT) sites ranging from rural to remote areas. The sites are spaced along 5 degrees of latitude, extending into the sub-Arctic. Samples were collected using two precipitation sampler designs. The first design employs a large diameter tube for passive collection. This sampler is continuously exposed to the environment over the entire year, enabling the collection of wet and dry PFAA deposition. The second design employs custom-built automated precipitation samplers, which selectively collect wet PFAA deposition as incident and canopy-throughfall measurements. Differences in PFAA deposition profiles using these sampling designs could provide insight into dry deposition inputs into the NL-BELT. In order to accurately quantify PFAAs in precipitation, liquid chromatography-tandem mass spectrometry was used as the method of detection. Spatial, temporal, and homologue trends will be discussed, as well as the implications for mechanisms of long-range transport. The measurement of PFAAs in precipitation from multiple sites using different collection methods will help to understand long-range transport processes.

TP149 Analysis and screening of per/polyfluoroalkyl substances in a coastal urban ecosystem in California

T. Anumol, Agilent Technologies Inc.; S. Dagnino, Imperial College / Dept of Chemical Environmental Engineering ChEE; N. Dodder, San Diego State Univ; K.A. Maruya, SCCWRP; S.A. Snyder, Univ of Arizona / Chemical and Environmental Engineering

Per/polyfluoroalkyl substances (PFAS) have uniquely desirable properties that ensure their usage in many commercial applications. However, these properties also cause PFASs to be environmentally persistent, bioaccumulative in wildlife and humans and recalcitrant during water and wastewater treatment. The presence of several PFASs has been shown in wastewater and drinking water while manufacturers continue to introduce newer alternatives to the market. This study aimed to characterize the PFAS load into an urban coastal ecosystem through water, fish and sediment monitoring. A targeted approach using an LC-MS/MS was utilized to measure 11 PFAS including perfluorocarboxylic acids (PFCAs), perfluorosulfonic acids (PFSAs) and fluorotelomer acids (FTCAs) in each of the three matrixes at several points across the urban waterway. Concentrations in the water were low ng/L but PFOA and PFOS were detected while the sediment and fish had ng/g levels of total PFAS. While PFOA and PFOS were the most predominantly detected compounds, longer chain PFAS were also detected especially in the sediment. The fish sampled had higher levels of targeted PFAS and were further investigated using an untargeted approach with a UHPLC-QTOF/MS to identify other perfluorinated compounds while also screening for >1,000 organic contaminants including pharmaceuticals, hormones, pesticides and others using a database and library. The results of this screen provide a qualitative representation of the organic flux in the urban coastal ecosystem. Further, the identification of other potential perfluorinated compounds that may have been ingested in the fish were proposed and statistical analysis of the fish samples was performed to identify other organic contaminants while differentiating fish collected at different points across the urban waterway. The results of this study provide an idea of the perfluorinated compound loading and overall organic contaminant flux in an urban coastal ecosystem that will inform future monitoring programs.

TP150 Occurrence and composition of Per- and poly-fluoroalkylated substances (PFASs) in wastewater for direct potable reuse

B. Wang, Wright State Univ; E. Villegas, USEPA; K. Dasu, USEPA / National Risk Management Research Laboratory; A. Agrawal, Wright State Univ; M. Mills, USEPA / National Risk Management Research Laboratory

Faced with freshwater shortages, wastewater is increasingly utilized for the augmentation of water-starved environments. With the emergence of wastewater effluent as a viable alternative source for potable water use, additional research is needed to further characterize the contaminants of emerging concern (CECs) present in wastewater effluent and the risks associated with exposure to these contaminants. EPA Office of Research and Development (ORD) and EPA Region 6 publicly Owned Treatment Works (POTW) have partnered on a research project focused on waterborne pathogens and CECS that are present in wastewater effluent from advanced wastewater treatment plants. This project will assist the States in Region 6 that use wastewater effluent as a drinking water source by providing data on the occurrence and composition of potential waterborne pathogens and CECs. In this project, we will determine the types of pathogens and CECs that are found in wastewater effluent and the potential impacts (e.g. increase in levels of contaminants) of using wastewater effluent as a drinking water source on the overall water quality of the drinking water produced. This presentation will focus on the occurrence and composition of per- and poly-fluoroalkylated substances (PFASs) in the wastewater used in direct potable reuse. Monthly samples are collected and characterized for PFASs. The seasonal concentration and composition of these PFASs from wastewater influent and effluent of three POTWs will be reported to date. The PFASs concentration vary among plants. Summing the ten PFASs, the total concentration of PFASs in POTW1 were higher in both wastewater influent and effluent compared to other plants. PFOS, PFOA and PFHxA are commonly detected analytes with higher concentrations in wastewater influent. Other PFASs showed increasing concentrations during treatment processes with higher concentrations in wastewater effluent compared to the influent.

TP151 Analysis of poly- and perfluoroalkyl substances (PFASs) in drinking water: compliance with new USEPA Health Advisory Guideline

S. Crispo Smith, California Environmental Protection Agency / Dept of Toxic Substances Control; J. VillaRomero, W. Duong, A. Zamora, M. Wang, M. Petreas, J. Park, California Environmental Protection Agency / Dept of Toxic Substances Control / Environmental Chemistry Laboratory

Our recent study showed that serum concentrations of PFOS and PFOA in California women were linked to their presence in their drinking water supplies (as reported by UCMR3 (The third Unregulated Contaminant Monitoring Rule)). This finding, coupled with the May 2016 USEPA Lifetime Health Advisory Level for PFOA and PFOS (individual or combined) of 70 ng/L, warrants developing a method for drinking water with much lower detection limits. The aims of this study are to validate our new method for the analysis of poly- and perfluoroalkyl substances (PFAS) in drinking water and to test its feasibility by analyzing PFAS in drinking water from Northern California. Our new method for water PFAS analysis builds upon the USEPA method 537 (solid phase extraction and liquid chromatography/tandem mass spectrometry) and expands the list of PFASs to include: eight perfluoralkyl carboxylic acids (PFCAs), four perfluoroalkane sulfonic acids (PFSAs), two perfluoralkyl phosphonic acids (PFPAs), three perfluoralkyl phosphinic acids (PFPiAs), eleven PFCA precursors/intermediates, and three PFSA precursors. We use a WAX SPE cartridge (Oasis, Waters) for concentration and a 9 minute analysis using liquid chromatography (Nexera UFLC system, Shimadzu) coupled to a triple-quadrupole tandem mass spectrometer (SCIEX QTRAP 5500 MS/MS system). The instrument detection limits range from 1.0 to 480 ng/L, with detection limits of 1.2 ng/L and 6.2 ng/L for PFOS and PFOA, respectively, which are sufficiently sensitive to comply with the new USEPA Health Advisory Guideline. Disclaimer: The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

TP153 Need for Data on Environmental Fate of Perfluoro Ethers

L. Libelo, USEPA / OPPT RAD; J. Miller, R. Fehir, USEPA; J. Roberts, USEPA / Office of Pollution Prevention and Toxics

Perfluoro ethers (PFEs) are widely used in a variety of applications including electronic, aerospace and high temperature lubricants, membranes in fuel cells, and consumer applications. They are also increasingly being used as replacements for perfluoro carboxylic acids (PFCAs) and sulfonic acids (PFSAs) in these and other applications. Perfluoro ethers are released to the outdoor and indoor environment, and have recently been detected in water and biota. Understanding the fate and exposure of PFEs are required to evaluate risk to human and non-human species. USEPA has attempted to determine the fate of PFCs as part of an evaluation of potential risk for a number of perfluoro ethers using standard New Chemical assessment approaches. Review of the environmental and industrial chemistry literature and confidential literature submitted to the New Chemicals program by EPA found only very limited information on PFE degradation. PFEs are reported to degrade in laboratory studies at elevated temperatures and in the presence of photocatalysts, strong Lewis acids, hydroxyl and other radicals suggesting that the ether linkage can be degraded to form smaller compounds, shorter poly ethers and PFCAs. It is unknown if these processes occur in the environment, at what rates and under what conditions. Information on the environmental fate of PFCs, needed to be able to evaluate their fate under environmental condition, does not exist. Studies of abiotic degradation including hydrolysis, direct and indirect photolysis, catalysis by dissolved species and on geologic surfaces are needed to determine fate and transport properties of PFEs. Biological transformation data are also needed including data on aerobic and anaerobic microbial degradation in water wastewater sediment, sludge, and soil. These studies should provide sufficient information to determine environmental degradate rates, mechanisms and pathways to better understand exposure to humans and environmental species. Until this information is available, significant uncertainty will be associated with estimates of potential risk of perfluoro ethers. The views expressed in this abstract are those of the authors and do not represent Agency policy or endorsement.

TP154 Accumulation Potentials of Perfluoroalkyl Acids (PFAAs) in Crops Irrigated With Reclaimed Water

J. Jiang, Univ of California, Riverside / Dept of Environmental Sciences; C. Sun, J. Gan, Univ of California, Riverside / Dept of Environmental Science

Significant contamination of perfluoroalky acids (PFAAs) in wastewater treatment plants (WWTPs) implicates that the reuse of treated wastewater for agricultural irrigation and the practice of applying treated sludge as a potential source of these contaminants onto agricultural farmlands. The aim of the present study was, therefore, to determine the accumulation potential of perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkyl sulfonic acids (PFSAs) in crops irrigated with treated wastewater under field conditions. Reclaimed water with or without a fortification of PFAAs was used to irrigate crops until harvest. Results from the present study will enhance the understanding on the accumulation of PFAAs in crops irrigated with treated wastewater under field conditions.

TP155 Transformation of poly- and perfluoroalkyl substances (PFAS) in petroleum hydrocarbon-contaminated soil during biopile treatment

R. Li, McGill Univ / Dept of Civil Engineering; J. Liu, McGill Univ / Civil Engineering; Y. Liu, Donghua Univ

Aqueous film-forming foam (AFFF) formulations that contain poly- and perfluoroalkyl substances (PFAS) are used to extinguish hydrocarbon-fuel fires for their excellent performance in lowering surface tension at the air-AFFF interface. PFAS were detected at ppb to ppm levels in soil biopiles for petroleum hydrocarbon bioremediation. The PFAS presence was the result of the AFFF release for fire-fighting at an oil leakage site. Under the biopiling conditions when petroleum hydrocarbons biodegradation are augmented, some PFAS with hydrocarbon functionalities may be biotransformed to produce persistent perfluoroalkyl acids such as perflurooctane sulfonic (PFOS) and carboxylic acids (PFOA). PFOS and PFOA are subject to stringent regulations due to their toxicity and persistence. Therefore, it is essential to understand the environmental fate of PFAS in soils co-contaminated with petroleum hydrocarbons and AFFF. The main objective of this research is to examine, under biopile treatment conditions when petroleum hydrocarbons are biodegraded, possible biotransformation of the PFAS present in a field-contaminated soil. Contaminated soils from bioplies with and without nutrient (e.g., N, P, K, micronutrients and organic matter) amendment were incubated aerobically for 3 months. The levels of petroleum hydrocarbon and PFAS were monitored. Petroleum hydrocarbons of Fraction 2 and 3 were solvent extracted and analyzed by GC-FID. A total of 34 PFASs were monitored using LC-MS/MS, including PFOS, PFOA and their homologues, fluorotelomer sulfonates and fluorotelomer betaines. 6:2 fluorotelomer sulfonamide alkylbetaine (6:2 FTAB), a major constituent of AFFF formulation, was also spiked to the same soil to examine for its possible biotransformation under the similar conditions with three different nutrition levels. Biotransformation kinetics of the petroleum hydrocarbons and 6:2 FTAB, formation yeilds of high-priority PFAS, and the impact of nutrient amendment will be presented and discussed. It is expected that this research would help us understand the behaviour of PFAS in soil co-contaminated with petroleum hydrocarbons thus to better manage such contaminated sites.

TP156 Perfluoroalkyl acid tissue distribution in healthy and pansteatitis-affected Tilapia (Oreochromis mossambicus) at Loskop Dam, South Africa

J.T. Bangma, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences; J.A. Bowden, National Inst of Standards and Technology / Environmental Chemical Sciences Group; J. Reiner, National Inst of Standards and Technology; L.J. Guillette, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences OBYGYN

Perfluoroalkyl acids (PFAAs) are anthropogenic contaminants of concern that are found predominantly in blood and blood-rich organs (e.g., kidney and liver) largely because PFAAs are predisposed to associating with blood proteins like albumin. Measuring PFAAs in blood or plasma is advantageous as it provides a medium to asses PFAA levels without animal sacrifice. Thus, many experimental designs measure blood or plasma levels of PFAAs in studies where sacrifice is not preferred or possible. However, the health status of an individual can alter the level of protein and albumin in the blood (e.g., inflammation) and could impact the levels of proteins available to associate with PFAAs. Under this premise, it is unknown whether the PFAAs that can no longer bind to albumin remain in the blood rich matrices, are sequestered in alternate organs, or are excreted. A population of Mozambique tilapia (Oreochromis mossambicus) at Loskop Dam, South Africa, has been suffering from an inflammatory disease known as pansteatitis for many years. Preliminary investigations of PFAA plasma levels in this population of pansteatitis-affected tilapia have shown significantly lower levels of both albumin and PFAAs in the diseased tilapia plasma compared to healthy tilapia plasma. In this study, we investigate the possibility that disease and inflammation in this population of tilapia could alter the PFAA tissue distribution compared to healthy tilapia, resulting in potential wider implications in the understanding of PFAA burden as it relates to disease for the perfluorinated scientific research community.

TP157 Perfluoroalkyl phosphinic acids form the corresponding phosphonic acids and 1H-perfluoroalkanes in rats

S. Joudan, Univ of Toronto / Chemistry; L.W. Yeung, S.A. Mabury, Univ of Toronto / Dept of Chemistry

Perfluoroalkyl acids (PFAAs) are a class of widespread contaminants that are generally accepted as recalcitrant under environmental conditions. A 2012 paper from our group showed evidence of the first biotransformation of any PFAA, where perfluoroalkyl phosphinic acids (PFPiAs, $(F(CF_2)_x)(F(CF_2)_y)PO_2^-$) were metabolically hydrolyzed to perfluoroalkyl phosphonic acids (PFPAs, $F(CF_2)_xPO_3^{2-}$) in fish. PFPiAs and PFPAs are found together in industrial mixtures that have been used directly as surfactants for both agricultural and industrial applications. To confirm the in vivo transformation in mammals and identify the remaining PFPiA metabolite, rats were dosed with 50 µg/kg of either C6/C8 PFPiA, C8/C8 PFPiA, or C8 PFPA via oral gavage. Blood, kidneys and liver were sampled to determine pharmacokinetic and partitioning properties. PFPAs and PFPiAs were quantified via UPLC-MS/MS using matrix matched calibration. An additional group of rats was dosed at 2 mg/kg to probe the formation of volatile products.1H-perfluoroalkane metabolites were detected in blood using a novel headspace solid phase microextraction method with negative chemical ionization GC/MS. Both PFPiAs were hydrolyzed in vivo to form PFPAs and 1H-perfluoroalkanes. 1H-perfluoroalkanes were not detected in rats dosed with C8 PFPA, suggesting the C-P bond cleavage requires the presence of a second electron withdrawing perfluoroalkyl group. Although metabolism decreases the concentration of PFPiAs, the products formed have the potential to be more persistent and toxic. PFPAs have been shown to be persistent in the literature and in this work, while shorter 1H-perfluoroalkanes have been shown to form reactive acid fluoride intermediates that covalently bind to proteins. In vitro experiments using rat subcellular liver S9 fraction were performed to further investigate the metabolism of PFPiAs. This work shows the first detected mammalian hydrolysis of C-P bonds in phosphinates and the first confirmation of 1H-perfluoroalkanes as metabolites of PFPiAs.

TP158 Endocrine-disruption potential of perfluoroethylcyclohexane sulfonate (PFECHS) in chronically exposed Daphnia magna

M. Houde, M. Giraudo, K. Jean, M. Lépine, C. Spencer, Environment and Climate Change Canada; A.O. De Silva, Environment and Climate Change Canada; M. Houde, Environment and Climate Change Canada / St Lawrence Center

Perfluoroethylcyclohexane sulfonate (PFECHS), mainly used in hydraulic fluids in aircrafts, is a member of the perfluoroalkyl sulfonate family which includes the regulated perfluorooctane sulfonate (PFOS). PFECHS has been reported in environmental samples but its toxicity to aquatic organisms is unknown. The objectives of this study were to identify biological pathways impacted by sublethal exposure (12d) of D. magna to PFECHS (0.06, 0.6, and 6 mg/L) using microarray and quantitative real-time PCR and to develop a relevant biomarker to link transcriptomic to phenotypic responses. PFECHS was also quantified in surface water samples (1.04 to 1.38 ng/L)collected from the St. Lawrence River, Canada. All transcriptomic analyses indicated the under-regulation of vitellogenin-related genes (VTG1 and VTG2)in treatment groups. PFECHS exposure also led to the up-regulation of genes related to cuticle. VTG was selected as a cellular marker and identified in D. magna using an immuno-specific assay and quantified using Western Blot and LC/MS/MS. Results indicated a decrease of VTG content in exposed D. magna which was in concordance with the transcription of VTG-related genes. No impacts were observed on survival, molting, or reproduction at the individual/population levels. Overall, results suggest endocrine disruption potential for PFECHS in these invertebrates.

TP159 Sources of human exposure to poly- and perfluoroalkyl substances (PFASs)

X. Hu, Harvard Univ; G.M. Webster, Simon Fraser Univ / Faculty of Health Sciences; P. Grandjean, Harvard Univ; P. Weihe, The Faroese Hospital System / Dept of Occupational Medicine and Public Health; F. Nielsen, Univ of Southern Denmark; C. Dassuncao, Harvard Univ; X. Zhang, Harvard Univ / Environmental Health Sciences School of Public Health; E.M. Sunderland, Harvard Univ / School of Engineering and Applied Sciences

Human exposure to poly- and perfluoroalkyl substances (PFASs) has been linked to a variety of adverse health effects including cancer, elevated cholesterol, and disrupted immune and endocrine systems. Consumer products, drinking water and marine foods are all sources of exposure to PFASs. Those with environmentally mediated pathways (drinking water and marine foods) respond to regulations over different time scales than consumer sources, which can be altered quickly by changes in manufacturing. Most available exposure source attribution for PFASs is based on estimated chemical doses from different sources (external doses) without validation against exposure biomarker concentrations. Many of the parameters involved in this process such as exposure frequencies and pharmacokinetic parameters are hard to measure, resulting in large uncertainties in the exposure estimates. Here we use measured serum concentrations for 11 frequently detected PFASs homologues and a chemical fingerprinting technique to refine understanding of exposure sources. Data are from multiple cohorts representing diverse exposure pathways in the Faroe Islands, Vancouver, Canada and the US National Health and Nutrition Examination Survey, collected around the same time. We found the homologue profiles from a seafood consuming population in the Faroe Islands are distinctly different from the one in Vancouver where exposures from consumer products may be more dominant. We quantify the impact of exposure frequencies (such as frequency of marine food consumption and consumer good exposure) on serum PFASs homologue composition to identify the PFASs that best represent each exposure source. We use this analysis to better understand the relative contribution of these two sources to PFAS exposures in the US general population.

TP160 Perfluoroalkyl acids among Korean children and adolescents of 4 to 18 years of age: serum levels, related sources, and health outcomes

H. Kang, Seoul National Univ / Environmental Health Sciences; H. Lee, Hanyang Univ; J. Lee, Seoul National Univ; S. Kim, Seoul National Univ / Dept of Environmental Health; H. Moon, Hanyang Univ / Marine Sciences and Convergent Technology; K. Choi, Seoul National Univ / School of Public Health

Perfluoroalkyl acids (PFAAs) have been frequently detected in humans. However, their exposure among children and adolescents and associated health effects are not well understood. In this study, 16 perfluoroalkyl acids (PFAAs) were analyzed from a total of 150 serum samples collected from 4-18-year-old children and adolescents of Seoul and Gyeonggi, Korea, in 2012 and 2014. Among the target PFAAs, PFOA, PFNA, PFHxS, PFOS, and PFUnDA were detected in >98% of the samples. PFOS showed the highest detected concentration with a median concentration of 5.68 ng/mL, followed by PFOA, PFNA, PFHxA, and PFUnDA. Detection rates of PFDA and PFDS were between 60% and 80%, while the other PFAAs were detected in less than 50% of the samples. Among 16-18-year-old adolescents, total PFAAs concentration in serum was significantly higher among males than in females. However, this gender difference was not significant in the other age groups. Concentrations of several PFAAs, i.e. PFOA, PFNA, and PFOS, decreased as age increased. Using questionnaire data, several dietary and behavioral factors, i.e. breastfeeding, fish/shellfish consumption, use of frying pan, and use of waterproof coating cloths, were identified as potential exposure sources of PFAAs. Among the target PFAAs, PFUnDA showed significant positive association with total cholesterol, low-density lipoprotein cholesterol, or fasting blood glucose. The effects of PFAAs on cholesterols warrant confirmation in other juvenile populations and should be tested in animal experiments.

TP161 Using Cats as Model for indoor Exposure – PFAS and Association to Feline Thyroidogenicity

J. Weiss, Stockholm Univ; A. Bergman, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry ACES

Thyroidogenic disruption as an endocrine endpoint is of growing concern for human health and the environment. Hence, the MiSSE project (Mixture aSSessment of EDCs) is specifically aiming to assess the indoor exposure situation to thyroid hormone disrupting compounds (THDCs), and accordingly the mixture effects of these compounds. As cats and toddlers have a similar behavior with their grooming and hand-to mouth activity cats are here used as sentinels for human and child exposures to indoor related chemicals and their thyroidogenic effects. Recently, an association was demonstrated between domestic cat's thyroid health status and levels of brominated flame retardants in their blood (Norrgran et al 2015, ES&T 49:5107). We have further investigated the exposure pathway via dust by correlating the levels in the two matrices dust and cat blood. The THDCs are searched for by applying in silico similarity models comparing known THDCs (Zhang et al 2015, ES&T 49:10099; Weiss et al 2015, ABC 407:5625) and using target analysis of a selection of key-THDCs. Dust and cat serum samples have been sampled in the Stockholm/Uppsala region, Sweden between 2013-2014. The families had healthy pet cats and at least one child living at home (< 10 years old). Dust samples were vacuumed from the living room and bedrooms of the participating families. Still-standing dust were collected using a dust collector ((Dustream™, Indoor Biotechnologies Ltd., Wiltshire, UK) containing a disposable filter (mesh size 40 µm) attached to a household vacuum cleaner tube. The dust was collected from surfaces little influenced by daily life e.g. walking and/or containing bread crumbs and soil. The samples were sieved (1 mm) to isolate the estimated ingested fraction for cats (0.04-1.0 mm). The target analytes, e.g. brominated flame retardants, organophosphorus compounds, organochlorines, perfluoroalkyl substances (PFAS) and some phenolic compounds have been determined with GC and LC-MS/MS instrumentations. Statistical correlations between cat serum and house dust in paired samples have been assessed. In addition, an Effect-Directed Analysis approach utilizing advanced chemical instrumentation and bioassay guided fractionation will be performed on the household dust in the strive to identify key-THDC. We will focus the presnetation on the PFAS analysis specifically but also the current status of the project, focusing on dust and cat serum contaminants, mixture effects and evaluation of the indoor exposure to a set of emerging compounds of concern.

TP162 Addition of metals to enhance abiotic transformation of perfluorooctane sulfonic acid in vitamin B12 and permanganate systems

S. Park, Purdue Univ / Agronomy; L.S. Lee, J.E. Zenobio, Purdue Univ / Dept of Agronomy

The use of adding nano(n)- or micro(m)-sized zero valent metals to enhance the potential of vitamin B_{12} (B12) and permanganate (PM) in transformation of perfluorooctane sulfonic acid (PFOS) was evaluated in aqueous batch systems. In the B12 systems in which nFe^0 and nZn^0 were evaluated with temperature and over time, loss of linear (L-) and branched (Br-) PFOS isomers were quantified using time of flight (TOF)/MS/MS and generation of F^- and SO_4^{2-} byproducts were monitored using ion chromatography. For identification/exploration of polyfluoroalkyl intermediates, the aqueous phase, meal extracts and headspace were analyzed using TOF/MS/MS and GC-ECD/MS, respectively. In B12 with nFe^0 at pH 10.4 and 21 d, increasing temperature from 22 to 70 °C increased the degree of PFOS removal (20 ± 2 % at 22 °C and 32 ± 5 % at 70 °C) with 1 ± 0.1 and 9 ± 1 moles of F^- for every mole of PFOS removed was observed at 22 and 70 °C, respectively. In addition, 0.8 ± 0.1 mole of SO_4^{2-} per mole of PFOS lost was detected at 70 °C. In B12 with nZn^0 at pH 10.4 and 21 d, 22 ± 3 % of PFOS loss with 7 ± 1 moles of F^- generated per mole of PFOS lost and 34 ± 3 % of PFOS loss with 19 ± 2 moles of F^- generated per mole of PFOS lost was observed at 22 and 90 °C, respectively. The estimated first-order removal rates of the branched PFOS isomers were 2.9, 1.4, and 0.3/d for 6-PFOS, 3&4-PFOS and 5-PFOS, respectively at 90 °C in the B12-nZn^0 system. No loss of L-PFOS was observed, thus limiting B12 technologies considering that L-PFOS is the most prevalent isomer in groundwater. This led to exploring enhancing the PM system, which has been shown to have potential to degrade PFOS. The addition of mMg^0 and mZn^0 as catalysts to PM solutions at 65 °C and pH 6~7 (12 d) enhanced PFOS removal to 35 ± 6 % and 29 ± 0.1 %, respectively, compared to only 11 ± 2 % in PM alone. The PFOS lost included Br- and L-PFOS unlike the B12 system. F^- generation was quantified in the aqueous phase and observed in all three systems but appeared inversely correlated to the % PFOS lost with 9 moles of F^- per mole of PFOS lost in PM alone and only ~ 4 and ~ 2 moles of F^-/PFOS lost with mZn^0 and mMg^0, respectively. Additional F^- was likely generated, but readily adsorbed to the metal catalysts. Extraction of adsorbed F^- and SO_4^{2-} is underway as well as a more detailed characterization of kinetics, organic metabolites, and mechanisms in the PM system.

TP163 Reduction of perfluorooctanesulfonate (PFOS) and perfluorohexanesulfonate (PFHxS) by synthesized activated carbon-supported bimetals

J.E. Zenobio, L.S. Lee, Purdue Univ / Dept of Agronomy

Perfluoroalkyl substances (PFASs) have been detected in various environmental and biological matrices including groundwater. Perfluorooctanesulfonate (PFOS) and perfluorohexanesulfonate (PFHxS) are stable and resistant to typical environmental degradation processes. Here we examine the degradation performance of PFOS and PFHxS by activated carbon (AC) supported bimetallic nanoparticles (NPs). Bimetallic NPs included a combination of Ni, Fe, Cu, Pd, Ce, Sr, and Mg, which were synthesized onto AC. Various approaches for enhancing reactivity of the bimetallic catalyst were investigated, including increasing temperature (60°C) and adding a third metal/catalyst or magnetite (Fe_3O_4) as well as a combining reduction-oxidation processes by addition of persulfate. Batch reactions were carried out for 5 days in triplicates with 3 mg/L of PFOS and PFHxS. Degradation of PFOS and PFHxS was quantified in the aqueous and in solvent extracts after a series of exhaustive sequential extraction. F^- and SO_4^{2-} were identified using ion chromatography and organic byproducts using LC/MS/TOF. Among the several bi/trimetal systems probed, the NiFe° bimetal system plated on an AC support at 60°C resulted in the greatest loss of PFOS (~35% in 5 d). PFOS removal was accompanied by the release of the sulfate ion (SO_4^{2-}) in $NiFe^0$,Fe^0-AC and $NiFe^0$-AC samples (~0.33, ~0.30, and ~1.08 moles of sulfate per mol of PFOS removed, respectively). Also in all samples that showed PFOS loss, pH values increased to ~9. Fluoride could not be quantified due to the presence of an unknown peak in the AC systems. The addition of Fe_3O_4 to the NiFe-AC did not enhance or reduce reactivity towards PFOS; however, its presence may serve to aid in degradation of co-contaminants in mixed-contaminant systems. The addition of a third catalyst to the NiFe-AC system did not increase PFOS removal and the addition of persulfate decreased PFOS removal. No clear trend in PFOS loss with the reduction potential of the various metal catalysts was apparent suggesting that catalyst selectivity rather reduction potential is controlling PFOS removal.

Modeling and Monitoring of Environmental Pesticides Exposure: Regulatory Context and Improvements from Science

TP164 Impacts of Seawater on Photoproduct Formation of Dichloran

E.N. Vebrosky, Louisiana State Univ / Dept of Environmental Sciences; K. Armbrust, Louisiana State Univ / Environmental Sciences School of the Coast and Environment

The salinity of seawater can influence both the overall rate of degradation of chemicals and impact the distribution and types of photoproducts from the photodegradation of a pesticide. The fungicide dicloran, 2,6-dichloro-4-nitroaniline (DCNA), is applied to crops grown in areas near both freshwater and saltwater bodies where it is susceptible to photolysis; limited information is published on the photodegradation of DCNA. The photodegradation of DCNA was measured in distilled water, artificial seawater, estuarine water, and phosphate buffer to determine the degree of differences in the degradation rate and product distribution of the compound in various matrices. Solutions of DCNA at a concentration of 1 ppm were prepared and irradiated for 24 hours in an Atlas SUNTEST XXL+ photochamber that mimics the wavelength distribution and intensity of sunlight. Samples were withdrawn at 0, 2, 4, 6, 12, and 24 hours and analyzed for residual DCNA using an Agilent 1260 Infinity High Performance Liquid Chromatograph. The formation of ions such as nitrate, nitrite, bromide, and chloride were measured using a Thermo Dionex ICS-5000+ Ion Chromatograph. The half-life of DCNA in distilled water was calculated to be 7.62 ± 0.094 hours and 7.37 ± 0.279 hours in artificial seawater; statistically there was no significant difference in the degradation rate. Analysis of the quick formation of nitrite and chloride ions, and later formation of nitrate ions, suggests photonucleophilic substitution processes are occurring as the compound is degrading, followed by further degradation of nitrite to nitrate likely also due to photolysis processes. Measurable intermediate photoproducts were analyzed for formation rate; a difference in the concentration of product was noted between distilled water and artificial seawater suggesting salinity affects the rate of formation of this photoproduct.

TP165 Photo-induced Toxicological Effects of 2,6-dichloro-4-nitroaniline (DCNA) on P. promelas (Fathead Minnow)

E.N. Vebrosky, Louisiana State Univ / Dept of Environmental Sciences; K. Armbrust, Louisiana State Univ / Environmental Sciences School of the Coast and Environment

Toxic effects of chemicals can be initiated after that chemical has been exposed to light. The fungicide 2,6-dichloro-4-nitroaniline (DCNA) is applied to many crops that are grown in areas where agricultural runoff enters bodies of water. DCNA is susceptible to photolysis as it enters the surface layer of water bodies, therefore increasing the chances of toxicological effects on various aquatic species that may be exposed to the chemical itself as well as the intermediate photodegradation products. This can be especially relevant in shallow water aquatic system such as salt marshes and estuaries. Previous research on PAHs has shown increased toxicological effects to species exposed to both the chemical and sunlight (or UV light). Many of these effects seem to be related to quinone intermediates generating intercellular oxidant ultimately resulting in cell damage. DCNA appears to photo-degrade through quinone-hydroquinone intermediates, thus juvenile fish or aquatic invertebrates may be especially susceptible to phototoxic impacts from exposure to this chemical.

TP166 Determination of Physicochemical Properties of Atrzanie, Fipronil and Difficult-to-Test Substances: Pyrethroid Pesticides, in Freshwater and Seawater

P. Saranjampour, E.N. Vebrosky, Louisiana State Univ / Dept of Environmental Sciences; K. Armbrust, Louisiana State Univ / Environmental Sciences School of the Coast and Environment

Salinity has been reported to impact the water solubility of organic chemicals entering marine ecosystems however, there is scarce data available on salinity impacts for pesticides potentially entering seawater. Impacts on water solubility would corresponding impact chemical sorption as well as overall bioavailability and corresponding exposure estimates used in the regulatory assessment of pesticides. The insecticides fipronil, bifenthrin, cypermethrin and the herbicide atrazine are used heavily worldwide and can potentially be transported to water bodies through runoff or leaching. The water solubility and n-octanol/water partition coefficient (log K_{ow}) of atrazine and fipronil were determined in distilled water and artificial seawater using the OECD 105, flask method, and OECD 107, shake flask method, respectively. The water solubility and log K_{ow} of pyrethroids were determined in distilled water and artificial seawater using the OECD 105, column elution method, and the OECD 123, slow stir method, respectively. The water solubility of atrazine, fipronil, cypermethrin (a mixture of eight isomers), and bifenthrin were 56 ± 1, 4.8 ± 0.96, 0.78 ± 0.1, and 0.1 ± 0 in distilled water, versus 45 ± 0.24, 1.9 ± 0.25, 0.08 ± 0.02, and 0.04 ± 0.01, in artificial seawater. The log K_{ow} of atrazine, fipronil, cypermethrin, and bifenthrin were 2.55 ± 0.07, 3.48 ± 0.22, 5.53, and 6.63 in distilled water, versus 2.74 ± 0.09, 4.24 ± 0.35, 7.86, and 7.05 in artificial seawater, respectively. To date the log K_{ow} values of the pyrethroids in distilled water and artificial seawater were estimated from their water solubility. Overall, the water solubility of pesticides were decreased in artificial seawater versus distilled water while the log K_{ow} of pesticides were increased in artificial seawater versus distilled water. Salinity appears to generally decrease the water solubility and increase partitioning potential, as indicated by the log K_{ow}. Dramatic differences in chemical partitioning behavior in seawater versus freshwater suggest salinity should be taken into account when conducting exposure estimates for marine organisms.

TP167 A Spatially-distributed Modeling Framework to Integrate Effects of Agricultural Best Management Practices: A Midwest Case Study

D. Perkins, R. Gali, A. Jacobson, M. Gloe, Waterborne Environmental Inc; C. Truman, Syngenta Crop Protection, Inc.

The EPA pesticide risk assessment framework does not currently quantitatively account for off-field transport and exposure effects of best management practices (BMPs). Within the agricultural landscapes of the U.S., numerous structural and cultural BMPs are currently in place, mostly developed from NRCS programs to address agrichemical and soil loss reduction, natural resource conservation, and yield increase. In this work, a Midwest watershed was used as a case study for development of a spatially-distributed modeling approach to quantitatively evaluate potential impact of pesticide reduction (load and/or concentration) from multiple BMPs at multiple scales. This framework included a hydrologic and chemical transport model that was paired with stream flow and routing components to represent upland hydrologic processes, land management practices, and a flowing, receiving water body. Within the upland model, specific sub-areas were modeled separately to represent various structural BMPs, based on their physical location. Furthermore, cultural BMPs (non-structural such as application type, rate, and timing) were also incorporated into the upland model to different degrees to evaluate model sensitivity. A baseline scenario was developed and used to define comparative difference between addition (adoption) and elimination of BMPs in a step-wise fashion. As part of the baseline scenario, relevant literature values and publically-available environmental data were used to inform model parameterization. This modeling framework can be used to explore how BMPs may be considered in a regulatory framework, addressing issues such as: BMP adoption rate and viability, weather-dependent behavior, and frequency and extent of BMP efficacy.

TP168 Advances in the Refined National-Scale Drinking Water Assessment Framework: Case Study Chlorpyrifos

D. Perkins, N. Snyder, Waterborne Environmental, Inc.; P. Havens, Dow AgroSciences LLC; J. Amos, Waterborne Environmental, Incorporated / Geospatial Data Technologies; N. Poletika, Risk Analysis Solutions, LLC; K. Jones, Waterborne Environmental Inc

In the US pesticide regulatory scheme for human dietary exposure, estimates of the surface-derived drinking water contribution are assessed with simple scenario-based modeling techniques. Such estimates can be a useful and conservative approach in a tiered risk assessment to systematically eliminate potential concern; however, the limited conclusions that can be reached are often not adequate to address the true extent of potential exposures. The current work focuses on advances in national-scale drinking water concentration estimation techniques, using chlorpyrifos as a case study. The method incorporates spatially-distributed environmental and management information in a risk framework at the watershed (HUC12) scale. Concepts of standard scenarios to create conservative, regionally representative (at an extent wider than HUC12) estimates of exposure patterns were applied and then were distributed at the HUC12 watershed scale by matching them with HUC12-specific cropping patterns derived from five years of cropland data layer (CDL) data. As a conservative first approximation, it was assumed that a drinking water source co-occurs within every HUC12 where applications were made to labeled crops. In this way, HUC12-specific exposure estimates were derived for all chlorpyrifos-labeled crops. Then, county-level community water system (CWS) locations were included to eliminate risk concern from HUC12 watersheds that did not co-occur with a CWS. Results from this first approximation eliminated concern in 83% of HUC12 watersheds with labeled crop(s). The impact of refinements and assumptions on the remaining 17% of HUC12 watersheds was further explored. Potential refinements included higher-resolution rainfall, soils, runoff and erosion data inputs, more realistic environmental fate, application timing and application type information, and percent crop treated. Significant impact was observed from the inclusion of these refinements, with at least 92% of the remaining HUC12 watersheds yielding a conclusion of no concern. Characterization of potential risk in a spatially-distributed fashion increases risk characterization accuracy/certainty because of the inclusion of best-available data to inform estimates of exposure and co-occurrence. In conclusion, it was discovered that spatially-distributed environmental and management factors must be considered to increase certainty and characterize potential risk, rather than relying solely on a scenario-based approach.

TP169 Current Pesticide Regulations Do Not Protect Global Surface Waters

S. Stehle, R. Schulz, Univ Koblenz-Landau / Inst for Environmental Sciences

Current high-intensity agricultural practices lead to serious consequences for the global environment. Pesticides, in particular, are highly biologically active substances that can threaten the ecological integrity of nontarget ecosystems such as surface waters. However, considering particularly larger scales, our field-data based knowledge regarding the pesticide exposure of aquatic ecosystems is very restricted. The current study evaluated based on a comprehensive meta-analysis of 838 scientific studies the insecticide exposure of global agricultural surface waters (>2,500 sites in 73 countries). This analysis tested whether insecticide field concentrations (water and sediment) exceed legally accepted regulatory threshold levels (RTLs) derived from official EU and US pesticide registration documents and, amongst others, how risks depend on insecticide development over time and stringency of environmental regulation. The most important result of this study is that 52.4% out of 11,300 insecticide field concentrations exceeded respective RTLs. This finding indicates a substantial risk for the biological integrity of global water resources as we show that the regional aquatic biodiversity is reduced by approximately 30% at pesticide concentrations equaling the RTLs. Further analyses prove that RTL exceedances are significantly higher for newer-generation insecticides (i.e., pyrethroids) and are high even in countries with stringent pesticide regulations (e.g., United States; EU member countries). The overall findings of this meta-analysis substantiate that agricultural insecticides threaten surface waters globally and that the current pesticide regulatory risk assessment approaches fail to protect the aquatic environment.

TP170 Modeling spray drift and runoff related inputs of pesticides to receiving water

X. Zhang, California Dept of Pesticide Regulation / Environmental Monitoring; K. Goh, California Dept of Pesticide Regulation

Pesticides move to surface water via various pathways including surface runoff, spray drift and subsurface flow. Surface runoff is often considered as the most important transport route in many areas. However, in some watersheds, spray drift has been shown to be a significant contributor. Little is known about the relative contributions of surface runoff and spray drift in agricultural watersheds. This study attempts to develop a modeling framework to address the contribution of spray drift to the total loadings of pesticides in receiving water bodies. The modeling framework will consist of models for simulating spray drift, surface and subsurface runoff and environmental fate processes in receiving water. Monitoring data collected from daily samples were used for model evaluation. Preliminary results showed good agreement between model predicted concentrations for drift events and less so for runoff events. Once validated, the modeling framework could be a valuable tool to the decision making in pesticide risk management and mitigation such as where and what types of best management practices to implement in a watershed.

TP171 Deposition and spray drift ratio of commercially used sprayers

S. Mermer, Oregon State Univ / Dept of Horticulture; G.A. Hoheisel, Washington State Univ / Regional Extension Specialist in Tree Fruit and Grape Affiliate in Center for Precision and Automated Agricultural Systems; L.R. Khot, Washington State Univ / Dept of Biological Systems Engineering; V. Walton, Oregon State Univ / Dept of Horticulture; H. Bahlol, Washington State Univ

Optimal pesticide spray deposition is essential in order to achieve effective pest, weed and disease management. Differing designs of commercially available sprayers can possibly increase deposition especially as crop type, canopy density, and geographic features of the field change. Most sprayers can be adjusted to maximize application efficiency. Common changes include nozzle size, vertical orientation of nozzles, and fan speed. However, these adjustments may not completely eliminate spray drift onto non-target areas which can increase the environmental — bees, parasitoids, predators and aquatic and terrestrial organisms— and farm-worker risk. We evaluated three different spray technologies— airblast, cannon, and electrostatic technologies—in order to create comparable baseline knowledge regarding canopy deposition, aerial drift and mid-row floor deposition. Spray applications were conducted using a tank mix containing water-soluble Pyranine 10G® fluorescent tracer. Air and ground drift samplers were placed above the canopy zone and on the ground in adjacent rows to measure the respective levels of fluorescent spray deposition. Replicated samples were collected, refrigerated, and subsequently measured by using fluorometry technique. Preliminary results showed that electrostatic sprayer had increased in-canopy coverage and lower levels of aerial drift. The cannon sprayer displayed lower levels of ground deposition compared to electrostatic and airblast sprayers. These results indicate both advantages and drawbacks of the respective tested sprayers and may help growers make more informed decisions regarding optimal application technologies for their field and the environment.

TP172 Importance of Time-Dependent Sorption in Ground Water Modeling in Regulatory Assessments

R.L. Jones, Bayer CropScience / Environmental Safety; R. Sur, Bayer CropScience AG / Environmental Safety; E. Henry, Bayer / Environmental Safety; B. Jene, BASF / Environmental Fate; W. Chen, Syngenta

Scientists have recognized for over 30 years that sorption of crop protection products and their metabolites increase with time. This process is typically referred to as time-dependent sorption (TDS), aged sorption, or kinetic sorption. From a regulatory viewpoint, these effects are especially important for compounds with moderate sorption when assessing potential movement to ground water, but in some cases the effect of increasing sorption with time can be a critical factor for quite mobile compounds. This will be illustrated with examples comparing monitoring data with modeling including and not including TDS. Currently TDS is generally modeled considering a liquid phase and two soil phases, one in equilibrium with the liquid phase and the other with sorption and desorption with the liquid phase described kinetically. Incorporation of TDS in the registration process has been discussed in Europe since 1997 and guidance first issued in 2000. The ability to model TDS was introduced in 2000 in the regulatory models used in the European Union for assessing movement to ground water, but discussions on guidelines for experimental studies and the derivation of model parameters are still continuing. In the United States, use of TDS for regulatory applications has been delayed as discussions continue on the appropriateness of describing of the process using a liquid phase and two solid phases.

TP173 Use of a tiered modeling approach for EU GW modeling

P. Sharma

The EU approval and national authorisation processes under Regulation (EC) 1107/2009 require the assessment of the potential of an active ingredient and its metabolites to move to ground water (FOCUS, 2015). FOrum of Coordinated USe of Pesticides (FOCUS, 2015) presents a standard set of scenarios and models that can be used to assess the potential movement of pesticides and their metabolites with soil leachate under a broad range of environmental conditions in Europe. The scenarios are intended to be broadly representative of a wide range of European agricultural settings vulnerable to leaching. The FOCUS guidance offers a tiered structure to groundwater modeling with conservative inputs and approaches at the lower tier and possibility of refinements at the higher tier. Refinements with field data, plant uptake factors, inverse modeling and use of aged sorption parameters can be considered as higher tier approaches. For this study, the leaching behavior of dummy substances provided in FOCUS,2015 were assessed by means of simulation runs with the leaching model FOCUS PEARL 4.4.4. Tomato was used as an example crop for simulations. The following tiered approach was used: 1) tier 1 gw modeling – lab degradation endpoints, 2) tier 2 – field degradation parameters 3) field data with plant uptake factor 4) field data, default plant uptake factor and default aged sorption parameters from FOCUS, 2015 5) default plant uptake and variation of default aged sorption parameters from FOCUS, 2015 gw guidance. Results were compared for all the tiers modelled. The simulations indicate that predicted environmental concentrations in groundwater for active substances and/or metabolites can vary by up to 3-5 times depending with parameter refinements and higher tier modeling approaches.

TP174 Use of laboratory determined subsoil sorption data to refine EU ground water leaching assessments

F.P. Donaldson, BASF Corporation / APDEFR

In European regulatory leaching assessments, the predicted concentrations of pesticides and their degradation products in ground water are highly dependent on soil adsorption input values. Modeling results are particularly sensitive for low sorbing compounds, e.g. those with organic-carbon normalized sorption coefficients ($K_{f,oc}$) of < 100 mL g^{-1}. Demonstrating that sorption is not correlated with soil organic carbon can be difficult with low sorbing compounds, leading to the implementation of a $K_{f,oc}$ in ground water leaching models and often exceedances of the pertinent ground water limit (e.g. 0.1 ug L^{-1}) for parent and relevant metabolites. Studies investigating sorption to subsoils, particularly those of low organic carbon, may demonstrate that sorption occurs both independently of organic carbon and throughout the soil profile. Such studies could thus lead to refinement of the sorption parameter for ground water modeling and more realistic estimates of ground water leaching potential. A refinement of the sorption endpoint for ground water modeling, based on subsoil sorption studies, will be presented and discussed. In particular, a high speed centrifugation plus filtration technique to enable accurate determination of sorption values for low sorbing compounds will be presented. The resulting subsoil sorption endpoints will be compared with topsoil sorption endpoints, and their implementation in ground water leaching models will be compared against the more conservative $K_{f,oc}$ approach.

TP175 Use of Pesticides Groundwater Monitoring data as higher tier for regulatory risk assessment – Feedbacks from France

A. Boivin, ANSES

Pesticides risk assessment in the EU regulatory framework is mandatory performed for pesticides. In both cases, no unacceptable risk of groundwater contamination has to be proven. Routinely, Predicted Environmental Concentrations in GroundWater (PECgw) are derived using numerical models for pesticides and metabolites. In addition to modelling, the European regulatory framework also allows for Groundwater Monitoring data to be used for pesticides approval. In the tiered approach, Groundwater Monitoring data are identified as higher tier that may supersede the modelling. Still, there is currently no European guidance document available on the use of groundwater monitoring data for regulatory purposes. In France, Groundwater Monitoring data have been submitted to Anses (French Agency for Food, Environmental and Occupational Health & Safety) in order to support the renewal of pesticides. The aim of this presentation is to provide a feedback based on different worked examples. These feedbacks include focus on the main issues that were identified and the general recommendations that were made when targeted monitoring were submitted. The main issues when dealing with Groundwater Monitoring data interpretation were related to site selections and related vulnerably, and then of how representative was the GroundWater monitoring. Recommendations were made to address both issues and will be presented. In addition, proposal to combine targeted together with public Groundwater Monitoring dataset were made to enhance the representativeness of the GW monitoring conducted and will also be presented.

Modeling Human and Ecological Exposure over the Life-Cycle of Consumer Products

TP176 Aqueous leaching of chemical additives from microplastics

R.C. Hale, Virginia Inst of Marine Science / Aquatic Health Sciences; H. Hubbard, ICF International; M.J. La Guardia, D.R. Luellen, K. Uhlig, Virginia Inst of Marine Science / Aquatic Health Sciences

Plastics are ubiquitous in our daily lives; where they constitute major components of materials in our homes, workplaces, hospitals, schools & vehicles. Our food, beverages & medicines are stored in plastic containers. Most plastics are eventually discarded & enter terrestrial & aquatic environments in massive quantities. They fragment over time into microplastics, which exhibit greatly enhanced surface areas & reactivities. Once released, plastics may impact health & ecological processes. As plastics are compositionally diverse & exhibit differing properties, treating them as a homogenous class in terms of fate & health impacts is inappropriate. A multitude of additives are also incorporated into polymers, often at % by weight levels, to alter their appearance, flame retardancy, flexibility & other properties. The additives themselves exhibit varying behaviors & toxicities. While it was long assumed that additives remained within polymers indefinitely & thus exposure risks were minimal, this is untrue. For example, humans & wildlife contain substantial burdens of additives, such as persistent, lipophilic brominated flame retardants (BFRs). Approaches to systematically evaluate the mobility of additives from polymers under a wide array of conditions are needed. We examined here the ability of aqueous fluids of varying temperature & humic acid composition to leach additives from polyurethane foam (PUF), acrylonitrile butadiene styrene (ABS), polyvinylchloride (PVC) & expanded polystyrene. (EPS). The PUF examined contained PentaBDE and Firemaster 550. ABS contained decabromodiphenylethane. EPS contained HBCD & PVC the plasticizer DEHP. Polymers were crogenically milled & air-jet sieved to generate particles of similar size (53-300 um) for testing. Microplastics were examined by electron microscopy & their surface areas measured. Ground polymer (0.4 g) was mixed with sand and packed into a HPLC column located in a temperature controlled incubator. Water of the desired temperature & humic acid content was pumped through the column at ~1 ml/min, the eluent collected and analyzed by LC or GC/MS. In addition to BFRs, several tris phosphate FRs were detected in the water. These tris phosphates were not detected in the PUF as they were present at relatively low levels. Elevated temperature (40^0C) and humic acid content leached greater amounts of the hydrophobic additives (e.g. DBDPE, PBDEs, TBB). Levels of HBCD in the leachate were surprisingly low.

TP177 Environmental Costs and Benefits of Nano-Silver Textiles: combining LCA and MCDA

A. Hicks, Univ of Wisconsin – Madison / Civil and Environmental Engineering

Silver has been utilized for its antimicrobial properties since antiquity. Those same antimicrobial properties have produced a myriad of nano-silver (nAg) enabled products, and in particular nAg textiles. These textiles are currently market as “anti-stink gear”, embracing the notion that the addition of the nAg will inhibit the growth of bacteria on the textile and reduce odor. Manufacturers of these textiles tout the ability to launder them less, and thus reduce the overall life cycle impact of the textile, as laundering has historically been found to be the greatest contributor to the overall life cycle environmental impact of textiles. However, the addition of nAg to textiles comes at an additional environmental cost when compared to conventional textile counterparts. And a wide variability exists with respect to the concentration of silver attached to the textiles, ranging from 0.9 µg nAg per gram of textile to 21,000 µg/g. Losses of nAg due to laundering also vary significantly as a function of the attachment method of the silver, ranging from < 1-100% of the initial silver content of the textile. The loss of silver not only decreases the antimicrobial efficacy of the textile, but also provides a pathway for nAg to enter the environment. The silver will eventually enter the wastewater treatment plant, and is expected to be in the form of AgCl or Ag_2S. Approximately 90-95% of the silver entering the wastewater treatment plant will be removed into the biosolids, with the rest entering the aquatic environment. At the same time there are expected benefits to these textiles, which are not only limited to reduced laundering. In a medical setting, the antimicrobial benefits may vastly outweigh the increased environmental burden of nano-enabling the textile. In order to fully investigate the environmental costs and benefits of nAg enabled textile when compared to the conventional counterpart life cycle assessment is coupled with multi-criteria decision analysis. This case study provides a framework for evaluating the benefits and costs of nano enabled products from an environmental and human health perspective. This methodology has the potential to advance the state of the filed, when assessing the environmental and human health costs and benefits of nano-enabled products.

TP178 Human exposure analysis of airborne halogenated flame-retardants

M.J. La Guardia, Virginia Inst of Marine Science / Aquatic Health Sciences; E. Schreder, Washington Toxics Coalition; R.C. Hale, Virginia Inst of Marine Science / Aquatic Health Sciences

Halogenated flame-retardants (FRs) (e.g. PBDEs), used in a wide array of polymer-containing products, are being detected in indoor environments. Positive correlations have been observed between PBDE levels in house dust & those in human breastmilk. PBDEs have been largely phased out, but replaced by other halogenated FRs that lack comprehensive toxicity testing. Positive associations are now being observed between levels of replacement FRs (i.e. 2-ethylhexyl 2, 3, 4, 5-tetrabromobenzoate (TBB) & bis (2-ethylhexyl) 3, 4, 5, 6-tetrabromophthalate (TBPH)) in house dust & on handwipes of children. Inhalation exposure for several chlorinated organophosphate FRs (ClOPFRs: tris (1, 3-dichloro-2-propyl) phosphate (TDCPP), tris (2-chloroethyl) phosphate (TCEP), & tris (1-chloro-2-propyl) phosphate (TCPP)) was estimated to exceed exposure from dust ingestion, indicating that the toxicological importance of inhalation of indoor airborne FRs. However, not all airborne particulates are respirable. Larger particulates can be trapped on the mucosal lining of the respiratory tract, then expelled or swallowed. Therefore, to explore the route of airborne FR exposure, we compared respirable (< 4µm) & inhalable (> 4µm) personal air levels within common indoor spaces (i.e. residences & mixed (office/residences)) to levels detected in gymnasiums. The latter environments are laden with FR-treated polyurethane foam & have previously been reported to contribute to gymnast PBDE blood levels. Within residences, office/residences & gyms, the air particulates > 4µm carried > 93% of the FR burden, consisting mostly of TCPP. Total ∑ClOPFRs levels in personal air showed no significant difference among the three environments ($p > 0.05$), with levels of 595, 428, 546 ng m^{-3} (respirable + inhalable), respectively. Total Penta-PBDEs & TBB + TBPH levels within the gyms were < $1/3^{rd}$ of the ∑ClOPFRs concentrations, but exceeded those in residences & office/residences by several fold ($p < 0.05$). However, the respirable air levels (< 4µm) of TBB + TBPH in all three environments & Penta-PBDEs levels between the gyms & residences were not significantly different ($p > 0.05$). Although the gym air levels exceeded those of the residences & office/residences for some FRs, these findings indicate that the respirable exposure may be similar between these spaces. These findings indicate that ingestion of airborne particulates should be considered in future risk assessments.

TP179 Models for Estimating Exposure to Chemicals used in Consumer Products and Indoor Environments

C. Bevington, USEPA; Z. Guo, H. Hubbard, ICF International; E. Wong, X. Liu, USEPA

The U.S. Environmental Protection Agency’s Office of Pollution Prevention and Toxics (OPPT) assesses exposures, including consumer exposure, for its New and Existing chemicals Programs. Consumer exposure estimates can be based on measured exposure data, modeling approaches, or a combination of both. OPPT’s Consumer Exposure Model (CEM) was recently updated to include six inhalation models, five ingestion models, and four dermal models that can be used to approximate nearly 100 product and article exposure scenarios. All CEM models are used to estimate time-varying chemical concentrations in exposure media, including the product or article itself, indoor air, airborne particles, settled dust, and soil. The model also evaluates dermal flux of a chemical through the skin from contact with liquid or gas-phase chemical, and estimates the migration of a chemical from an article into saliva. OPPT has also developed a higher-tier model based on EPA’s Office of Research and Development’s existing Indoor Air Quality and Inhalation Exposure (IAQX) and Indoor-Semi-Volatile Organic Compound (I-SVOC) models. This new OPPT model is a simulation program for estimating chemical emissions from consumer products, articles, and building materials and their impact on Indoor Environmental Quality in Buildings with Conditioned and Unconditioned zones (IEQ-CU). IEQ-CU characterizes short and long-term emissions of volatile organic compounds (VOCs) and SVOCs and estimates subsequent air, airborne particle, and dust concentrations. CEM was developed for wide application for both data-poor and data-rich chemical and use scenarios. IEQ-CU was developed for refined estimates of exposure and requires more model inputs than CEM. Selection of the most applicable model depends on the scenario under evaluation, the chemical and pathway of interest, and the quantity and quality of available data. This presentation will provide an overview of approaches to measure or estimate required CEM and IEQ-CU model inputs such as emission rates, gas-phase mass transfer coefficient, material-air partition coefficient, and solid-phase diffusion coefficient, source dimensions, inter-zonal air flow, and initial concentrations of chemical in the source. Potential next steps for model development and application will also be discussed. The views expressed in this abstract are those of the authors and do not represent Agency policy or endorsement.

TP180 Testing Protocols for Evaluating Exposure to Chemicals from Products

M.T. Lee, Environmental Protection Agency / Office of Pollution Prevention and Toxics; L. Libelo, USEPA / OPPT RAD; Z. Guo, H. Hubbard, ICF International; C. Bevington, USEPA

The U.S. Environmental Protection Agency's Office of Pollution Prevention and Toxics (OPPT) assesses exposures, including consumer exposures, for its New and Existing Chemical Programs. Consumer exposure estimates are based on available product testing data, monitoring data, or modeling approaches. Existing methods have been used by organizations to test products for chemical content and emissions. There is variation and lack of consensus across testing protocols that evaluate exposure to chemicals from products. Such protocols are typically tailored to the scenario of interest and will vary based on information about chemical use and measured or estimated physical-chemical properties. However, some aspects of product testing could be standardized to promote efficiency, data comparability, and more routine use of such data in exposure assessments. OPPT developed a first set of generic exposure testing protocols in 2015 and is now updating those protocols. The updated protocols have information on experimentally measuring the chemical content in products or articles; emission rates, including short-term emission rates, long term emission rates, and determination of material-air partition coefficients and solid-phase diffusion coefficients; and generation of particles by abrasion. The updated protocols also have information on direct transfer of chemical to dust in contact with the article, chemical transformation due to photolysis, migration/leaching of chemical from article into water, migration of chemical from article into saliva and sweat, and dermal exposure to chemicals transferred from liquids or particles to the skin. This presentation will provide an overview of testing protocols and general considerations for how these testing protocols could be applied to different chemical/product or chemical/article combinations. This presentation will also summarize how results from product testing could be used directly in exposure assessment or as inputs for available consumer exposure models. The views expressed in this abstract are those of the authors and do not represent Agency policy or endorsement.

Science of Sediment Toxicity Testing: Method Advances, Interpreting Results and Use of Data in Ecological Risk Assessments

TP181 Future Challenges in Sediment Toxicity Testing for the Risk Assessment of Plant Protection Products

D. Faber, E. Bruns, V. Herno, Bayer CropScience AG / BCS D ETX Ecotoxicology; M. McCoole, Bayer CropScience / Environmental Toxicology and Risk Assessment

Sediment toxicity testing is gaining an increasing awareness within the scientific community. In 2015, a scientific opinion on environmental risk assessment for sediment organisms was published by the European Food Safety Authority (EFSA). In the EU, this scientific opinion is of high interest for risk assessors and aquatic ecotoxicologists because so far, only the Tier I risk assessment for sediment organisms was addressed in the existing aquatic guidance document published in 2013 by EFSA. In addition, the number of currently available standardized and validated OECD guidelines is limited. These tests mainly cover invertebrates (e.g.,Chironomus riparius, Lumbriculus variegatus). A sediment test with the macrophyte Myriophylum is also available. In the United States, sediment toxicity is considered differently within the risk assessment as reflected by the ASTM and USEPA guidelines. There are also a higher number of standardized test methods available for sediment dwelling or epibenthic organisms (e.g.,Hyalella azteca, Chironomus dilutus, Leptocheirus plumulosus). There are a number of differences between the OECD and USEPA guidelines, including the use of natural or artificial sediment, equilibration time, and a flow-through or static test design. These test method differences lead to changes in the physiochemistry of the sediment, in the bioavailability of the test compound, and the concentrations of the test substance in the overlying water, pore-water, and bulk sediment. Due to these differences, the test results of studies performed according to OECD and USEPA test methods are difficult to compare. In recent years, it has been discussed which matrix (overlying water, pore-water, sediment, or total loading) should be used to determine effects endpoints in sediment toxicity studies. Most of the test organisms used are epibenthic and live on the sediment surface, rather than in the sediment itself. Therefore, being aware of the discrepancies between the OECD and USEPA test methods, some common issues need to be considered. These issues include the relevant route of exposure, as well as how to express test results to be used in the environmental risk assessment.

TP182 Interlaboratory Evaluation of Bioaccumulation from Field Collected Sediments Using Hexagenia spp., Lumbriculus variegatus and Pimephales promelas

T. Watson-Leung, Ontario Ministry of the Environment / Aquatic Toxicology Unit; M. Oke, Ontario Ministry of the Environment and Climate Change; M. McElroy, Pacific EcoRisk Laboratories; M. Stuart, Canadian Nuclear Laboratories Limited CNL / Environmental Technologies; M. Rendas, AquaTox; M. Raby, Univ of Guelph / School of Environmental Sciences; K. Mahon, Ontario Ministry of the Environment and Climate Change

Standardized bioaccumulation testing of aquatic organisms is essential to understanding the impact of historical contamination on the quality of water and sediment. Input of contaminants into aquatic ecosystems has been reduced through the regulation of discharges, however historical contamination continues to impact the quality of water and sediment. In addition to the physicochemical characterization of sediment, toxicity testing, and benthic surveys, an assessment of the bioaccumulation of contaminants is now part of the decision-making framework for contaminated sediments in Ontario and elsewhere. A standardized freshwater sediment bioaccumulation method for the mayfly Hexagenia spp., the oligochaete Lumbriculus variegatus, and the fathead minnow Pimephales promelas, has been developed and validated by the Ontario Ministry of the Environment and Climate Change (MOECC). Interlaboratory testing is needed to understand precision and variability of bioaccumulation test results and assist with the interpretation of bioaccumulation data. An interlaboratory comparison was conducted to assess the precision of this method. Three field collected non-toxic sediments contaminated with bioaccumulative compounds were used in this study. Sediment contaminated with arsenic was tested with Hexagenia spp., polycyclic aromatic hydrocarbon (PAH) contaminated sediment was assessed using L. variegatus, and sediment with high levels of polychlorinated biphenyls (PCBs) was tested with P. promelas. Control and test sediment were sub-sampled and sent to six (Hexagenia spp.) or seven (Lumbriculus variegatus and Pimephales promelas) laboratories to perform the bioaccumulation test. Survival, growth and tissue accumulation of the contaminant of concern will be presented and method precision, challenges and opportunities for method refinement will be discussed.

TP184 An evaluation of endpoints from benthic invertebrate chronic toxicity tests based on draft US FIFRA guidance – Part II

J. Gates, Waterborne Environmental, Inc. / Ecotoxicology; T.W. Valenti, Syngenta Crop Protection LLC / Environmental Safety; A.K. Kabler, Syngenta Crop Protection, Inc. / Ecological Risk Assessment; A.J. Jones, DuPont Crop Protection / Inst of Environmental Toxicology; A. Samel, DuPont Crop Protection; J.W. Green, DuPont / Applied Statistics Group; J.P. Staveley, Exponent; B. Sharma, FMC Corp/ Global Regulatory Sciences / Senior Ecotoxicologist; S.P. McGee, Bayer CropScience LP / Environmental Health Sciences; M. McCoole, Bayer CropScience / Environmental Toxicology and Risk Assessment; J. Wang, BASF Corporation / Environmental Toxicology; M. Habekost, BASF Corporation; H.O. Krueger, Wildlife International / Aquatic Plant and Insect Toxicology; M.J. Bradley, Smithers Viscient / Sediment Toxicology; C.R. Picard, Smithers Viscient / Sediment and Plant Ecotoxicology; J.M. Giddings, Compliance Services International; M.A. Cafarella, Waterborne Environmental, Inc / Ecotoxicology; S. Thomas, Wildlife International; I. Saab, CropLife America

On October 26, 2007, sediment chronic toxicity testing with benthic aquatic invertebrates became a conditional requirement as part of the Office of Pesticide Program's ecological effects data requirement contained in 40 CFR Part 158 Subpart G. Studies are now required for any pesticides with soil partition coefficient (Kd) ≥ 50, log Kow ≥ 3, or Koc ≥ 1000. Due to the novelty and complexity of the study designs, it is important to gain a critical understanding of the relative sensitivities of required test endpoints within and among tests. At the 2015 SETAC North America annual meeting, the CropLife America (CLA) Ecotoxicology Work Group Sediment team presented a poster detailing key findings from a sediment toxicity testing database that was compiled by CLA. For the Chironomus dilutus life-cycle tests, larval survival, growth and emergence were the most sensitive parameters, whereas endpoints based on reproduction or adult survival (i.e., number of days to death) were consistently less sensitive. For, for chronic sediment studies with amiphipods (Hyalella azteca and Leptocheirus plumulosus), survival, growth, and reproduction proved to be important parameters to measure and each parameter yielded the most sensitive endpoint for certain studies. This presentation will provide an update and recommendations for streamlining relevant endpoint selection, as well as more closely consideration of the variability within control responses and subsequent implications.

TP185 Development of whole-sediment toxicity identification evaluation (TIE) techniques for use in Australia

W.T. Mehler, Univ of Melbourne / Zoology; V.J. Pettigrove, The Univ of Melbourne / Zoology

A majority of the public literature and available guidance documents on "how-to" conduct whole-sediment toxicity identification evaluations (TIEs) detail the use of test organisms and amending agents that are readily available in the United States. Although much of the information in these documents can be utilized regardless of location, the test organisms and amending agents documented in the current TIE literature are both not available and largely inappropriate (i.e. not native species) for conducting whole-sediment TIEs in Australia. Thus, the overall objective of this study was to build foundational methodologies for performing whole-sediment TIEs with native Australian species. In this study, we examined the capability of three readily available amending agents in Australia: a local produced zeolite product (for ammonia), an activated carbon (for non-polar organics), and Lewatit Monoplus TP 207 (for cationic metals) on two Australian native freshwater species: Chironomus tepperi (midge) and Austrochiltonia subtenuis (amphipod). To evaluate the effectiveness of each amendment, bioassays were conducted with spiked sediments of ammonia, permethrin, and copper using mortality and growth as endpoints. For each amendment, the effectiveness in reducing toxicity differed based on which test organism was used. Understanding the differences in testing methodologies (such as test duration), species sensitivities, and the niche and behavior of the organism is impetrative for building a solid foundation for TIE work in areas were these techniques have yet to be applied.

TP186 Defining Equilibration Time of Spiked Sediments for Use in Whole Sediment Toxicity Testing: A Post Hoc Assessment

M.J. Bradley, Smithers Viscient / Sediment Toxicology

Spiked whole sediment toxicity testing in support of US pesticide registration typically utilizes a prolonged aging period of spiked sediments prior to organism exposure, during which concentrations of the applied test compound presumably achieve a state of equilibrium between sediment and pore (interstitial) water. In recent years, regulators have requested that compound-specific equilibration periods be defined prior to organism exposure, as opposed to using default aging periods (e.g., 30-days) described in older test methods. A test design for determining a compound-specific equilibration period can be conceptualized relatively easily, however, interpretation of the results can be made difficult by multiple confounding factors, most notably the adsorptive qualities of the compound, organic carbon content of the sediment-pore water matrices, and the conventional analytical methods employed (e.g., liquid-liquid extraction). While partitioning of a compound with a relatively low adsorption coefficient can be interpreted rather clearly, compounds with a higher adsorption coefficient may result in more variable data, which also may not be considered realistic or relevant to anticipated aqueous concentrations (e.g., measured values exceeding solubility). These findings are generally attributable to the suspended and dissolved organic carbon content of a pore water sample to which the compound may be bound, which ultimately leads to an over estimation of freely dissolved compound following extraction and analysis. The uncertainty of these data results in a subjective interpretation which may thereafter be contended or be considered inconclusive. This presentation will review a number of data sets related to compound-specific sediment-pore water equilibration studies to look at the relevance and reliability of the data collected, in light of varying compound physicochemical attributes and assumptions of equilibrium partitioning theory. Ultimately, the goal of this presentation is to refine an approach for objectively determining an appropriate compound-specific equilibration period for spiked sediment testing, while understanding the limitations of the methods employed.

TP187 Development of site-specific sediment quality guidelines for a tropical region (Ceará State, Northeast Brazil)

L.B. Moreira, Sao Paulo State Univ – UNESP / Instituto de Biociências Câmpus do Litoral Paulista; T.F. Peres, Federal Univ of Ceará / Instituto de Ciências do Mar LABOMAR; S.t. Sasaki, Instituto Oceanografico da Universida de Sao Paulo / Oceanografia Química; R.B. Choueri, Unifesp Univ Federal de São Paulo / Departamento de Ciências do Mar; S. Taniguchi, Univ of São Paulo / Physical Oceanography Dept; M.C. Bícego, IOUSP; R.V. Marins, Federal Univ of Ceará / Instituto de Ciências do Mar LABOMAR; D. Abessa, Unesp / Marine Biology and Coastal Management

Dredging operations involves the excavation and removal of sediments and rocks from the bottom of harbors zones for the maintenance of depth of navigation channels. However, sediment contamination can cause environmental impacts and economic losses, offering ecological risks to animals exposed to such material, both at the time of dredging as in the oceanic disposal. To deal with this environmental concern, normative enforcements and criteria have been created to support management actions. Such criteria involve the development of sediment quality guidelines (SQGs) through different approaches (e.g. theoretical, empirically and site-specific) which represent thresholds that reflect the relationship between concentrations of contaminants and adverse biological effects. In Brazil there are differences in climate and sedimentology along the coastal zone resulting in different conditions of geochemical aspects that control the bioavailability of contaminants in sediments that need to be addressed. Also, The Federal Resolution CONAMA 454/12 was published with the purpose of establishing SQGs for dredging activities in Brazil, but however, such parameter were based on international values and fails to predict toxicity, supporting the need of site-specific assessments. In this study we developed site-specific SQVs for harbor areas of Ceará State located in the Tropical region of Brazil, based on an integrated analysis of sediment contamination (trace metals and hydrocarbons) and sediment toxicity of solid and liquid phases by using multivariate analysis and geochemistry indices calculated from background values. The results allowed the identification of chemicals of concern and the toxic effects range related to sediment contamination. Also, site-specific SQGs are more restricted than SQGs applied in most countries, including Brazil supporting the hypothesis that the aplication of international SQGs may result in failures to predict impacts associated with dredged materials.

TP188 The Importance of Sediment in Aquatic Toxicology: Refined Hazard Assessment of the POEA surfactant in Roundup

J. Rodriguez Gil, Univ of Calgary / Biological Science; R.S. Prosser, Environment and Climate Change Canada / Canada Centre for Inland Waters; M.L. Hanson, Univ of Manitoba / Dept of Environment and Geography; K.R. Solomon, Univ of Guelph / School of Environmental Sciences

Due to the lack of exposure data, it has been challenging to assess the potential ecological hazard/risk posed by MON 0818, the polyoxyethylene amine (POEA) surfactant present in the original formulations of glyphosate (e.g. Roundup Original). To date, hazard/risk assessments for this surfactant have been performed following traditional Tier-1 approaches. These are based on acute (24-48h), water-only toxicity tests compared to worst-case-scenario water-column concentrations assuming constant exposure over the duration of the experiment. We recently showed that MON 0818 presents a high affinity for sediment and that, in its presence, the water column half-life of the surfactant can be very short (generally < 10h, and commonly < 5h). Here, we present a refined hazard assessment of MON 0818 based on the re-evaluation of the existing toxicity data, supplemented by water-only toxicity data for an additional 15 species, tested with standard methodologies and confirmation of exposure concentrations. In order to further explore the role that sediment plays in the exposure of aquatic organisms to MON 0818, we also present the results of a series of test following novel approaches such as water column toxicity tests in the presence of sediment and the evaluation of pulse-recovery approaches to mimic water column exposures for compounds with short water-column half-life. When evaluated in this manner, no acute (24-h) mortality was observed for three of the five species tested in the presence of clean sediment up to 10 mg L^{-1} MON 0818 initial water concentration. The EC50s for the other two species were significantly greater than for parallel water-only tests. Our results indicate that quick dissipation of MON 0818 in the presence of sediment can reduce the effects on exposed organisms, and that full recovery from 24-h exposures to concentrations of MON 0818 equal to, or greater than, those expected in the environment is possible. These results highlight the inappropriateness of simple screening-level approaches for the assessment of the risk posed by compounds for which the expected exposure regimes may deviate from that more typically used in traditional standard acute laboratory tests. For compounds with similar characteristics, toxicity testing in the presence of sediment can serve as a valuable tool, even when the sediment is not the initial source of exposure.

TP189 Toxicity of Pharmaceuticals and Personal Care Products to the Estuarine Amphipod, Leptocheirus plumulosus, Exposed to Sediments from an Urban Waterway

J. Gondek, GEI Consultants; R. Gensemer, GEI Consultants / Ecological Division; J. Nuwer, D.G. Gunster, NewFields; A.K. Kovach, GEI Consultants

For sediments in industrial urban waterways, benthic invertebrate toxicity is often used as a basis for developing preliminary remediation goals for chemicals such as polycyclic aromatic hydrocarbons (PAHs) and metals. Understanding how both legacy and ongoing sources (from run off and combined sewer overflows) of contamination contribute to ecological risk are important for informing such sediment remedial decisions. Furthermore, pharmaceuticals and personal care products (collectively referred to as PPCPs) represent a group of chemicals that are commonly found in sediments from urban waterways, but are often not analyzed for or considered in ecological risk assessments. Sediment chemistry and 28-day benthic toxicity data (using the estuarine amphipod, Leptocheirus plumulosus) were evaluated from Newtown Creek, a large industrial intertidal waterway in New York, which receives significant input from CSOs and stormwater run off. The objective of this study was to evaluate whether there were any apparent relationships between PPCP sediment concentrations and benthic toxicity. Comparisons were also made to more typical ecological risk drivers, such as PAHs and metals. Dose-response curves were generated using toxicity data compared to both bulk sediment concentrations and estimated pore water toxic units (TU). Several of the PPCPs analyzed, namely bisphenol A, nonylphenol, and 4-tert-octylphenol, showed clear concentration-dependent relationships to benthic toxicity. These results suggest PPCPs could be contributing to the overall toxicity observed in benthic invertebrates exposed to Newtown Creek sediment. The sum of the estimated pore water TU for these three PPCPs also showed a strong relationship to benthic toxicity, particularly survival. Statistical analysis further indicates PPCP TUs are strongly correlated with toxicity (Pearson's correlation coefficient = -0.80). Additional studies would be needed to confirm these results given the uncertainty of the pore water PPCP TUs, which were based on pore water concentrations estimated from equilibrium partitioning.

TP190 Recent advancements in sediment elutriate (dredged material) water column evaluations

A.J. Kennedy, CEERD-EPR / Environmental Laboratory; G.R. Lotufo, US Army Corps of Engineers ERDC; J.D. Goss Laird, Us Army Engineer Research & Development Center / Environmental Laboratory; L. Rabalais, US Army ERDC; J.H. Lindsay, US Army Engineer Research and Development Center; J. Biedenbach, US Army ERDC; D. Farrar, US Army ERDC / Enviromental Laboratory

Evaluations to determine the suitability of dredged material for open water placement may require physical, chemical and biological evaluation of the sediment in the suspended phase and solid phase. Bioassays are used to determine potential acute toxicological effects to pelagic organisms, and acute and chronic implications to benthic organisms. This work focuses on evaluations of the suspended particulate and dissolved chemical phases in the water column while dredged material settles in open water. While greater concern may be on the acute effects of persistent contaminants such as metals, ammonia often causes toxic effects in elutriate toxicity bioassays. In this presentation, freshwater (Ceriodaphnia dubia, Pimephales promelas) and marine (Americamysis bahia, Menidia beryllina, Mytilus edulis, Arbacia punctulata, Arcatia tonsa, Pseudodiaptomus pelagicus) organisms were exposed to both suspended sediments (elutriates) and model contaminants (copper, ammonia) that may be released to the water from suspended sediments. Comparison between marine test species indicated dramatic differences in sensitivity, most notably to ammonia. Recently adapted ammonia toxicity reduction evaluation methods for elutriates (zeolite, pH reduction, EDTA, C18) were employed to determine that ammonia was the main driver of toxicity in specific freshwater and marine elutriates (survival increased from < 20% to >90%), and metals and organics were not at sufficient concentration to induce mortality. These data were used develop support for applying alternative safety (application) factors for ammonia, rather than the default 0.01 factor, loosely based on a NOEC/LC50 ratio. Low effect endpoints (EC5, EC10) were modeled due to criticism of the NOEC. In addition, testing with Mytilus embryo development endpoints indicated extreme sensitivity to unionized ammonia (EC50 = 0.17 mg/L) questions need for a safety factor embryo development is the organisms' most sensitive life stage, based on chronically exposed juvenile mussels being two times more tolerant. Since urchin and mussel embryos are not holozooplankton, international marine copepod methods were adapted and indicated that while copepods (Acartia, Pseudodiaptomus) are very sensitive to copper, they are less confounded by ammonia. These data support methods to make relevant and representative risk-informed decisions for dredging evaluations.

TP191 Exposure to Sediments Spiked with Deepwater Horizon Oil Inhibited Growth in Juvenile Red Drum and Pacific White Shrimp

J.M. Morris, I. Lipton, C. Lay, M. Carney, R. Takeshita, H. Forth, M.O. Krasnec, A. McFadden, R. Hall, J. Lipton, Abt Associates; J.C. Cegan, US Army Corps of Engineers ERDC; S. Bonnot, Texas Parks and Wildlife; M.L. Gielazyn, NOAA / co USEPA Region IV

In support of the Deepwater Horizon (DWH) Natural Resource Damage Assessment, we exposed juvenile (21 days post-fertilization) red drum (Sciaenops ocellatus) and post-larval Pacific white shrimp (Litopenaeus vannamei) to sediment spiked with DWH oil. We initiated these tests simultaneously using identical sediment spiked with naturally weathered DWH oil and identical flow-through exposure systems. We exposed juvenile red drum for 13 days and Pacific white shrimp for 6 days. Exposure to DWH oil in sediment inhibited growth in both species. The 13-d EC20 for red drum growth was 37 mg/kg TPAH50 (sum of 50 polycyclic aromatic hydrocarbons). The 6-day EC20 for Pacific white shrimp growth was 3.9 mg/kg TPAH50. We will discuss the methods used to conduct these bioassays, present our results and compare them to growth- inhibition effects we observed in similar bioassays that we conducted with amphipods (Leptocheirus plumulosus) and southern flounder (Paralichthys lethostigma) using sediment spiked with DWH oil. We will also discuss all of these results in the context of sediment equilibrium partitioning theory with PAHs.

TP192 Human health and ecological risk assessment of a Department of National Defense water lot

I. Koch, Royal Military College of Canada / Environmental Sciences Group; R. Lavoie, Royal Military College of Canada / Biology; T. Laing, V. Paquin, D. Loock, K.P. Weber, Royal Military College of Canada / Environmental Sciences Group

A human health risk assessment (HHRA) and an ecological risk assessment (ERA) were performed at a Department of National Defense water lot. Previous and concurrent site assessments indicated the presence of inorganic elements, polychlorinated biphenyls (PCBs), petroleum hydrocarbons (PHCs), tributyltin (TBT), and polycyclic aromatic hydrocarbons (PAHs) in sediment at concentrations that exceeded guidelines. The overall objective of the study was to determine whether there are potential human health and ecological risks associated with contaminants in sediments at the site to help inform risk management and remediation options. Water, sediments, and fish were analyzed for contaminants. Benthic comparative and toxicity evaluations were completed. Risks to macrophytes, fish, mammals, and birds were evaluated using uptake models and food chain modelling. For the HHRA, the chemicals identified as contaminants of potential concern in sediments through the screening process were arsenic (As), chromium (Cr), lead (Pb), PCBs, and PAHs. No guidelines were exceeded for water. Concentrations of chemicals in fish tissues were compared with tissue guidelines and from reference locations; PCBs as well as PAHs represented a risk. Unacceptable health risks were predicted for the exposure scenarios for human receptors. Risks were predicted from PCBs via fish consumption and from As, Pb, PCBs, and PAHs via sediment contact. For the ERA, the chemicals identified as contaminants of potential concern in sediments were As, barium (Ba), copper (Cu), Pb, mercury (Hg), tin (Sn), zinc, (Zn), TBT, PAHs, PHCs, and PCBs. Risk was assessed for benthic organisms by comparing the benthic community structure at the water lot with reference site. Significant effects on taxonomic richness, diversity, and proportion of tolerant taxa were also seen at the water lot compared to the reference site. The risk to the benthic community was also assessed by evaluating the survival and growth of Hyalella azteca and Chironomus dilutus test organisms exposed to site sediments in laboratory chronic toxicity tests. Significant effects were seen for growth rate and survival of test organisms at the water lot compared to the reference site. Risk was predicted for wildlife from inorganic elements, PAHs, PHCs, and PCBs. This presentation will highlight some of the challenges in performing HHERAs and how results can differ from federal guidelines in the context of making contaminated site management decisions.

TP193 Transcriptional profiling of a native estuarine amphipod exposed to road dust and the related chemicals by cDNA-AFLP

K. Hiki, F. Nakajima, Dept of Urban Engineering, The Univ of Tokyo / Urban Engineering; T. Tobino, The Univ of Tokyo

Benthic environment is usually contaminated with mixtures of chemicals and can cause adverse effects on ecosystems. Recently transcriptomic analysis has been demonstrated to have the potential to identify causative toxicants in contaminants, which can aid environmental decision making. However studies on transcriptional analysis using a native species are still lacking, since most of the studies have used model species whose sequences were well-known. This study aimed to investigate the potential of transcriptional analysis using a native species to link the biological effects and the causative stressors. We performed transcriptional profiling of a native estuarine amphipod Grandidierella japonica exposed to sublethal levels of road-deposited dust and the contained substances such as Cu, Zn and nicotine for 24 h by cDNA-amplified fragment length polymorphism (AFLP) analysis with 12 combinations of arbitrarily selected primers. The estuarine amphipods were collected from a tidal flat near Tokyo, and the road-deposited dust was collected from highways around Tokyo, Japan. Our results demonstrated that the most of transcripts-derived fragments (TDFs) were differentially expressed in response to only one chemical, and that about 10% to 30% of TDFs were up- or down-regulated in common between different chemicals. These specific TDFs might be the possible biomarkers to detect each chemical exposure. However there were also few up- or down-regulated TDFs in common between the road dust sample and reference chemicals, which implied the contribution of unmeasured toxicants to gene expression profile of road dust or/and the interaction of measured toxicants. These results were consistent with the previous study in which the measured toxicants (Cu, Zn and nicotine) could not explain the observed road dust toxicity. Although the causative toxicants have not been identified yet, the current study showed the specific transcriptional patterns to chemical exposure and provides the experimental support for the potential utility of transcriptional analysis using a native species.

TP194 Direct and indirect toxicity of single walled carbon nanotube to freshwater organisms

M. Revel, INRS-Institut Armand-Frappier; M. Fournier, INRS-Institut Armand Frappier / ISMERUQAR; P. Robidoux, AGAT Laboratories, Ltd / Specialty services Division

Production and development of carbon nanomaterials has increased for the past few years. In Canada, the forestry industry experienced an economic crisis which has led to the elaboration of new forestry products: nanomaterials, including single-walled carbon nanotubes (SWCNT). Because carbon nanomaterials have a large specific surface area giving them high adsorption capacity, they are closely studied for drug targeting and water treatment. Indeed, this property is very interesting for the removal of contaminants like metals in wastewater. Adsorption of metals is greater for purified or functionalized carbon nanotubes. Production increase of nanomaterials and applications for water treatment raises the question of their direct but also indirect toxic effects on aquatic organisms which may be exposed. The adsorption properties of SWCNT may alter the bioavailability of contaminants present in the medium and change the global toxicity of the mixture.

Issues, Challenges and Opportunities for Protection of Water Resources from Emerging Organic Contaminants

TP195 Combining bacterial loading and nutrient loading analyses to point source agricultural impacts from large livestock facilities

M. Borrello, Alma College; T.P. Keeton, Alma College / Biology; A.D. Harwood, Alma College

Large livestock facilities called Confined Animal Feeding Operations (CAFOs) have been the source of significant nutrient and bacterial loading in the nation's lakes and streams. Hypoxic zones in Chesapeake Bay, Lake Erie and the Gulf of Mexico have been attributed to CAFO impacts. In Michigan, there are over 230 registered CAFOs which threaten the health of the Great Lakes and their associated watersheds, as well as the health of the people who live in them. Gratiot County Michigan has one of the highest concentrations of CAFOs (23) in the state and has measured significant impacts all over the local drainage basin. These impacts include high concentrations of nutrients and coliform bacteria (exceeding state and EPA standards) as well as extremely low concentrations of dissolved oxygen producing hypoxic and anoxic conditions. Additionally, significant antibiotic resistance has been found in E. coli associated with CAFO impacts within the watershed. Problems with changing current policy and regulatory structures are hampered, in part because of non-point source designation of this kind of aquatic pollution. Past research has utilized statistical relationships between nitrogen ammonia (NH_3) and soluble reactive phosphorus (SRP) to identify CAFO facility inputs and manure application sites as point sources. If inputs from animal waste impact waterways within a relatively short time, a strong correlation between NH_3 and SRP will occur. Calculation of potential septic system inputs utilizing the NH_3 / SRP correlation, however, is more problematic since nutrients can take a relatively long time from septic system to nearby waterway and thereby allow NH_3 volatilization and SRP uptake by plants. This study employed the method of combining: 1. NH_3/SRP correlations and E. coli concentrations, and 2. NH_3/SRP correlations and fecal coliform fingerprinting to enhance the effectiveness of point sourcing nutrient and bacterial inputs from both CAFOs and septic systems. If these methods prove effective, it will provide a reliable means by which inputs can be identified and designated as point source. That would change the regulatory landscape and allow environmentally-friendly restrictions to occur more easily.

TP196 Fate and Mass Balance of Pharmaceuticals, Personal Care Products, and Hormones in Septic Systems of Drainfields

Y. Yang, Univ of Florida; G.S. Toor, Univ of Florida / Soil Water Science Dept; P.C. Wilson, Univ of Florida / IFAS / Soil and Water Science; C.F. Williams, USDA / Lead Research Soil Scientist

Household wastewater discharged from septic systems, a common type of onsite wastewater treatment systems (OWTS), can be a potential source of micropollutants in the environment. This study investigated the fate and mass balance of 17 micropollutants (i.e., wastewater markers, pharmaceuticals, personal care products, and hormones) in the drainfields of OWTS. Three replicate drainfields (1.5 m length, 0.9 m width, and 0.9 m height) were constructed and managed similar to the field practice. Each drainfield received 9 L of septic tank effluent (STE) per day (equivalent to 32.29 L/m_2 per day) that dispersed from a drip line with over 8 months. We detected 17 micropollutans in STE and 12 in the leachate from OWTS at variable concentrations. Three micropolutants, including acetaminophen, carbamazepine, and sulfamethoxazole were observed from the soil of OWTS at the end of the study. Approximately 85% of effluent-borne micropollutants attenuated withinin 60 cm deep of OWTS, suggesting that vadose zone processes such as sorption and microbical degradation likely limited transport of micropollutants from the OWTS. Further, maintaining aerobic conditions in parts of the OWTS are needed to effectively remove micropollutants. We suggest that a better understanding of micropollutnts in OWTS is needed to protect groundwater quality.

TP197 Incidence of veterinary pharmaceuticals in West Texas playa wetlands

M. Sandoz, Texas Tech Univ / The Inst of environmental and human health; K. Wooten, L. Hensley, Texas Tech Univ / Dept of Environmental Toxicology The Inst of Environmental and Human Health TIEHH; P.N. Smith, Texas Tech Univ / Environmental Toxicology

Veterinary pharmaceuticals, such as antibiotics, steroid hormones, and β-adrenergic agonists, are commonly used to promote weight gain and increase feed efficiency at beef cattle feedyards. These veterinary pharmaceuticals have been found in surface water and groundwater downstream of cattle feedyards. Veterinary pharmaceuticals can also be transported via airborne particulate matter. However, it is unknown whether wind-blown dust is a substantial transport mechanism for veterinary pharmaceuticals entering adjacent surface waters. This study assessed the incidence of veterinary pharmaceuticals in playa wetlands of the Southern High Plains region of West Texas. Playa wetlands located approximately 1-10 miles from a feedyard were included in this study due to potential for entrapment of feedyard dust but not wastewater. Water and sediment samples were obtained from 32 individual playa wetlands and analyzed using LC-MS/MS to quantify veterinary pharmaceuticals indicative of feedyards: 5 antibiotics, 6 steroid hormones, and a β_2-adrenergic agonist (ractopamine). Preliminary results indicate that 61% of sampled playa wetlands contain veterinary pharmaceuticals. These chemicals have potential to disrupt endocrine function and alter microbial community composition and dynamics. Results of this study have implications for aquatic wildlife reproduction and potentially human health in arid or semi-arid regions that contain beef cattle feedyards.

TP198 Reusing Wastewater in Agroecosystems: Groundwater quality, plant uptake, and antibiotic resistance?

A. Franklin, Pennsylvania State Univ / Ecosystem Science and Management; C.F. Williams, USDA / Lead Research Soil Scientist; J. McLain, Univ of Arzona / Water Resources Research Center; D. Andrews, The Pennsylvania State Univ / Ecosystem Science Management; E. Woodward, The Pennsylvania State Univ / Ecosystem Science and Management; J. Watson, Penn State Univ / Ecosystem Science and Management

With demands on water supplies rising, wastewater treatment plant (WWTP) effluent is often reused to irrigate agricultural lands. Emerging contaminants, like antibiotics, are frequently found in effluent due to limited removal during WWTP processes. Concern has arisen about their environmental fate, particularly possible contamination of groundwater, plant uptake, and health effects linked to antibiotic resistance in the environment. The aim of this study was to examine the environmental impacts of spray irrigating WWTP effluent on cropped lands at The Living Filter, a wastewater reuse site, by quantifying three antibiotics: sulfamethoxazole (SMX), trimethoprim (TMP), and ofloxacin (OFL), in WWTP effluent, soil, groundwater, and wheat plants (Triticum aestivum) and providing analysis of antibiotic resistance in environmental bacteria. Water samples were collected three times annually, while wheat was collected once and soil was collected twice in the summer. Throughout the year, the three antibiotics are present in WWTP effluent and groundwater. Effluent concentrations range from 2 ng/L to 22 ug/L and vary based on the time of the year. In groundwater, SMX and OFL are quantifiable with a concentration range of 0.37 – 313 ng/L, and TMP is typically only detectable, but had a high concentration of 22 ng/L. Considering the concentrations associated with wheat plants, OFL was found in straw (10.2 ± 7.05 ng/g) and grain (2.28 ± 0.89 ng/g); TMP was only found on wheat plant surfaces; and SMZ was concentrated within the grain (0.64 ± 0.37 ng/g). Concentrations in soil by depth will also be presented. Based on data to date for antibiotic resistance in soil bacteria, antibiotic resistance to OFL was absent, while resistance to SMX and TMP was elevated compared to a control site not receiving WWTP effluent nor manure applications. These findings indicate that antibiotics are present in groundwater and wheat plants following irrigation with WWTP effluent. Additionally, the introduction of human antibiotics appears to impact antibiotic resistance in soil bacteria. Overall, this study suggests that antibiotics introduced into the environment due to WWTP reuse may pose potential risks to the long-term health of ecosystems, with consequences for human and animal health due to antibiotic resistance. However, additional research is necessary to determine the full environmental and health implications of reusing WWTP effluent for the purpose of irrigating agricultural lands.

TP199 Concentrations of bisphenol A in North American surface waters: calculating from summary statistics used in deterministic and distributional risk analyses

C.A. Staples, Assessment Technologies, Inc.; E.M. Mihaich, ER2; J. Woelz, Currenta; S. Hentges, American Chemistry Council

Bisphenol A (BPA) is mainly used as a chemical intermediate to produce polycarbonate plastics and epoxy resins. During and following manufacturing, processing, use, and disposal of polycarbonate and epoxy resin products, as well as other products containing BPA as a functional additive, some BPA can enter wastewater treatment plants for treatment or landfills for disposal, and thus may reach surface waters. BPA is frequently included as an analyte in surface water sampling programs targeting compounds of emerging concern. Concentrations of BPA in North American fresh and marine waters were compiled from published scientific literature and governmental reports. The dataset now contains ca. 2300 entries of data from 85 sources. Three issues were identified that needed to be addressed to enable calculation of summary statistics. First, most of the measured values were actually below a detection limit and detection limits varied over several orders of magnitude across all studies. The Kaplan-Meier method was used to estimate concentrations below detection limits from the distribution of values above these detection limits in studies with a lower detection limit. Second, many studies only reported summary statistics such as means or ranges. When the number of samples was known, values were imputed for that number of samples so that the summary statistics of the imputed concentrations were identical to the summary statistics reported and the distribution of the imputed concentrations approximated a log-normal distribution. Third, many sampling campaigns collected samples over broad areas, while others collected multiple samples at few locations thus requiring the use of weighting factors such that each location carried the same weight in calculating summary statistics. For North America, a total of 804 freshwater and 32 marine water weighted observations are available. For freshwater locations, 72% were below a detection limit (varying detection limits). Median and upper 95th centile concentrations for the full distribution of weighted observations were 0.005 and 0.30 µg/L. For marine locations, 49% were below a detection limit. Median and upper 95th centile concentrations were 0.0011 and 0.023 µg/L. The distribution of weighted observations of BPA will be compared to the distribution of aquatic ecotoxicity data for freshwater and marine organisms to estimate potential risks.

PFAS: Recent Developments in Science, Risk Assessment and Regulation

TP200 Avian Exposures to Seven Perfluorinated Alkyl Substances in Aquatic Habitats Impacted by Aqueous Film Forming Foam Releases

E. Stinson, J. Arblaster, J.M. Conder, Geosyntec Consultants

Information on the adverse effects of perfluorinated and polyfluorinated alkyl substances (PFAS) in animals is primarily limited to perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS). While detectable levels of PFOS and PFOA in environmental media are known to be present at many sites as a result of Aqueous Film Forming Foam (AFFF) releases, less is known about other prominent PFAS chemicals. Since birds may have relatively high exposure potential due to consumption of fish, invertebrates, and sediment in aquatic habitats affected by AFFF releases, avian exposures were evaluated for seven PFAS chemicals (PFOS, PFOA, perfluorodecanoic acid (PFDA), perfluorononanoic acid (PFNA), perfluorodecane sulfonate (PFDS), perfluorohexanoic acid (PFHxA), and perfluorohexane sulfonate (PFHxS)) using measurements from four AFFF sites. Exposure modeling was conducted for four avian receptors representing various avian feeding guilds including: lesser scaup (Aythya affinis) and spotted sandpiper (Actitis macularia), Great blue heron (Ardea herodias), and osprey (Pandion haliaetus). For all measured PFASs at all four sites, predicted exposures to the spotted sandpiper were the highest of the four species (excluding one instance where exposure to PFDA for the osprey was higher), by a factor ranging from three-fold to four-thousand fold. At the 4 sites, 70 to 98% of the modeled daily total PFAS exposures for the spotted sandpiper, lesser scaup, and great blue heron were comprised of PFOS while 2 to 11% were comprised of PFHxS, < 1 to 8% of PFNA, and < 1 to 7% of PFDA. For osprey, PFOS exposure accounted for 83-99% of the modeled daily total PFAS exposure followed by 1-6% PFHxA, < 1-4% PFNA, and < 1-4% PFDS. These results suggest the need for ecological modeling at sites potentially affected by AFFF releases to include multiple representative species and expand the current focus on PFOS and PFOA to other bioaccumulative PFAS chemicals. This evaluation enhances risk management and risk communication by identifying additional PFAS chemicals (e.g., PFHxS, PFHxA, PFNA) that have the potential to influence ecological risk-based decision making at AFFF sites.

TP201 Do we understand ongoing sources of perfluorooctane sulfonic acid and its precursors? Lessons learned from developing a new global emissions inventory

Z. Wang, Swiss Federal Inst of Technology / Inst for Chemical and Bioengeneering; J. Boucher, ETH Zurich; I. Cousins, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry ACES; K. Hungerbuehler, M. Scheringer, ETH Zurich / Inst for Chemical and Bioengineering

Among the family of per- and polyfluoroalkyl substances (PFASs), perfluorooctane sulfonic acid (PFOS) and its precursors may have attracted the most attention. Between the late 1950s and early 2000s, they were favored by various industry sectors and widely used in numerous commercial and consumer applications for their unique characteristics such as high surfactant ability and durability/persistence. After their worldwide presence was revealed and 3M's voluntary global phase-out in the early 2000s began, they soon drew significant attention from the global regulatory and scientific community. The Scifinder® Database shows that over 3000 peer-reviewed articles in relation to PFOS were published between 2002 and early 2016. Building on the increasing scientific evidence, regulatory and voluntary programs have been initiated with the intention to reduce associated risks. In particular, PFOS and its precursors were added to Annex B (restriction of production and use) of the Stockholm Convention on Persistent Organic Pollutants in 2009. This led to another wave of data being generated on these substances, in particular in developing and transition countries. In light of this increasingly available knowledge and data, we recently developed a new global emissions inventory of PFOS and its precursors. During the course of this project, we identified that despite the vast number of studies available, substantial critical knowledge and data gaps still exist in terms of the production, use, and release of PFOS and its precursors. For example, there is a general lack of adequate information on the use and disposal phase of PFOS and its precursors. Large uncertainties also remain regarding the abiotic and biotic degradation of PFOS precursors including side-chain fluorinated polymers. Here we present these critical knowledge and data gaps, possible implications based on conceptual calculations, and our recommendations to address these gaps. Important to note is that addressing them may not only improve the understanding of the ongoing sources, transport and fate of PFOS and its precursors, but also provide useful insights into understanding the same for other PFASs including fluorotelomer-based substances.

TP202 Evaluation of Site-specific Human Health Risks and Calculation of Risk-based Threshold Concentrations of PFOS and PFOA in Fish

J. Arblaster, E. Stinson, J.M. Conder, Geosyntec Consultants

The United States Environmental Protection Agency recently finalized toxicity reference doses (RfD) and drinking water quality criteria for the perfluoroalkyl and polyfluoroalkyl substances (PFASs) perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA). Along with drinking water and indoor dust, diet items including fish and shellfish may be a significant contribution to human intake of PFASs. To evaluate the potential risks to human health from consumption of fish tissue by recreational fishermen, a Fish Tissue Criteria (FTC) was derived from the RfD for the sum of the PFOS and PFOA. A Relative Source Contribution (RSC) of 20% and 100% were both assumed for evaluation of human health risks from sites with historical PFAS contamination. The FTC for the sum of PFOS and PFOA ranged from 15 ng/g to 73 ng/g, wet weight for a 20% and 100% RSC, respectively. The FTC was compared to empirical concentrations of PFASs in fish from four sites with historic PFAS contamination, and concentrations in fish exceeded the FTCs at 75% of sites using an RSC of 100% and all four sites when using an RSC of 20%. PFOS represented 99% of the sum of the PFOS and PFOA exposure in fish where measured concentrations of both were available. Additionally, a food web model was used to calculate risk-based concentrations of PFOA and PFOS in sediment and water that would be associated with the FTC. The model showed good agreement between modeled and empirical concentrations in fish (when available for a site) with a mean model bias of 0.9 for PFOS and 2.9 for PFOA. Assuming a 20% RSC, absence of model-predicted risk is expected if concentrations of PFOS in sediment and surface water are both less than 0.75 ng/g, dw (assuming 1% OC) and 12.4 ng/L respectively. Assuming a 100% RSC, absence of model-predicted risk is expected if concentrations of PFOS in sediment and surface water are both less than 3.7 ng/g, dw and 62 ng/L, respectively.

TP203 Per- and polyfluoroalkyl substances: Environmental concerns and regulatory measures in the EU

A. Biegel-Engler, German Environment Agency – UBA; L. Vierke, German Environment Agency – UBA / Chemicals; C. Schulte, Umweltbundesamt / Chemicals

The European Chemicals Regulation REACH aims at enhancing innovation and competitiveness of the EU chemicals industry and at improving the protection of human health and the environment. Authorization and restriction of the use of chemicals are risk management options under REACH. Per- and poylfluoroalkyl substances (PFASs) are one group of substances partly addressed by these risk management measures. The aim of this presentation is to show which concerns of PFASs lead to risk management measures in Europe, and to introduce these regulatory activities. PFASs are characterised by special properties, e.g. chemical and thermal stability, these substances are used in several industrial as well as consumer applications. They are used as surfactants and polymers in for example textiles, papers, fire fighting foams and biocides. During production of PFASs itself, during their application in different processes and articles as well as during use and disposal of such articles PFASs are released into the environment. A number of long chain perfluoroalkyl carboxylic acids (PFCAs) are listed as Substances of Very High Concern (SVHC) on the REACH Candidate List. These long-chain PFCAs are ubiquitously found in the environment, e.g. in surface water and biota, as well as in humans. To minimize exposure of humans and the environment with C_8 PFCA (PFOA perfluroinated octanolic acid) a restriction of manufacturing, use and placing on the market of C_8 PFCA itself, its salts as well as substances which might degrade to C_8 PFCA has been submitted by Germany and Norway in 2014 and is now on hand of the EU Commission. Moreover the EU-Commission proposed PFOA as a Persistent Organic Pollutant (POP) under the Stockholm Convention in 2015. At the moment a draft risk profile is being developed. Due to regulatory and voluntarily measures the producing companies are switching to short-chain PFASs. Also short-chain PFCAs are persistent. Furthermore they have a high mobility in the aqueous environment, which poses a threat for drinking water. Drinking water contamination with long-chain PFCAs already caused substantial remediation costs. Moreover, there are studies available indicating endocrine disrupting properties of the short chain PFAS. It hase been shown that short chain PFAS can be enriched in plants which could be a posiibility for human exposure as well. To contribute to a sustainable chemistry use of stable perfluoralky moieties should be avoided.

TP204 Summary of an ICPPR Non-Apis Workshop – Subgroup Higher Tier (Bumble bees and Solitary bees) with recommendations for a semi-field experimental design

S. Knaebe, EAS Ecotox GmbH / Ecotox Field; O. Klein, Eurofins Agroscience Services Ecotox GmbH / Ecotox Field; T. Jütte, Eurofins Agroscience Services Ecotox GmbH / Ecotoxicology Field

The workshop was held from 29 Feb. – 01 Mar. 2016 at the Julius-Kühn Institute (JKI), Braunschweig, Germany. 47 participants took part representing Industry, CRO, authorities and academia. One part of the workshop discussed laboratory testing with bumble bees and solitary bees. The part discussing semi-field design will be presented here. At the semi-field workshop participants presented their experiences in semi-field and field studies. Seven laboratories conducted semi-field or field tests. The majority of tests were done with bumble bees (10 semi-field and 6 field tests). Solitary bee tests were done with the red mason bee (Osmia bicornis) in 6 semi-field and 2 field tests. In general, as no guidance on the design or endpoints was available all tests followed different designs / set-ups. Furthermore, several studies were designed to answer a specific question in a plant protection product registration. Based on the limited experience and the still ongoing discussion about exposure in field studies it was decided to proceed with a semi-field study design. Semi-field in this context relates to tunnel studies with bumble bees and solitary bees. For bumble bees a colony is the smallest experimental unit, for solitary bees the individual bee. For bumble bees it was agreed the main endpoint of a study is queen reproduction. Additional endpoints like flight activity (in crop and entrances) and sugar consumption were not included in the minimum requirements of the future ring test. Solitary bee studies in Europe are at the moment run with Osmia bicornis. This species is commonly called the red mason bee and is used in the laboratory experiments, too. The main endpoint of a semi-field study with O. bicornis will be the number of offspring produced. Assessment of flight/foraging activity is needed as additional information on actively nesting females and on exposure during application. For both organisms it was agreed to establish an experimental test design and run a ring test with interested parties in 2016. The data collected in the ring test will be used in a general database as a basis for further discussions. In the talk the single endpoints will be discussed in more detail and practical examples used to explain the methodology. The semi-field test design recommendation for both species will also be presented in more detail.

TP205 Wildlife TRVs for Emerging Chemicals: PFOS, PFOA and PFBS

H. Loso, AECOM / Remediation; U. Vedagiri, AECOM / Environmental Remediation; C. Archer, AECOM Environment; K. Schwach, AECOM / Environmetnal Remediation

This presentation provides a practical case study applying the overarching principles for developing ecological toxicity reference values (TRVs) to perfluorinated compounds (PFCs) along with its implications for risk-based decision-making. Reliable TRVs are critical to evaluate ecological risks for persistent, toxic and bioaccumulative chemicals such as PFCs, but there are no readily available published wildlife TRVs that have been universally accepted. Numerous PFC toxicological studies of varying quality have been published since the early 2000's, but the current state of the science for PFCs research is still very active and studies with new information are continuously being published. A broad review of the literature was conducted in search of toxicity studies for PFCs that could be used to derive dose-based TRVs for birds, mammals, and reptiles. In developing

TRVs for wildlife receptors, studies that measure concentrations in the diet, and then relate that dietary concentration to an effects level are most useful for TRV development. However, there are numerous studies in which PFC concentrations have been measured in liver, blood serum, or bird egg tissue and related to the desired sub-lethal endpoints (e.g., reproductive and developmental). Although these studies are not directly usable as TRVs, they provide critical information regarding toxicity potential and mode of action for various PFCs, relative sensitivities between taxonomic classes to the same PFC or different PFCs, etc. This supporting information was used qualitatively in the decision-making process for selecting dietary TRVs for wildlife, in particular for certain PFCs for which adequate ecotoxicity data were not identified. In many cases, the secondary sources and agency documents reviewed referenced the same few primary articles and each adjusted these primary toxicity data in different ways to generate TRVs. It is important to understand these adjustments when selecting a final TRV for a specific project. The key outcome of this exercise is the development of TRVs that can be considered reasonable candidates for use in ecological risk assessments (ERAs) on a global scale. Until more universally accepted studies are published, these TRVs can be used with an understanding of their associated uncertainties and assumptions. Finally, use of these TRVs to support project-level decision-making for PFOS, PFOA and PFBS is also discussed.

Frequent Fliers: Effects of the Deepwater Horizon Oil Spill to Birds

TP206 Development of oil exposure methods for testing the physiological effects of petroleum crude oil on waterbirds

K. Hanson-Dorr, USDA APHIS WS NWRC / Dept of Agriculture; F. Cunningham, National Wildlife Research Centre / Aquaculture; K. Dean, Abt Associates; B. Dorr, USDA/WS/National Wildlife Research Center; C.K. Ellis, USDA National Wildlife Research Center; K. Healy, US Fish and Wildlife Service; K. Harr, URIKA, LLC; K. Horak, USDA; J. Link, Michigan State Univ / Dept of Animal Science; S. Shriner, USDA National Wildlife Research Center; S.J. Bursian, Michigan State Univ / Animal Science

During the Deepwater Horizon (DWH) oil spill, many live birds were observed with trace, low and moderate levels of oil on their plumage, but the fate of these birds was unknown. A series of studies were developed to determine the physiological effects of exposure to petroleum crude oil, and its link to hemolytic anemia observed in live oiled birds in field studies during the DWH oil spill. Inherent in study design was determination of appropriate amounts and routes of exposure of avian species to oil. We chose 2 species of piscivorous birds, Laughing Gulls (Leucophaeus atricilla; LAGU) and Double-crested Cormorants (Phalacrocorax auritus; DCCO), to use as models based on relevance to the Gulf of Mexico region, abundance and adaptability to captivity. Previous research in gull chicks orally dosed with 10 mL crude oil/kg daily induced hemolytic anemia after 5 days. Our initial study sought to replicate these findings by gavaging LAGU and DCCO with a 1:1 mixture of artificially weathered DWH oil and catfish fillet slurry to achieve a daily dose of 20 ml/kg body weight for 5 days. The results of this trial resulted in few adverse effects characteristic of exposure to oil. This may have been due to reduced absorption of oil from the gut based on rapid excretion of oily feces. Two subsequent studies were designed to deliver low amounts of oil in food fish throughout the day rather than a single gavage to increase gut retention time and decrease bird handling. Food fish were injected with oil to achieve target doses of 5 or 10 mL oil/kg body weight. Gulls were fed frozen-thawed minnows injected with 200 uL or 400 uL of oil for 28 days. Cormorants were fed live channel catfish fingerlings given an intraperitoneal injection with 2 mL of oil over 21 days. Both species developed clinical signs consistent with oil toxicity induction; however, cormorants more readily accept oil-injected food fish. Lastly, an external exposure study was conducted on cormorants. The breast and back were treated with 13 mL of oil every 3 days for 21 days, applied to cover 20% of the feathered surface area. This method of exposure induced hemolytic anemia, organ abnormalities, and provided evidence of thermoregulatory stress due to greater heat loss in oiled birds. These studies provide information on methods and toxicity effects of multiple routes of exposure of oil to avian species; direct ingestion, indirect ingestion through consumption of exposed prey, and external oiling.

TP207 Development of Methods for Avian Oil Toxicity Studies using the Double Crested Cormorant (Phalacrocorax auritus)

F. Cunningham, National Wildlife Research Centre / Aquaculture; D. Cacela, Abt Associates; B. Dorr, USDA/WS/National Wildlife Research Center; K.D. Dean, Stratus Consulting Inc. / Dept of Animal and Avian Sciences; K.C. Hanson-Dorr, USDA/WS/National Wildlife Research Center; K. Harr, URIKA, LLC; K. Healy, US Fish and Wildlife Service; K. Horak, USDA; J. Link, Michagan State Univ / Dept of Animal Science; A. McFadden, Abt Associates; P.L. Tuttle, US Fish and Wildlife Service / Deepwater Horizon NRDAR Field Office; S.J. Bursian, Michigan State Univ / Animal Science

The majority of previous oil dosing studies conducted on wild-caught birds used gavage methods to dose birds and determine toxicity. However, rapid gut transit time of gavaged oil likely reduces oil absorption. Instead, new oral dosing methods were developed that relied on intra-peritoneal injection of oil into live, sedated feeder catfish for consumption by piscivorous birds to provide better replication of field exposure in the double-crested cormorant (DCCO). Twenty-seven DCCO were collected from Leflore County, MS using boats and a night-lighting capture technique and transported to the National Wildlife Research Center Mississippi Field Station. Upon arrival at the NWRC-MFS, birds were identified by a unique leg band and quarantined in individual 3.3 m x 1.52 m x 2.0 m (L x W x H) concrete floored pens for 14 days in a 23 m x 10 m environmentally controlled building. DCCO were assigned to one of three treatment groups (n=9) to test the toxicity of artificially weathered Deepwater Horizon Mississippi Canyon 252 oil: a control group that was fed fingerling catfish containing no oil, a group that was fed oil-injected catfish that targeted a daily dose of 5 ml oil/kg body weight and a group that targeted a daily dose of 10 ml oil/kg body weight. Clinical signs reported in oil -treated birds included hypothermia, weight loss, lethargy, feather damage, morbidity, and some cases, death. Oral dosing studies identified oil-related toxicity endpoints associated with oxidative stress such as hemolytic anemia, liver and kidney damage, and immuno-modulation or compromise. The results of this study indicate that oral dosing of DCCO with artificially weathered MC 252 oil from the DWH oil spill resulted in clinical signs and changes in a number of hematological, biochemical, and tissue endpoints consistent with petroleum intoxication.

TP208 Avian Toxicity for Laughing Gulls exposed to weathered Deepwater Horizon oil

K. Horak, USDA; S.J. Bursian, Michigan State Univ / Animal Science; F. Cunningham, National Wildlife Research Centre / Aquaculture; F.L. Cunningham, USDA National Wildlife Research Center; K. Dean, Abt Associates; C.K. Ellis, USDA National Wildlife Research Center; K. Hanson-Dorr, USDA APHIS WS NWRC / Dept of Agriculture; K.E. Harr, Urika Pathology LLC; K. Healy, US Fish and Wildlife Service; J. Link, Michigan State Univ / Dept of Animal Science; S. Shriner, USDA/WS/ National Wildlife Research Center

Understanding the potential fate of the tens of thousands of birds oiled during and after the Deepwater Horizon (DWH) oil spill is an important goal of the DWH Mississippi Canyon 252 (MC252) Oil Spill Natural Resource Damage Assessment. Consequently, we conducted an avian toxicity study of laughing gulls (Leucophaeus atricilla; LAGUs) exposed to artificially weathered MC252 oil administered in food fish. Study objectives were to determine if orally dosed LAGUs develop clinical signs indicative of hemolytic anemia (Heinz bodies and a decrease in packed cell volume [PCV]), and to determine if there were other responsive endpoints that could be used to indicate injury due to oil exposure. We tested three treatment groups: a control group fed minnows containing no oil, a group fed oil-injected minnows targeting a daily dose of 5 mL oil/kg body weight, and a group fed oil-injected minnows targeting a daily dose of 10 mL oil/kg body weight. Birds were dosed for up to 28 days. Blood samples were taken twice weekly for determination of Heinz bodies, complete blood counts, blood electron microscopy, PCV, hemoglobin concentration, and plasma clinical chemistries. Moribund birds were euthanized and necropsied prior to the end of the study, while the remaining birds were necropsied on day 28. Of the 30 birds tested, 1 of 7 LAGUs dosed with 10 mL oil/kg and 8 of 13 LAGUs dosed with 5 mL oil/kg died or were euthanized within 20 days. Clinical signs reported in oil-dosed birds included lethargy, reduced food consumption, moribundity, and death. PCV was significantly decreased by exposure to oil in a dose-related manner. Transmission electron micrographs confirmed that red blood cells (RBCs) contained Heinz bodies in both dose groups. There were no oil-related changes in plasma clinical chemistry or electrophoresis endpoints with the exception of 3-methyl histidine concentration, which was significantly higher in the 10 mL group compared to the control and 5 mL groups. All of the hepatic antioxidant endpoints measured at necropsy except superoxide dismutase were significantly increased in LAGUs exposed to oil. At necropsy, relative kidney and absolute and relative liver weights were significantly increased in oil-dosed birds. These results indicate oral dosing of LAGUs with artificially weathered MC252 oil from the DWH oil spill resulted in some clinical signs and changes in hematological, biochemical, and tissue endpoints that have been reported in birds exposed to oil.

TP209 Changes in plasma chemistry and organ size in double-crested cormorants after consuming artificially weather DWH oil by contaminated food

F. Cunningham, National Wildlife Research Centre / Aquaculture; D. Cacela, Abt Associates; B. Dorr, USDA/WS/National Wildlife Research Center; K.D. Dean, Stratus Consulting Inc. / Dept of Animal and Avian Sciences; K. Hanson-Dorr, USDA APHIS WS NWRC / Dept of Agriculture; K. Harr, URIKA, LLC; K. Healy, US Fish and Wildlife Service; K. Horak, USDA; J. Link, Michigan State Univ / Dept of Animal Science; A. McFadden, Abt Associates; P.L. Tuttle, US Fish and Wildlife Service / Deepwater Horizon NRDAR Field Office; S.J. Bursian, Michigan State Univ / Animal Science

The toxicological effects of oil spills on birds have been studied sporadically over the decades. The devastating effects of oil spills on birds have meant that most rehabilitation centers focus on heavily oiled birds that are clearly distressed and in need of extensive veterinary care. Additionally, there have been few field studies that have focused on toxicological effects other than those directly related to hemolytic anemia, and oral dosing studies of oil are notoriously difficult due to rapid excretion. Methods of oral dosing and external oil application developed for use in the DWH USFWS avian toxicity testing program will add considerably to our knowledge of the toxicological effects of oil on birds. Double-crested (DCCO) were assigned to one of three treatment groups for an oral dosing study: a control group, nominal daily dose of 5 ml oil/kg body weight group and a nominal daily dose of 10 ml oil/kg body weight. Oral dosing occurred by providing live feeder catfish that had been given intraperitoneal injections of oil. The study resulted in statistically significant changes in plasma markers of kidney and liver function, white cell counts, organ weight changes and histological signs of oil intoxication, as well as indications of as yet unidentified markers of oil toxicity in birds, such as cardiotoxicity and effects of clotting processes. DCCO dosed via feed showed severe clinical signs of oil intoxication including hypothermia, weight loss, lethargy, feather damage, morbidity, and some cases, death. This study provided a clear insight into the dose-dependent effects of oil, and how avian health declines as oil ingestion continues. DCCO exposed to high doses via their food source were unable to maintain homeostatic mechanisms and were likely to succumb to oil intoxication.

TP210 Weathered MC252 crude oil-induced anemia and erythropathology in double-crested cormorants (Phalacrocorax auritus) upon oral and dermal exposure

K. Harr, URIKA, LLC; K. Dean, Abt Associates; J. Link, Michigan State Univ / Dept of Animal Science; F. Cunningham, National Wildlife Research Centre / Aquaculture; B. Dorr, USDA/WS/National Wildlife Research Center; D. Cacela, Abt Associates; K. Hanson-Dorr, USDA APHIS WS NWRC / Dept of Agriculture; K. Horak, USDA; A. McFadden, Abt Associates; K. Healy, US Fish and Wildlife Service; S.J. Bursian, Michigan State Univ / Animal Science

Injury assessment of birds in the field following the Deepwater Horizon oil spill documented Heinz body formation. However, there is little information about the relationship between route and magnitude of oil exposure and induction of anemia in birds. Here we present two studies that induced anemia in wild-caught birds. In the first experiment, adult mixed-sex double-crested cormorants (DCCOs) were randomly divided into groups and fed oil–injected fish for up to 21 days. In the second experiment, adult, mixed-sex DCCOs had oil (test) or water (control) applied to the breast and back feathers every 3 days, covering approximating 20% of the body surface. Whole blood samples collected during the exposure period were analyzed both by light microscopy using new methylene blue stain and by transmission electron microscopy. Oral and dermal exposure of DCCOs to weatheredDeepwater Horizon crude oil induced hemolytic anemia as indicated by decreased packed cell volume, relative reticulocytosis with an inadequate regenerative response, and presence of degenerate hemoglobin, which is consistent with other reports of oil-exposed birds. Additionally, this study documented extravascular blood loss through hematochezia contributing to the severity of anemia and probable coagulopathy. Ultrastructural assessment of suspected Heinz bodies in birds is recommended as identification by light microscopy is challenging.

TP211 Induction of oxidative stress following light to moderate oral or external oil dosing of double-crested cormorants

K.L. Pritsos, Univ of Nevada Reno / Dept of Agriculture Nutrition and Veterinary Science; T. Muthumalage, Univ of Nevada Reno / Dept of Agriculture Nutrition and Veterinary Sciences; K.C. Hanson-Dorr, USDA/WS/National Wildlife Research Center; F.L. Cunningham, USDA/APHIS/WS/National Wildlife Research Center / Mississippi Field Station; B. Dorr, USDA/WS/National Wildlife Research Center; K. Dean, Abt Associates; S.J. Bursian, Michigan State Univ / Animal Science; K. Horak, USDA; C.A. Pritsos, Univ of Nevada / Agriculture Nutrition and Veterinary Sciences

The Deepwater Horizon oil spill exposed tens of thousands of birds to oil. This exposure ranged from heavily oiled birds to lightly oiled birds. While acute mortality was the fate of most heavily oiled birds, the effect of light to moderately oiled birds was not clear. Several of the oiled birds captured in the field were diagnosed with hemolytic anemia through the identification of Heinz bodies in their red blood cells. Heinz bodies are formed through an oxidative mechanism in which hemoglobin sulfhydryl bonding is altered through oxidation resulting in protein denaturation and subsequent aggregation of these proteins. Oxidative stress is a fundamental mechanism by which chemicals can exert toxicity to organisms. Crude oil is a complex mixture of chemicals, including several polycyclic aromatic hydrocarbons which can generate toxic oxygen species upon metabolism. In this study we assessed several liver tissue markers of oxidative stress in cormorants repeatedly exposed either orally or externally to artificially weathered Deepwater Horizon (DWH) Mississippi Canyon 63 252 (MC252) source oil. Significant increases in total glutathione, reduced glutathione and total antioxidant power as well as significant decreases in glutathione peroxidase were observed in both oral and externally dosed birds. Orally dosed birds also showed significantly increased levels of oxidized glutathione and decreased superoxide dismutase activity in liver tissues. These results clearly demonstrate that cormorants exposed to these light to moderate levels of oil either orally or externally are undergoing oxidative stress. This oxidative stress could lead to hemolytic anemia or other detrimental conditions resulting from protein, lipid and nucleic acid oxidation. This project was funded in part by the Deepwater Horizon Natural Resource Damage Assessment Trustees and the Nevada Agricultural Experiment Station.

TP212 AROD and CYP1A Protein Expression in Four Avian Species Experimentally Exposed to Deepwater Horizon Mississippi Canyon 252 Oil

C.R. Alexander, Texas Tech Univ; K. Smelker, C. Summers, Texas Tech Univ / Dept of Environmental Toxicology The Inst of Environmental and Human Health; D. Cacela, K. Dean, Abt Associates; M. Hooper, USGS Columbia Environmental Research Center / Columbia Environmental Research Center; S.J. Bursian, Michigan State Univ / Animal Science; F. Cunningham, National Wildlife Research Centre / Aquaculture; C.G. Guglielmo, Univ of Western Ontario / Dept of Biology; K. Hanson-Dorr, USDA APHIS WS NWRC / Dept of Agriculture; K. Horak, USDA; J. Isanhart, Dept of the Interior / Office of Restoration and Damage Assessment; I. Maggini, Univ of Western Ontario / Dept of Biology; C.A. Pritsos, Univ of Nevada / Agriculture Nutrition and Veterinary Sciences; S. Shriner, USDA/WS/National Wildlife Research Center; K. Healy, US Fish and Wildlife Service; C. Godard-Codding, Texas Tech Univ / Dept of Environmental Toxicology The Inst of Environmental and Human Health; J. Link, Michigan State Univ / Dept of Animal Science

Four avian species, Double-crested cormorant (DCC, Phalacrocorax auritus), Western sandpiper (WS, Calidris mauri), Laughing gull (LG, Leucophaeus atricilla), and Rock dove (RD, Columba livia), were experimentally exposed to Deepwater Horizon Mississippi Canyon 252 (DWH) oil, orally or applied to feathers, to investigate oil-induced toxicological impacts. Liver and gut tissues were collected for multiple analyses including cytochrome P4501A (CYP1A) enzymatic activity and protein expression. CYP1A is involved in the biotransformation and activation of polycyclic aromatic hydrocarbons (PAHs) found in oil. CYP1A induction is a widely used measure of exposure to specific contaminants including PAHs in avian, as well as laboratory, and other wildlife species. CYP1A enzymatic activity was measured by alkoxyresorufin O-dealkylase (AROD) assays and CYP1A protein expression, as detected by western blot analysis. ARODs demonstrate tissue and species variability in measuring CYP1A activity. We measured activities specific to each of four resorufin ethers: benzyloxyresorufin O-debenzylase (BROD), ethoxyresorufin O-deethylase (EROD), methoxyresorufin O-demethylase (MROD), and pentoxyresorufin O-depentylase (PROD). Enzymatic induction was detected via BROD, EROD, and PROD in livers of DCC orally exposed to 20ml/kg oil as a single dose or for 5 days. Western blot showed a significant increase in CYP1A expression in livers but not in the gut. In a second DCC study (5ml/kg oil or 10ml/kg oil 21 day dosing), all four ARODs were induced in livers as was BROD in the gut. Western blot revealed CYP1A protein induction in the liver. All four ARODs were induced in livers of WS orally exposed to 1ml/kg or 5ml/kg for 20 days. A thermoregulation study on WS after oiling feathers showed enzymatic induction in livers detected via BROD, EROD, and PROD. A wind tunnel study on WS after oiling feathers showed all 4 ARODs induced in livers. 50-mile and 100-mile flight studies in RD after oiling feathers showed only BROD induced in livers in the 50-mile study. CYP1A protein expression was below the western blot limit in WS and RD studies. Hepatic CYP1A activity occurred in all DWH oil-exposed avian species. Further analyses will investigate correlations among these detected changes and other endpoints examined in the birds.

TP213 Gene expression in Seaside Sparrows exposed to oil in Louisiana salt marshes

A. Bonisoli Alquati, California State Polytechnic Univ, Pomona / Dept of Biological Sciences; P. Stouffer, Louisiana State Univ AgCenter; C. Bergeon Burns, Indiana Univ; S. Woltmann, Austin Peay State Univ; W. Xu, S. Taylor, Louisiana State Univ AgCenter

Oil from the 2010 Deepwater Horizon oil spill (DWHOS) entered the Louisiana salt marshes food web, where it was incorporated in Seaside Sparrows (Ammodramus maritimus) feathers. In 2011, cytochrome P450 (CYP1A) expression was higher in Seaside Sparrows from oiled sites compared to birds from 'clean' sites, confirming that they had been exposed to oil. While CYP1A expression went down in 2012, the next year birds in both oiled and 'clean' sites had high CYP1A levels compared to 2012, indicating that oil in the sediments was remobilized, possibly by storms. The overall transcriptomic response of birds to oil remains, however, largely unknown. Understanding this response will help us develop sensitive biomarkers of exposure to oil, and clarify the regulation of the CYP1A pathway in metabolism and physiology. In the present study, using microarray techniques we analyzed genome-wide transcriptomic profiles in liver samples from Seaside Sparrows collected in 2011 and 2013 across oiled and 'clean' sites in Barataria Bay, Louisiana. In addition, we compared gene expression profiles in birds that showed high CYP1A levels in 2011 and in 2013, to test whether the transcriptomic response to oil exposure changed with time since the DWHOS. Our study identified genes that are relevant as biomarkers of exposure to oil from the DWHOS or from future oil spills. Our analysis of changes in gene expression across time will contribute to clarifying the persistence of oil from the DWHOS in the affected Louisiana salt marshes.

TP214 How a Single Exposure to Crude Oil Affects Feather Integrity and Flight Performance in Homing Pigeons: A Model for Assessing Migratory Bird Exposures

C. Perez, J.K. Moye, Univ of Nevada, Reno / Agriculture Nutrition and Veterinary Sciences; K. Dean, D. Cacela, Abt Associates; K. McGlamery, B. Sage, Univ of Nevada Reno / Dept of Agriculture Nutrition and Veterinary Sciences; C.A. Pritsos, Univ of Nevada / Agriculture Nutrition and Veterinary Sciences

External oil contamination of feathers is the most common form of oil exposure to birds, and the acutely lethal effects of heavy external oiling to birds is well known. Many birds died as a result of the Deepwater Horizon oil spill, but the sublethal effects lightly oiled birds may have suffered are not well described. This study utilizes the homing pigeon as a surrogate species for migratory birds to investigate the effects a single external oiling event has on the flight performance of birds. Homing pigeons were equipped with GPS data loggers and released 50 miles from their home loft for a series of baseline and experimental flights. After completion of the baseline flights, MC 252 crude oil was applied to the wing and tail feathers of the birds in the treated group (approximately 20% of their surface area). Repeated experimental flights followed the single application of oil and flight performance parameters were recorded. Data from GPS data loggers found that lightly oiled pigeons flying repeated 50 mile flights took significantly longer to return home and spent more time stopped on route than unoiled birds without changing sustained flight speed. After only a single oil application, feather damage was apparent and increased over time with repeated flight, likely causing changes to flight aerodynamics and requiring the need for compensatory behaviors during flight. These data suggests that birds affected by the Deepwater Horizon oil spill could have experienced long-term flight impairment, inhibiting a bird's ability to sustain flight. This would ultimately decrease the speed of migration and contribute to late arrival dates to desired destinations such as wintering grounds, breeding grounds or stopover sites. Delays during migration have been shown to cause reductions in reproductive success and survival. This work was funded in part by the U.S. Department of Interior's Natural Resource Damage Assessment for the Deepwater Horizon/Mississippi Canyon 252 Oil Spill and the Nevada Agricultural Experiment Station.

TP215 Towards a Physiologically Based Oiling Model (PBOM) for Predicting Thermoregulatory Response and Mortality in Seabirds

L. Knopper, Stantec / Environmental Services; M. Stephenson, Stantec Consulting Ltd. / Environmental Services; F.K. Wiese, Stantec Consulting Services Inc / Enviornmental Services; P. Boily, Western Connecticut State Univ / Dept Biological and Environemntals Sciences; P. Tuarze, P. Mazzocco, Stantec Consulting Ltd. / Environmental Services

When seabirds are exposed to spilled oil, mortality often results through hypothermia caused by the reduction of feather insulative properties. Some stakeholders in the risk assessment process consider oiling of seabirds to be a non-threshold event, with even the smallest amounts of oil on a bird assumed sufficient to cause mortality. This view is contrary to the prevailing paradigm established in the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) Type A Natural Resource Damage Assessment Model for Coastal and Marine Environments (NRDAM/CME) where a threshold volume of 350 mL is defined as the lethal external exposure threshold for birds. This quantity translates into a threshold oil thickness of 10 µm for spills with diameters over 230 m. Neither approach (i.e., no threshold vs. 10 µm) provides the flexibility to evaluate risk of mortality to seabirds, shorebirds and waterfowl of different body sizes and feeding guilds, or habitats ranging from the tropics to the polar regions. To address this deficiency, we explored the development of a physiologically-based model to predict thermoregulatory response in seabirds after oiling. Here we present: 1) a conceptual model of the physiological response of seabirds to oil exposure; 2) data pertaining to key variables related to avian metabolic response to oiling; and 3) results of preliminary modelling (based on points 1 and 2) from a collaborative effort to establish a Physiologically Based Oiling Model (PBOM) to quantify thermoregulatory responses in seabirds after oiling. We provide and invite discussion on how to incorporate such a model into the ecological risk assessment process to address seabird exposure to spilled oil.

TP216 How has the Deepwater Horizon oil spill changed what we think about the effects of oil on birds?

K.D. Dean, Stratus Consulting Inc. / Dept of Animal and Avian Sciences; D. Cacela, M. Carney, Abt Associates; F. Cunningham, National Wildlife Research Centre / Aquaculture; B. Dorr, USDA/WS/National Wildlife Research Center; K. Hanson-Dorr, USDA APHIS WS NWRC / Dept of Agriculture; C.A. Healy, US Fish and Wildlife Service; M. Hooper, USGS / Columbia Environmental Research Center; K. Horak, USDA; J. Isanhart, Dept of the Interior / Office of Restoration and Damage Assessment; J. Link, Michigan State Univ / Dept of Animal Science; I. Lipton, Abt Associates; I. Maggini, Univ of Western Ontario; A. McFadden, Abt Associates; M. McKernan, US Fish and Wildlife Service / Ecological Services; J.K. Moye, Univ of Nevada, Reno / Agriculture Nutrition and Veterinary Sciences; C. Perez, Univ of Nevada Reno; C.A. Pritsos, Univ of Nevada / Agriculture Nutrition and Veterinary Sciences; S. Shriner, USDA/WS/National Wildlife Research Center; P.L. Tuttle, US Fish and Wildlife Service / Deepwater Horizon NRDAR Field Office; S.J. Bursian, Michigan State Univ / Animal Science

Our understanding of the effects of oil on birds has largely been limited to data collected from heavily oiled birds during a spill, embryo toxicity studies and long-term low-dose feeding studies. Deepwater Horizon (DWH) oil spill studies documented free-flying birds with external oil exposure in the vicinity of the spill. Maintenance of feather integrity is fundamental to bird survival, and oil disrupts that integrity. This can rapidly lead to hypothermia and death in cold climates, but under warmer, more favorable conditions, birds will try to remove the oil through preening. Preening can have a two-fold effect: 1) further damage to feathers as the oil is spread over a greater surface area in an effort to remove it and 2) oil toxicity caused by ingestion. The US Department of the Interior-directed DWH avian toxicity studies were designed to improve understanding of the mechanisms of ingested oil intoxication in birds and effects of externally applied oil on flight. More effective and realistic methods for dosing birds were developed as was a more thorough understanding of how oxidative metabolic processes, acting on polycyclic aromatic hydrocarbons, affect avian physiology. It became clear that Heinz body formation and resulting hemolytic anemia are only one type of damage to avian red blood cells. There were also effects on multiple organ systems, immune function, cardiac function, oxidative processes and blood clotting, all of which reduce the overall health of the birds. Additionally, laboratory and field based flight studies showed that even light oiling to wings and tail feathers reduced aerial capabilities in western sandpipers and pigeons. For western sandpipers, flight became costly out of proportion to the mass of the oil applied. They had reduced take off speeds and reduced ability to control flight in a wind tunnel. Homing pigeons flew slower, changed their flight patterns and elevation, and (very importantly for migratory species) changed their flight path. For pigeons in particular, these effects were long-lasting after only a single oiling event because feather damage continued until primary feathers began to be replaced one month after oil application. The combined effects of oil toxicity and feather effects in wild populations have yet to be investigated, but the findings of these studies indicate that even light oiling, as detected in free-flying birds in the vicinity of the DWH spill, may be far more detrimental than expected.

Computational Toxicology: Integrating -Omics and Chemistry to Identify Chemicals of Environmental Concern

TP217 A Practical Guide for Green Molecular Design: Using in silico Approaches To Reduce Toxicological Risk

D. Faulkner, Univ of California Berkeley; L. Rubin Shen, Univ of California Berkeley / College of Chemistry; V.Y. De La Rosa, Silent Spring Inst; D. Johnson, Univ of California Berkeley / Nutritional Science and Toxicology; J. Arnold, Univ of California Berkeley / Dept of Chemistry; C.D. Vulpe, Univ of Florida / Physiological Science

Making “greener” chemicals involves more than improving atom economy or working with less solvent, and designing less hazardous chemicals can be difficult for chemists without at least some training in biology and toxicology. This review presents a practical guide to computational tools that a chemist could use early in the molecular design process to spot potential concerns before too much time is invested in synthesis or development. The first part of the guide presents a summary of concepts borrowed from medicinal chemistry and drug development, and how these concepts may be applied to engineer chemicals that are lesslikely to be absorbed or biologically active. Next, we discuss the current milieu of software tools used for drug development and toxicity prediction and the challenges which remain to be overcome in the computational toxicology field. Finally, we provide two workflows using some of the tools deemed most useful, present a case study as an example of how a workflow might be implemented, and conclude by outlining our ideal Green Molecular Design (GMD) tool.

TP218 Exploring comparative oxidative stress toxicity in two common animal models: towards the design of less hazardous chemicals

J. Corrales, Baylor Univ / Environmental Science; L.A. Kristofco, Baylor Univ / Dept of Environmental Science; B. Steele, Baylor Univ / Biomedical Studies; G. Saari, Baylor Univ / Environmental Science; M. Mills, Univ of Washington; K. Gallagher, USEPA / Office of Water; T. Kavanagh, N. Simcox, Univ of Washington; L. Shen, Yale Univ / Center for Green Chemistry and Green Engineering; F. Melnikov, Yale Univ / Forestry and Environmental Studies Center for Green Chemistry and Engineering Molecular Design Research Network; J. Kostal, The George Washington Univ; J. Zimmerman, Yale Univ; A. Voutchkova-Kostal, George Washington Univ / Chemistry; P. Anastas, Yale Univ / Center for Green Chemistry and Green Engineering; B.W. Brooks, Baylor Univ / Dept of Environmental Science

Sustainable molecular design of less hazardous chemicals presents a potentially transformative approach to protect public health and the environment. Relationships between molecular descriptors and toxicity thresholds derived by our group previously identified the octanol-water partition coefficient, log P, and the HOMO-LUMO energy gap, dE, as two useful properties in the identification of reduced aquatic toxicity. To determine how these two property-based guidelines need to be expanded when studying chemicals that exert oxidative stress (OS) responses, two common aquatic in vivo models, the fathead minnow (Pimephales promelas) and zebrafish (Danio rerio), were employed to examine lipid peroxidation, DNA damage, total glutathione, and antioxidant gene activation following exposure to 17 different compounds. The first eight compounds included structurally diverse industrial chemicals (bisphenol A, cumene hydroperoxide, dinoseb, hydroquinone, indene, perfluorooctanoic acid, R-(-)-carvone, tert-butyl hydroperoxide) and the second nine compounds included chemicals with SN2 nucleophilic substitution and Michael addition reactivity (3-bromo-1-propanol, (±)-3-chloro-1,2-propanediol, dibromoacetonitrile, glycidol, lindane, sodium decyl sulfate, styrene oxide, tris(2,3-dibromopropyl) phosphate, and tris(1,3-dichloro-2-propyl) phosphate). Overall, acute toxicity and oxidative stress responses varied between fish models and across chemicals. Bisphenol A, cumene hydroperoxide, dinoseb, and hydroquinone ranked highest as inducers of OS. Glutathione was the most consistently affected biomarker, suggesting its utility as a sensitivity response to support the design of less hazardous chemicals. Genotoxicity (changes in nrf2, gclc, gst, and sod) was most significantly ($p < 0.05$) altered due to R-(-)-carvone, cumene hydroperoxide and bisphenol A. Among the SN2 compounds dibromoacetonitrile, tris(1,3-dichloro-2-propyl) phosphate, tris(2,3-dibromopropyl) phosphate, styrene oxide and glycidol were most acutely toxic for both species. Results from the present study indicate that metabolism of parent chemicals and the metabolites resulting in molecular initiation events (MIEs) should be considered during the design of less hazardous chemicals. Moreover, new sustainable molecular design guidelines to reduce OS for electrophilic reactive chemicals (e.g., SN2 nucleophilic substitution, Michael addition reactivity) are being derived by our group.

TP219 In-Silico studies of Organophosphates toxicity with human Acetylcholinesterase by Docking, Site Directed Mutagenesis and Molecular dynamic simulation

A. Ranjan, Amity Univ / Amity Inst of Environmental Toxicology Safety and Management AIETSM; J.S. Almeida, Military Inst of Engineering / Laboratory of Molecular Modeling Applied to Chemical and Biological Defense; A. Chauhan, T. Jindal, Amity Univ / Amity Inst of Environmental Toxicology Safety and Management AIETSM

Drinking water is considered a potential pathway for dietary exposure due to pesticide contamination of drinking water sources. Organophophates(OPs) have been reported worldwide in waterbodies including drinking water. OPs have distinct feature of inhibiting Acetylcholinesterase enzyme which is required for hydrolyzing the neurotransmitter (acetylcholine) after the signaling. Docking, site directed mutagenesis and molecular dynamic simulation (MDS) approaches were used to explore mode of binding and inhibition for human acetylcholinesterase (hAChE) and organophosphates (OPs). More than 200 OPs molecules were investigated using Glide docking module of Schrodinger suit as co-crystal structure between two are not available in Protein Data Bank. In initial screening Trp86 was found to be involved in maximum Pi-Cation interaction on anionic subsite of hAChE other than Ser203 (Catalytic site). With extra precision glide docking Phoxim Ethyl Phosphonate (PEP) tops among 200 OPs based on glide docking score and interacted with Trp86, Gly121 and Ser203 whereas MM-GBSA score shows less binding affinity than heptenophos and dichlorovos. Trp86 preferred Pi interaction with ring bearing OPs and hydrophobic interactions with smaller OPs without ring bearing structures. Site directed mutagenesis at Trp86 (Trp86 to Ala86) shown the deterioration of the binding site in terms of size reduction, loss of electrostatic and geometric stabilization in binding cavity and significant reduction in binding of OPs in preferred orientation. Dock score of both wild and mutated hAChE shows a perfect qualitative agreement (R^2=64.1%) towards the study. Molecular dynamic simulation (GROMACS 4.5.5) of hAChE-PEP complex for $4X10^4$ picosecond with SPC16 water system at 310K temperature explained the evident role of Trp86 in stabilizing the ligand at P-site of the enzyme. Asp74 and Tyr124 were noticed in conveying H-bonds. Trp86 have shown consistent and stable distance between residues and ligand. Asp74 and Tyr124 appeared as important residues which contributed H bonds and Ser203 was expected to be closer for interaction to happen as it disappeared during simulation. Study suggests role of Trp86 on binding site is equally important for consideration and infers further investigation. Study also suggests trp86 may play a keyrole in development of more efficient antidotes to overcome the case of human poisoning.

TP220 Differentiating pathway-based toxicity from non-specific effects in high throughput toxicity data: A foundation for prioritizing AOP development

K.A. Fay, Univ of Minnesota – Duluth / Biology; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; B.R. Blackwell, ORISE / National Health and Environmental Effects Research Laboratory; S. Edwards, USEPA / Integrated Systems Toxicology Division; M. Nelms, Oak Ridge Inst for Science Education at USEPA / Integrated Systems Toxicology Division NHEERL; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory

The ToxCast chemical screening approach enables the rapid assessment of large numbers of chemicals for biological effects, primarily at the molecular level. Adverse outcome pathways (AOPs) offer a means to link biomolecular effects with potential adverse outcomes at the level of the individual or population, thus enhancing the utility of the ToxCast effort for hazard assessment. Thus, efforts are underway to develop AOPs relevant to the pathway perturbations detected in ToxCast assays. However, activity ('hits') determined for chemical-assay pairs may reflect target-specific activity relevant to a molecular initiating event of an AOP, or more generalized cell stress and cytotoxicity-mediated effects. Previous work identified a 'cytotoxic burst' phenomenon wherein large numbers of assays begin to respond at or near concentrations that elicit cytotoxicity. The concentration range at which the "burst" occurs is definable, statistically. Consequently, in order to focus AOP development on the ToxCast assay targetswhich are most sensitive and relevant to pathway-specific effects, we conducted a meta-analysis to identify which assays were frequently responding at concentrations well below the cytotoxic burst. Assays were ranked by the fraction of chemical hits below the burst concentration range compared to the number of chemicals tested, resulting in a preliminary list of potentially important, target-specific assays. After eliminating cytotoxicity assays and other generic xenobiotic response assays (e.g., cytochrome P450 induction and pregnane X receptor activation), the resulting list indicated numerous assays with targets previously identified for AOP development (e.g., thyroid peroxidase, peroxisome proliferator-activated receptor γ, estrogen receptor α, aromatase) along with several novel targets (e.g,, matrix metalloproteinase, thyroid hormone receptorα). Additional analyses identified chemicals that consistently were active within the cytotoxic burst region and compared to predictions of their baseline or narcosis toxicity concentrations. Finally, the analysis of assay responses was used to highlight current ToxCast assays of limited discriminatory ability, which either had zero hits among all chemicals tested or were only activated at cytotoxic concentrations. The contents of this abstract neither constitute nor necessarily reflect USEPA policy.

TP221 Targeted gene expression in zebrafish exposed to chlorpyrifos-oxon confirms phenotype-specific mechanisms leading to adverse outcomes

N. Vinas, Mississippi State Univ / Environmental Laboratory; L. Escalon, US Army Engineer Research and Development Center / Environmental Laboratory; E. Prats, CSIC; M. Faria, D. Raldua, IDAEA-CSIC

Zebrafish models for mild, moderate, and severe acute organophosphorus poisoning were previously developed by exposing zebrafish larvae to chlopyrifos-oxon. The phenotype of these models was characterized at several levels of biological organization. Oxidative stress and mitochondrial dysfunction were found to be involved in the development of the more severe phenotype. Here we used targeted gene expression to understand the dose-responsiveness of those two pathways and their involvement on generating the different zebrafish models. As the severe phenotype is irreversible after only 3h of exposure, we also analyzed the response of the oxidative stress pathway at 3h and 24h. Some of the genes related to oxidative stress were already differentially expressed at 3h. There was an increase in differentially expressed genes related to both oxidative stress and mitochondrial function from the more mild to the more severe phenotype, suggesting the involvement of these mechanisms in increasing phenotype severity. Temporal data suggest that peroxynitrite leading to lipid peroxidation might be involved in phenotype transition and irreversibility.

TP222 Toxicity evaluations in Japanese medaka embryos exposed to 1,2-naphthoquinone with metabolomics

M. Kawano, S. Uno, Kagoshima Univ / Faculty of Fisheries; E. Kokushi, Kagoshima Univ / Education and Research Center for Marine Resources and Environment; J. Koyama, Kagoshima Univ / Faculty of Fisheries

Oxygenated PAHs (oxyPAHs) are discharged with the exhaust gas from automobile, and generated with photodegradation of parent PAHs in the atomosph ere. They widely distribute in environment including aquatic environment. In previous study, Japanese medaka (Oryzias latipes) embryos were seriously affected exposures of individual oxyPAHs as following; individual oxyPAH specific effects to embryos were caused such as deformation of embryonic yolk, blackened oil globule, mortality, hatching delay, and decrease of hatching rate and induced the malformations on hatched larvae such as incomplete development of the cephalic region and palate, pericardial edema, tubular heart, unabsorbed and hypertrophied yolk sac, and underdeveloped caudal fin. 1,2-Naphthoquinone (NaQ) of 100 mg/L induced the serious malformations on most medaka larvae and that more than 200 mg/L arrested the embryo development and led lethal within a few days from starting the exposure. In this study, we examined the toxicities of 1,2-naphthoquinone in fish embryo using GC/MS metabolomics method, because of exploring the mechanism of that toxicities. Medaka embryos were individually exposed to 200 mg/L and 2 mg/L of NaQs for 6 days, and collected for metabolomics analysis at every day. All metabolome profiles detectable with GC/MS analysis were collected, analyzed with principal component analysis (PCA), and explored the relationship between the effects and the variations of metabolome in embryos. In early embryo development in the first 3 days of exposure, glucose, glucose-1-phosphate, and glucose-6-phosphate were significantly low compared with control group, although the energy is not generated in TCA cycle but mainly glycolytic system. These decrease could cause the development delay. In addition, lactate, which play a critical role in cell differentiation, significantly increased during first 2 days of exposure. This disturbance of lactate might induce the disturbing the embryo development. These abnormal metabolome profiles should deeply relate to the arrest of fish development within a few days from starting the exposure. Ammonia is generally used for the osmotic modulation in fish embryo. Urine significantly increased exposed to NaQ for 5 or 6 days. Then, ammonia resulted to extremely increase in embryos, and affected to hatch larvae as causing malformations.

TP223 Integrating metagenomic sequencing with physicochemical variables to infer historical trends within the cyanobacterial community in freshwater lakes

T. Tse, Univ of Saskatchewan / Toxicology Centre; S. Tang, Univ of Saskatchewan; S.B. Wiseman, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; L. Doig, Univ of Saskatchewan / Toxicology Centre; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre; J.P. Giesy, P.D. Jones, Univ of Saskatchewan

Eutrophication has become a worldwide environmental issue for many freshwater lakes and reservoirs. Increased nutrient pollution can contribute to water degradation via the production of harmful algal blooms. This phenomenon has contributed to significant water quality issues for many North American Prairie lakes and potable sources. In addition, long-term monitoring data are often lacking for many aquatic ecosystems and studies are frequently initiated only after serious problems arise. Paleolimnological techniques are often used to reconstruct long-term environmental trends when long-term monitoring data are unavailable. One emerging tool in paleolimnological investigations with potential to accurately track and reconstruct historical trends or changes within the aquatic environment is metagenomic analysis. In this study, sediment cores were collected from a Prairie reservoir, and a combination of physicochemical variables and metagenomic analyses were conducted to investigate trends in algal community composition, identify the presence of potentially harmful cyanobacteria and their toxin-producing genes, and to identify relationships among the phytoplanktic community and various physicochemical variables. Temporal trends in algal community composition were identified through sedimentary phytopigment analyses. Insight into trends in the cyanobacterial community was gained through 16S rRNA sequencing. Finally, a component for the microcystin toxin-producing pathway, the mcyA gene, was identified in sections of the sediment cores and was positively correlated to the abundance of Dolichospermum, a genus of harmful cyanobacteria commonly found in many affected freshwater lakes and reservoirs. Thus, metagenomic analyses in combination with supporting physicochemical characteristics, can provide insight into long-term lake ontogeny and serve as a practical substitute for long-term data where such data is lacking or absent.

Assessing Ecological Risk to Inland Environments Due to Increases in Major Ions

TP224 Timing is everything: assessing the effects of pulse exposure patterns on salt toxicity in Daphnia magna

T.J. Woo, A. East, Towson Univ / Environmental Science; C.J. Salice, Towson Univ / Biological Sciences/ Environmental Science

Road salts used for deicing roads can runoff and have adverse impacts on freshwater ecosystems. Salt concentrations in aquatic systems, however, are not constant. In Maryland, for example, the flashiness of urban streams translates to pulses of high salinity resulting from periodic runoff events. There is a strong need to better understand the ecological impacts of pulsed exposure patterns of salt in urban freshwater streams as a means to inform road salt regulation. Standard ecotoxicological tests are designed to observe the chronic effects of a chemical stressor at a constant exposure level and therefore provide limited insight into more realistic fluctuating exposures. We aimed to elucidate the effects of fluctuating salt exposure patterns using a 21-day toxicity assay on the freshwater cladoceran, Daphnia magna. Four exposure patterns were used, each controlled for total time and intensity of exposure by using the same time-weighted average. The time-weighted average for all exposures was based off of the reference exposure of 4720 mg/L NaCl for 24 hours; this concentration was the 48-hour LC10. From this time-weighted average, we derived the following exposure patterns: one 24-hour pulse, three 8-hour pulses, or six 4-hour pulses of 4720 mg/L NaCl, and a 21-day constant exposure of 225 mg/L NaCl. We collected data on survival and reproductive endpoints throughout the assay, and measured initial and final lengths. Results strongly suggested that the magnitude of sublethal toxic effect was related to pulse duration and frequency. Shorter and more frequent pulses caused greater detriment to growth and reproduction, suggesting that longer recovery periods between exposures may be important for recovery and energetic homeostasis. Alternatively, survival data suggested a convergence of mortality around 50 percent at day 21, when all treatments reached the same total exposure. The exception to this was the pulse pattern of intermediate duration and frequency (three 8-hour pulses), which had the lowest survival at 20 percent. These data are being used to explore different modeling approaches for predicting lethal and sublethal effects of pulse exposures to salt. Our goal is to develop a model that may be used to address concerns regarding effects of road salt runoff on freshwater organisms. Our results suggest that the influence of pulse exposure patterns must be taken into account when assessing the ecological impact of road salt runoff.

TP225 Establishing baseline exposure histories of fish in watersheds with energy-related resource extraction activity through otolith microchemistry

N. Bailes, The Ohio State Univ / Environmental Science Graduate Program; R.P. Lanno, The Ohio State Univ / Dept of Evolution Ecology and Organismal Biology Subsurface Energy Resources Center

The proliferation of unconventional oil and gas wells using high volume horizontal hydraulic fracturing (HVHHF) technology has yielded enormous quantities of highly saline produced waste waters. Releases of these waste waters into surface waters have been known to occur, but in the absence of continuous monitoring of baseline water chemistry, it is difficult to assess exposure to aquatic organisms. Employing effective methods to monitor for exposures to HVHHF waste water and other effluents produced by resource extraction operations (e.g., coal mining) in surface waters is crucial for mitigating the potential risks of these technologies. Teleost fish bioaccumulate ambient metals in otoliths throughout their life history and thus represent potentially valuable tools for tracking metal exposures associated with energy-related resource extraction processes. Accessing this exposure history through laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), we hope to reconstruct and discriminate the exposure histories of fish from watersheds that contain various energy-related resource extraction activities. Otolith microchemistry will be compared between fish sampled from watersheds with no resource extraction activity and those from watersheds with resource extraction activities to determine a baseline presence-absence signal. Additionally, otoliths will be compared between fish in watersheds that have either HVHHF or coal mining activity. For example, Li, Sr, and Ba have been associated with waste waters produced by HVHHF and would be a likely biomarker in the otoliths of fish exposed to these waters, while a different set of metals would be detected in otoliths of fish exposed to acid mine drainage or coal mine effluents. Fish will be sampled in watersheds with and without resource extraction activities (e.g., HVHHF, coal) in Ohio or West Virginia during summer 2016 to establish baseline otolith microchemistry and preliminary results will be presented. Trace element analysis of otoliths may provide a method for tracking exposures of fish in watersheds experiencing changes in water quality connected to energy-related resource extraction.

TP226 Effects of Winter Road Salt Application and Episodic High Conductivity Mesocosm Pulses on Southern Appalachian Headwater Stream Macroinvertebrates

M. Fleetwood, Appalachian State Univ; S. Tuberty, Appalachian State Univ / Biology; J. Colby, Appalachian State Univ / Geography and Planning; K. Cockerill, Appalachian State Univ / Sustainable Development; D. Martin, Appalachian State Univ / Geography and Planning; C. Gu, Appalachian State Univ / Geology

Freshwater organisms are at risk from exposure to elevated levels of salts due to runoff following winter road salt applications. Climate records of winter snow falls were compared to data gathered every 15 minutes from In Situ water monitors installed at the ouflow of seven headwater sub-basins of the Upper South Fork of the New River (USFNR) by the AppAqua research cluster. Data displays mean background specific conductivity levels (over a five year period, 2010 – 2015) of 30 – 50 uS/cm at reference sites, 140 – 185 uS/cm at moderately impacted sites, and 610 – 740 uS/cm at highly impacted sites. While episodic high conductivity pulses during/after winter storms reach levels as high as 7,000 – 12,000 uS/cm (equivalent to salinities of 6.6 – 11 ppt) in the urbanized stream catchments. A negative correlation exists between long-term waterhsed specific conductivity (SC) trends (monitored during 2010 – 2015) and macroinvertebrates NCBI stream health values (calculated with Family and Genus tolerance values) along with Family and Genera richness (r^2 of 0.7306, 0.5999, 0.6366, and 0.6114 respectively). To determine the salt tolerance of benthic macroinvertebrates to these short term episodes of high road salt levels, acute toxicity tests were performed with a focus on one sensitive Family [Heptageniidae: tolerance value (TV) of 2.44 on a scale of 10] and two sensitive Genera [TV of 0.5 to 1.33 on a scale of 10] of Ephemeroptera at a concentration of 10,000 uS/cm [SC values used for mesocosm exposures were determined from analyzing the water monitoring data] for up to 96 hr with varying rest periods between trials (23, 18, 12, 6, and 0 hrs). Two exposure methods were utilized: 1) baseline results – macroinvertebrates returned to reference water (< 100 us/cm) post – exposure, 2) pulse results – macroinvertebrates returned to water that mimic background SC levels that occur between storm events. When utilizing exposure method two, salt induced mortality from acute salt exposure begins to occur during an exposure of 1 hr on at 10,000 uS/cm and 23 hr off at 900 uS/cm. An LC_{50} response was first measured during 6 hr on/18 hr off after 96 hr. When comparing 6 hr on/18 hr off with 12 hr on/12 hr off, no statistical difference was observed, but once compared to the longer time duration pulse exposures, a statistical difference is evident (i. e. 12 hr on/12 hr off vs. 18 hr on/6 hr off).

TP227 Evaluation of spatial and temporal responses of multiple aquatic taxa to stressors related to surface mining

S. Ciparis, Virginia Tech / Fish and Wildlife Conservation; S.E. Lingenfelser, US Fish and Wildlife Service / Virginia Field Office

The Powell River (Virginia and Tennessee, USA) is a biologically diverse ecosystem, supporting several species of threatened and endangered fish and freshwater mussels. Coal mining is extensive in the upper watershed, with 28% of land area in active surface mining permits and 72% of the underground area in active and abandoned deep mines. In the upper Powell River, elevated concentrations of major ions and associated measurements of total dissolved solids and specific conductance have been attributed to surface mining activities. In this study, we examined recent (2000-2015) and historical data (1963-1999) on biological communities, including macroinvertebrates, fish, and freshwater mussels, to determine their spatial and temporal relationships with surface mining, specific conductivity, and other stressors in the tributaries and mainstem of the upper Powell River. Evaluation of recent data illustrates widespread impairment of macroinvertebrate communities in Powell River tributaries, with a negative relationship between the presence of Ephemeroptera taxa and measured specific conductivity as well as the proportion of the watershed in surface mining permits. Mining-influenced tributaries and their receiving streams also have an impaired fish community, with a general predominance of tolerant species and omnivores and few darter species and insectivores. In the mainstem Powell River, condition of the macroinvertebrate, fish, and freshwater mussel communities improves with distance downstream from surface mining operations. However, evaluation of historic data showed that impairment of aquatic communities in the tributaries and mainstem of the Powell River began more than 40 years ago, before the rapid increase in surface mining and associated major ion concentrations that occurred in the 1990s. We will discuss methodology used to discern effects of major ions relative to other stressors on various taxa, the limitations of these methods, and relevance to ongoing efforts of regulation and restoration.

TP228 Stream periphyton responses to mesocosm treatments of equal specific conductance but different major ion contents measured with in situ fluorometry

S. Guglielmi, Pegasus Technical Services Inc. / co USEPA Cincinnati; S. DeCelles, The McConnell Group / co USEPA Cincinnati; N. Smucker, J.M. Lazorchak, USEPA / Office of Research and Development; C.T. Nietch, USEPA / Water Supply and Water Resources Division

A stream mesocosm experiment was designed to compare biotic responses among streams exposed to an equal excess specific conductivity target of 850 µS/cm relative to a control that was set at 200 µS/cm. Three treatments were based on dosing the background mesocosm water, a continuous flow-through mixture of natural river water and reverse osmosis treated water, with stock salt solutions prepared from 1) a mixture of sodium chloride and calcium chloride (Na/Cl chloride), 2) sodium bicarbonate, and 3) magnesium sulfate. Here we focus on comparing stream periphyton communities across treatments based on measurements obtained from a Pulse-Amplitude Modulated (PAM) fluorometer. The fluorometer is used in situ and, with built in algorithms, distributes the total aerial algal biomass (µg/cm2) of the periphyton among cyanobacteria, diatoms, and green algae. Eight locations within each of the 1 m2 (0.3 m W x 3.33 m L) mesocosm gravel sections were assessed approximately every other day throughout the dosing period. The fluorometer based assessment showed all mesocosms were statistically similar in terms of algal periphyton before dosing began. Changes in the community began as early as 2 days into dosing and were statistically significant by 1 week of dosing, with the magnesium sulfate treatment exhibiting greater cyanobacteria biomass relative to the control and the sodium bicarbonate and Na/Ca chloride treatments. This effect persisted throughout 28 days of dosing. Diatoms biomass was significantly greater in the Na/Ca chloride treatment and the sodium bicarbonate treatment than in the control and magnesium sulfate treatment. Total algal biomass was greater in the magnesium sulfate treatment compared to the control and Na/Ca chloride treatments, but not until 28 days. These results suggest that the ca. 834 µS/cm conductivity treatments did not significantly affect stream periphyton biomass until 28 days of continuous dosing and only for the magnesium sulfate treatment. However the major ion content of the elevated conductivity can be particularly important to controlling the relative abundances of cyanobacteria and diatoms. This effect is realized relatively quickly and this could translate to important differences in the food source for grazers in the systems. Changes in food quality may explain why the total periphyton biomass elevated later in the experiment, because cyanobacteria are not a favored food source compared to diatoms.

TP229 Chronic Salt Impact on Mayflies down under

A. Henderson, Inst for Applied Ecology, Univ of Canberra / Inst of Applied Ecology; S. Foster, Univ of Canberra / Environmental Science; B.J. Kefford, Univ of Canberra / Inst for Applied Ecology

The stream macroinvertebrate orders Ephemeroptera (mayfly), Plecoptera and Thricoptera (EPT) species are known for their sensitivities to changes in water quality and are thus widely used in biomonitoring studies. Species Sensitive Distribution (SSD) of the acute lethal sensitivity of stream macroinvertebrates exposed to salinity suggest no adverse effect at 1 mS/cm. Instead, a 50% reduction in EPT species has been seen in south-east Australia at 1 mS/cm. Suggesting either (a) the current protection limit of 1 mS/cm for effluent discharges is not achieving “no adverse effects” to the environment or (b) other factors confounded with salinity are causing the loss of EPT. To resolve which of these hypothesises we aim to determine sub-lethal effects of salinity with chronic exposures, using Ephemeroptera. Growth rates and generational effects will be investigated to determine sub-lethal effects from low salinity exposures. Ephemeroptera species in Australia are not known to be parthenogenetic, providing difficulties in culturing methodology. This data will aid in forming a true representation of what the guidelines should be achieving and if sub-lethal effects are occurring, explaining the reduction in ETP species in low effluent salinity areas.

TP230 Relationships between water mineralization and electric conductivity of natural waters in the Aral Sea Basin

B. Karimov, Scientific-consulting Center ECOSERVICE / Ecosystem Services Conservation; B.J. Kefford, Univ of Canberra / Inst for Applied Ecology; M. Canedo-Arguelles, Univ of Vic, Spain / BETA Technology Centre Aquatic Ecology Group; T.A. Talskikh, Uzhydromet

Salinization of surface waters as a consequence of re-introduction of water from irrigated fields and industrial effluent is a common problem in plain areas within Aral Sea Basin (ASB) with negative effect on aquatic ecosystems and human health, mostly in lower reaches of rivers. Many water quality standards for human consumptions around the world, including the ASB region, are set at 1 g/L (total ions content). There was no trend in salinity levels between 1913 (when measurements began) and he 1960’s where salinity average annual salinity levels were between 0.42-0.62 g/L. In the 1960’s, salinity started to rise reaching 0.92-1.12 g/L between 2005 and 2014. The objective of the present work was to analyse ionic composition, dynamics of water salinization (WS) and its relationship with electric conductivity (EC, µS/cm) in the main rivers of the ASB – Amudarya (AD) and Syrdarya (SD). We used data from the State Hydrometeorological Service of Uzbekistan for 2005-2014. In upper reaches of main rivers: Amudarya (AD) and Syrdarya (SD) the total water mineralization usually does not exceed: 0.5 g/L in the period May – October and 0.8 g/L in the period November – April. The dominant ions in upstream of rivers are: AD – sulphate? hydrocarbonate? chloride? calcium? sodium? magnesium and SD – hydrocarbonate? sulphate? chloride? calcium? sodium? magnesium. However, in midstream and downstream of both rivers dominant ions are: sulphate? chloride? hydrocarbonate? sodium? calcium? magnesium. There were strong linear relationships between salinity and EC with r^2 values of 0.91-0.99. Mean values of salinity and EC for the study period (2005-2014) were 0.65 g/L and 916 µS/cm; for the upper AD reach; 1,12 g/L and 1644 µS/cm for the lower AD reach; 0.61 g/L and 925 µS/cm for SD upper reach; and 0.97 g/L and 1375 µS/cm for SD middle reach. Thus, in AD 1 mg of salinity was equal to 1.41 µS/cm in the upper reach and to 1.47 µS/cm in the lower reach. However, in SD 1 mg of salinity was equal to 1.52 and 1.42 µS/cm in the upper and middle reaches, respectively. This is most likely explained by considerable variations in ionic composition of water. Preliminary results reveal that the water quality standard of 1 g/L in ASB basin will be reached when EC equal to about 1410-1520 µS/cm depending on the river basin.

A SETAC Pellston Workshop® on Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Substances Data

TP231 Challenges in Assigning Endocrine Specific Modes of Action: Recommendations for Researchers and Regulators

E.M. Mihaich, ER2; C. Schaefers, Fraunhofer-Institut / Ecotoxicology; D.A. Dreier, Univ of Florida / Physiological Sciences; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre; L.S. Ortego, Bayer CropScience / Environmental Toxicology and Risk Assessment; Y. Kawashima, JAPAn NUS Co., Ltd.; Z. Dang, RIVM / LIEC CNRS UMR; K.R. Solomon, Univ of Guelph / School of Environmental Sciences

As regulatory programs focus on evaluating substances for their endocrine disrupting properties, there is a need for careful study design and data interpretation to distinguish between endocrine versus non-endocrine specific responses. This is particularly important where specific criteria are under development to identify endocrine disrupting properties to enable hazard-based regulation. Irrespective of the regulatory process, most jurisdictions use the WHO IPCS definition of an endocrine disruptor (ED), requiring that a substance is demonstrated to cause a change in endocrine function that consequently leads to an adverse effect in an intact organism. Such a definition is broad, and at its most cautious, might capture many mechanisms that in general would not specifically be considered ED. For instance, stress is a non-specific, neuro-endocrine response that can lead to adverse outcomes. In addition, non-endocrine toxic mechanisms (e.g. hepatotoxicity, acetylcholinesterase inhibition) may operate secondarily or in parallel to impact the endocrine system and apical endpoints downstream. Furthermore, endocrine responses may be adaptive in nature and designed to maintain homeostasis rather than inducing an irreversible adverse effect. The likelihood of indirect effects is increased in (eco)toxicological studies requiring the use of maximum tolerated dose levels, which must produce some adverse effect. The misidentification of indirect effects as truly ED has serious consequences in terms of triggering animal and resource intensive testing and potentially severe regulatory consequences. This poster will expand on the issues and recommendations made in the oral presentation of a review, based on 6 case study substances, conducted to evaluate scenarios that could complicate the assessment of whether or not a substance is an endocrine disruptor. Various lines of evidence were identified that can be considered when evaluating if an adverse effect is causally linked to a primary endocrine system interaction. A weight of evidence approach was used to evaluate available data for the case-study substances. In this approach, the weight of evidence was based on biological plausibility, empirical support, and essentiality of key events in adverse outcome pathways to determine whether an endocrine mode of action can be conclusively assigned to the effects observed for a given substance.

TP232 Uncertainties in biological responses that influence hazard or risk approaches to the regulation of endocrine active substances

S. Kadlec, Univ of Minnesota – Duluth / Integrated Biosciences; J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division; P. Bjerregaard, Univ of Southern Denmark / Biology; K. Brugger, DuPont Crop Protection; L. Gray Jr, US E.P.A. / Office of Research and Development; T. Iguchi, National Inst for Basic Biology / Molecular Environmental Endocrinology; L. Weltje, BASF SE / Crop Protection Ecotoxicology; J. Wheeler, Dow Agrosciences

Endocrine Disrupting Substances (EDSs) may have certain biological effects including delayed effects, multigenerational effects, and non-monotonic dose response relationships (NMDRs) that require careful consideration when determining environmental hazards. The case studies evaluated for the SETAC Pellston Workshop™: Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Chemicals and other key examples from the literature are discussed in this poster and we summarize the key issues and examples presented in the platform session. EDSs can have specific and profound effects when exposure occurs during sensitive windows of the lifecycle (development, reproductive). This creates the potential for delayed effects where the adverse effect becomes manifest when exposure has ceased, possibly in a different lifestage. This underscores the need for testing in appropriate (sensitive) lifestages and full lifecycle designs that capture adverse effects wherever they occur in the lifecycle. Such tests are available in the tool box and should be employed to derive endpoints that can be considered protective of all life stages. Similarly, the potential for effects to be manifest in subsequent generations (multigenerational effects) has also been raised as a potential issue in the derivation of appropriate endpoints for EDSs. However, the evidence for such effects beyond the second generation is limited. Indeed this is reflected in the design of new higher tier tests to assess endocrine active substances (EASs) developed by the OECD and US-EPA that move to extended one-generation designs and away from multi-generational studies for fish and mammals. The occurrence of non-monotonic dose or concentration response relationships is also considered a limiting factor for reliable risk assessment of EDSs. Substantial data reviews are underway to inform on their occurrence. However, evidence to date indicates they are more prevalent in in vitro and mechanistic data, not often translating to adverse apical endpoints that would be employed in risk assessment. A proposal of how to evaluate NMDRs in the context of endocrine hazard and risk assessment procedures is presented. If careful consideration of delayed, multigenerational and NMDR effects are made, it is feasible to assess environmental endocrine hazards and derive robust apical endpoints for risk assessment procedures ensuring a high level of environmental protection.

TP233 Current limitations and a path forward to improve testing for the environmental assessment of endocrine active substances

K.K. Coady, The Dow Chemical Company / Toxicology Environmental Research and Consulting; R.C. Biever, Smithers Viscient / Dept of Environmental Toxicology; N.D. Denslow, Univ of Florida / Physiological Sciences; M. Gross, WCA Environment; P.D. Guiney, Retired- S C Johnson & Son, Inc / Molecular and Environmental Toxicology Center; H. Holbech, Univ of Southern Denmark / Dept of Biology; N.K. Karouna-Renier, USGS Patuxent Wildlife Research Center / Beltsville Lab; I. Katsiadaki, Cefas Weymouth Laboratory / Environment and Animal Health; H.O. Krueger, Wildlife International / Aquatic Plant and Insect Toxicology; S.L. Levine, Monsanto Company / Global Regulatory Sciences; G. Maack, Federal Environment Agency / Ecotoxicological Assessment; M. Williams, CSIRO / Land and Water; J.C. Wolf, Experimental Pathology Labs., Inc.; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory

To assess the hazards and risks of possible endocrine active chemicals (EACs), there is a need for robust, validated test methods that detect perturbations of endocrine pathways and provide reliable information for evaluating potential adverse effects on apical endpoints. One issue of significant concern for current EACS screening/testing programs involves resources such as cost, time, trained personnel, and animal use. This is especially problematic when considering the number of chemicals that some regulatory authorities need to assess. One way to address this challenge is to prioritize chemicals for possible in vivo testing by using in vitro high throughput (HTP) assays focused on a suite of endocrine molecular initiating events (MIEs). Additional challenges associated with the design and conduct of in vivo EAC screening and testing include the selection of appropriate species (i.e., sensitive and amenable to laboratory testing), endpoints and life-stages. A component of this involves experience gained in the use of existing tests to determine, for example, assays that have demonstrated exceptional sensitivity to perturbation of a given MIE. However, the strategic use of HTP data and/or early screening level information may help guide the selection of existing assays that can further evaluate a given EAC modality. Further challenges for EAC screening and testing involve guidance and optimization in several areas, such as concentration setting, statistical power to detect biologically significant adverse effects, delivery and analytical measurement of test substances, availability of technical expertise, and study interpretation, including linking mechanistic to apical effects. Some of these areas can be addressed by the lessons learned and best practices developed through recent experiences conducting EAC screening/testing. Additionally, the collective assessment of EAC screening and testing data (e.g. compilation of historical control data) can be leveraged to refine test designs and performance criteria to maximize the power and utility of EAC screening/testing. Finally, a number of recommendations are provided for longer term research to address areas of uncertainty, including identifying potentially sensitive species for which test methods currently do not exist (e.g., invertebrates) and key endocrine pathways in addition to estrogen, androgen and thyroid signalling.

TP234 Assessing the Effects of Endocrine-active Substances on Wildlife Populations: A Case Studies Summary

S. Marty, Dow Chemical Company; A. Blankinship, USEPA; J. Chambers, Mississippi State Univ; L.A. Constantine, Pfizer, Inc. / Pharmacokinetics Dynamics and Metabolism; W. Kloas, Liebniz Inst of Freshwater Ecology & Inland Fish.; A. Kumar, CSIRO / Center for Environmental Contaminants Research; L.L. Lagadic, Bayer CropScience / Environmental Safety; J. Meador, NOAA Fisheries / Ecotoxicology and Environmental Fish Health Program; D. Pickford, Syngenta / Inst for the Environment; T. Schwarz, Cefas / Environmental and Animal Health; T.A. Verslycke, Gradient

For ecological risk assessment, endocrine disruptors require the establishment of an endocrine mode of action (MoA) with a plausible linkage to a population-relevant adverse effect. Current ecotoxicity test methods mostly incorporate apical endpoints although some also include mechanistic endpoints, at the subcellular through organ level, which can help establish an endocrine MoA. However, the link between these endpoints and adverse population-level effects is often unclear. In preparation for a 2016 Pellston Workshop® on Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Substances (EAS), several case studies of EAS (tributyltin, ethinyl estradiol, perchlorate, trenbolone, propiconazole, and vinclozolin) were used to evaluate the population relevance of toxicity endpoints in various taxa. For some taxa, like mollusks, the population relevance of tributyltin-induced imposex is well established. However, for other taxa, the population relevance of observed effects is not as well understood. Furthermore, potential adaption and recovery processes also are important to consider when evaluating the adverse effects of EAS on wildlife populations. As our understanding of endocrine perturbations and key event relationships improves, adverse population level effects will be more easily and accurately predicted. This poster presentation expands on a platform presentation on the topic of assessing the effects of EAS on populations and will focus on examples of potential population relevance from the case study chemicals as well as briefly discuss future needs to better predict population level effects.

TP235 Evaluating the Credibility of Histopathology Data in Environmental Endocrine Toxicity Studies

J.C. Wolf, Experimental Pathology Labs., Inc.; G. Maack, Federal Environment Agency / Ecotoxicological Assessment

Agencies responsible for environmental protection are tasked with developing regulatory guidance that is based on the best available scientific evidence. Histopathology is a common endpoint in toxicologic bioassays; however, because of the subjective nature of this endpoint, and the advanced level of specialized training required for its effective utilization, the reliability of histopathology data can be inconsistent. For the present study, a total of 189 papers that involved investigations of endocrine active substances (EAS) were reviewed for the credibility of their reported histopathology findings. The review process incorporated standardized criteria for article and data selection, and systematic procedures for data evaluation and histopathology credibility (HC) scoring. A major outcome of these efforts was the finding that 54% of the examined papers contained histopathology data that were considered to be either highly credible or credible, whereas such data were deemed to be of equivocal, dubious, or no credibility in 46% of cases. The ultimate goals of this work are to draw attention to reliability issues that can affect the histopathology endpoint, provide recommendations to improve the quality of this endpoint, and suggest an approach for the expeditious and judicious use of histopathology data in weight of evidence determinations required for hazard and/or risk assessment. This exercise was conducted initially as part of a SETAC-Pellston Workshop™ entitled "Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Chemicals (EHRA): Developing Technical Guidance Based on Case Studies to Support Decision Making" that was held in Pensacola, Florida, USA, from January 31st to December 5th, 2016.

Regulatory Directions – Poster Only

TP236 A strategic approach to fulfilling data gaps for environmental risk assessment of iso-alcohols

G.E. Bragin, ExxonMobil Biomedical Sciences, Inc. / Environmental Sciences Division; B. Hedgpeth, Exxon Mobil Biomedical Sciences Inc; C. Sutherland, ExxonMobil Biomedical Sciences, Inc. / Toxicology and Environmental Science; B. Kelley, D. Letinski, M. CONNELLY, Exxon Mobil Biomedical Sciences Inc; J.D. Butler, ExxonMobil Biomedical Sciences, Inc / Environmental Toxicology and Chemistry Laboratory

Environmental risk assessments require quality data to provide defensible environmental quality benchmarks. Quantitative Structure Activity Relationship (QSAR) endpoint estimates are often appropriate for alcohols with a very strong correlation to aquatic toxicity test data. However, QSAR estimates require comprehensive justification to demonstrate applicability, and still may not fully meet regulatory requirements, leading to extensive long-term toxicity testing. Here, limited, strategic environmental testing was used to support QSAR predictions, thereby reducing animal testing while still meeting regulatory requirements. Aquatic toxicity testing with algae, daphnids and fathead minnows (OECD 201, ISO 20665 and OECD 210) was performed with isooctanol and isoundecanol. The study objective was to employ a testing program consisting of long-term fish (limit test), invertebrate and algal toxicity tests to demonstrate that QSAR estimations accurately predict aquatic effects from long-term continuous exposure to these substances, further supporting the use of QSAR models across a range of iso-alcohols. The data demonstrate that the QSAR model employed accurately characterized the hazard of iso-alcohols and is protective of these endpoints. Moreover, this combined information, by demonstrating a regular and predictable pattern of toxicity amongst these substances, further justifies read-across between substances for other endpoints (such as bioaccumulation) and supports efficient use of data for general purpose risk assessments.

TP237 Development and application of a density dependent matrix population model for Atlantic killifish (Fundulus heteroclitus)

D.H. Miller, USEPA / Midcontinent Ecology Division; B. Clark, D.E. Nacci, USEPA / Atlantic Ecology Division

Ranging along the Atlantic coast from US Florida to the Maritime Provinces of Canada, the Atlantic killifish (Fundulus heteroclitus) is an important and well-studied model organism for understanding the effects of pollutants and other stressors in estuarine and marine ecosystems. Matrix population models are useful tools for ecological risk assessment because they integrate effects across the life cycle, provide a linkage between endpoints observed in the individual and ecological risk to the population as a whole, and project outcomes for many generations in the future. We developed a density dependent matrix population model for Atlantic killifish by modifying a model developed for fathead minnow (Pimephales promelas) that has proved to be extremely useful, e.g. to incorporate data from laboratory studies and project effects of endocrine disrupting chemicals. We developed a size-structured model (as opposed to one that is based upon developmental stages or age class structure) so that we could readily incorporate output from a Dynamic Energy Budget (DEB) model, currently under development. Due to a lack of sufficient data to accurately define killifish responses to density dependence, we tested a number of scenarios realistic for other fish species in order to demonstrate the outcome of including this ecologically important factor. We applied the model using published data for killifish exposed to dioxin-like compounds, and compared our results to those using a previously published stage-based density-independent killifish matrix model. By considering how models can accommodate variation in life histories and account for ecological factors such as density dependence, we can more easily develop other fish species-specific matrix models to characterize population status and predict more realistically the ecological impacts of stressors.

TP238 Ecological Risk Assessment of Complex Substances (UVCBs) using a holistic approach: A Case Study with Resins and Rosins

M. Fernandez, Environment and Climate Change Canada / Ecological Assessment Division; A. Okonski, M. Bonnell, Environment and Climate Change Canada

Ecological risk assessment of complex multi-component substances (e.g. UVCBs – Unknown or Variable Composition, Complex Reaction Products or Biological Materials) pose a challenge to regulators due to these substances' variable and often unknown composition, including both identity and quantity of chemical species present in the UVCB substance being evaluated. Furthermore, there are additional challenges in accurately matching of test data to the substances registered and being assessed by the regulator. Approximately 300 organic UVCBs remain to be addressed in Canada as part of the next phase of the Chemicals Management Plan (CMP). The approach taken for assessing UVCBs is to consider multiple lines of evidence in a weight of evidence approach when assessing a substance's potential to cause harm under the Canadian Environmental Protection Act, 1999. More specifically, in order to evaluate fate, exposure and effects of a UVCB within our ecological risk assessment, data for the whole UVCB substance (e.g., whole-substance toxicity tests) and data available on individual constituents, together with reasonably accurate compositional information, is usually needed as reliable whole substance data for all end-points of interest are often not available. Thus, there is a requirement to understand how significant a contribution each major component may have in the UVCB to the endpoint or property being evaluated, as well as, determine if component data provides sufficient evidence and weigh the evidence accordingly to conclude on environmental risk for the whole UVCB substance. In this way, all reliable and available information is used in order to conduct the most accurate, robust and comprehensive assessment possible. Here we illustrate this approach using a case study for the assessment of four resins and rosins (HR, HRPE, HRGE and HRTE) published under the first phase of the CMP (2006-2012) known as The Challenge. Resins and rosins are high volume organic substances that are used in Canada for various purposes, which may include application in adhesives and sealers, cosmetics, electronics, paints and coatings, and inks and paper. A summary of the analysis of substance identity, physical-chemical properties, environmental fate and exposure, biological effects and ultimately ecological risk outcome will be presented for these four substances.

TP239 Progressing from Alternatives Assessment to De Novo chemistry: Part II

H. Plugge, 3E Company; L. Shen, Yale Univ

Presently selection of functionally equivalent chemicals is mainly limited to Alternatives Assessment. As Green Chemistry based de novo design progresses, Alternatives Assessment will gradually transition to functionally equivalent de novo chemicals as alternatives to existing chemicals. Recent TSCA legislation indicates that future new chemical regulations will be partially driven by alternatives assessment as well as hazard and exposure screening (which is actually risk screening). Such a screening phase would be followed by an appraisal of all available data for a more detailed hazard/exposure/risk assessment. More detailed information might also allow for a life cycle assessment screening. Currently "Read-across" is used as the main available technique for filling data gaps, but QSAR, toxicogenomics, computational chemistry, molecular toxicology and big data analytics are leading to more powerful solutions. These same techniques inform de novo design and increase the size of the modeling database, thereby reducing uncertainty, hence increasing reliability.- If only for regulatory purposes, chemicals based on both Alternatives Assessment and de novo design-all go through a detailed hazard and exposure assessment phase. When minimizing hazard, a principle inherent to de novo design, risk is simultaneously decreased depending on the exposure assessment (as risk=hazard*exposure.) Exposure assessment can provide information to prioritize the hazards and hence the risk. Functionally equivalent alternatives that fail the screening and assessment phase(s) will require a return to R&D to design other functional equivalents, with most likely different structural features. Going forward, de novo design and alternatives assessment will thus provide a convergent pathway to attaining sustainability.

TP240 Updates to the proposed Canadian regulatory framework for the environmental assessment of new active ingredients in human and veterinary drugs

J. Chateauvert, Health Canada / Environmental Impact Initiative Division; S. Kullik, Health Canada / Environmental Impact InitiativeLinitiative dun impact environmental

A Canadian regulatory framework has been developed specifically for active ingredients in human and veterinary drugs regulated by the Food and Drugs Act (F&DA) to assess risks to the environment and to human health resulting from environmental exposure. This regulatory framework has been designed to harmonize with the drug approval process stipulated by the F&DA and its regulations. Health Canada developed this framework in collaboration with stakeholders including Environment and Climate Change Canada, industry and environmental non-governmental organizations. The framework was endorsed in principle by all stakeholders in 2011. Since then, the proposed regulatory framework has been revised to increase alignment with environmental assessment approaches in other jurisdictions and incorporate recent technical developments related to the environmental assessment of active ingredients in human and veterinary drugs. Highlights include a proposal to adopt VICH guidelines 6 and 38 for environmental assessment of active ingredients in veterinary drugs, and updates to screening level exposure assessments such as new Canada specific defaults for predicting environmental concentrations of veterinary drugs in soils. The proposed changes will be the subject of an upcoming stakeholder consultation. The purpose of this poster is to present the revised regulatory framework being proposed and generate feedback on the updates.

Aquatic Toxicology and Ecology – Poster Only – Part 2

TP241 Characterization of Copper Residuals in Sediments of a Freshwater Reservoir Following Copper-citrate and -gluconate Algaecide Treatments

A. Calomeni, Clemson Univ / School of Agriculture Forest and Environmental Science; K. Iwinski, Clemson Univ / Dept of Forestry and Environmental Conservation; C.M. Kinley, Clemson Univ / School of Agricultural Forestry and Environmental Sciences; T.D. Geer, M. Hendrikse, Clemson Univ; A.D. McQueen, Clemson Univ / Dept of Forestry and Environmental Conservation; J. Rodgers, Clemson Univ / Forestry and Env Conservation

Copper algaecide applications provide unique opportunities to ask questions about copper residuals following pulse exposures in aquatic systems. Following applications of copper citrate and gluconate algaecide in a reservoir, copper residuals in sediments were characterized in terms of factors (i.e. concentration and form) that influence risks to benthic invertebrates. The specific objectives of this experiment were to 1) predict and measure "total" sediment copper concentrations from an algaecide application, 2) measure concentrations of ligands in sediments and copper availability and 3) measure copper concentrations necessary to elicit adverse effects for an amphipod (Hyalella azteca) in 10d laboratory toxicity experiments. Comparison of copper concentrations using a mass balance model (assuming complete partitioning of copper from the aqueous to sediment phase) to measured concentrations in situ assessed the relative influence of fate processes in post-treatment sediment copper concentrations. Predicted concentrations overestimated measured concentrations by approximately 20 times, indicating the influence of dilution and dispersion on copper partitioning to sediments. To measure copper form, multiple lines of evidence were used. Ligands including organic matter concentration (OM), acid volatile sulfides and particle size distribution (PSD) were quantified. Two divergent sediments (based on OM and PSD) were used to bound the sediment types at this site. The sediments were amended with a series of concentrations of the algaecide. Correlations between copper amendment concentrations and copper concentrations sequentially extracted from sediment fractions were used to identify ligands available for binding copper. Sediment toxicity experiments with second instar H. azteca were used to measure the mass of copper from a pulse-exposure eliciting bioavailable copper species. For the silt dominated sediment with high OM (2.35%), oxidizable and residual fractions were correlated with amended copper (R^2=0.98 and 0.85 respectively). For the sand dominated sediment with low OM (0.46%), carbonate, reducible and oxidizable fractions were correlated with increasing copper amendments (R^2=0.84, 0.81 and 0.80 respectively). LC_{50s} ranged as a function of sediment type [444 (367-521 mg Cu/kg) and 46 (31-60 mg Cu/kg]). These results suggest the influence of in situ exposure modifying factors in decreasing concentrations and toxicity of copper from algaecide inputs.

TP242 Probabilistic Risk Evaluation of Metals to Aquatic Organisms Using Species Sensitivity Distribution

J. Park, S. Kim, Gwangju Inst of Science and Technology; W. Kim, Gwangju Inst of Science and Technology / School of Earth Sciences and Environmental Engineering

The water quality criteria (WQC) in South Korea is not appropriate to protect aquatic organisms from the exposure of metals. The continuous discharges consisting of metals into the water environment have been occurred due to human activities, so the environmental concentration and the risk of organisms should be observed. In the present study, the exposure and sensitivity of aquatic organisms by metals were examined. The study focused on domestic species and four metals including copper, cadmium, zinc, and lead. Species sensitivity distributions (SSDs) and environmental concentration distributions (ECDs) were established using toxicity data and monitoring data, respectively. For each metal, hazardous concentration affecting 5% of species (HC5) was calculated and both distributions were compared. In addition, the distributions were combined to one curve depending on probability. In result, we found that the Korea water environment is rarely risky to aquatic organisms for cadmium and lead. However, the organisms were not considered to be safe with copper and zinc because some of organisms could be exposed to the metals in the environment.

TP243 Acute toxicity of waters from the Rio Doce Basin after the breakage of a major tailings' dam

D. Abessa, Unesp / Marine Biology and Coastal Management; O. Pinheiro, São Paulo State Univ UNESP; F. Pusceddu, Univ Santa Cecilia / Laboratorio de Ecotoxicologia; F. Cortez, Univ Santa Cecilia; J. Camargo, Univ of São Paulo USP; H. Albuquerque, São Paulo State Univ UNESP; L.G. Morais, Univ Estadual Paulista UNESP; L. Buruaem, São Paulo State Univ UNESP

In November 5th 2015, a major tailing dam was broken and released more than 60 million of cubic meters of residues and mud to the close water bodies. The "mud wave" destroyed the downstream districts located in the states of Minas Gerais and Espirito Santo, killed 16 people, and travelled about 600km through the Rio Doce Basin until reach the Atlantic Ocean and spread along the coast. The disaster immediately caused massive mortalities of fish and invertebrates, and turned waters into brownish orange color due to the presence of suspended fine particles. This study is part of an independent initiative involving citizen science that aims to evaluate the impacts of this disaster; and in this case the main objective was to assess the water toxicity in the affected areas. Fourteen water samples were collected along the Rio Doce Basin, includig the rivers Doce, Carmo and Gualaxo do Norte, and tested for acute toxicity to Daphnia similis. Raw and 4h-aerated samples were tested. The raw samples were not considered toxic after 48h exposure, while 8 aerated samples were considered toxic to D. similis. Worst toxicities occurred in the samples collected closer to the broken dam. We compared our results with the official reports on the water chemistry, and the concentrations of metals were high in most samples and exceeded the Brazilian standards for As, Cd, Pb, Cr, Mn, Ni and Se, which could explain, at least partially, the observed toxicities. The effects of aeration on the toxicity may indicate that in field, natural conditions would allow the exposure to metals and negative effects on the local biota. The analyses showed that the waters from the Rio Doce Basin are potentially toxic, possibly due to release of contaminated residues from the broken dam.

TP244 EPA's 2016 Updated National Cadmium Ambient Water Quality Criteria for the Protection of Freshwater and Estuarine/ Marine Aquatic Life

M. Elias, K. Gallagher, USEPA / Office of Water; G. Smith, Ohio Valley Regional Chapter; C. Voros, Great Lakes Environmental Center

EPA's National Recommended Water Quality Criteria for aquatic life were first developed for cadmium in 1980 and last updated in 2001. Consistent with provisions in the Clean Water Act, National Recommended Water Quality Criteria are periodically revised to ensure they incorporate the latest scientific information and are protective of aquatic life. Substantial additional toxicological data have become available since 2001, and these data were used to support development of the 2016 revised criteria. The final updated criteria collectively incorporate new toxicological data for an additional 75 species and 49 genera and now encompass 75 freshwater genera for acute toxicity (compared to 55 genera in the 2001 criteria), 20 freshwater genera for chronic toxicity (compared to 16 genera in the 2001 criteria), and 79 estuarine/marine genera for acute toxicity (compared to 54 genera in the 2001 criteria). Although additional toxicological data were not available to directly derive an estuarine/marine chronic criterion, the acute-to-chronic ratio was revised using data for a broader range of marine and representative freshwater species to provide a more robust revised criterion value. The final updated criteria also incorporate additional toxicological data that are protective of federally threatened and endangered species, most notably salmonids. A summary of the toxicological data and approach used to derive the revised criteria is presented, along with final criteria values that were published in March 2016.

TP245 Influences of pH changes in the boundary layer on Cd bioavailability to Chlamydomonas reinhardtii

F. Liu, C. Fortin, Institut national de la recherche scientifique Centre – Eau Terre Environnement; P. Campbell, Université du Québec, INRS / INRS Eau Terre Environnement

Over the last 30+ years, a general consensus has emerged that the best predictor of the biological uptake of trace metal cations by phytoplankton is normally the concentration (or activity) of the free metal ion. In the present study, we observed that at a fixed free Cd^{2+} concentration, the short-term Cd uptake rate by nitrate-acclimated Chlamydomonas reinhardtii was significantly lower in a cysteine-buffered medium than in anitrilotriacetic acid (NTA)-buffered medium. However, when the experiments were repeated with ammonium-acclimated C. reinhardtii, there was no significant difference in the Cd uptake rate between the cysteine- and NTA- buffered media. Because the free Cd^{2+} concentration and pH remained constant in the bulk solutions, the lower Cd bioavailability in the presence of cysteine does not appear to be associated with chemical changes in the bulk exposure media. On the other hand, in a poorly-buffered medium we observed that the extracellular pH increased progressively over time for nitrate-acclimated cells but not for the ammonium-acclimated ones. A simulation of Cd speciation in the cysteine- and NTA-buffered media with MINEQL+4.62 shows that an increase in pH results in a lower Cd^{2+} in the cysteine-buffered medium than in the NTA-buffered one, which could well explain the observed difference in Cd uptake rates. Taking the results together, we speculate that the pH and the chemical speciation of Cd in the boundary layer of the alga are different from the conditions in the bulk solution, and that the chemistry of the boundary layer is influenced by the algal nitrogen source. Direct measurement of the pH in the boundary microenvironment could help elucidate the relative importance of biologically-mediated surface processes and abiotic chemical processes in determining metal bioavailability.

TP246 Effects of the nanoparticle size of ZnO on bacterial bioluminescence, seed germination, algal growth, and gene mutation

I. Kong, M. Lee, H. Jang, E. Lee, Yeungnam Univ / Dept of Environmental Engineering

The potential effects of different particle sizes of ZnO nanoparticles (NPs) were evaluated in the context of bacterial bioluminescence, seed germination, gene mutation in bacteria, and algal growth. Different sensitivities (EC_{50s}) were observed, showing the following orders of toxicity: bacterial bioluminescence (0.31–0.40 mg/L) > algal growth (1.08–2.90 mg/L) > seed germination (6.56–9.98 mg/L). The mutation ratios of the 5 and 15 nm NPs were 2.4 and 2.03, respectively, whereas they were 1.7 and 1.1 for 25 and 80 nm, respectively, at 100 mg/L ZnO. The effects of the particle size of ZnO differed according to the tested assays. Under exposure conditions with large sizes, the toxicity of ZnO NPs increased on seed germination, but decreased on algal growth and gene mutation. The toxicity results (EC_{50s}) of algal growth and seed germination showed statistically significant differences (p-values < 0.05) between 5 nm and 80 nm sizes. In the case of bacterial bioluminescence, no significant differences were observed among each of the sizes tested. These findings show that a toxicity evaluation of NPs needs to consider the different effects with respect to the particle sizes and tested organisms for an accurate assessment of the NP toxicity in ecosystems.

TP247 Effects of Cadmium and Nickel on cell cycle progression, growth and antioxidant enzymes of green algae Chlamydomonas reinhardtii

M. Saenz, National Scientific and Technical Research Council Ecotoxicology Research Program, Dept of Basic Sciences, National Univ of Luján.; K. Bišová, Centre Algatech; W.D. Di Marzio, CONICET-PRIET

Among aquatic organism, microalgae have an important role in aquatic system as they are a key component of food chains. It is crucial to has early assessment tools to evaluate effects of metals at the cellular level, which can lead to disturbance in structure and productivity of the algae community. Cd and Ni were evaluated on cell cycle progression, growth and antioxidant enzymes kinetic of the green algae C. reinhardtii. Synchronized cultures of this multiple fission dividing algae were used for the study. Aliquot from growing cultures were taken hourly during 36 hours. The attainment of commitment points (CP) was evaluated by transfering hourly aliquot into aerated tubes at 30 °C in the dark. In hourly samples analysis of cellular division, nuclear divison changes in cell size, protein and antioxidant enzymes activities of catalase, guaiacol peroxidase, ascorbate peroxidas, glutathion reductase were performed. The proportion of mother cells and daughter cells were assessed at the end of the cell cycle. Ecotoxicity of both metals was assessed by algal growth inhibition test, estimating toxicity endpoints, growth rates and concentration of chlorophyll a, chlorophyll b and carotenoids at the end of 96 hs of exposition. Both metals provoked a block of cell cycle at the highest concentration tested. At lower concentrations, cell cycle progression was observed with different pattern of attained CP, depending the exposure concentration. Antioxidant enzyme activities were inhibited at concentration above 0,05-1 mg/L (Cd, Ni). Cd affected both growth rates and pigments in a worse manner than Ni. The effects of both metals on concentration of pigments were less evident than the effects on growth rates, indicating a lower sensitivity of these parameters. Cd and Ni provoked severe damage on algal cell growth, cell cycle progression, photosynthetic pigments as well as modification of antioxidant enzymes activities. An integrated analysis is done discussing the consequences on population performance in natural environment affected by metal discharged from different anthropogenic sources.

TP248 Assimilation of contaminants by invertebrates after a coal ash spill

N. Jones, Xcel Engineering / Environmental Sciences Division; J.G. Smith, Oak Ridge National Laboratory / Environmental Sciences Division; J.G. Morris, Restoration Services, Inc / Environmental Sciences Division; M. Jones, Oak Ridge Natinoal Lab / Environmental Sciences Division; T.J. Mathews, Oak Ridge National Laboratory / Environmental Sciences Division

Dietary exposure is an important pathway for metal uptake in aquatic organisms, and assimilation efficiencies of metals are often the most relevant parameter to quantify the bioaccumulation of metals in aquatic food chains. In field studies, however, metal body burdens in aquatic animals are often measured even though body burdens typically include gut content in the analysis. In benthic invertebrates collected from contaminated sites, gut contents can often contain sediments which can comprise a large proportion of the animal's body weight and can have elevated metal concentrations. While body burdens measured in this way can be useful in assessing exposure, risk can potentially be overestimated for metals that are not efficiently assimilated. Here we evaluated metal assimilation and bioconcentration in two invertebrate species with different feeding habits, the mayfly nymph (Hexagenia bilineata) and the silty horn snail (Pleurocera canaliculatum) at the site of the Tennessee Valley Authority's coal ash spill in Kingston, TN. We collected water, sediment, periphyton, and biota from sites both up- and down-stream of the coal ash spill and allowed a subset of animals to purge their gut contents before analysis to compare assimilation between metals, animals, and sites. Samples were analyzed for six elements which include both essential (selenium (Se), iron (Fe), zinc (Zn), and copper(Cu)) and non-essential (arsenic (As), mercury (Hg)) metals. We found that concentrations of the coal ash associated contaminants Se and As were higher in snails and nymphs collected from sites downstream of the ash spill than upstream. Spatial trends for Cu, Fe, and Zn did not indicate that exposure to ash affected bioaccumulation of these essential elements in either snails or nymphs. Selenium concentrations were higher in both snails and nymphs than in periphyton or sediment samples, but there were no significant differences between concentrations in purged vs. non-purged animals, suggesting high assimilation of this element. Arsenic, Fe, and Hg concentrations were higher in non-purged nymphs than in purged nymphs suggesting sediment concentrations of these elements were elevated with respect to their assimilation. Results from this study provide valuable information on the bioaccumulation of coal ash contaminants by invertebrates, which is relevant to evaluating risk at contaminated sites.

TP249 Acute and chronic ecotoxicity of safe by design copper oxide nanoparticles on the pond snail Lymnaea stagnalis

V. Ricottone, V. Stone, Heriot-Watt Univ / School of Life Science; T. Henry, T.F. Fernandes, Heriot-Watt Univ / School of Life Sciences

Nanotechnology is a rapidly developing field in the 21st century, and the commercial use of nanomaterials for novel applications is increasing exponentially. Copper oxide nanoparticles (CuO NPs) are frequently employed for their antimicrobial properties in antifouling paints and other applications. Their extensive use can contaminate aquatic ecosystems. The main objective of this study was to evaluate and compare the aquatic toxicity of different CuO NPs through acute and chronic toxicity tests with different life stages of the snail Lymnaea stagnalis, a representative organism of the benthic ecosystem. Acute waterborne exposure was focused on the evaluation of the acute lethal toxicity of CuO NPs to juveniles (7-9 day old) of the pond snail L. stagnalis exposed for 96h at 20°C to Cu in a static experiment, either as pristine CuO NPs or "safe by design" CuO NPs. The latter were CuO-ASC and CuO-PVP NPs with respectively Na ascorbate and Polyvinylpyrrolidone as capping agents. LC50 value estimated in tests showed that CuO-ASC ($LC20_{96h}$ = 1540 $\mu g\ L^{-1}$ Cu) is the least toxic among all the CuO investigated. Chronic toxicity tests aimed to investigate the effects of exposure to CuO NPs pristine and "safe by design" on the reproduction to L. stagnalis. Young adult snails(22±2mm) were exposed to Cu as CuO NPs at 20°C for 30 days in a semi-static experiment. Endpoints such as: mortality, feeding rate and weight changes were also evaluated, along with the reproduction parameters. $LC50_{30d}$ value estimated in tests with pristine CuO NPs was 500 $\mu g\ L^{-1}$ Cu, indicating a 5 time fold higher toxicity than the acute test. Additionally, exposure to "safe by design" CuO NPs showed significant effects ($p< 0.001$) on the growth and reproduction parameters relative to the control; indicating, in contrast with acute exposure, an higher toxicity of CuO-ASC in the long term. The experiments' results demonstrate a time-related increasing toxicity of CuO NPs on L. stagnalis, emphasizing the need for more chronic study to accurately evaluate the impact of nanomaterials in the real environment. Furthermore, long-term experiment using juveniles L. stagnalis exposed to CuO NPs are ongoing, evaluating growth and time-related expression profiles of antioxidant enzymes and heat shock proteins response in snails to thermal shock. This research project is funded by the European FP7 project SUN "Sustainable Nanotechnologies".

TP250 Effects of Arsenic, Cadmium, Copper and Zinc on the Larval Survival of an intertidal gastropod, Nassarius festivus

C. Lee, EH R&C / Research Inst of Environmental Health and Safety; S. Kang, C. Sung, J. Chung, D. Park, J. Lee, EH R&C; S. Moon, J. Lee, NeoEnBiz Co

There are many kinds of industrial complexes and large cities in coastal areas of Korean peninsula. Benthic communities adjacent to these areas are subjected to environmental contamination by various kinds of anthropogenic toxicants including metals and persistent organic pollutants. Nassa snail, Nassarius festivus (Powys, 1835) is a small gastropod and one of dominant scavenger in benthic community inhabiting sandy and muddy intertidal and subtidal areas of western and southern coasts of Korea. Although there are studies on the effects of some metals on the acute and chronic responses of N. festivus, information on the sensitivity of larvae of this species is still lacking. The tolerance range to pollutants at larval stage can be a critical factor for the successful recruitment to adult population. To this end, we set the purpose of this study to know the acute responses of veliger larvae of N. festivus to 4 priority metals (As, Cd, Cu, and Zn). The 96-hr LC50 was 2.61 mg/L for As, 2.51 mg/L for Cd, 0.049 mg/L for Cu and 2.25 mg/L for Zn. The acute toxicity of Cu to veliger larvae of N. festivus was highest than other 3 metals. For As, Cd, and Zn, larvae of N. festivus was more sensitive than or comparable to Aplexa hypnorum (gastropod) and Tigriopus japonicus (copepod), less sensitive than Neomysis japonica (mysid) and larvae of Mytilus gallo-provincialis (bivalve). However, for Cu, N. festivus was more sensitivity than any other species of taxonomic groups (copepod, mysid, amphipod, isopod, bivalve, fish etc.). We concluded that the bioassay using this species can be quite useful for the evaluations of environmental quality and risk assessments of contaminated marine ecosystems.

TP251 Effects of diet on embryogenesis of the great pond snail, Lymnaea stagnalis exposed to cadmium, tributyltin or pyraclostrobin

E.G. Reategui-Zirena, Texas Tech Univ/TIEHH / Environmental Toxicology; C.J. Salice, Towson Univ / Biological Sciences/ Environmental Science

Diet quality can have a strong impact on organismal fitness although diet quality is infrequently considered as a factor in toxicity tests, especially in embryotoxicity testing. The purpose of this study was to evaluate how diets of adults that differ in nutritional content affect sensitivity to cadmium, tributyltin or pyraclostrobin in Lymnaea stagnalis offspring. Three groups of hatchlings were fed a different diet each, either lettuce, high-caloric pellets, or a combination of both alternating every week until they reached reproductive maturity. Snails fed pellets and both diets had similar growth in length and mass; however, snails fed lettuce showed lower growth until about the 4th month when all groups had the same length and mass. Egg masses were collected from 6-7 month old adult snails fed each diet and exposed to three concentrations of either cadmium, tributyltin or pyraclostrobin. We assessed time to hatch, hatching success and the different developmental stages of the embryo. Results indicated that for the three contaminants egg masses from parents fed lettuce hatched earlier than egg masses from parents fed both diets. For cadmium and pyraclostrobin, egg masses from parents fed pellets did not hatch at all, not even the controls. Interestingly, control egg masses from parents fed pellets and exposed to tributyltin did not hatch either but a few individuals from the lowest concentration did. The nutrient rich pellet diet was surprisingly inferior to lettuce and apparently altered the biology of the study organisms causing offspring to be non-viable. These observations on offspring performance suggest that there are important diet effects that can strongly influence responses but in a non-intuitive way. Additional studies are needed to better understand the mechanisms by which increased nutrient availability affects an organism's offspring when exposed to a toxicant.

TP252 Toxic and genotoxic effect of cadmium, chromium and lead on Japanese oyster Crassostrea gigas larvae

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; C. Cáceres-Martínez, Universidad Autónoma de Baja California Sur

The Japanese oyster is an introduced species that grows in the Mexican Pacific coastal systems, because of its economic importance we performed an evaluation of the genotoxic effects of the metals: Cd, Cr and Pb on Japanase oyster larvae. Bioessays, lasting 72 hours, were carried out with 5 concentrations of each metal and its mixture (1:1). Lethalconcentration 50 (LC_{50}) were determined in the assays, and surviving organisms was performed evaluation genetic damage by means of unicellular electrophoresis technique (comet assay) in a tissue sample, which were revised between 300 to 500 cells, evaluating the frequency of occurrence of cells with damage (tails) and its length. The toxicity of metals based on the LC_{50} calculated was (high to low effect): Cd > Cr > Pb. The most toxic mixture of metals was Cd + Cr and less toxic Cd + Pb. The interaction in the mixtures of metals, Cd + Cr and Cd + Cr + Pb was potentiation, with magnification factors from 5 to 2 respectively. The Kruscal-Wallis test indicated that significant differences exist between the level of DNA damage in organisms exposed to different metals and the control. The metal with major genotoxic effect was cadmium followed by chromium. Lead showed the lowest genotoxic effect. The mixture of metals with more genotoxic effect was Cd + Cr and the mixture of the three metals. Metal concentrations used in this study have been reported in sediments from coastal areas in the state of BC and BCS. for this reason is important to continue research and monitoring to detect responses that indicate possible damage to oyster populations by the action of different tensors, to prevent irreversible deterioration of the stocks in the medium and long term.

TP253 Short-term induced molecular stress responses in coelomocytes of Eisenia fetida earthworms in vivo exposed to silver nanoparticles

S. Curieses, CONICET-PRIET; N. García-Velasco, Univ of Pais Vasco; K. Bišová, Centre Algatech; W.D. Di Marzio, CONICET-PRIET; M. Saenz, National Scientific and Technical Research Council Ecotoxicology Research Program, Dept of Basic Sciences, National Univ of Luján.; M. Soto, Univ of the Basque Country UPV/EHU; W. Di Marzio, CONICET

In recent years the production of a great variety of products containing nanoparticles (NPs) has increased massively. The subsequent release of NPs into the environment has created a need to assess the potential ecological risk in soil, water and air. Silver nanoparticles (Ag-NPs) have the highest degree of commercialization due to their high thermal and electric conductivity, high catalytic activity, and powerful antimicrobial properties. Eisenia fetida is a model specie in soil toxicity studies and has been broadly used due to its sensitivity to different toxicants at different levels of biological organization. The main aim of the present investigation was to understand the effects produced by AgNPs (5.08±2 nm sized and PVP-PEI coated) in comparison with the soluble form of the metal ($AgNO_3$) at molecular level in coelomocytes of E. fetida at different exposure times. E. fetida were in vivo exposed to different concentrations of Ag-NPs and $AgNO_3$ (0.05 and 50 mg Ag/kg soil) through OECD artificial soil for 1, 3 and 14 d. Then, the transcription levels of selected genes associated to oxidative stress (Catalase) and metal detoxification (MTs-metallothioneins) were determined in coelomocytes extruded from exposed earthworms. In addition, the enzymatic activity (Catalase) and protein content (MTs) were quantified. The responses varied significantly among days, exposure concentration and Ag form. Exposure to Ag-NPs led to a significant induction of CAT at day 1, followed by an increase in its transcription levels after 3 and 14 d of exposure. Similarly, exposure to $AgNO_3$ induced the transcription of CAT at day 1 but at day 14 a down-regulation was observed. The CAT activity increased at both treatment and exposure times (1 and 3 d). After 14 d of exposure, CAT activity was inhibited at the highest concentration tested. The highest increase of MTs at protein level was observed after 3 d of exposure. Our results indicate that short-term exposures to Ag-NPs induced early molecular stress responses (MT induction and oxidative stress) in coelomocytes that precede other responses at higher levels of biological organization. The responses in translational level in E. fetida tissues were according. The study indicates the importance of using integrative biomarkers for the evaluation of the potential risk of Ag-NPs in soils.

TP254 The effect of sediment pH on the toxicity of silver nanoparticles to Lumbriculus variegatus

J.E. Rajala, Univ of Jyvaskyla; E. Vehniäinen, Univ of Jyvaskyla / Dept of Biological and Environmental Science; A. Väisänen, Univ of Jyvaskyla / Dept of Chemistry; J.V. Kukkonen, Univ of Jyvaskyla / Biological and Environmental Science

The toxicity of silver nanoparticles (AgNP) to aquatic organisms is a major concern, as the increasing use in industry and consumer products leads to increasing release of AgNP into the aquatic environment. Sediments are believed to be a major sink for AgNP, but only limited amount of data is available on the toxicity and behavior of sediment-associated AgNP. We studied the effects of sediment pH on the toxicity of AgNP on benthic oligochaeta Lumbriculus variegatus. In addition, the toxic effects were related to the bioaccessible amount of dissolved Ag compounds in the sediment. Artificially prepared sediments (pH 5 and pH 7) were spiked with uncoated AgNP (7-1365 mg/kg sediment dry height), polyvinylpyrrolidone coated AgNP (9-1132 mg/kg sediment dry weight) and silver nitrate ($AgNO_3$, 4-334 mg/kg sediment dry weight) as dissolved Ag reference. Reproduction, mortality and inhibition of growth were used as endpoints for the 23-day toxicity test. The concentration of dissolved Ag in sediment was assessed by two-step extraction procedure followed by centrifugation to remove AgNP from the extracts. The concentration of dissolved Ag in the AgNP-spiked pH 7 sediment was negligible, and no toxicity was observed even in the highest (1365 mg of Ag/kg dry sediment) exposure concentration. In pH 5 sediment, the toxicity of both AgNP was significantly promoted, and toxic effects were observed already at the concentration of 38 mg Ag/kg sediment dry weight. When the effects were plotted against the concentration of bioaccessible dissolved Ag in the sediment, $AgNO_3$ treatments resulted in toxicity at the similar level as AgNP treated pH 5 sediment. Our results indicate that the dissolution of AgNP is significantly higher in the sediment with low pH. Also the toxicity of AgNP and $AgNO_3$ to L. variegatus was well related to the concentration of dissolved Ag in the bioaccessible fraction of the sediment.

TP255 Water level management effects on Cd, V, and Zn biogeochemistry and toxicity to Hyalella azteca and Daphnia magna

S. Nedrich, Univ of Michigan; M. Hudson, Univ of Michigan / School of Natural Resources and Environment; S.S. Brown, The Dow Chemical Company / Environmental Remediation and Restoration; A. Burton, Univ of Michigan / School of Natural Resources Environment

Current understanding of the fate and effects of vanadium (V) on aquatic organisms is limited, with relatively few investigations of sediment dynamics. Chronic thresholds for toxicity have been established for dissolved V in water, but no equivalent exists for sediment and very few studies have considered V speciation and toxicity. Further, binding of V to sediment ligands, such as iron/manganese oxy-hydroxides, sulfides, and carbonates is likely to decrease V toxicity in field settings. The objective of this study is to assess the role of hydrologic manipulation on the speciation and toxicity of V to benthic and water column organisms. Sediments were collected from a dammed-river reservoir located in a former mining area, and these sediments contained elevated concentrations of vanadium (range: 635 to 1620 $\mu g\ g^{-1}$) and other metals. Water level fluctuation experiments were conducted to emulate 7-day drying and re-inundation periods. Porewater and sediment metals (Ca, Cd, Cu, Fe, Mg, Mn, Ni, V, and Zn) and important metal binding phases (iron-oxide speciation, acid-volatile sulfide) were quantified. Test organisms H. azteca and D. magna were exposed to sediments during the first 7 and 10 days, respectively, of re-inundation to assess toxicity. Preliminary results show V to be highly bound to sediments and generally not biologically available. Surface water V (+5) remained low in concentration throughout the experiment (< 17 $\mu g\ L^{-1}$), below reported thresholds for surface water toxicity. While a small flux of V (+5) was released into porewater upon re-inundation of oxidized sediments, the concentration also remained low (0.2 – 6.5 $\mu g\ L^{-1}$). Upon inundation, a flux of Zn and Cd into porewater and surface water exceeding the USEPA threshold for chronic and acute toxicity to freshwater organisms was observed for two of the three sediments tested. This increase in Zn and Cd is possibly tied to decreased survival observed for H. azteca during the experiment. Results from this study suggest that V bioavailability and environmental risk is low despite relatively high sediment concentrations, and V is less susceptible to redox changes associated with water level fluctuations than other more labile metals.

TP256 A comparison of the effect of inorganic chemicals to Daphnia magna

T. Abe, National Inst of Technology, Tsuruoka College / Creative Engineering

Various inorganic chemicals exist in environment, their come from not only natural source but also artificial source. Inorganic chemicals include metal, metal ion, metal salts, and nano materials. We expect that the metal salts also affect organisms (for example the metal ion in aqueous solution). The following studies mainly use metal salts as inorganic chemicals. Since metal chloride, metal nitrate and metal sulfate is one of the forms which are stabilized as for a metal salt. Chloride is one of the most popular atomic element in the sea. Nitrate salts play important role in nitrogen cycle. Sulfuric acid is one of the most important reagent in industrial chemistry and good applications for oil refining, wastewater processing, and mineral extraction. And sulfate salts play important role in sulfur cycle. Median effective concentration (EC_{50}) were selected as prediction of adverse effect of Daphnia magna. The EC_{50}s were used from previous studies and several literatures. D. magna immobilization test is listed in OECD Guidelines for the Testing of Chemicals (TG202). Acute EC_{50}s of alkali metal salts employed values of metal chloride, metal nitrate and metal sulfate. Following listed compounds. Lithium chloride (LiCl), sodium chloride (NaCl), potassium chloride (KCl) rubidium chloride (RbCl) and Cesium chloride (CsCl) were used for metal chloride. Lithium nitrate ($LiNO_3$), sodium nitrate ($NaNO_3$), potassium nitrate (KNO_3), rubidium nitrate ($RbNO_3$) and Cesium nitrate ($CsNO_3$) were used for metal nitrate. Lithium sulfate (Li_2SO_4), sodium sulfate (Na_2SO_4), potassium sulfate (K_2SO_4), rubidium sulfate (Rb_2SO_4) and Cesium sulfate (Cs_2SO_4) were used for metal sulfate. In acute EC_{50}s of alkali metal salts have poor correlation with ionic radius, covalent radius aqua ion diameter and electronegativity (r = -0.4 – 0.4), on the other hand, have good correlation with abundance in earth's crust, sea and space (r = 0.7 – 0.9). These results suggest this organism historically play important role in aquatic ecosystem.

TP257 Assessment of the Effects of Mining-Derived Metals on Caged Crayfish and Wild Crayfish Populations in Madison County, Missouri, USA

A. Allert, USG.S. – Biological Resources Division / Columbia Environmental Research Center; R.J. DiStefano, Missouri Dept of Conservation; D. Cleveland, B.G. Brumbaugh, USGS / Columbia Environmental Research Center; C.J. Schmitt, USGS – CERC / Columbia Environmental Research Center

Deposits of lead (Pb) and other metals of southeastern Missouri, USA have been exploited since the 1700s, which has left a legacy of metals-contaminated streams. Contamination of fish and other aquatic biota, alteration of fish and invertebrate communities, and public health advisories against human consumption of Pb-contaminated fish have resulted. Previous studies in mining districts in Missouri have documented adverse effects on crayfish populations in mining-contaminated streams, but streams in mine-impacted Madison County, Missouri have not been previously assessed. Crayfish population density surveys and in-situ toxicity tests with caged laboratory-reared crayfish (Orconectes quadruncus) were conducted at sites upstream and downstream of historical mining areas in the Little Saint Francis River watershed. O. quadruncus, an endemic species in this watershed, is listed as imperiled by the state of Missouri and has been petitioned for listing as a Federal endangered species. Sites downstream of mining areas had significantly higher metal concentrations in water, sediment, organic matter and biota, and significantly lower riffle densities of Orconectes luteus and O. quadruncus compared to reference sites. Survival of caged O. quadruncus was not significantly different at sites upstream or downstream of mining-impacted sites. Nickel (Ni) and cobalt (Co) concentrations were elevated in water, and Ni, Co, and copper concentrations were elevated in crayfish at sites downstream of mining. Probable effects concentration quotients for metals in fine (< 250 µm) sediment, which were primarily driven by Ni and Pb concentrations, indicate that sediments are likely toxic to sediment-dwelling organisms at all sites downstream of mining areas. Crayfish are important prey for many aquatic and terrestrial animals and they play important roles in organic matter processing and nutrient cycling in stream food webs. Thus, adverse effects of metals on crayfish populations will likely extend to other components of Ozark streams and surrounding ecosystems.

TP258 Concentrations of heavy metals in tissues of commercially-harvested red crabs from the northwestern Atlantic

I. Simmons, Florida AM Univ; C. Jagoe, Florida A&M Univ / School of the Environment; P.L. Pennington, NOAA National Ocean Service / NOSNCCOSCCEHBR

Red crabs (Chaceon quinquedens) are benthic and inhabit the continental slope of the Atlantic, Pacific and Indian oceans, usually at depths of 200 to 1800+ meters. There is a small commercial, federally-managed fishery on the US Atlantic coast for deep-sea red crabs. However, management is hindered by the absence of information on their biology, abundance, growth, age, reproduction, or contaminant concentrations. Red crab samples were collected from three locations from the northwestern Atlantic, and metal concentrations were determined in edible muscle and hepatopancreas. Metal concentrations (As, Pb, Hg, and Cd) did not differ among locations or sexes, and concentrations were not correlated with carapace width or length. Median As, Cd and Pb concentrations in muscle were 62, 0.35, and 0.35 mg/kg dry weight, respectively. Most Hg in muscle was methyl mercury, but inorganic mercury was dominant in hepatopancreas. Median Hg concentration was higher in edible muscle (1.07 mg/kg dry weight, range 0.22-4.46) than in hepatopancreas (0.65 mg/kg, range 0.18-2.4). Most Hg in muscle was methyl mercury, but inorganic mercury was dominant in hepatopancreas. Some crabs exceed established consumption advisories for Hg in seafood.

TP259 The effect of temperature on ecotoxicity of nano copper oxide to midge species

H. Mo, Korea Univ / Inst of Life Science and Natural Resources; Y. Kim, Y. Lee, Korea Univ; J. Wee, Korea Univ / Division of Environmental Science and Ecological Engineering; K. Cho, Korea Univ / Division of Environmental

Temperature is one of the most important factors changing toxicity to organisms in ecosystem. In addition, we are living in the era of rapid climate change. There are few studies about nano toxicity related to temperature in mesocosm. This study was about the temperature-dependent toxicity of nano copper oxide to midge species, Chironomus yoshimatsui, in microcosm consisting of artificial sediment and water. We investigated and compared the protein patterns of C. yoshimatsui exposed to different temperature and nano concentrations using SELDI-TOF MS (surface enhanced laser desorption/ionization time-of-flight mass spectrometry). The low level of nano copper oxide didn't effect on lethality of tested organisms, but there was alterations of protein pattern with temperature. This suggests that we need an in-depth study about nano toxicity with temperature.

TP260 Trace Element Accumulation in Six Dragonfly Nymph Genera from a Wetland Constructed for Cu and Zn Effluent Treatment

A.H. Lindell, P.T. Stankus, D.B. Pitt, G.L. Mills, D.E. Fletcher, Univ of Georgia – Savannah River Ecology Laboratory / Savannah River Ecology Laboratory

Dragonfly adults and their aquatic immature stages are an important part of food webs and provide a link between aquatic and terrestrial components. Our previous work in a stream receiving coal combustion waste indicated dragonfly nymphs accumulate coal-ash contaminants such as Cu and Zn. The H-02 wetland system was constructed on the Department of Energy's Savannah River Site, Aiken SC to treat building process and stormwater runoff water from a portion of H-area. Constructed wetlands play an important role in the SRS environmental plan to achieve both federal and state regulatory compliance for the discharge of effluent waters. The H-02 wetlands were built to remove trace metals, primarily Cu and Zn, from the water before release to state waters. The system consists of a retention basin, two wetland treatment cells, an effluent pool, and a discharge stream. We are using 6 genera of dragonfly nymphs as biomonitors to assess bioavailable contaminants throughout all components of the wetland system as well as two reference wetlands. A total of 600 composite samples were formed by pooling individuals within size classes developed from length frequency analysis. Whole body concentrations of 15 elements (Cu, Zn, Pb, B, Al, V, Cr, Fe, Mn, Co, Ni, As, Se, Cd, Ba) were determined for each composite. Patterns of accumulation in dragonfly nymphs varied by genus and element. Variation among genera clearly exceeded variation within genera indicating that genus is a reasonable taxonomic level for both spatial and taxonomic comparisons. Some elements such as Cu were elevated above reference site levels throughout the wetland system and not lower in the effluent pool. This suggests significant escapement of contaminants through the system. Whether Mn accumulated to higher levels in the upper or lower end of the system depended upon genus. Some genera accumulated Cd to higher levels in the treatment cells, but to only low levels. Zn appears to be better regulated by the nymphs and some elements accumulated to only low levels. Anax and Tramea that typically inhabit vegetation well above the substrate often accumulated lowest concentrations of many elements. In contrast, Erythemis, Libellula and Pachydiplax, genera that more frequently inhabit a zone closer to the substrate, tended to accumulate the highest concentrations. Association with the sediment may increase accumulation of some elements in dragonfly nymphs.

TP261 Assessing the trophic transfer of selenium to Hyalella azteca and Pimephales promelas through a diet of field-collected periphyton communities

K. Raes, Univ of Saskatchewan – Toxicology Centre / Toxicology; L. Doig, K. Liber, D.M. Janz, B.E. Markwart, Univ of Saskatchewan Toxicology Centre; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

The contamination of aquatic systems with selenium (Se) is of significant global concern. A variety of natural and anthropogenic sources of selenium exist, and their source can contribute different forms and concentrations of Se (eg. selenate [SeO_4?^{2}] and selenite [SeO_3?^{2}]) to aquatic environments. Inorganic forms of Se are assimilated and bioaccumulated by aquatic microorganisms and biotransformed into organoselenium compounds. Organic-Se is then transferred to higher trophic levels via dietary pathways. The present study aims to quantify the trophic transfer factors of selenomethionine to a primary consumer through the biotransformation of inorganic oxyanion Se forms (selenate and selenite) by field-collected communities of periphytic microorganisms. Biofilm samplers will be placed in the photic zone of uncontaminated lakes in northern Saskatchewan, Canada, and allowed to accumulate natural communities of microorganisms representative of these lake habitats. Samples will be collected from each biofilm sample for microscopic and metagenomic characterization of the biofilm communities. Samples will then be exposed in the laboratory to aqueous concentrations of selenite and selenate respectively, and Se uptake by the biofilm will be quantified. The amphipod Hyalella azteca, a primary consumer characteristic of Canadian freshwater ecosystems, will graze on the selenized biofilm communities to determine trophic transfer efficiencies as a function of microorganism community structure. Selenized amphipods (batch cultured) will be fed to fathead minnows (Pimephales promelas) to further characterize Se trophic transfer in this representative aquatic food web. This research will serve to assist in improving environmental risk assessment strategies for the release of Se into aquatic environments.

TP262 Effects of copper on primary culture of a rainbow trout gill epithelium (DSI system): intracellular and paracellular aspects

L. Nogueira, CAPES – Brazil; C.C. Chen, S. Kelly, York Univ; S. Wood, Univ of Toronto / Dept of Physical and Environmental Sciences

The gill is a multifunctional organ in fish and the critical site of acute toxicity to waterborne contaminants, including copper. Alternative approaches are now needed in fish toxicology testing due to pressures for refining, reducing and replacing (3Rs) live animal studies. A promising alternative method is the primary culture of a freshwater rainbow trout (Oncorhynchus mykiss) gill epithelium on a flat permeable membrane (DSI system). This system is unique in its ability to generate a polarized epithelium, which can tolerate prolonged freshwater exposure at the apical surface. Thus, the present study investigated the toxicological effects of copper on gill epithelial cultures of rainbow trout (DSI), emphasizing intracellular and paracellular aspects. The primary gill epithelia were prepared using the double seeding technique and grown at 18°C in culture media. The development of the intact gill epithelium was monitored daily through measurements of transepithelial electrical resistance (TER). When the TER achieved a plateau (7-8 days), a heterogeneous gill epithelium similar to that found in vivo was completely formed. At this point, the exposure of the gill epithelium was initiated by replacing cell culture media on the apical side with filtered freshwater. The gill cell cultures were exposed to 3.14µM and 15.75µM of copper for 24h. In order to evaluate the effects of copper, the parameters analyzed were: copper accumulation, cellular ionic content (sodium, calcium, magnesium, potassium and chloride), carbonic anhydrase and Na,K-ATPase activities and gene expression, paracellular permeability (PEG) and tight junction protein analyses. TER values differed between control and exposed groups until 6 h of exposure, after which time the values remained without significant difference. (IDRC, NSERC Discovery).

TP263 New insights into the toxic effects of arsenic with cellular evidences in the green algae and zebra fish

J. Zhang, J. Chen, J. Cao, Zhejiang Univ / Environmental Science; C. Zhang, Univ of Houston Clear Lake / Dept of Environmental Sciences

Arsenate and arsenite are the primary chemical forms of arsenic to exert toxic effects on biota. The aim of our study was to explore the use of several novel biomarkers and laboratory tools for indicating the response of green algae and zebra fish exposure to arsenic in the aquatic environment. Two lines of new evidence are included as follows: (1)Arsenate exposure caused subcellular damage to chloroplast and decreased PSIIefficiency in green algae. The EC50 values of growth inhibition to C. pyrenoidosa and S. Quadricauda were 5.14 $mM{\cdot}L^{-1}$ and 1.06 $mM{\cdot}L^{-1}$, respectively. TEM images showed the structural damage of chloroplast, including the vacant thylakoid membrane, an increased number of starch grains and diminished pyrenoid following 24-h exposure of arsenate. The maximum relative electron transport rate (ETRmax), initial slope of rapid light curve (α) and half saturation light intensity (Ik) were significantly reduced and the reduction was positively correlated with the concentration of arsenate. ETRmax, α, and Ik were decreased. The effects of arsenate on the maximum relative electron transport rate, light utilization efficiency, and strong light tolerance of S. quadricauda were more significant than those of C. pyrenoidosa. (2) Arsenite induced disturbance on acid-base and electrolyte balance distinct from the normal zebrafish embryos were demonstrated. The dose-dependent activation of immunoregulatory NF-κB signaling pathway was revealed with ion fluorescent probes and the dual-luciferase reporter system. The results showed that arsenite at 0.5-5mM significantly inhibited the survival and hatching rates of zebra fish. The calculated 96-h LC50 was 1.94 mM and the hormesis of arsenate was observed on hatching rate. Furthermore, intracelluar pH and Ca^{2+} concentration of zebrafish embryos decreased significantly after treatment with sublethal concentrations of arsenite (0.5~ 2.0 mM). Under this exposure condition, arsenite exhibits a significant time-dependent activation of NF-κB signaling pathway. The results indicated that arsenite induced disturbances of acid-base and electrolyte balance might be the underlying cause for the activation of NF-κB signaling pathway. This work contributes to the better understanding of the chemical regulation mechanism of arsenic toward aquatic immunotoxicity. Our results will help differentiate the toxic biota effects of arsenic from other co-existed contaminants from arsenic-based insecticides and metal processing wastes.

TP264 Water chemistry alters toxicity of copper oxide nanoparticles in early life-stage zebrafish

D. Boyle, Plymouth Univ; R.D. Handy, Plymouth Univ / School of Biological Sciences

The increased use and global spread of nanoparticle- (NP-) enabled technologies means that NPs are expected to be released into diverse aquatic environments. Characterising how variable abiotic factors such as water pH may alter NP toxicity is therefore a priority for risk assessment. Furthermore, NPs are unlikely to enter the environment as continuous discharge streams and pulsed intermittent exposures are more ecologically relevant to study toxic effects in organisms. The aims of this study were to investigate how pH and other water chemistry variables altered the toxicity of copper oxide (CuO) NPs in early life stage zebrafish and also to consider toxicity of CuO NPs in a pulsed exposure experimental design. Data showed a significant stepwise decrease in toxicity of CuO NPs at pH 5, 6 and 7 which was different to what was observed for Cu^{2+} (as $CuSO_4$). Calculated 96 h LC_{50} at pH 5, 6 and 7 were: 4.7, 24.8 and 150.8 mg L^{-1}, respectively. Calculation of NP dissolution at these concentrations also indicated that dissolution decreased with increasing pH and was in broad agreement with the corresponding LC_{50} of Cu^{2+}. This suggested a central role of Cu^{2+} dissolution in CuO NP toxicity. This observation was further confirmed in exposures to CuO NPs and Cu^{2+} at corresponding LC_{10} values. Both CuO NPs and Cu^{2+} caused same magnitude depletions in whole zebrafish glutathione concentrations and inhibitions of Na^+/K^+-ATPase activity. Accumulation of Cu in tissues was also measured. Further experiments exposed zebrafish embryos to CuO NPs in discrete windows to assess sublethal and lasting effects at 96 h of development from early (0-24 h), pulsed intermittent (24-48, 72-96 h) and continuous (0-96 h) exposures. This study is part of the Sustainable Nanotechnologies Project funded by the EU 7th Framework Programme.

TP265 Tissue Distribution of Essential and Nonessential Trace Elements in Ocean Sunfish (Mola mola) and Sharptail Mola (Masturus lanceolatus)

J. Dutton, Texas State Univ / Dept of Biology; B.P. Jackson, Dartmouth College / Dept of Earth Sciences; D. Adams, Florida Fish & Wildlife Commission / Fish and Wildlife Research Inst

Sharptail mola (Mola lanceolata) and ocean sunfish (Mola mola) stranded on the Atlantic coast of Florida, USA during 2010 and 2011 (with an additional stranding of sharptail mola during 2014). These two species are not commonly observed within Florida waters and the multiple mortalities during these time periods were atypical. During each stranding event we collected fish length, sex and multiple tissues (muscle, gill, liver, kidney, spleen, gonad and heart) which were analyzed for the concentration of seven essential trace elements (Co, Cu, Fe, Mn, Ni, Se, Zn) and seven nonessential trace elements (Ag, As, Cd, Cr, Hg, Pb, Sn) using Inductively Coupled Plasma Mass Spectrometry (ICP-MS). With the exception of Ag, Hg, Pb and Sn, all elements were detected in all tissues of both species. Tin was below detection in all samples and Ag, Hg, and Pb was not detected in all tissues. Of all the investigated essential trace elements, Fe was found in highest concentration in the liver, kidney, spleen and gonad, whereas Zn was highest in the muscle, gills and heart. The average concentration of Fe in the liver was 8.8-times higher in the sharptail mola than in ocean sunfish (2110 µg/g dry wt and 239 µg/g dry wt, respectively). For the nonessential elements, As was found at the highest concentration in all investigated tissues. Mercury was found at low concentration in the muscle tissue of all fish, averaging 0.58 µg/g dry wt for sharptail mola and 0.17 µg/g dry wt for ocean sunfish, reflecting the low trophic position of both species. The average concentration of Cd in the liver was 4 times higher in sharptail mola than in ocean sunfish (8.17 µg/g dry wt and 2.11 µg/g dry wt, respectively); this concentration is elevated compared to other fish species, but below the 10 µg/g wet wt concentration that is known to cause deleterious effects in the liver. This is the first study to examine a full suite of trace elements in multiple tissues from two globally occurring mola species and the first to analyze any contaminant type in sharptail mola.

TP266 Subcellular distribution of trace elements in the livers of Alaskan yelloweye rockfish

B.D. Barst, McGill Univ / Dept of Natural Resource Sciences; M. Rosabal, Université de Québec à Montreal / Departement des sciences biologiques; P.E. Drevnick, Univ of Michigan School of Natural Resources Environment / Biological Station; N. Basu, McGill Univ / Dept of Environmental Health Sciences; P. Campbell, Université du Québec, INRS / INRS Eau Terre Environnement

Yelloweye rockfish (Sebastes rubberimus) are an extremely long-lived species (up to ~120 years), which inhabit the coastal waters of Alaska. Due to their long lifespan, yelloweye are known to accumulate high levels of mercury, and potentially other trace elements, in their tissues. Relatively little is known about the subcellular distribution of trace elements in the organs of yelloweye rockfish, which can provide important insight into detoxification/toxicity mechanisms at the subcellular level. To address this question, we collected yelloweye rockfish (n=8) from the eastern coast of Prince of Wales Island, Alaska in 2014. We determined the subcellular partitioning of trace elements (total Hg, Cd, Pb, and As) in yelloweye liver by carrying out a partitioning procedure to separate liver cells into putative metal-sensitive fractions (cytosolic enzymes, organelles) and detoxified metal fractions (metallothionein-like proteins and peptides, granule-like structures) using differential centrifugation, NaOH digestion and heat denaturation techniques. The resulting fractions were then analyzed for Hg with a direct mercury analyzer and for trace element concentrations by ICP-MS. For Cd, Pb, and As, the greatest contributions were found in the detoxified fractions, whereas the majority of total Hg was found in sensitive fractions. Results indicate that although yelloweye sequestered and immobilized potentially toxic trace elements, detoxification did not occur to the same extent for all elements (Cd > As > Pb > Hg). In yelloweye rockfish livers, the accumulation of non-essential metals in sensitive sites could lead to deleterious effects at the subcellular level, which should be evaluated in future studies.

TP268 Cadmium potential as endocrine disruptor in catfish Rhamdia quelen

L.d. Fernandes, UFPR / Pharmacology; M. Vicentini, UFPR / Dept of Pharmacology; L. Oya Silva, UFPR / Genetics; F. Tincani Osório, UFPR / Dept of Genetics; A.M. Marques, UFPR / Genetics; M. Cestari, UFPR / Genética; H. Silva de Assis, UFPR / Pharmacology

Several studies demonstrated that cadmium (Cd) can impair the endocrine system in mammals, including humans and other vertebrates, as fish. The Cd effects in endocrine system can include alteration of hormones concentration, and in activity and/or in expression of enzymes, as aromatase. Cd can promote changes in integrity, development and maturation of gonads. The aim of this study was to evaluate the Cd effects in the reproductive system in males and females of the freshwater fish Rhamdia quelen. Fish were exposed (separated by gender) to different Cd concentrations (0, 0.1, 1, 10 and 100 µg L-1). The cadmium was replaced daily with 1/3 of water change. After 15 days of exposure, animals were anesthetized, the blood was sampled for estradiol and testosterone concentration measurement, and they were euthanized by medullar section and weighed. Gonads were weighed for gonadossomatic index (GSI) calculation, and used for genotoxic biomarker (comet assay) and biochemical biomarkers analysis: activities of catalase, glutathione peroxidase, superoxide dismutase, glutathione S-transferase, the concentration of glutathione reduced and levels of lipid peroxidation. Hypothalamus (HYP) expression of brain aromatase (CYP19a1b) was carried out by real time PCR. Normality of the data was evaluated by Kolmogorov Smirnov. Normal data were tested by one-way ANOVA, followed by Newman-Keuls and non normal data by Kruskal Wallis followed by Dunn with significance level of $p< 0.05$. No significant changes were observed in biochemical biomarkers, comet assay and GSI in gonads (testicles and ovaries) of exposed animals compared to control group. These results indicated that Cd did not cause stress oxidative, genotoxicity and cell membrane damage in gonads. Estradiol and testosterone concentrations and brain aromatase gene expression were not altered by Cd exposure. Thus, it was not detected endocrine disruptor effect of those Cd concentrations in the biomarkers tested for this catfish. One possible explanation is that the Cd, in the same conditions of this work, is accumulated mainly in the liver of R. quelen, indicating that the metal cannot reach the gonadal tissues in 15 days. Others studies demonstrated that longer exposures to Cd, as 30 or 60 days, cause toxic effects on fish gonads. Therefore, others parameters should be evaluated before conclude this investigation, since for some fish species is well documented effects of Cd in impairment of the endocrine system.

TP269 Evaluation of mercury concentrations in harvestable-sized fish from freshwater resacas in south Texas, USA

M. Marquez, Florida A&M Univ / School of the Environment; S. Salinas, B. Lessley, A. Fierro-Cabo, C. Cintra-Buenrosto, Univ of Texas Rio Grande valley; C. Jagoe, Florida A&M Univ / School of the Environment

The bioaccumulation and biomagnification of mercury (Hg) were investigated in freshwater fish from resacas in Brownsville, Texas. Resacas are a series of secondary channels (distributaries) and oxbow lakes left from flooding periods of the Rio Grande River. One of the few types of freshwater wetlands in extreme southern Texas, resacas provide valuable aquatic habitat and fishery resources. They are subjected to runoff pollution from urban centers and agricultural operations, creating potential health concerns for local subsistence fishers who use the resacas heavily. About 90 catchable size fish (20-70 cm total length) from eight species were collected from eight different resacas with known runoff pollution, and edible muscle was analyzed for total mercury. Total mercury was highest in freshwater drum (Aplodinotus grunniens, median 0.71 mg/kg dry weight) and alligator gar (Atractosteus spatula, median 0.77 mg/kg dry weight), and lowest in invasive armored catfish (Loricariidae) and tilapia (Cichlidae), median Hg 0.07-0.04 mg/kg dry weight, respectively. Stable isotope analyses are underway to relate Hg concentrations to trophic position and diet. Some fish may exceed risk-based consumption advisory limits, although there are presently no advisories for these waters. This study provides baseline data for mercury accumulation in fish from this area and for risk assessments for subsistence fishers and minority groups that regularly consume fish from resacas.

TP270 The effects of food web complexity on mercury bioaccumulation in upper trophic level fish

M. Jones, Oak Ridge Natinoal Lab / Environmental Sciences Division; M.D. Poteat, Oak Ridge National Laboratory / Environmental Sciences Division; J.G. Morris, Restoration Services, Inc / Environmental Sciences Division; T. Jett, J.G. Smith, Oak Ridge National Laboratory / Environmental Sciences Division; N. Jones, Xcel Engineering / Environmental Sciences Division; M.J. Peterson, T.J. Mathews, Oak Ridge National Laboratory / Environmental Sciences Division

Benthic macroinvertebrate communities are commonly monitored as indicators of water quality, and can be particularly useful in assessing changes in water quality due to contaminant exposure. Mercury (Hg) is a globally important contaminant which has recently been recognized as a concern in stream ecosystems. Mercury (especially when transformed to methylmercury (MeHg)) is one of the only metals known to biomagnify in aquatic food webs, leading to elevated concentrations of this toxicant in fish. Mercury is predominantly accumulated in fish through the food chain rather than aqueous exposure, so food web length and complexity play important roles in controlling Hg bioaccumulation in fish. Here we examined trends in invertebrate community structure and density at two sites over a 30 year time period in East Fork Poplar Creek (EFPC) in East Tennessee to determine if Hg bioaccumulation patterns in resident fish within this Hg-contaminated stream could be explained. We examined changes in overall invertebrate community structure (e.g., species richness and EPT richness) and temporal trends in different invertebrate feeding guilds. We measured Hg and MeHg concentrations in invertebrates in 2014-2015 to infer the magnitude of Hg trophic transfer from each invertebrate guild over time, comparing predictions to long term Hg bioaccumulation trends in fish. While benthic macroinvertebrate community surveys do not provide direct information on Hg bioaccumulation, long term changes in community structure provide useful information relevant to understanding food web dynamics that can affect trends in Hg bioaccumulation in upper-level consumers.

TP271 Acute toxicity of copper to the larval stage of three species of ambystomatid salamanders

S.M. Weir, Queens Univ of Charlotte / Biology; S. Yu, Queens Univ of Charlotte / Environmental Science and Chemistry; S.L. Lance, D.E. Scott, Univ of Georgia / Savannah River Ecology Laboratory

Copper (Cu) appears to be consistently toxic to amphibian species relative to other taxa. There has been limited Cu toxicity data for salamanders, and much of the data available used embryos. We performed acute toxicity experiments with three species of ambystomatid salamanders using the larval stage. We found very high toxicity for these three species compared to previously published research on the embryo stage. Specifically, the 4 d LC50s for Ambystoma tigrinum and Ambystoma opacum were 35.3 µg/L and 18.73 µg/L, respectively. The same test concentrations of Cu caused similar toxicity to Ambystoma talpoideum (LC50 = 47.88 µg/L), but exposures required up to 48 days to elicit the same toxicity. Our results suggest that Cu is much more toxic to larval salamander stages than for embryos, which has been found for anurans as well.

TP272 Concentration of copper in gulls: A Review of published data

W.E. Espejo, Universidad de concepcion / Facultad de Ciencias Ambientales Eula; J. Celis, Universidad de concepcion / Departament of Animal Science, Faculty of veterinary science; D. González-Acuña, Universidad de concepcion / Departamento de Ciencias Pecuarias Facultad de Ciencias Veterinarias; K. Sáez, Universidad de concepcion / Departamento de Estadística Facultad de Físicas y Matemáticas; R.O. Barra, Universidad de concepcion / Aquatic systems

Gulls are birds that are present in most aquatic and terrestrial ecosystems. These birds are excellent bio-indicators of anthropogenic pollution, because they are opportunistic, omnivores and coexist with humans. They are particularly important to assess the ecosystem´s health because can reflect the environmental levels of pollutants. Copper is an essential trace element which can become toxic depending on dosage. We reviewed the Cu levels (dry weight) in different species of gulls, taking into account the biological matrix analyzed and the geographical location. The highest Cu concentrations were reported in Larus argentatus (19.87 ± 8.05 µg/g, n=18), whereas the lowest levels were in Larus genei (0.33 µg/g, n=18). The highest Cu concentrations were reported in excreta (60.1 µg/g, n=13), and the lowest in the subcutaneous fat (0.77 µg/g, n=5). With regard to the geographic location, the higher and lower Cu concentrations were reported in the Southern Hemisphere (11.41 ± 6.68 µg/g, n=166) and in the Northern Hemisphere (9.78 ± 8.61 µg/g, n = 1583), respectively. According to metal distribution in gull matrices, the Cu levels are as follows: excreta > liver > kidney > muscle > heart > feathers > stomach contents > intestine > brain > lung > salt gland > uropygial gland > gallbladder > gonads > stomach > pancreas > eyeball > eggs > skin > bones > blood > subcutaneous fat. High Cu levels in excreta may correspond to detoxification processes. Since most of the data at global scale are from Northern Hemisphere, future studies should be conducted in gulls from Southern Hemisphere. The gull excreta can be a good biological matrix for monitoring Cu. Standardized methodology for Cu detection in excreta is quite needed in order to compare data at global scale. Acknowledgements: Winfred E. Espejo is a scholarship CONICYT-Chile for PhD studies. This study was financially supported by FONDECYT-Chile 1140466 granted to R. Barra.

TP273 Concentration of Manganese in gulls: A global overview

W.E. Espejo, Universidad de concepcion / Facultad de Ciencias Ambientales Eula; J. Celis, Universidad de concepcion / Departament of Animal Science, Faculty of veterinary science; D. González-Acuña, Universidad de concepcion / Departamento de Ciencias Pecuarias Facultad de Ciencias Veterinarias; K. Sáez, Universidad de concepcion / Departamento de Estadística Facultad de Físicas y Matemáticas; R.O. Barra, Universidad de concepcion / Aquatic systems

Gulls are present in extensive aquatic and terrestrial ecosystems. They are typically coastal species and fly long distances. They are excellent bio-indicators of pollution, because they are opportunistic, omnivores, and it is often possible to see them in towns, far to the coast. They are particularly important to assess the ecosystem´s health and can reflect the environmental levels of pollutants. In this work, we made an extensive review about gulls and manganese (Mn), to understand in a better way, this trace element distribution in the environment and its biological matrix selection, at a global scale. We reviewed the Mn levels (dry weight) in different species of gulls, depending on the biological matrix analyzed and the geographical location. This analysis gathered bibliographic data from Scopus, Springer, Web of Science and Science direct. The highest Mn concentrations were reported in Larus crassirostris (14.93 ± 32.5 µg/g, n=889), whereas the lowest levels were in Larus atricilla (0.003 ± 0.0017 µg/g, n=10). The highest Mn concentrations were reported in stomach contents (78.6 µg/g, n=20), and the lowest in the subcutaneous fat (0.18 µg/g, n=5). With regard to the geographic location, the higher and lower Mn concentrations were reported in the Southern Hemisphere (2.37 ± 4.08 µg/g, n= 61) and in the Northern Hemisphere (7.84 ± 21.62 µg/g, n = 2205), respectively. According to metal distribution in gull matrices, the Mn levels are as follows: stomach contents > feathers > liver > kidney > pancreas > gonads > salt gland > intestine > bones > eyeball > gallbladder > eggs > stomach > heart > muscle > brain > lung > blood > uropygial gland > skin > subcutaneous fat. The main studies are performed in genus Larus from Northern Hemisphere. Feathers were the main biological tissue that accumulated this metal. Moreover, we can conclude that standardized non-lethal methodology for measuring metals in biotic matrices can be an adequate methodology to compare data at global scale. In order to understand the effects of metals on gulls, more studies from the Southern Hemisphere are urged. Acknowledgements: Winfred E. Espejo is a scholarship CONICYT-Chile for PhD studies. This study was financially supported by FONDECYT-Chile 1140466 granted to R. Barra and FONDECYT 1140164.

TP274 Impaired swim bladder inflation in early-life stage fathead minnows exposed to a deiodinase inhibitor, iopanoic acid

J.E. Cavallin, USEPA / USEPA Mid-Continent Ecology Division; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; B.R. Blackwell, ORISE / National Health and Environmental Effects Research Laboratory; C. Blanksma, USEPA; K.A. Fay, Univ of Minnesota – Duluth / Biology; K.M. Jensen, M. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory

The thyroid axis plays a critical role in teleost fish development. The present study investigated whether inhibition of deiodinase, the enzyme which converts thyroxine (T4), to the more biologically-active form, 3,5,3'-triiodothyronine (T3), would impact inflation of the posterior and/or anterior swim bladder (SB), processes which we previously demonstrated to be thyroid-hormone regulated. Two experiments were conducted using iopanoic acid (IOP), a pharmaceutical used to treat hyperthyroidism, as a model deiodinase inhibitor. In the first study, fathead minnow (Pimephales promelas) embryos (~1 day post-fertilization [dpf]) were exposed in a flow-through system to three concentrations of IOP (0.6, 1.9, 6.0 mg/L) or control water and sampled at 4 and 6 dpf. Whole body T4 and T3 concentrations were measured using LC-MS/MS. Abundance of deiodinase 1-3 (dio1-3), thyroid-stimulating hormone (tsh), and thyroperoxidase (tpo) transcripts was examined using quantitative polymerase-chain reaction. Posterior SB inflation was assessed at 6 dpf. To examine effects on anterior SB inflation, a second study was conducted in which 6 dpf larvae, whose posterior SB had already inflated, were exposed to the same IOP concentrations. Fish were sampled at 10, 14, 18, and 21 dpf for T4/T3 measurements, gene transcription analyses, and thyroid histopathology. In the embryo study, incidence and length of inflated posterior SBs were significantly reduced in the 6.0 mg/L treatment at 6 dpf. Dose-dependent increases in T4 and T3 concentrations were measured at 4 dpf, but only T3 concentrations remained elevated until 6 dpf. Significant dose-dependent down-regulation of tpo transcript abundance was observed at 6 dpf. Incidence and length of anterior SB inflation in larval fish were significantly reduced in all IOP treatments at 14 dpf. However by 18 dpf, anterior SBs had inflated in fish from all treatments, suggesting inflation was delayed, not prevented. Significant up-regulation of dio2 mRNA was observed at 14, 18, and 21 dpf, and significant down-regulation of tpo mRNA was observed at 10, 14, and 18 dpf in all IOP treatments. Overall, exposure to IOP altered thyroid hormone concentrations, gene transcription, and swim bladder inflation in early-life stage fathead minnows. The contents of this abstract neither constitute nor necessarily reflect USEPA policy.

TP275 The effects of early-life stage thyroid disruption on morphology, thyroid signaling, and reproduction in fathead minnows (Pimephales promelas)

P. Bruns, Texas Christian Univ; M.K. Sellin Jeffries, Texas Christian Univ / Dept of Biology

The thyroid hormone signaling pathway has been a major focus of research into the effects of endocrine disrupting compounds (EDCs). Thyroid disruptors are typically associated with alterations in growth, development, and metabolism and elicit their effects by binding to thyroid hormone receptors and transport proteins or interfering with hormone synthesis. This study examined the effects thyroid disruption in the fathead minnow (Pimephales promelas), a commonly used model organism for EDC screening and toxicity testing. Specifically, this study sought to assess the impacts of early life stage thyroid disruption on growth, thyroid hormone signaling, reproductive endocrine signaling, and reproductive success in minnows. Newly-hatched fathead minnows were exposed to either thyroxine (T_4) or propylthiouracil (PTU) for 42 days to induce hyper- and hypothyroidism, respectively. At the end of the exposure, the length, weight, and overall physical appearance (i.e., body shape and pigmentation) of exposed fish was recorded and gene expression analysis was performed to identify alterations in thyroid hormone signaling (e.g., thyroid hormone receptors, transthyretin, deiodinases, etc.), and sex steroid hormone signaling (e.g., aromatase, estrogen receptor, etc.). In addition, a subset of fish were transferred to clean water and raised to sexual maturity for the assessment of reproductive performance. It was found that thyroid disruption leads to significant changes in the growth, morphology, and expression of genes related to thyroid hormone signaling. Overall, this study represents an effort to better understand the effects of thyroid disruption in a common model species and provides information that will aid in making predictions about mechanisms of thyroid EDC action on early life stage organism.

TP276 Evaluation of the toxic effect of 2 analgesics in juvenile of zebrafish Danio rerio

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; S. López-Sagredo, A. López-Sagredo, Universidad Autonoma Metropolitana Iztapalapa

Nonsteroidal anti-inflammatory analgesics, such as aspirin and paracetamol are important pharmaceuticals worldwide, with an estimated annual production of several kilotons. These drugs are sold freely and are substances that are eliminated in considerable amounts aquatic systems it is detected in concentrations 0.001-5 mg L^{-1}. The purpose of this study was to evaluate the toxicity of two analgesics (Paracetamol and Acetylsalicylic acid) in juvenile of zebrafish. Static bioassays were performed with a duration of 96 hours, where five drug concentrations were tested to determine the LC_{50}. Subsequently a chronic test with duration of 22 days was performed exposing the fish to two sublethal concentrations (LC_1 and LC_{10}) to evaluate the following responses: increase in weight rate and 3 biomarkers: lipoperoxidation, Ache activity and genotoxicity (micronucleus frequency). The results showed that the most toxic compound was acetylsalicylic acid (LC_{50} = 34.9 mg L^{-1}). Organisms exposed to sublethal concentrations of analgesics showed a decrease in weight ranged from 23 to 66%. Also a decrease in activity of AChE enzyme between 12 to 34% was observed. The degree of lipid peroxidation ranged from 112.3 to 85.2 and 51.8 to 58.7 nM MDA g^{-1} on tests with Paracetamol and Acetylsalicylic acid respectively (control = 18.2 nM MDA g^{-1}). Micronucleus frequency was high in tests with acetylsalicylic acid, indicating that probably have a genotoxic effect. According to the results we can conclude that both drugs affect the juveniles of Danio rerio, and probably cause adverse to other species of aquatic organisms that are exposed to these medications.

TP277 The effects of Ibuprofen, Naproxen, and 17α-ethinylestradiol on American Flagfish (Jordanella floridae)

L. Beyger, Univ of Ontario Inst of Technology; J.C. Anderson, Univ of Ontario Inst of Technology / Faculty of Science; J. Guchardi, Univ of Ontario Inst of Technology / Faculty of Science Aquatic Toxicology; D.A. Holdway, Univ of Ontario Inst of Tech / Science

Pharmaceuticals are a very diverse group of bioactive compounds that are frequently detected in the environment. Steroid hormones and non-steroidal anti-inflammatory drugs are often detected due to their high level of use. More knowledge regarding the impacts of environmentally relevant concentrations of pharmaceuticals alone and in mixture are required. American flagfish (Jordanella floridae) were exposed to ibuprofen (0.1 µg/L), naproxen (0.1 µg/L), and 17α-ethinylestradiol (10 ng/L) alone, and in a mixture. Flagfish were placed into breeding harems with 4 females and 2 males per treatment and both a pre-exposure phase (21-d) and an exposure phase (21-d) were completed. Total length, wet weight, liversomatic index, and gonadosomatic index were assessed and had no significant differences. Fertilization, hatchability, and egg production were also monitored. Flagfish exposed to 0.1 µg/L naproxen, and 10 ng/L 17α-ethinylestradiol had a significant decrease ($p \leq 0.05$) in fertilization. 17α-ethinylestradiol (10 ng/L) had a significant decrease ($p \leq 0.05$) in hatchability and average cumulative egg production for ibuprofen (0.1 µg/L) was significantly increased ($p \leq 0.05$). The reproductive effects of 17α-ethinylestradiol are well known, but effects of naproxen and ibuprofen are much less so. These findings suggest that more research is needed to assess the potential reproductive effects of naproxen and ibuprofen on fish and other aquatic organisms.

TP278 An investigation of the mechanisms of action of ethinylestradiol and ammonia on fathead minnow (Pimephales promelas) reproduction

A.L. Lister, Wilfrid Laurier Univ / Dept of Biology; S. Deeming, D. MacLatchy, Wilfrid Laurier Univ / Biology

Understanding the mechanisms of action of individual toxicants and how combined effects manifest at the level of the individual may improve our knowledge of multiple-stressor impacts on fish populations. Complex, municipal effluents in the aquatic environment often are a source of the synthetic estrogen, 17a-ethinylestradiol (EE2) and ammonia (NH3); both compounds are known to negatively affect fish reproduction. This study employed a flow-through exposure of fathead minnows to target concentrations of EE2 (10 ng/L) and NH3 (3 mg/L) alone and in combination to investigate the hormonal and molecular effects of treatment on spawning inhibition. The pre-exposure and exposure phases of the experiment were 25 and 15 days, respectively. LC-MS-MS analyses confirmed the EE2 exposure levels (ng/L) to be 8.2 ± 0.31 and 8.4 ± 0.23 in the EE2 and EE2+NH3 treatments. NH3 was quantifiable in all treatments due to the nitrogenous waste cycle of the fish but was significantly higher in the treated groups with average total NH3 levels (mg/L) of 2.73 ± 0.21 (NH3) and 3.18 ± 0.10 (EE2+NH3). The corresponding levels of calculated unionized ammonia (UIA) in these treatments were 0.36 and 0.42 mg/L. As expected, both treatments containing EE2 and NH3 alone significantly reduced egg production by 84% and 46%, respectively. Liver and gonadosomatic indices were unaffected, but all treatments significantly reduced the condition factor of male and female fish. The average length, but not body weight, of exposed fish was significantly greater in treated fish. Ovarian estradiol levels were reduced 3.5 and 2 fold by EE2 and EE2+NH3 treatments, but NH3 alone had no effect. A suite of genes related to steroid biosynthesis and growth were examined by qPCR. There were increases in ovarian mRNA levels of receptors for growth hormone (GH) and IGF1 by EE2 and NH3 treatments, but GH and ERa receptor mRNA were reduced by all treatments in the female liver. Males exposed to the EE2 containing treatments showed increases in liver vitellogenin mRNA. Molecular analyses are ongoing to further our knowledge of the genes involved in growth and reproduction that may be altered by EE2 or NH3. This study demonstrated that both EE2 and NH3 negatively impact egg production, but their differential effects on ovarian steroid synthesis and their overlapping effects on gene expression highlight the complex nature of delineating the mechanisms behind whole organism responses to environmental contaminants.

TP279 Low-dose exposure to 17alpha-ethinylestradiol rapidly regulates expression networks of gonad differentiation in the adult fathead minnow testes

A. Feswick, Univ of New Brunswick Saint John / Biology; J.R. Loughery, Univ of New Brunswick / Biological Sciences; M. Isaacs, U New Brunswick / Biology; K.R. Munkittrick, COSIA; C.J. Martyniuk, Univ of Florida / Physiological Sciences

In wild fish inhabiting wastewater effluent with estrogenic components, the presence of both oocytes and spermatogenic tissue in the testes has been documented. However, the molecular networks underlying the manifestation of the intersex condition are not completely characterized. Here, we used an environmentally relevant concentration of 17alpha-ethinylestradiol (EE2), the active component of the birth control pill, to determine the response of the fathead minnow testis transcriptome after 96 hrs. The goal was to capture early molecular initiating events that may lead to the intersex condition. There were no effects of EE2 on gonadosomatic index nor proportion of gametes within the testes. However, in vitro production of 11-ketotestosterone and testosterone in the testis was decreased relative to controls following EE2 exposure. Gene expression profiling revealed that there were 10 transcripts that were differentially expressed in the testis using a 8x60K fathead minnow microarray, the most dramatic change being that of coagulation factor XIII A chain (20-fold increase). Guanine nucleotide binding protein (Beta Polypeptide 2), peroxisome proliferator-activated receptor delta, and WNK lysine deficient protein kinase 1a, were down-regulated by EE2. Subnetwork enrichment analysis revealed that EE2 suppressed transcriptional networks associated with steroid metabolism, hormone biosynthesis, and sperm mobility. Most interesting was that gene networks associated with doublesex and mab-3 related transcription factor 1 (dmrt1) were suppressed, despite the fact that dnmt1 expression itself was not different from controls. Moreover cell processes involving forkhead box L2 (foxL2) such as ovarian follicle development and granulosa cell development were increased in the testis. Cell processes that included glucose homeostasis, response to heavy metal, amino acid catabolism, and the cyclooxygenase pathway were decreased with EE2 while lymphocyte chemotaxis, intermediate filament polymerization, glucocorticoid metabolism, carbohydrate utilization, and anterior/posterior axis specification were increased. These data demonstrate that a low dose of EE2 rapidly suppresses male hormone secretion and gene networks related to male sex differentiation, and induces transcriptional networks related to female sexual differentiation in the adult testis. These responses are hypothesized to be the molecular initiating events that occur prior to the development of the intersex phenotype after prolonged exposures to estrogens.

TP280 Exposure to the Contraceptive Progestin, Levonorgestrel, Disrupts Reproductive Behavior, Fecundity, and Morphology in the Fathead Minnow

T. Frankel, Univ of Maryland-College Park / Dept of Animal and Avian Sciences; M. Meyer, USGS / Organic Geochemistry Research Laboratory; D.W. Kolpin, USGS / Iowa Water Science Center; A. Gillis, Univ of Maryland College Park; D.A. Alvarez, USGS-CERC / Physiology and Biochemistry; E. Orlando, Univ of Maryland / Animal & Avian Sciences

Historically, endocrine disrupting chemical research has focused on environmental androgens, estrogens, thyroid hormones, and their antagonists. Recent efforts have begun to examine the effects of gestagens, which include endogenous progestogens and synthetic progestins, on aquatic wildlife. Progestins have been measured in wastewater treatment plant effluent, and exposure studies have demonstrated profound effects on the fecundity, morphology, and most recently reproductive behavior of fish and amphibians. In this study, fathead minnows (Pimephales promelas) were exposed to environmentally relevant concentrations of levonorgestrel (LNG) using a flow-through exposure system consisting of thirty-two 15 L glass tanks (8 tanks per treatment, 6 full volume turnovers/d). One reproductively active triad (two females and one male) was placed into each tank containing a single breeding tile and acclimated for 7 d. Treatments began on day 8, with each tank receiving H_20 only, EtOH (vehicle control), 10 ng/L, or 100 ng/L of LNG. Fecundity (defined as the number of eggs laid) was quantified daily. To determine effects on reproductive behavior, a 1 h recording was obtained on days 1, 2, and 8 from each tank using a front mounted webcam, and various behaviors (lateral displays, lateral quivers, rubbing of the tile ceiling, etc.) quantified using Jwatcher™ (V 1.0). After 8 d of exposure, all fish were euthanized and examined for the presence of secondary sexual characteristics, including nuptial tubercles, dorsal fin spots, and fatpads. Exposure to both concentrations of LNG decreased fecundity, with complete cessation of egg deposition observed on day 5. LNG exposure also caused morphological masculinization of females, indicated by the development of nuptial tubercles, dorsal fin spots, and fatpads. Both LNG treatments caused decreases in approach and leading behaviors on day 1, with significant decreases of all behaviors observed on days 2 and 8. Together, results from this study, androgen receptor activation research in our lab, and research by others indicate that LNG functions at least as an environmental androgen in fishes. As alterations of normal reproductive behavior were observed after just one day of exposure, this study also provides further support that behavior is an extremely sensitive endpoint that merits increased attention in future aquatic toxicology studies.

TP281 Exposure effects of the cyprinid progestogen pheromone, DHP, on the reproductive behavior and sperm characteristics of the male fathead minnow

G. DeWitt, Univ of Maryland / Animal and Avian Sciences; T. Frankel, E. Lavin, Univ of Maryland College Park / Dept of Animal and Avian Sciences; M. Meyer, USGS / Organic Geochemistry Research Laboratory; E. Orlando, Univ of Maryland / Animal & Avian Sciences

In fish, pheromones stimulate reproduction by way of heightening sexual attraction and/or stimulating gametogenesis. In carp and goldfish, several pheromones have been identified including DHP, androstenedione, and prostaglandins. In these species, DHP (17α,20β-dihydroxy-4-pregnen-3one) excreted by ovulating females affects reproductive behavioral and physiological changes in males, and has been hypothesized to function similarly in related species such as the fathead minnow (FHM, Pimephales promelas). Because of the easily identifiable reproductive behaviors of the FHM and its broad use in aquatic toxicology, this species was used to test the effects of DHP on male FHM nest tending behavior and sperm motility. Singly-housed, adult, male FHMs (n=7) were exposed to an ethanol control, 1 or 10 ng/L of DHP overnight using a flow-through system. Exposure began at 6 pm and reached nominal concentrations for each treatment at approximately 12 am, after which dosing was ceased and DHP concentrations allowed to decrease through dilution with water only. Water samples were collected at 6 pm, 10 pm, 12 am, and 8 am and analyzed using LC/MS/MS. At 8 am, 1 h video recordings of each tank were obtained and analyzed for % active time, % static time, and frequency and duration of nest tending behaviors using JWatcher^{TM} (V1.0). Four randomly selected males per treatment were then euthanized, and semen samples obtained via testicular maceration. Total % motility (MOT), average path velocity (VAP), straight line velocity (VSL), curvilinear velocity (VCL), linearity (LIN), and beat cross frequency (BCF) were quantified using computer assisted sperm analysis (Hamilton Thorne). Both concentrations of DHP resulted in increased activity inside the breeding structure, and males exposed to the 10 ng/L treatment also spent more time exploring outside of the tile. Spermatozoa from fish treated with both concentrations of DHP exhibited greater MOT, VAP, and VCL, as well as decreased LIN. No differences between any treatments were observed for BCF and VSL. Our results suggest that DHP causes increased activity in males, and at higher concentrations may initiate searching behavior for ovulating females. As several endocrine disrupting chemicals have been shown to bind the same receptors as DHP and greatly affect fecundity, further research is required to determine if these compounds can also function via the disruption of pheromonal communication.

TP282 Developmental toxicity of sulfamethazine in marine medaka (Oryzias melastigma) embryos

X. Wang, Xiamen Univ / Dept of Environmental Science and Technology

Sulfamethazine (SMZ) is not only extensive used in treatment of human diseases, but also largely used as the long-term additive in animal feed. It has been a kind of ubiquitous contaminants in the marine environment. Bioaccumulaition and potential developmental toxicity of SMZ in marie madaka (Oryzias melastigma) embryow were studied. Results indicated that bioaccumulation of SMZ in embryos showed a significant dose-response relationship. The main malformation in embryoic stage was hemoglutination, and the region and manifestation of hemoglutination were irregular. Yolk sac edema was the main malformation at the larvae stage. The trend of embryonic mortality was so similar with the trend of hemoglutination rate, implied the hemoglutination was proably the main cause of embryonic death. The embyonic heart beats increased with SMZ concentrations on 4 dpf and 12 dpf. Suffering from exposure to SMZ, superoxide dismutase (SOD) and catalase (CAT) activities of embryos showed a significant dose-effect relationship. When the concnetrations of SMZ in embryos reached to 10 ng/embryo, SOD activiiesy were significant inhibited and caused oxidtive lessions. These results indicated that fish at the early develomental stage were sensitive to antibiotic and the rational administration of drugs in fries aquaculture should be concerned.

TP283 The Effects of Risperidone, an Antipsychotic, on American Flagfish (Jordanella floridae) Reproduction

M. Overturf, Univ of Louisiana at Monroe / Biology; J.C. Anderson, Univ of Ontario Inst of Technology / Faculty of Science; D.A. Holdway, Univ of Ontario Inst of Tech / Science

Concern of pharmaceuticals and personal care products (PPCPs) in the environment has increased in the last decade. Most research concerning fish reproduction been focused on pharmaceuticals that directly affect the endocrine system. The goal of this study was to understand the effects of a non-endocrine active pharmaceutical, risperidone, on fish reproduction using American flagfish (Jordanella floridae). Risperidone is an antipsychotic drug whose side effects in mammals include increased prolactin levels from inhibiting dopamine signaling. Prolactin's role in reproduction is understudied in fish; however, prolactin may impact reproduction through modulation of steroid hormones and gonad development and maturation. Additionally, risperidone inhibition of dopamine signaling has caused low libido and sexual dysfunction in mammals. Risperidone has been detected in surface waters at concentrations in the low ng/L range. Sexually mature American flagfish were exposed to 1, 10, and 100 ng/L risperidone for 21 days in breeding harems (2 males:4 females). Risperidone exposure did not adversely affect with fecundity, fertilization, or hatching success. The results of the present study suggest that risperidone exposure at environmental levels may not pose a significant risk to fish reproduction.

TP284 Effect of carbamazepine and valproate exposure on development of zebrafish (Danio rerio) embryos

E. Gasca-Pérez, Universidad Veracruzana / Facultad de bioanalisis; M. Galar-Martinez, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional / Laboratory of Aquatic Toxicology Dept of Pharmacy; F. Ramos Morales, Universidad Veracruzana / SARA

Carbamazepine (CBZ) and valproic acid (VP) are wide utilized in epilepsy treatment with good results in seizure control, but the exposure to this compounds result in a risk factor on developing, therefore, in many countries low levels of these compounds have been detected in treatment plant effluents, surface waters, seawaters, groundwater and some drinking waters. A fast and simple method to study chemical toxicity after exposure of the complete vertebrate embryo during embryogenesis in ovo is the zebrafish embryotoxicity test (ZET). In this study, we determinate the teratogenic index (TI) and embryotoxic effect with respect to a general morphology scoring (GMS) of two anticonvulsant drugs, CBZ and VP, using an easy, fast and semiquantitative method. Embryos were exposed to four concentrations of CBZ (62.5, 125, 250 and 500 μM) and VP (12.5, 25, 50 and 100 μM) in a static exposure systems for 12, 24, 48 and 72 h. Results showed that in CBZ treatment only in highest concentration (500 μM) presents pericardial edema, with a TI of 0.016. VP groups present pericardial edema, heart deformation, scoliosis and deformation yolk in high concentrations (50 and 100 μM), the minimal TI was found in 25 μM (0.016), increasing in 50 μM (0.13) and 100 μM (0.23). V group has a mortality of 10.42%, while in CBZ, the maximum mortality were 14.58% in 62.5 μM and VP showed a concentration-dependent behavior, with 25 % in 50 μM and 96.87 % in 100 μM of death embryos. CBZ showed hatching delay and pericardial edema in high concentration (500 μM), with a low incidence of defects. VP showed high toxicity producing abnormalities as pericardial edema, scoliosis, tail deformation, absence of pectoral fins and wide mortality. We concluded that CBZ and VP are two pharmaceutical products that could affect the normal aquatic fauna development.

TP285 The combinatorial effects of Hydroxypropyl-β-cyclodextrin (HPβCD) and synthetic steroids on American Flagfish growth and reproduction

J.C. Anderson, Univ of Ontario Inst of Technology / Faculty of Science; M. Overturf, Univ of Louisiana at Monroe / Biology; L. Beyger, Univ of Ontario Inst of Technology; J. Guchardi, Univ of Ontario Inst of Technology / Faculty of Science Aquatic Toxicology; D.A. Holdway, Univ of Ontario Inst of Tech / Science

The risk of pharmaceuticals and personal care products (PPCPs) in the aquatic environment has been a concern for the past two decades. Many studies have demonstrated the growth and reproductive toxicity of PPCPs to non-target aquatic organisms. The aims of this study were to firstly, understand the toxicity of commonly consumed synthetic steroids, 17α-ethinylestradiol (EE2), levonorgestrel (LNG), and etonogestrel (ENG) on the American flagfish (Jordanella floridae). Secondly, to determine if the odour suppressant/excipient, hydroxypropyl-β-cyclodextrin (HPβCD) can alter the identified toxicity of EE2, LNG, or ENG. EE2 is a synthetic estrogen, while LNG and ENG are both synthetic progestins, all of which are commonly found in oral contraceptives. In current literature, both EE2 and LNG have demonstrated the ability to alter early life-stage growth and adult reproduction. To date, ENG has not been studied in an environmental toxicological setting, however, it is of high interest due to its similar physio chemical properties to LNG, including a high relative binding affinity for the human progesterone receptor. HPβCD is both used as an excipient in the pharmaceutical industry as well as an odour suppressant in Febreze®. HPβCD is amphiphilic and toroidal in shape with the ability to include non-polar compounds within its central cavity, including many synthetic steroids. Results from this study indicate that in the presence of HPβCD, the 96 hr acute toxicity of EE2 to larval American flagfish was significantly reduced in a 1:1 molar ratio (EE2:HPβCD) ($P \leq 0.05$). Thus an interaction between HPβCD and EE2 can be detected though a biological assay. In order to characterize the environmentally relevant concentrations of these compounds in a chronic setting, a 30 day early life stage toxicity test was undertaken using juvenile American flagfish. Fish were exposed to 1 ng/L, 3.2 ng/L, 10 ng/L, 32 ng/L, 100 ng/L, and 320 ng/L LNG in triplicate. No significant differences in wet (n=96-104) or dry weight (n=30) were observed. A minor increase in length was observed at 32 ng/L LNG when compared to the control ($P \leq 0.05$). Given that the aim of this study is to determine if HPβCD can alter the toxicity of synthetic steroids to fish, eliciting a toxicological response is vital to this study. As such, a series of reproductive exposures involving EE2, LNG, and ENG, alone and in combination with HPβCD are currently being conducted with results to be discussed.

TP286 Transgenerational effects of triclosan on the demography of Brachionus havanaensis (ROTIFERA)

B.K. González Pérez, Universidad Autonoma Metropolitana; S.S. Sarma, UNAM Mexico City Campus iztacala / Laboratory of aquatic zoology; M.E. Castellanos Páez, Universidad Autonoma Metropolitana / Campus Xochimilco; N. Sarma, UNAM Mexico City Campus iztacala / Laboratory of aquatic zoology

Triclosan is an antimicrobial agent commonly used worldwide in several personal care products, such as hand soaps. It is an endocrine disruptor that affects a variety of aquatic and terrestrial organisms. It can potentially mimic estrogens, androgens or even thyroid hormones. In Mexico different concentrations of triclosan have been reported in aquatic systems. However, there is no law regulating the presence of chemicals such as triclosan, in aquatic systems. The lack of information about possible effects on aquatic organisms of this chemical has increased concern among ecotoxicologists. Rotifers which are the common components of aquatic ecosystems are sensitive indicators and are frequently used in bioassays. Brachionus havanaensis is a common rotifer in freshwater ecosystems of Mexico and has been used in ecotoxicological bioassays. In this work, the median lethal concentration (LC_{50}, 24h) of Brachionus havanaensis exposed to triclosan was determined. Based on the LC_{50}, we tested three sublethal concentrations of triclosan to quantify the demographic responses of B. havanaensis for two successive generations (F_0, and F_1). The 24 h LC_{50} of triclosan for B. havanaensis was 500 µg L^{-1}. B. havanaensis exposed to sublethal concentrations of triclosan showed that both the survival and reproduction-related variables were negatively affected with increasing concentrations of the endocrine disruptor. There were also significant differences in relation to the demographic responses of B. havanaensis at F_0 and F_1 exposed to triclosan. The impact of this compound on aquatic ecosystems is discussed.

TP287 Early exposure to triclosan impairs heart formation, metamorphosis and reproduction in zebrafish

R. Botka, A. Stenzel, A. Saley, M. Hess, K. Miller, C. Fuchs, D. Howard, Univ of Wisconsin La Crosse; T.C. King-Heiden, Univ of Wisconsin – La Crosse / Biology

Triclosan (TCS) is an antimicrobial agent that is prevalent within surface waters and readily bioaccumulates within aquatic organisms. Here we demonstrate that exposure to environmentally relevant concentrations of TCS during critical periods of development can impair key processes of development in zebrafish. Fish were exposed to concentrations ranging from 0 – 400 ?g TCS/L via static waterborne exposure with daily renewal either from 0-5 days post fertilization (dpf) or from 21 – 35 dpf. While cardiac edema and reduced heart function of embryos were only seen in larvae exposed to high concentrations of TCS (≥ 40 ?g TCS/L), impacts on heart looping and regurgitation were seen following exposure to as little as 0.4 ?g TCS/L. Our preliminary findings suggest that exposure to as little as 0.4 ?g TCS/L may impair ability to capture prey, and may also impair the development of craniofacial structures. Larvae exposed to as little as 0.4 ?g TCS/L showed delayed juvenile development and reductions in egg production. Taken together, this work suggests that chronic exposure to environmentally relevant concentrations of TCS has the potential to impact wild fish populations, and warrants further study.

TP288 Early-life Stage Effects of Metformin in Japanese medaka (Oryzias latipes)

E. Ussery, Univ of Ontario Inst of Technology / Biologcal Sciences; M. Overturf, Univ of Louisiana at Monroe / Biology; Z. Pandelides, Univ of Ontario Inst of Technology / Biological Sciences; J. Guchardi, Univ of Ontario Inst of Technology / Faculty of Science Aquatic Toxicology; D.A. Holdway, Univ of Ontario Inst of Tech / Science

In recent years, there is a growing concern that human pharmaceutical waste threatens to disrupt many natural processes of living organisms by the introduction of stressors and unnatural contaminants in the environment. One of the most abundant environmental contaminants is the type 2 diabetic drug metformin. Metformin has been measured in surface waters and wastewater effluents in the µg/L concentration range. Recent studies have observed adverse effects of metformin on adult fathead minnows, resulting in an increase in vitellogenin expression, an increase occurrence of intersexuality, a decrease in weight and condition factor in males, and a decrease in the size of amount of egg clutches produced by breeding minnows. To date, there has been no studies investigating the effect of metformin on the sensitive early life stages of aquatic organisms. The present study utilized the Organization for Economic Cooperation and Development (OECD) 210 Early-life Stage (ELS) study to investigate the impacts metformin has on Japanese medaka growth and development. Medaka were treated with a concentration range of 1.0, 3.2, 10, 32 and 100 µg/L metformin from embryo through 21 days post hatch. Results will be presented showing length, weight (wet and dry), and condition factor of fish treated with metformin compared to control fish. Growth and developmental effects of this major pharmaceutical on this important early-life stage will be discussed.

TP289 Dose-dependent impacts of wastewater contaminant metformin on the reproductive system of zebrafish (Danio rerio)

J. Crago, Texas Tech Univ/TIEHH / Environmental Toxicology The Inst of Environmental and Human Health TIEHH; R. Klaper, Univ of Wisconsin-Milwaukee / School of Freshwater Sciences

The discovery of intersex in freshwater fish in the early 1990s suggested the presence of endocrine disrupting compounds in the aquatic ecosystem, likely from human waste. Although synthetic estrogens from birth-control medications found in wastewater have been pointed to as one likely cause of observed endocrine disruption in the environment, other pharmaceuticals and personal care products have been implicated as causing endocrine disruption in fish. One such drug, metformin is prescribed worldwide as a treatment for Type 2 diabetes. This biguanidine is excreted in human waste in its active form and, although it is removed to a high degree by wastewater treatment, recent studies have found this compound in many freshwater systems around the world and it is now estimated to be the pharmaceutical most deposited into the aquatic environment by mass. In our previous work we found evidence of intersex in males and gene expression changes in fathead minnows (Pimephales promelas) exposed to 40 ppb of metformin from fry stage to adulthood. For this talk, we have continued to examine metformin as well as its main wastewater treatment metabolite guanylurea. We exposed zebrafish (Danio rerio) to 0.4, 4 or 40 ppb of metformin from 6 hours post fertilization to 5 months and then performed a 21-day reproductive study. Zebrafish exposed to 4 and 40 ppb metformin had a reduction in egg production as compared to control and 0.4 ppb exposed metformin. There was no difference in egg production in zebrafish exposed to guanylurea versus the control. As part of this study, we also found genes associated with reproduction and steroidogenesis were altered in response to exposure to metformin and guanylurea. This study will describe the potential impacts of metformin and guanylurea as a non-traditional endocrine disrupting compound.

TP290 Evaluation of the effects of chronic exposure to fluoxetine (Prozac) and norfluoxetine on the benthic macroinvertebrate Chironomus riparius

R.L. Webb, Univof Pittsburgh at Johnstown / Biology; H. Barton, Univ of Pittsburgh at Johnstown / Dept of Biology; C.A. Kinney, Coloraodo State Univ-Pueblo / Chemistry; A. May, L. Fecik, B. Rivera, N. Felton, Univ of Pittsburgh at Johnstown / Dept of Biology

Approximately half of those prescribed an antidepressant, for conditions such as depression, anxiety and eating disorders, are given a Selective Serotonin Reuptake Inhibitor (SSRI), such as Prozac (fluoxetine, FLX). Interestingly, a large percentage of FLX, and its metabolite, norfluoxetine (NFLX), are excreted from the body. Due to incomplete removal of FLX and NFLX during wastewater treatment, FLX has been identified in surface waters receiving municipal effluent within the U.S., with levels reaching up to 1.4 ppb. The FLX and NFLX present in waterways are likely to adsorb to aquatic sediment, due to their lipophilic properties. The benthic macroinvertebrate, Chironomidae, has been used in several studies to test the effects of FLX on reproduction, development and gene expression, with conflicting results. There has been limited research on NFLX's effect on aquatic organisms, even though it is thought to be more biologically active and has a longer half-life than FLX. Our research examines changes in growth, emergence timing, survival, reproduction, fecundity and generational survival in Chironomus riparius due to exposure to varying levels of fluoxetine or norfluoxetine. We have found that FLX and NFLX negatively affect survival, in concentration ranges of 5-18 ppm and 1-6 ppm respectively. NFLX, but not FLX, reduces emergence timing and reproduction. We are currently evaluating if chronic exposure is significantly affecting growth or generational survival, as well as determining if the FLX and NFLX are accumulating in the larvae. In addition to developmental effects on Chironomidae, we are determining larval behavioral consequences due to chronic exposure to FLX and NFLX, by evaluating the rate of movement and distance traveled in both light and dark conditions. Analysis of the effect of SSRI contamination on ecological integrity will influence water quality regulations.

TP291 Effect of selective serotonin reuptake inhibitor (SSRI) citalopram on hybrid striped bass predatory behavior and brain chemistry

L. Stoczynski, Clemson Univ / Environmental Toxicology; J.H. Bisesi, Univ of Florida / Environmental and Global Health; P. van den Hurk, Clemson Univ / Biological Sciences

Antidepressants are commonly prescribed drugs in the United States. Selective serotonin reuptake inhibitors (SSRIs) are one of the most prescribed antidepressant classes. Waste water treatment facilities are often ill-equipped to handle the removal of pharmaceuticals from incoming waters, leading to the discharge of SSRIs into the environment. Fish populations around discharge pipes could be experiencing exposures to sub-lethal concentrations (low ppb to high ppm) of SSRIs which could affect their ecological fitness in the environment. The goal of this research is to determine whether antidepressants have a sublethal effect on fish populations through a change in feeding behavior, further quantified by analyzing brain chemistry. Past research of SSRIs on hybrid striped bass (HSB) showed a decrease in serotonin concentrations in the brain and concentrations of SSRIs equivalent to therapeutic levels in humans. We hypothesize a decrease in feeding behavior and decrease in serotonin levels in HSB after exposure to citalopram. HSB were exposed to citalopram concentrations ranging from 50-150 ug/L followed by feeding periods every three days (3,6,9,and 12 days) to determine if citalopram has an effect on their predatory behavior. Blood and brain samples collected from euthanized fish at the end of an exposure were analyzed for concentrations of citalopram and serotonin. Preliminary work has shown medium and high exposure to citalopram may cause a decrease in feeding ability and/or causing satiation. From an ecological standpoint an increased feeding time could make exposed bass populations less ecologically fit compared to other fish populations not as affected by the antidepressants.

TP292 The effects of atorvastatin at environmentally relevant concentrations on steroidogenesis of the Western African Clawed frog (Xenopus tropicalis)

J. Johnson, R.J. Griffitt, Univ of Southern Mississippi / Coastal Sciences

Micropollutant pharmaceuticals (MP) have become an emerging threat to aquatic ecosystems. Atorvastatin has been detected in wastewater effluent at a variety of levels from 1 ng L^{-1} to 0.47 µg L^{-1}. Statin drugs work to inhibit endogenous production of cholesterol by inhibiting 3-hydroxy-3-methyl-glutaryl-CoA reductase from producing mevalonic acid in the mevalonate pathway. The reduction in circulating cholesterol levels may affect steriodogenesis by reducing the levels of estrogen and testosterone produced in the steroidogenesis pathway. Due to the increased sensitivity of amphibians to aquatic toxins, we hypothesize that the frog population could be significantly impacted by interruption of endogenous synthesis of cholesterol which may lead to altered steroidogenesis due to low concentrations of atorvastatin in wastewater effluent. The central hypothesis of this study is to directly address this issues by using a combination of chronic exposure bioassays at critical life stages to assess the potential for atorvastatin to cause overt reproductive and developmental dysfunction to wetland amphibians. Xenopus tropicalis tadpoles will be exposed to 5 environmentally relevant concentrations at critical development stages. A chronic 21 day exposure will evaluate the effects during early life exposures from fertilization to free swimming tadpole stages. A chronic 30 day exposure will evaluate effects during metamorphosis and growing into adulthood. These two exposures combined allow for evaluation of the complete lifecycle from fertilization to adulthood. The adult reproductive exposure will be performed by injecting adults with relevant concentrations of atorvastatin, then breeding the injected pairs. The offspring will then be evaluated for effects of atorvastatin exposure resulting from parental exposure. This research will elucidate the effects of MPs in wastewater effluent on the growth and development of a model amphibian.

TP293 Marine Bivalve Cellular Responses to Beta Blocker Exposures

B. Khan, National Research Council of the National Academies / Biology; R.M. Burgess, USEPA / Atlantic Ecology Division; S. Fogg, Oak Ridge Associated Universities; M.G. Cantwell, D.R. Katz, K.T. Ho, USEPA / Atlantic Ecology Division

β blockers are prescription drugs used for medical treatment of hypertension and arrhythmias. They prevent binding of agonists such as catecholamines to β adrenoceptors. In the absence of agonist induced activation of the receptor, adenylate cyclase is not activated which in turn limits cAMP production and protein kinase A activation, preventing increases in blood pressure and arrhythmias. After being taken therapeutically, commonly prescribed β blockers may make their way to coastal habitats via discharge from waste water treatment plants (WWTP) posing a potential risk to aquatic organisms. The aim of our research is to evaluate cellular responses of three commercially important marine bivalves – Eastern oysters, blue mussels and hard clams – upon exposure to two β blocker drugs, propranolol and metoprolol, and to find molecular initiating events (MIEs) indicative of the exposure. Bivalves were obtained from Narragansett Bay (Rhode Island, USA) and acclimated in the laboratory. Following acclimation, gills and hepatopancreas (HP) tissues were harvested and separately exposed to 0, 1, 10, 100 and 1000 ng/l of each drug. Tissues were bathed in 30 parts per thousand (ppt) filtered seawater, antibiotic mix, Leibovitz nutrient media, and the test drug. Exposures were conducted for 24 hours and samples were saved for cellular biomarker assays. A lysosomal destabilization assay, which is a marker of membrane damage, was also performed at the end of each exposure. EC50 values were calculated and compared across species to evaluate drug and dosage effects as well as species sensitivities. Exposed tissues had significantly higher membrane damage than controls at environmentally relevant concentrations. Differences in species sensitivities were also observed. The results suggest that propranolol is more toxic than metoprolol in all three species. Cellular damage and enzymatic markers are currently being analyzed. These studies enhance our understanding of the impacts of commonly used prescription medication on organisms in coastal ecosystems and demonstrate that filter feeders such as these marine bivalves can serve as good model organisms to examine the effects of water soluble drugs like propranolol and metoprolol. Evaluating a suite of biomarkers allows us to better define MIEs that can be used to develop adverse outcome pathways (AOPs) for environmental exposure to β blockers.

TP294 Effects of exposure to two organic ultraviolet filters and a related commercial sunscreen product in adult coral nubbins

T. He, City Univ of Hong Kong; T. Mei Po Mirabelle, City Univ of Hong Kong / Biology and Chemistry; C. TAN, T. Fan, National Museum of Marine Biology and Aquarium; M.B. Murphy, City Univ of Hong Kong

Ethylhexylmethoxy-cinnamate (EHMC) and octocrylene (OC) are two widely used organic ultraviolet (UV) filters added to personal care products (e.g. sunscreens) to protect skin from sunburn and cancers caused by UV radiation. They possess relatively high octanol-water partition coefficients (Log Kow) and bio-concentration factors (BCF), and are two of the most prevalent organic UV filters found in environmental samples. Previous studies reported that organic UV filters and sunscreen products caused coral bleaching at low concentrations/quantities. Coral reefs are known to be one of the most important ecosystems on Earth. Despite the potential negative effects of organic UV filters and sunscreens on the health of corals, information is lacking about their toxicities. In this study, seven-day exposures were conducted to evaluate the toxicities of EHMC, OC and a related sunscreen product containing both compounds [EHMC, 7% w/w; OC, 3.6% w/w] to two coral species, Seriatopora caliendrum and Pocillopora damicornis. The tested concentrations of EHMC and OC ranged from 0.1 to 1000 µg/L. The sunscreen product was tested by applying it to the hands of volunteers (2 mg/cm^2), after which the volunteers waved their hands gently in 2L filtered seawater for 20 minutes. Serial dilutions of 5%, 20%, and 50% were prepared and were tested along with 0% and 100% treatments. Three replicates of 3 nubbins were prepared in glass bottles, and mortality, bleaching, and polyp retraction were measured. After seven days, death (33.3%) and bleaching (83.3%) of S. caliendrum nubbins were found in the 1000 µg/L EHMC treatment. Thorough polyp retraction was the only adverse effect found in P. damicornis exposed to EHMC; this effect was found in both S. caliendrum and P. damicornis exposed to OC. In the sunscreen product exposures, 5% sunscreen water caused death of S. caliendrum (66.7%) and P. damicornis (33.3%); chemical analysis showed that the 5% sunscreen water contained approximately 400 µg/L EHMC and 30 µg/L OC at the beginning. Based on all of these results, EHMC and OC may not be the major contributors causing the effects of this sunscreen product on S. caliendrum and P. damicornis nubbins. The results of a probabilistic risk assessment showed that EHMC poses high risks to the health of corals in Hong Kong and Taiwan. In the future, more studies should be conducted to investigate the toxicities of organic UV filters and sunscreen products to corals.

TP295 Genotoxicity assessment of mixtures of veterinary antibiotics to fish through the micronucleus test and other nuclear abnormalities

R. Botelho, Univ of São Paulo / Ecotoxicology; J. Correia, UNESP Univ Estadual Paulista Júlio de Mesquita Filho / Biology; C.A. Christofoletti, Fundacao Herminio Ometto / Environmental Mutagenesis; Y. Ansoar, São Paulo State Univ UNESP / Biology; V.L. Tornisielo, CENA Center for Nuclear Energy in Agriculture

Veterinary antibiotics are one of the most used pharmaceuticals class in Brazilian fish farming for the treatment of bacterial diseases, and because of their intensive use, contamination of the aquatic environment may occur with effects to the native biota which lives where the fish farming is located. The goal of this study was to investigate the genotoxic effects of mixtures of environmental concentration of oxytetracycline and florfenicol and the mixtures of their half and double on juveniles of native fish from brazil (Prochilodus lineatus) through the occurrence of micronucleus (MN) and other nuclear abnormalities (NA) after 96 hours exposure. Environmental concentration of oxytetracycline (8000 ng L-1) and florfenicol (425 ng L-1) were determined in surface water of a fish farm located at Ilha Solteira Reservoir (Santa Fé do Sul, São Paulo, Brazil) through Online-Solid-Phase Extraction coupled to Liquid Chromatography-Tandem Mass Spectrometry (Online-SPE-LC/MS-MS) in a previous study of our laboratory and exposed (8000 ng L-1 + 425 ng L-1) along with its double (16000 ng L-1 + 850 ng L-1) and its half (4000 ng L-1 + 212.5 ng L-1) on juveniles of P. lineatus during 96 hours in a static system. Tee genotoxic results are being analyzed and will be presented at the event.

TP296 Genotoxicity assessment of mixtures of veterinary antibiotics to fish through the comet assay

R. Botelho, Univ of São Paulo / Ecotoxicology; C.A. Christofoletti, Fundacao Herminio Ometto / Environmental Mutagenesis; J. Correia, UNESP Univ Estadual Paulista Júlio de Mesquita Filho / Biology; Y. Ansoar, São Paulo State Univ UNESP / Biology; V.L. Tornisielo, CENA Center for Nuclear Energy in Agriculture

Florfenicol and oxytetracycline are the two most commonly used antibiotics for bacterial treatment in fish farming in Brazil, and because of their intensive use, the potential harmful effects on aquatic organisms are of great concern. The goal of this study was to investigate the genotoxic effects of mixtures of environmental concentration of oxytetracycline and florfenicol and the mixtures of their half and double on juveniles of native fish from brazil (Prochilodus lineatus) through the comet assay after 96 hours exposure. Environmental concentration of oxytetracycline (8000 ng L-1) and florfenicol (425 ng L-1) were determined in surface water of a fish farm located at Ilha Solteira Reservoir (Santa Fé do Sul, São Paulo, Brazil) through Online-Solid-Phase Extraction coupled to Liquid Chromatography-Tandem Mass Spectrometry (Online-SPE-LC/MS-MS) in a previous study of our laboratory and exposed (8000 ng L-1 + 425 ng L-1) along with its double (16000 ng L-1 + 850 ng L-1) and its half (4000 ng L-1 + 212.5 ng L-1) on juveniles of P. lineatus during 96 hours in a static system. The genotoxic results are being analyzed and will be presented at the event.

Environmental or Analytical Chemistry – Poster Only – Part 2

TP297 A computational study of nucleophilic aromatic substitution reaction of 3-5-dinitroethoxylpyridine with piperidine using hybrid dft method

O.h. Okafor, Dept of chemistry, Univ of Lagos / Chemistry; O. Whenu, Univ of Lagos Nigeria / Chemistry Departament

This report involves a reaction between 3,5-dinitroethoxylpyridine and piperidine to give 3,5-dinitro(2-piperidinyl)pyridine. This reaction was carried out using density functional method at the B3PW91, 6-31G level of theory. The mechanism of this reaction begins with the attack on the leaving group (ethoxyl ion) in the compound 3,5-dinitroethoxylpyridine by the nucleophile; piperidine to form an unstable intermediate called Meisenheimer complex. When this intermediate is formed, the reaction can take either of two pathways; based-catalyzed pathway and base-uncatalysed pathway. The base-uncatalysed pathway is a direct decomposition of the intermediate to the product. The leaving group; ethoxyl ion and a hydrogen atom from the intermediate cleave off to form ethanol and leaves as a byproduct, the aromaticity of the compound is then restored. While for the base-catalysed pathway, a strong based is reacted with the intermediate to deprotonate the compound, then the leaving group in the compound cleaves off with a hydrogen atom to form the final product 3,5-dinitro(2-piperidinyl)pyridine. This reaction passes through two transition states going from the reactant to the final product. The first transition states lies between the reactant and the intermediate while second transition state is in-between the intermediate and the product. The structures of these transition states are viewed after optimizing the structures involved in this reaction. The structures were optimized using Gaussian software. The thermodynamics and chemical kinetics of the reaction were gotten using a computer-based model software; Chemcraft. Computational studies can be carried out to find a starting point for a laboratory synthesis, or to assist in understanding experimental data, such as the position and source of spectroscopic peaks. It can also be used to predict the possibility of so far entirely unknown molecules or to explore reaction mechanisms that are not readily studied by experimental means. This study is used in identifying correlations between chemical structures and properties.

TP298 A sensitive and reliable analytical method for free thyroid hormones in animal serum using ultrafiltration in combination with UHPLC-MS/MS

R. Tanoue, Ehime Univ / Center for Marine Environmental Studies; I. Kume, Ehime Univ; Y. Yamamoto, Ehime Univ / Center for Marine Environmental Studies; K. Nomiyama, Ehime Univ; S. Tanabe, T. Kunisue, Ehime Univ / Center for Marine Environmental Studies

Thyroid hormones (THs), such as L-thyroxine (T4) and 3,3',5-triiodo-L-thyronine (T3), play critical roles in regulating metabolism and maintaining energy balance in both human beings and animals. There has been a growing interest in animal exposure to environmental pollutants and corresponding adverse effects on thyroid hormone homeostasis. For THs measurement, liquid chromatography-tandem mass spectrometry (LC-MS/MS) has recently attracted attention as an advanced method superior to the conventional immunoassay methods that have been traditionally used. Although almost all THs in blood circulation are bound to transport proteins, approximately 0.03% of the total blood T4 and 0.3% of the total blood T3 are present as protein-unbound (free) form and are able to enter cells followed by physiological effects. For measuring free THs in serum/plasma, physical separation of the free fraction from the mixture of protein-bound and unbound fraction is required prior to quantitative analysis. The aim of the present study was to develop a sensitive and reliable analytical method for the determination of free THs: T4, T3, 3,3',5'-triiodo-L-thyronine (rT3), 3,5-diiodo-L-thyronine (3,5-T2), 3,3'-diiodo-L-thyronine (3,3'-T2), and 3-iodo-L-thyronine (3-T1), in serum/plasma of various animals. As a separation step prior to LC-MS/MS analysis, ultrafiltration (UF) was examined, and UF devises and several experimental conditions (centrifugal force, time, temperature, and serum pH) were optimized and validated. As a result, UF at 1100 g and 37oC for 30 min with a 30 kDa ultrafiltration device (Centrifree YM-30, Millipore) yielded the finest precision (CV: < 10%). There were no statistical differences in measurement values at serum pH values ranging from 7.3 to 8.7. Acceptable accuracy (recovery: 100%–126%) and intra- and inter-day precision (CV: < 10% and < 12%, respectively) were obtained, and method detection limits were between 1.7 and 6.0 pg mL^{-1} serum. The developed analytical method was successfully applied to the determination of free THs in serum/plasma samples of humans, bovines, and cats.

TP299 Analysis of Drugs and Poisons in Catfish

S. Boone, J. Atkins, C. Childers, Mississippi State / Chemical Laboratory; A. Meredith, D. Sparks, Mississippi State / Chemical Laboratory / Dept of Biochemistry Molecular Biology Entomology and Plant Pathology; G. Hagood, Mississippi State / Chemical Laboratory; A. Brown, Mississippi State / Chemical Laboratory / Dept of Biochemistry Molecular Biology Entomology and Plant Pathology

To ensure the safety of the food supply in the US many organizations are cooperating to develop and improve methods. In cooperation with the USDA/FSIS/FERN the Mississippi State Chemical Laboratory (MSCL) is working to improve the Drug and Poisons Screen using Acidic and Basic Extraction (FERN CHE.0006.01) with GC-MS in catfish and to implement the improved method. The MSCL currently analyzes multiple selected compounds (current used pesticides and metabolites) in farm-raised catfish. A surveillance program within the state supports the growth of the catfish industry in Mississippi and is based upon generating a product that tastes good and is safe for all consumers. The Drug and Poisons Screen has added an additional tool to the laboratory to test catfish for additional compounds (some which have been banned in the US) that may adulterate the edible catfish fillets. The compounds include: arecoline, nicotine, phorate, tetramine, diazinon, terbuphos, paraoxon, parathion, aldrin, pilocarpine, DDE, DDT, endrin, pentazocine, scomolamine, codein, phenylbutazone, morphine, fentanyl, strychnine, phenanthrene, and triphenylphosphate. The Agilent 7890A with the 7000 Triple Quad GC/MS was used for the analysis of the compounds. The FERN method has performed admirably with many different products in the past. The method includes extraction of fish fillets in glycine buffer (pH 3 and pH 10), acetonitrile, NaCl, and centrifugation. The extraction of the catfish fillets causes additional matrix issues that increase problems with the inlet more than other matrices resulting in failures with calibration verifications. The addition of an alumina clean-up column has decreased the matrix effects while maintaining excellent recovery rates for most compounds. A 10 g sample was combined with 10 ml buffer (pH 3 and pH10) and cleaned with 500 mg alumina columns. Recovery of most compounds was > 60%, except pentazocine – 45%, strychnine – 45%, morphine < 10%, and phenylbutaxone < 5% with the pH 10 buffer. Recovery of most compounds was > 60%, except arecoline – 20%, nicotine – < 5%, pilocarpine – 45%, scopolamine – 35%, codeine – 30%, morphine – < 5%, strychnine – 40% with the pH 3 buffer. The pH 3 buffer had more matrix issues than the pH 10 buffer. Additionally the preconditioning of the column with multiple injections of control extract increased the reliability of the results.

TP300 Analysis of Fragrance Ingredients in Fish with Ultrasonic Assistant Extraction and Purge & Trap

C. Chen, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry; K. Löfstrand, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry ACES; M. Adolfsson-Erici, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry ACES; M. MacLeod, ITM – Stockholm Univ / Dept of Environmental Science and Analytical Chemistry ACES

Fragrance materials are used in a wide variety of consumer products including both personal care and household products, such as essential oils. Assessing substances with unknown or variable composition like the essential oils is problematic under REACH, especially assessment of bioaccumulation. In vivo studies are still the 'gold standard' for these assessment, but are hindered by the lack of a simple and reliable analytical method for determining these substances in biota. Herein we present an analytical method for simultaneously measuring a group of model chemicals similar to components of essential oil mixtures with a wide range of volatility property (violate to semi-volatile organic compounds, VOCs – SVOCs) (α-pinene (PIN), camphene (CAM), limonene (LIM), 2-t-butyl-cyclohexyl acetate (Verdox), cashmeran (DPMI), cyclohexyl salicylate (CHS), acetyl cedrene (AC), musk xylene (MX) and globanone (GLO)) in rainbow trout using ultrasonic assistant extraction (UAE) and then a purge and trap (P&T) approach (home-made system), followed by analysis with gas chromatograph – mass spectrometer (GC-MS). Whole rainbow trout were homogenised and subsamples (~ 5 g) were spiked with the test chemicals and surrogate standards. Different organic solvents were tested to extract the compounds with UAE, with acetonitrile as the best choice because of the limited amount of fat extracted and easier subsequent clean up procedures. Gas phase extraction (P&T) was found to be the better method when compared to C18 clean-up method for recovering target chemicals. Hexane was used to exchange the acetonitrile to facilitate the evaporation for the P&T method. Then the P&T procedure was optimised in terms of temperature (50, 70 and 90 °C) and extraction time (0.5 – 310 h), and the best combination was 70 °C for 24 h. The finalized method has been evaluated for the blanks, overall spiked recoveries and robustness. The overall recoveries were 67% (PIN) to 140 % (verdox). While the RSDs of repeated spiked recoveries were in the range of 2.3 % (AC) – 12% (GLO) except CHS (21%) and were within 15% except CHS with 26% for the recoveries in three different weeks. This method is suitable for application to improve bioaccumulation assessment of essential oils.

TP301 Application of graphene-derivatized silica as an efficient solid phase extraction sorbent for enrichment of five polycyclic musks in water

C. Li, Beijing Academy of Agriculture and Forestry Sciences; J. Chen, J. Wang, Y. Luan, A. Lu, Beijing Academy of Agriculture and Forestry Sciences / Beijing Research Center for Agricultural Standards and Testing

Pharmaceuticals and personal care products (PPCPs) have gained increasing interest due to their potential risk in aqueous environment. Polycyclic musks (PCMs) which were often detected in water at low concentrations, are considered as important ingredients of PPCPs. To prevent adverse effects on the environment and human health, it is importance to develop a sensitive and fast method for the determination of PCMs in water. This work presents a novel analytical method based on graphene for the determination of PCMs in aqueous matrices. A solid-phase extraction (SPE) adsorbent was synthesized by covalently binding graphene sheet to silica (G@silica) for PCM enrichment in water. This new type of adsorbent was characterized by Fourier transform infrared (FT-IR) spectroscopy, scanning electron microscopy (SEM). Five PCMs (ADBI, AHMI, HHCB AHTN, ATII) were enriched from water samples using 50 mg G@ silica packed cartridge and determined by GC-MS. Various parameters, including eluting solvent and volume, absorbent amount were optimized. Validation experiments showed that the optimized method presented good linearity (r>0.998) in the concentrations ranged from 1 ng/mL to 500 ng/mL. Satisfactory precision (RSD < 10%), and high recovery (79.3-108%) were obtained. The limits of detection were from 0.02 ng/mL to 0.1 ng/mL. This method exhibited the advantages of simplicity, good sensitivity, and high efficiency.

TP302 Assessment subproducts generated from selected disperse dyes bearing azo groups biotransformed by reductase enzyme

J. Franco, G. Meireles, Unesp Inst of Chemistry; B.F. Silva, Unesp Inst of Chemistry / Analytical Chemistry; E. Franciscon, School of Technology UNICAMP / Laboratório de Ecotoxicologia e Microbiologia Ambiental "Prof. Dr. Abílio Lopes"; D.P. Oliveira, Univ of São Paulo USP / Faculdade de Ciências Farmacêuticas de Ribeirão Preto; M.V. Zanoni, UNESP Inst of Chemistry

It is known from literature that many environmental pollutants such as azo dyes are mutagenic and suspected of causing cancer. In recent years the result of the intake of these dyes present in drinking water is discussed by several authors. Toxicological risks of synthetic dyes human health are closely related to biotransformation processes enhanced by the mode and time of exposure to human, oral ingestion, skin sensitization, awareness airway and others. One way of azo dyes biotransformation is bacterial biodegradation, which is often initiated with cleavage of azo bonds by azoreductases, which is the key enzyme for the degradation of all azo dyes by bacteria. Therefore, analysis LC-MS/MS were performed to monitor the textile dyes, such as disperse red 73 (DR73), disperse red 78 (DR78) and disperse red 167 (DR167) biotransformation and major metabolites generated. The bacterium E. coli was isolated from different phases of activated sludge produced by the textile company Vicunha, Brazil. Selected strains were inoculated with a low concentration of glucose and mixed with the azo dye in a concentration of 100 mg L^{-1} each dye; and incubated for seven days. LC-MS/MS analysis showed the presence of two metabolites for each dye after the incubation. 3-4-Aminophenyl-ethyl-amino-propanitrile (m/z 190) was detected for both DR73 and DR78. 4-Nitroaniline (m/z 139) and 2-chloro-4-nitroaniline (m/z 173) were also detected for DR73 and DR78, respectively. These results suggested that DR73 lost the CN^- substituent during the biotransformation. The main products from DR167 biotransformation were dimethyl 3,3'-3-acetamido-4-aminophenyl-azanedyl-dipropanoate (m/z 337) and 2-chloro-4-nitroaniline (m/z 173). The detected products were corresponding to amines after the cleavage of the azo bond. All the compounds identified as metabolites of textile dyes have been classified as possibly human carcinogens (2B) by the IARC. Therefore, our findings corroborate with the recommendation of The European Union that prohibits importing and marketing products that could produce carcinogenic amines at levels of ppm (Decision 2002/657/EC). In conclusion, both the original textile dyes and their degradation products may harm the human health and the environment. Considering that the reduction steps used in this work mimic endogenous reactions, toxic compounds could originate in the human liver and gastrointestinal tract after oral exposure to DR 73, DR 78, and DR 167.

TP303 Derivatization, DLLME, and GC-FID analysis of mercury in fish tissue

A. Narro, St Edwards Univ; L.A. Curry, St. Edwards Univ / Chemistry

Fish consumption is one of the main routes of exposure to mercury in the United States. The Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA) are in the process of revising their 2004 Advisory of Mercury in Fish and Seafood. Current concentrations found in the FDA's monitoring program correspond to values reported as early as 1990 and as late as 2010. The task of updating and maintaining such a database requires the analysis of a large number of samples. Current methods for analysis of mercury in biological tissues require the use of specialized instrumentation such as Cold Vapor Atomic Fluorescence Spectroscopy. For many analytical laboratories this means the acquisition of new instrumentation and training of personnel. Another option is the development of methods that allow the analysis of mercury in biological tissues using instrumentation commonly found in analytical laboratories such as Gas Chromatography (GC). In this project we propose the development of a method for analysis of mercury in fish tissue samples using GC with flame ionization detector (FID). The new method consists of digestion of the fish tissue, phenylation of mercury(II), dispersive liquid-liquid microextraction (DLLME), and analysis by GC-FID.These experiences have given me an insight into the nature of both literature and experimental research.

TP304 Designing a Quality Control Program for Collection and Analysis of Siloxane samples from Environmental Monitoring Programs

J.A. Durham, Dow Corning Corp. / Health and Environmental Sciences; R.M. Seston, Dow Corning Corporation / Health and Environmental Sciences; N.A. Warner, NILU – Norwegian Inst for Air Research / Environmental Chemistry; D.E. Powell, Dow Corning Corporation / Environmental Sciences; S. Knoerr, Dow Corning Corporation / Health and Envrionmental Sciences

When embarking on an environmental monitoring study, it is critical that the proper quality control (QC) parameters are evaluated to ensure integrity of the results obtained from monitoring activities. This is especially critical when analytes under investigation can be present in personal care products, equipment and analytical instrumentation as is the case for cyclic siloxanes. Selecting an appropriate QC matrix is imperative to accurately account for loss or contamination during collection, transport, and laboratory processing and analysis. In addition, it is important to evaluate analytical variation introduced by the sample matrix itself to the overall signal measured to avoid reporting false positives. It is therefore important that QC matrices be determined prior to the initial design of the monitoring program. Key aspects when designing a QC program include applying an appropriate QC matrix which matches or mimics the sample matrix being collected; determining background contribution from sample collection and laboratory equipment; evaluating initial concentrations present within QC matrices prior to application and how they will evaluate analyte loss or contamination. This presentation will provide an overview of quality control evaluations from several different programs and the best practice for creating a proper QC program. The Loss and contamination of the analyte in the field has been assessed using a variety of materials including fish muscle/liver, sediments and sorbents such as low density polyethylene and XAD® resin. Additionally, processing and analysis QC are assessed to evaluate contamination from equipment such as collection and analysis jars, use of nitrogen as well as analysis equipment.

TP305 Determination of changes in molecular composition of crude oil due to microbial degradation by ultrahigh-resolution FT-ICR mass spectrometry

G. Hitz, C. Jagoe, Florida A&M Univ / School of the Environment; A. Chauhan, Florida A&M Univ; R. Gragg, Florida A&M Univ / Environmental Sciences Inst; E. Johnson, Florida A&M Univ / School of the Environment; E. Hilinski, Florida State Univ / Dept of Chemistry and Biochemistry

The ability of microbes to degrade crude oil in marine systems is well known. However, a detailed understanding of the changes in molecular composition of crude oil undergoing microbial degradation is lacking. To date, changes in oil composition during and after microbial degradation have been assessed using analytical techniques including gas chromatography/mass spectrometry (GC/MS), gas chromatography/flame ionization detection (GC/FID) and Fourier-transform infrared spectroscopy (FTIR). However, GC/FID is unable to discriminate among many compounds in the saturated hydrocarbon fraction of crude oil, and GC/MS cannot measure many high molecular weight compounds. Two-dimensional GC (GCxGC) with MS detection improves resolution, but many compounds in complex crude oil mixtures still cannot be resolved. Newer techniques provide higher resolution measurements that allow simultaneous quantitation of tens of thousands of organic compounds in complex mixtures. One such technique is Fourier Transform Ion Cyclotron Resonance (FT-ICR) mass spectrometry, which can be applied to crude oil to resolve and identify tens of thousands of chemical species at molecular masses measured in the parts per billion range in a single sample. A pilot project was done using a pure strain of Pseudomonas aeruginosa strain WC55previouslyisolated from Apalachicola Bay, FL, capable of using Macondo oil as the sole source of carbon and energy. In this study, a model light, sweet crude oil was incubated with P. aeruginosa in replicate microcosms simulating estuarine conditions over a 40-day period. Changes in molecular composition of oil were characterized using positive and negative ion electrospray FT-ICR mass spectrometry in neutral, acidic, and basic extracts of the degraded oil. This pilot study serves as a precursor to a larger research project to investigate the changes in molecular composition of various types of crude oils (light sweet to heavy sour) during and after microbial degradation by representative in-situ microbial communities present in northern Gulf of Mexico estuarine systems. Our goal is to understand in greater detail the process of microbial degradation of crude oil, and to couple observed changes in oil composition during degradation to specific bacterial communities and metabolic pathways.

TP306 Determination of residual characteristics and risk assessment on dimethomorph, fludioxonil, kresoxim-methyl, and pyridalyl in spinach

M. Jin, H. Noh, J. Lee, H. Park, Chungbuk National Univ; H. Jeong, Chungbuk National Univ / Agricultural Chemistry; S. Chae, T. Kim, Analysis technology & Tomorrow; C. Kwon, J. Kim, Ministry of Food and Drug Safety; K. Kyung, Chungbuk National Univ

In order to investigate the effect of spraying times on dimethomorph, fludioxonil, kresoxim-methyl, pyridalyl residues in spinach, the test pesticides were diluted 1,000 for dimethomrph (25% WP) and pyridalyl (10% EC), 2,000 for fludioxonil (20% SC) and 3,000 times for kresoxim-methyl (50% WG). And then the diluted solutions were sprayed onto the test crop growing three test plots; twice spraying 7 and 14 days (T-1) or 3 and 7 days (T-2) before harvest and three times spraying 7, 14 and 21 days before harvest (T-3). Residues in the crop were analyzed with an HPLC-DAD for dimethomorph, a GLC-NPD for fludioxonil and kresoxim-methyl, and a GLC-ECD for pyridalyl. Limits of detection (LODs) were 0.004-0.02 mg/kg. Recoveries at two levels, 10 and 50 times of the LODs, ranged from 80.3 to 114.3% in spinach. Amount of the test pesticides residue was highest in T-2, compared with T-1 and T-3. This result indicated that major factor affecting residue level of the pesticide was spraying day close to harvest rather than spraying time. The estimated daily intakes of the test pesticides calculated using the highest residues in spinach were less than 5.2% of their acceptable daily intakes.

TP307 Determining Nitrophenols in Diesel Exhaust Emissions from Heavy-duty Vehicles

K. Koshika, NTSEL; Y. IWAMOTO, National Traffic Safety and Environment Laboratory

Some nitrophenols, such as 4-nitrophenol, 2-methyl-4-nitrophenol and 3-methyl-4-nitrophenol, have been paid much attention because of their risk of biological effect, such as muscle-contracting and endocrine-disrupting. Diesel exhaust emissions have been known as one of their emission sources. However the detecting method for diesel exhaust emissions has never been authorized. Therefore we have developed a detecting method for not only actual vehicles complying with previous regulations but also vehicles complying with the newest emission regulation in Japan. We will introduce the method and demonstrate the results of emission tests for heavy-duty vehicles by using a chassis dynamometer. The method includes not only filter sampling but also synthetic absorbent sampling because gas sampling by using synthetic absorbents is very important for the vehicles complying with the newest emission regulation. We found most of the nitrophenols leaked through the filter, demonstrating a necessity for a combination of filter sampling and synthetic absorbent sampling to detect the total amount of emissions from the actual vehicles.

TP308 Development of a FT-IR Testing Method for 2,4 D and Dicamba Resistant Soybeans

A. Meredith, A. Brown, D. Sparks, Mississippi State Chemical Laboratory / Mississippi State Univ Dept of Biochemistry Molecular Biology Entomology and Plant Pathology; C. Reid, Mississippi State Univ / Dept of Biochemistry Molecular Biology Entomology and Plant Pathology; C. Atkinson, Mississippi State Chemical Laboratory; D. Reynolds, Mississippi State Univ / Dept of Plant and Soil Sciences; S. Boone, Mississippi State Chemical Laboratory / Mississippi State Chemical Laboratory

Bio-technology companies have developed cultivars of corn, soybean, and cotton with transgenic resistances to the synthetic auxin herbicides; 2,4-dichlorophenoxyacetic acid (2,4 D) and dicamba, which were slated for release in Mississippi for the 2015 and 2016 growing seasons. The introduction of new herbicide tolerant soybeans may provide many benefits for producers such as alternative control options for resistant weed species, decreased costs, and different modes of action. Along with these benefits, the use of auxin containing herbicides may also increase concern for issues such as herbicide drift, volatilization, and tank contamination. To combat these concerns Monsanto in collaboration with BASF (Dicamba-BAPMA) and Dow AgroSciences (2,4 D-choline) have developed new formulations that are less prone to volatilization and drift. Additionally these companies have created product stewardship programs. The Mississippi State Chemical Laboratory (MSCL) analyzes samples each year for off-target deposition of dicamba and 2,4 D, however, current-testing methods cannot differentiate between the amine, ester, or choline formulations. Therefore, our primary objective of this study was to determine the feasibility of using FT-IR technology to identify 2,4 D-choline and dicamba-BAPMA on field samples. Coupling FT-IR spectra to principal component analysis we have been able to separate and identify soybeans that were treated with dicamba-BAPMA and traditional dicamba formulations. The development of additional analytical testing methods will help to ensure an effective stewardship program.

TP309 Direct analysis of systemic insecticides in leaf using SALDI imaging mass spectrometry with sputter-deposited metal film

I. Osaka, japan Advanced Inst of Science and Technology

In agricultural chemistry, systemic insecticides have been used to administer to plant. Generally, the mobilization of systemic insecticides in plants could be evaluated by high resolution radioisotope imaging,although it is difficult to handle expensive and dangerous radioisotopes. It is necessary for radioisotope experiments to use expensive and exclusive facilities for preventing exposure to radiation. Therefore, simple and inexpensive new methods without the use of radioisotopes for imaging plants are required in agricultural fields to evaluate the mobilization of systemic insecticides and their metabolites in plants. Recently, Matrix-assisted laser desorption/ionization mass spectrometry (MALDI) imaging mass spectrometry (IMS) has been developed for detection of analytes and visualization of the distribution of analytes in a biological tissue. MALDI-IMS of thick plant leaves could not be achieved due to charge-up in the MALDI ion source. The charge-up effect in the ion source during ionization process causes low resolution of obtained mass spectra and low sensitivities of analytes. Therefore, a conductive surface is necessary to obtain good mass spectra in MALDI-IMS. On the other hand, surface-assisted laser desorption/ionization (SALDI) has been investigated for the detection of some analytes which could not be detected by MALDI-MS. I have developed the novel SALDI method. In the SALDI, sputter-deposited platinum film was used as matrix. SALDI with sputter-deposited platinum film (Pt-SALDI) allows IMS analysis of non-conductive materials without the need for extraction because the sputter-deposited film couldimpart conductivity to the surface of samples. In this study, the distribution and mobilization of systemic insecticides in thick and non-conductive leaves was investigated and evaluated. The analytical technique for the direct analysis of distributions and movements of the chemicals in plant leaves using Pt-SALDI-IMS without use of radioisotope are reported. It is conceivable that Pt-SALDI allows the imaging mass analysis of various samples such as plant tissue, biological tissue, paper, and film.

TP310 Dissipation of Pyridalyl and Thiamethoxam Residues in Korean Cabbage and Their Safety Evaluation

H. Noh, J. Lee, H. Park, Chungbuk National Univ; H. Jeong, Chungbuk National Univ / Agricultural Chemistry; M. Jin, Chungbuk National Univ; C. Kwon, Ministry of Food and Drug Safety / Safety Management Division; K. Kyung, Chungbuk National Univ

This study was carried out to investigate the residual characteristics and to evaluate safety of pyridalyl and thiamethoxam in Korean cabbage. The test pesticides were sprayed onto the Korean cabbage at 10 days before harvest and samples were collected 7 times, 0 (at 3 hours after spraying), 1, 2, 3, 5, 7 and 10 days after spraying. Limits of detection (LODs) of pyridalyl, thiamethoxam and clothianidin were 0.005, 0.01 and 0.005 mg/kg, respectively. Recoveries of the test pesticides ranged from 74.3 to 104.9, showing that these methods were appropriate for the analysis of the pesticide residues in the crop. Residual amount of pyridalyl from 0 day to 10 days after last spraying on Korean cabbage in field 1 and field 2 ranged from 0.238 to 0.246 mg/kg and from 0.044 to 0.057 mg/kg, respectively. In case of thiamethoxam, the residual amount at day 0 was found to be from 0.06 to 0.08 mg/kg. No residues were found in case of clothianidin, a metabolite of thiamethoxam, and samples sprayed with thiamethoxam at 7 days after treatment. Half-lives of pyridalyl and thiamethoxam residues in Korean cabbage using the equations of their regression curves were found to be from 3.6 to 4.2 days and from 2.2 to 2.7 days, respectively. These results represent that residues of the test pesticides were dissipated gradually after spraying. Also, during the experimental period, dilution effects in residual concentration of the test pesticides by growing of the test crops were negligible considering no significant change in the weight of the crop. The pesticide residues on the harvest day were expected to be lower than their maximum residue limits (MRLs) by predicting with their regression equations. Ratios of estimated daily intakes (EDIs) to acceptable daily intakes (ADIs) of the pesticides (% ADIs) in field 1 and field 2 on the treatment day (0 day) were 1.08 and 1.12% for pyridalyl and 0.64 and 0.85% for thiamethoxam, respectively. Also, those ratios at harvest day and 10 days after spraying were 0.21 and 0.26% for pyridalyl, respectively. These results indicated that the residues of the test pesticides evaluated to be safe.

TP311 Dissipation of residue and safety assessment on cyazofamid, cyhalothrin, and diflubenzuron in perilla leaves

H. Park, H. Noh, J. Lee, Chungbuk National Univ; H. Jeong, Chungbuk National Univ / Agricultural Chemistry; M. Jin, Chungbuk National Univ; S. Chae, T. Kim, Analysis technology & Tomorrow; C. Kwon, J. Kim, Ministry of Food and Drug Safety; K. Kyung, Chungbuk National Univ

This study was carried out to investigate residual characteristics of cyazofamid, lambda-cyhalothrin and diflubenzuron in perilla leaves. The test pesticides, cyazofamid (10% SC), lambda-cyhalothrin (1% EC) and diflubenzuron (10% WP) were sprayed three times with 7 day interval onto perilla leaves at a rate of 2,000 for cyazofamid, 1,000 for lambda-cyhalothrin, and 2,500 for diflubenzuron. Samples were sequentially harvested 0, 1, 3, 5, 7 day after last spraying. Limit of quantitation of both cyazofamid and diflubenzuron were 0.02 mg/kg and that of lambda-cyhalothrin was 0.004 mg/kg. Their recoveries ranged from 76.0 and 97.5%, indicating proper analysis methods. Amount of cyazofamid and its metabolite 4-chloro-5-p-tolylimidazole-2-carbonitrile (CCIM) residues were 12.76 mg/kg just after last spraying and 7.92 mg/kg 7 days after last spraying. Also, amounts of the pesticide residues after last spraying and 7 days after final spraying were 1.61 and 0.88 mg/kg in case of lambda-cyhalothrin, and 71.70 and 36.91 mg/kg in case of diflubenzuron, respectively. Residue patterns of the test pesticides including metabolite of cyazofamid were sequently dissipated, showing that half-lives of cyazopamid, lambda-cyhalothrin and diflubenzuron were 10.4, 8.1 and 7.2 days, respectively. Amount of lambda-cyhalothrin in sample was lower than those of cyazofamid and diflubenzuron, representing that not only active ingredient of lambda-cyhalothrin was higher than the others but also lambda-cyhalothrin has non-systemic characteristics. Percent acceptable daily intakes (%ADIs) and theoretical maximum daily intake (TMDI) of the pesticides were below 0.6 and 28.4%, respectively.

TP312 Effect of drying, steaming and boiling on tebuconazole residue in fresh ginseng

H. Jeong, Chungbuk National Univ / Agricultural Chemistry; H. Noh, J. Lee, H. Park, M. Jin, Chungbuk National Univ; J. Do, M. Chang, National Inst of Food and Drug Safety Evaluation; K. Kyung, Chungbuk National Univ

To determine fungicide tebuconazole residues in ginseng and its processed products, such as dried ginseng, red ginseng, and water extracts of dried ginseng and red ginseng, nine trials were conducted from three fields for two consecutive years in Korea. Tebuconazole 20% suspension concentrate combined with 10% trifloxystrobin was applied onto 4-year-old ginseng three times at a nominal rate of 0.134 kg a.i./ha (tebuconazole basis) with a 10-day interval, according to its pre-harvest interval (PHI) in Korea and sprayed consecutively onto 5-year-old ginseng next year. Tebuconazole residues in fresh and processed products were analyzed with GLC-NPD. Average recoveries of tebuconazole in fresh and processed products ranged from 79.40 to 119.48. Reduction factors of dried ginseng, red ginseng, water extract of dried ginseng and red ginseng ranged from 0.37 to 0.41, from 0.34 to 0.37, from 0.19 to 0.20, from 0.16 to 0.35 in first year and from 0.25 to 0.29, from 0.14 to 0.20, from 0.28 to 0.36, from 0.14 to 0.25 in second year, respectively. These results suggested that total amount of tebuconazole residue in fresh ginseng was removed by processing such as oven- or sun-drying, steaming, and high-temperature reflux.

TP313 Effects of Environmental Conditions on Aerobic Degradation of a Commercial Naphthenic Acid

C.M. Kinley, Clemson Univ / School of Agricultural Forestry and Environmental Sciences; D. Gaspari, Clemson Univ / Dept of Environmental Engineering and Earth Sciences; A. McQueen, Clemson Univ / Dept of Forestry and Environmental Conservation; J. Rodgers, Clemson Univ / Forestry and Env Conservation; J. Castle, Clemson Univ / Environmental Engineering and Earth Sciences; V. Friesen, M. Haakensen, Contango Strategies

Naphthenic acids (NAs) are problematic constituents in energy-derived waters (e.g. refinery effluents and oil sands process-affected waters), and aerobic degradation may provide a strategy for mitigating risks to aquatic organisms. The overall objective of this study was to determine the relative influence of four environmental conditions on aerobic degradation of a commercial (Fluka) NA in bench-scale reactors. These conditions included environmentally relevant ranges of nitrogen (N; as ammonia), phosphorus (P; as phosphate), and dissolved oxygen (DO) concentrations, as well as pH and temperature. Commercial NAs provided replicable model compounds necessary to compare influences of environmental conditions on degradation. Changes in NA concentrations for each treatment were measured with time using a derivatization method and high performance liquid chromatography. Microbial diversity and relative abundance were measured and compared among treatments using targeted DNA sequencing via PCR amplification of the v3/v4 region of the 16S rRNA gene. Approximately 50% removal of the initial Fluka NA concentration of 61±8 mg L^{-1} occurred in less than 2 days after NA introduction, achieving the method detection limit (5 mg L^{-1}) by day 6 of the experiment in treatments with a C:N:P ratio of 100:10:1 (in microbial growth medium), DO >8 mg L^{-1}, pH 8-9, and temperatures >23ºC. Negative controls (reverse-osmosis water with NAs and no added nutrients) had no measurable changes in NA concentrations throughout the experimental duration, supporting that NAs were not lost as a result of abiotic factors in treatments. Results indicated that key nutrients, DO, pH, and temperature (within environmentally relevant ranges) influenced rates of aerobic degradation of Fluka NAs. Commercial NAs serve as a simplistic and replicable analog to more compositionally complex mixtures of NAs (e.g. in energy-derived waters). This aerobic degradation study of Fluka NAs could serve as a model for systematically evaluating processes altering exposures of NAs and environmental factors that influence NA degradation in field scenarios.

TP314 Fluorescent assay for cadmium detection based on label-free aptamer

Y. Luan, A. Lu, C. Li, L. Xu, Beijing Research Center for Agricultural Standards and Testing

The selective detection of ultratrace amounts of cadmium ion (Cd2+) is extremely important for food safety and environment since it is one of the most toxic and widespread. In this work, we propose a facile, rapid, excellently sensitive, and highly selective method for the detection of Cd2+, based on label-free aptasensor using unmodified double-strand DNA specific dye (PicoGreen). This system achieved a superior linear dynamic range from 0.1 ng/mL to 100 ug/mL and a detection limit as low as 0.10 ng/mL, which was lower than the toxicity level of Cd2+ in drinking water (3 ng/mL) defined by World Health Organization, and exhibited excellent selectivity to Cd2+ ions. We also tested the application of the aptasensor in real irrigating water samples through spiked with a series of concentrations of Cd2+ and the results showed a good tolerance to matrix effect, compared with atomic absorption spectrometry. The developed approach was a simple, quick and sensitive detection method for Cd2+ monitoring and offered a great potential for on-site and high-throughput analysis in routine control.

TP315 Non-targeted analyses of organic compounds in shortfin mako sharks from US Atlantic waters

B. Crimmins, Clarkson Univ / Civil and Environmental Engineering; S. Fernando, A. Carroll, T. Holsen, Clarkson Univ; D. Adams, Cape Canaveral Scientific, Inc.

The majority of biomonitoring efforts involve targeted analyses of specific classes of compounds. This approach omits a wide array of potentially harmful chemicals. Recently non-targeted analytical methods have been employed to perform comprehensive screening of environmental compartments for a wide array of Persistent, Bioaccumulative and Toxic species (PBTs). Comprehensive gas chromatography (GCxGC) provides 2 dimensional orthogonal seperation of GC amenable species. Combined with a fast scanning High Resolution Time-of-flight mass spectrometer (GC×GC-HRT, Leco) this technique provides unsurpassed chromatographic and mass spectrometric resolution of environmental matrices, and allows for the chemical fingerprinting of biological tissues. In this study, liver tissue was analyzed from shortfin mako shark (Isurus oxyrhinchus) collected in US waters of the Atlantic Ocean. These highly migratory shark species occupy a high trophic position within the Atlantic and have a global distribution with various known sub-populations. Utilizing the GCxGC-HRT, halogenated and non-halogenated PBTs were detected and cataloged, representing an integrated assessment of the PBTs in the Atlantic Ocean. As expected polychlorinated biphenyls dominated the halogenated profile indicating this legacy contaminant continues to impact marine systems with several polybrominated diphenyl ethers and legacy chlorinated pesticides observed in high abundance. Using NIST, Wiley and in-house spectral libraries 1000's of individual species were identified and the current paper discusses the relative abundance and profiles observed for this novel marine bioindicator.

TP316 Organic pollutants, metals and biochemical biomarkers in Spartina densiflora in estuaries from Argentina, Brazil and Chile

M. Menone, Instituto de Investigaciones Marinas y Costeras CONICET/ UNMDP / Lab de Ecotoxicologia; M. Diaz-Jaramillo, IIMYC CONICET/ UNMDP / Laboratorio de Ecotoxicología y Contaminación Ambiental ECoA; F. Mitton, IIMYC CONICET/UNMDP; D.S. Garanzini, IIMYC CONICET/ UNMDP / IIMyC; P.G. Costa, Lababoratório de Microcontaminantes Orgânicos e Ecotoxicologia Aquática, Univ Federal do Río Grande / Escola de quimica e alimentos; L. Lupi, IIMYC CONICET/ UNMDP; G. Lukaszewicz, Universidad Nacional de Mar del Plata / Instituto de Investigaciones Marinas y Costeras; M. Gonzalez, Instituto de Investigaciones Marinas y Costeras CONICETUniversidad Nacional de Mar del Plata / Laboratorio de Ecotoxicología y Contaminación Ambiental ECoA; S. Jara, Universidad de concepcion; K.S. Miglioranza, Univ of Mar Del Plata / Laboratorio de Ecotoxicología y Contaminación Ambiental ECoA; G. Fillmann, Univ Federal do Rio Grande / Instituto de Oceanografia; R.O. Barra, Universidad de concepcion / Aquatic systems

During the last decades the South- American Atlantic and Pacific coasts have received antropogenic pollutants from industrial, domestic and agricultural sources. As a result, estuarine ecosystems work as sinks of xenobiotics and adverse effects in biota could be expected. Analysis of non- esencial metals, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCPs) were carried out in sediments and the macrophyte Spartina densiflora. Well-known polluted areas were sellected: Bahia Blanca estuary- Argentina (BB), the mouth of Saco da Mangueira of Lagoa Dos Patos- Brazil (LPII) and Lenga estuary- Chile (LEN). Non or low polluted areas were Mar Chiquita coastal lagoon- Argentina (MCH), the west coast of the Lagoa Dos Patos- Brazil (LPI) and Raqui estuary- Chile (RAQ). In addition, activities of glutathione- S- transferases (GST), catalase (CAT) and guaiacol-peroxidases (POD); total antioxidant capacity (ACAP) and malondialdehide content were measured in roots and leaves of S. densiflora. As it was expected, BB, LPII and LEN showed high levels of pollutants than MCH, LPI and RAQ, respectively. Lead dominated in most of the sediments and plants tissues, with the exception of LEN estuary in which a predominance of mercury was detected. Higher PAHs concentrations were detected in sediments from LPI and roots from LPII. In general, PAHs with 3, 4 and 5 rings predominated in both matrices. The higher total PCBs and OPCs concentrations were detected in LPII followed by BB and LEN. In sediments from Argentina and Brazil endosulfan was the main compound detected while in Chile PCBs and DDTs dominated. Roots from MCH showed the highest concentration of endosulfan, followed by LEN and LPII. Comparing estuarine sediment levels with some Sediment Quality Guidelines (SQG) showed that LEN exceded some effect levels in mercury concentrations mainly. Some clear patterns in biomarkers were observed; lower CAT activity in LPII than in LPI and lower GST activity in BB than in MCH. On the other hand, POD activity and ACAP in roots and leaves were higher in LPII than in LPII. Statistical analysis showed a positive correlation between the concentrations of organic pollutants with POD activity in roots and leaves.

TP317 Quantitative direct injection method and stability study for the detection of sodium fluoroacetate (Compound 1080) and methyl fluoroacetate in water

E. Parry, USEPA / Threat Consequence Assessment Division; S. Willison, USEPA / National Homeland Security Research Center

To support large scale environmental responses, the United States Environmental Protection Agency (EPA) established the Environmental Response Laboratory Network (ERLN) to serve as a national network of laboratories. The ERLN provides coordinated analytical capabilities and capacities, while ensuring quality data, during a large scale response effort. The EPA's Homeland Security Research Program developed and updates the Selected Analytical Methods for Environmental Remediation and Recovery (SAM) to provide the ERLN with recommended analysis methods for priority chemicals, radioisotopes, pathogens and biotoxins in different environmental matrices. Two priority chemicals, sodium fluoroacetate (Compound 1080, FAA) and methyl fluoroacetate (MFA), lack established, validated methods for water samples. These compounds are toxic vertebrate poisons that could contaminate water supplies and cause widespread harm. This research presents a direct injection liquid-chromatography tandem mass spectrometry (LC-MS/MS) method for analysis of FAA and MFA in water. The detection limits are compared to toxicity threshold values to ensure protection of human health and the environment during an incident. Several water sources will be used to evaluate matrix effects, method interferences, and investigate compound stability in water. The developed method will utilize equipment that is widely available, and possess high throughput capabilities, to assist with lab capacity and capabilitiy issues that arise during large scale remediation incidents.

TP318 Residual characteristics of spirotetramat and its metabolites in dried Angelica gigas Nakai

J. Lee, H. Noh, H. Park, Chungbuk National Univ; H. Jeong, Chungbuk National Univ / Agricultural Chemistry; M. Jin, Chungbuk National Univ; S. Hong, Natinal Academy of Agricultural Science / Chemical Safety; K. Kyung, Chungbuk National Univ

This study was carried out to determine residual characteristics of spirotetramat and its metabolites, BYI08330-enol, BYI08330-ketohydroxy, BYI08330-monohydroxy, and BYI08330-enol-glucoside in Angelica gigas Nakai with UPLC-MS/MS. Commercial spirotetramat (22% SC) which was diluted 2,000 times was sprayed onto the crop two or three times. Samples harvested were dried for 10 days under sunlight and then done again with hot-air oven at 50? for 60 hours. Recovery of the residues in the crop ranged from 72.7% to 108.0%. Amounts of spirotetramat, BYI08330-enol, and BYI08330-monohydroxy were less than their LOQ (0.01 mg/kg) in the dried crop. BYI08330-ketohydroxy, metabolite of BYI08330-enol, found to be from 0.02 to 0.10 mg/kg. Also, BYI08330-enol-glucoside, another metabolite of spirotetramat, found to be 0.02-0.06 mg/kg in the dried crop. Total amount of spirotetramat including its metabolires ranged from 0.04 to 0.21 mg/kg in dried crop sprayed two or three times.

TP319 Screening for Perfluoroalkyl Substances (PFASs) in Wildlife Using a Highly Sensitive LC-QTof MS

K.J. Rosnack, Waters Corporation / Food Env Business Operations; L. Mullin, Waters Corporation; I. Ericson Jogsten, MTM Research centre Örebro Univ

Perfluoroalkyl substances (PFASs) encompass a range of fully fluorinated alkyl compounds, typically with an anionic end group. These compounds have been implemented in a range of consumer goods and industrial processes due to their hydro- and lipophobic properties. As a result of their widespread use and subsequent leaching from materials, they have been found in various environmental and biological samples. For monitoring and research purposes, sub-ppb detection of these compounds is often required, in particular for water analysis. Traditionally, this type of analysis has been performed using the selective MRM approach on a tandem quadrupole MS. However, the ability to look for other contaminants of concern after the time of analysis or matrix components such as co-extracted bile acids supports the use of QTof MS. For 11 carboxylic and sulfonic acid PFASs, instrumental performance with respect to determination of limits of detection (LOD; peak-to-peak S/N 1:3) and quantification (LOQ; peak-to-peak S/N 1:10) and linear dynamic range were carried out with solvent standards. Exact mass fragment ion information was also obtained, where at least two ions were observed for each compound. As a result of full spectral acquisition, the entirety of the fragmentation pathways of analytes of interest can be obtained. Diluted mink liver extracts were also analyzed using this method. Samples were prepared with minor modifications according to Kärrman et al. Various PFASs including PFHpS, PFHxS, PFBS, PFOS, PFDS and PFNA in detected levels ranging from 0.2-0.8 ng/mL (without dilution and sample mass correction). In addition to isolating the PFASs of interest, the extraction method also will result in the co-extraction of the bile acid taurodeoxcyholate (TDCA), which co-elutes chromatographically with PFOS. This can result in a very large peak in the analysis, but using exact mass measurements afforded by Tof MS, can be easily distinguished from PFOS.

TP320 Strategic planning of studies to evaluate controls on mercury bioavailability and use of in-situ amendments in tidal marshes of Berry's Creek, NJ

S.S. Brown, The Dow Chemical Company / Environmental Remediation and Restoration; B. Henry, Anchor QEA; S. Kane Driscoll, Exponent Inc.; C.C. Gilmour, Smithsonian Env. Research Center; U. Ghosh, Univ of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering; J.A. Steevens, USGS / Environmental Laboratory

Berry's Creek (New Jersey, USA) is an urbanized tidal tributary to the Hackensack River which is, in many ways, characteristic of urbanized tidal creek-marsh systems dominated by Phragmites. The detrital food web supports mummichogs and white perch, and the bird community includes sandpipers, red-winged blackbirds, and herons. Studies by university researchers and others from the 1980s through early 2000s observed that mercury (Hg) bioavailability (i.e., net methylation, bioaccumulation) is limited despite quite elevated concentrations of inorganic Hg in Berry's Creek sediments. Beginning in the mid-2000s, we initiated a series of question-driven studies to better understand factors controlling mercury geochemistry, bioavailability, and bioaccumulation in Berry's Creek marshes. In parallel, we conducted studies to evaluate the potential efficacy of in-situ carbon-based sediment amendments to reduce risks in these marshes. These studies were completed as part of an RI/FS under Superfund and involved collaborative participation by academic, private sector, and government scientists. The basic science underlying this work was driven by "top-down" questions intended to help inform risk-based natural resource management decisions. Parallel and sequential studies were carried out in the laboratory and marsh plots to investigate relationships between marsh soil redox and Hg speciation, ligand binding, net methylation, sediment/porewater partitioning of Hg and methyl mercury, biouptake, and the effect of activated carbon on partitioning and Hg biouptake. This presentation focuses on the thought process, healthy debate, and iterative and adaptive learning that went into the planning and implementation of these studies, which collectively help to answer the question Why is mercury bioavailability and bioaccumulation limited in tidal marshes of Berry's Creek, New Jersey?.

TP321 Targeted and Non-Targeted Analysis in a Single Data Acquisition using a Novel Benchtop GC-ToFMS

J.D. Byer, L. Fell, LECO Corporation; J.E. Binkley, LECO Corporation / Separation Science Applications

As the number and volume of synthetic organic chemicals produced in commerce increases, so does the demand for a practical means to chemically characterize the components in environmental matrices. Non-target analysis provides a broader scope of chemical characterization than targeted analysis, however, targeted methods are still required for quantitation to determine compliance with regulatory guidelines. Here, we present the utility of a new benchtop gas chromatography – time of flight mass spectrometer (GC-ToFMS) to perform concurrent target and non-target analysis on the same sample for a variety of environmental applications including pesticides, EPA 8270, and disinfection byproducts in drinking water. Since GC-ToFMS can be used to acquire full mass range data with every acquisition, with minimal spectral skewing and without a reduction in sensitivity, targeted masses can be selected from the full mass spectra for quantitation, while at the same time full mass spectra can be used to library match non-targeted spectra for qualitative analysis. This enables the user to perform retrospective analysis of archived data to track historic trends and identify potentially new chemicals of concern in environmental matrices.

TP322 Temporal and spatial trends in DDx/DDT ratios in nestling bald eagle plasma from Michigan, USA from 1999-2016

M.E. Barton, Univ of Maryland, College Park / Dept of Environmental Science and Technology; H.T. Pittman, L. Fuentes, Univ of Maryland / Dept of Environmental Science and Technology; K.L. Simon, Univ of Maryland, College Park / Environmental Science and Technology; R. Eberius, W.W. Bowerman, Univ of Maryland / Dept of Environmental Science and Technology

Bald eagles are top-level predators and important sentinel species for exposure to organochlorine pesticides including dichlorodiphenyltrichloroethane (DDT) and its main metabolite dichlorodiphenyldichloroethylene (DDE). DDT and DDE have been measured in nestling bald eagle plasma from Michigan using solid phase micro extraction and gas chromatography. Plasma samples were collected fron 1999 through the 2016 field seasons ranging throughout the state of Michigan. The five congeners analyzed are 4,4'-DDT, 4,4'-DDE, 4,4'-dichlorodiphenyldichloroethane (DDD), 2, 4'-DDT, and 2,4'-DDE. 4,4'-DDE comprised the majority of total DDT in all samples, ranging from 78-100%. The areas from which the samples were collected were divided according to areas on one of the Great Lakes vs. inland areas, the Upper Peninsula vs. Lower Peninsula, what lake they were nearest, and finally what drainage basin they were associated with if they were inland. Preliminary results show that plasma concentrations from inland birds are lower (9.43 ul/mL) than birds associated with one of the Great Lakes (21.96 ug/mL). Further analysis will focus on 5-year and annual trends in total DDT and DDx/DDT ratios across regions. Additionally, important biological factors such as proximity to an anadromous fish source will be taken into consideration. These data will indicate localized rates of metabolism and the exposure of bald eagles to the DDT and the important metabolites.

TP323 The uptake of several short and long-chain Perfluorinated compounds (PFCs) in foodstuff crops

S. Lasee, Texas Tech Univ/TIEHH / Dept of Environmental Toxicology The Inst of Environmental and Human Health TIEHH; J. Jordan, S. Subbiah, Texas Tech UnivThe Inst of Environmental and Human Health; T. Anderson, South Central Regional Chapter / Dept of Environmental Toxicology The Inst of Environmental and Human Health

Perfluorinated compounds (PFCs) are incredibly stable environmental contaminants. In 2014, the United States Environmental Protection Agency labeled perfluorooctanoic acid and perfluorooctanesulfonic acid, the most persistent and toxic PFCs, as emerging contaminants due to their persistence in the environment. Data from animal studies on perfluorinated compounds indicate that they can cause several types of tumors, neonatal death, and may have toxic effects on the immune, liver, and endocrine systems. While many studies have evaluated the fate of PFCs in aquatic environments, the objective of this study was to determine PFC levels taken up by vegetation under a maximum availability scenario for a terrestrial environment. We grew carrots (Daucus carota), radishes (Raphanus sativus), and wheat (Triticum aestivum) in laboratory grade sand. Sand was chosen due to its low organic carbon content making PFC bioavailability highest. Plant specimens were grown in 200 g of sand contaminated with 10 ng/g (10 ppb) of either perfluorooctanoic acid (PFOA), perfluorohexanesulfonic acid (PFHxS), perfluorobutanesulfonic acid(PFBS), perfluorononanoic acid, or perfluoroheptanoic acid; five PFCs that are currently or previously used in manufacturing and vary in chemical chain length. The plants were watered as needed with nutrient solution and allowed to mature (roughly 60 d). PFC concentrations in plants were determined by LC-MS in an effort to calculate root, stem, leaf, and seed/fruit bioconcentration factors under this scenario. Our pilot study found PFOA whole plant bioconcentration factors ($[PFC]_{plant}/[PFC]_{soil}$) to be around 8 for carrots, 28 for radishes, and 20 for wheat. Bioconcentration factors for PFHxS were approximately 11 for carrots, 58 for radishes, and 35 for wheat. PFBS bioconcentration factors were approximately 54 for carrots, 65 for radishes, and 233 for wheat.

TP324 Trace metal accumulation in tissues of Tilapia nilotica and its relation to calculated free metal ions

C. Ponce de Leon, M. Hernández, Universidad Nacional Autonoma de Mexico / Facultad de Ciencias

Heavy metal pollution in rivers has become a matter of great concern, not only because of the threat to public water supplies but also due to damage to fishery resources for human consumption. Metals such as Fe, Cu, Zn are essential for its important role in biological systems, while Pb and Cd are not essential, and even toxic at trace levels. Studies on bioaccumulation of contaminants in fish are important to determine the tolerance of fish species, the effects of specific contaminants in fish and bio magnification through the food chain. Bioaccumulation differs even in the same fish species and is given by external influences such as sampling location, season, preferences in diet and body size. Likewise, different organs accumulate metals at different levels. The liver and gills are metabolically active organs, which are targets for the accumulation of metals, while accumulation in muscle tissue is smaller. Great efforts have been made to predict and explain these metal accumulation; nevertheless this has not been accomplished. The present work attempts to correlate the metal accumulation in Tilapia nilotica in a fresh water system with high metal concentration and high organic carbon content. WHAM calculations were made for free metal concentrations in the studied system and correlated to the organism's metal accumulation. Also, PCA analysis was made to associate the metal pattern accumulation.

TP325 Trend of PBDEs in Northern California Pregnant Women

J. Frankenfield, Public Health Inst / Environmental Chemistry Laboratory; G. Yeh, Public Health Inst / California Dept of Toxic Substances Control Environmental Chemistry Lab; Y. Wang, E. Parry, California Environmental Protection Agency / Dept of Toxic Substance Control Environmental Chemistry Laboratory; J. Park, California Environmental Protection Agency / Dept of Toxic Substances Control Environmental Chemistry Laboratory; T. Woodruff, Univ of California, San Francisco

Polybrominated diphenyl ethers (PBDEs) are components of flame retardant mixtures, which are used in a variety of products including textiles, furniture, and building materials; technical mixtures pentaBDE and octaBDE were banned in 2004 and decaBDE was voluntarily phased out in 2013. PBDEs have been found to be hormone disruptors, especially of estrogen and thyroid hormones, which can be particularly problematic during fetal development. Thus, this study focuses on how phase-out of these technical mixtures has affected PBDE levels found in second trimester pregnant women and their developing fetus(s). Three matrix types were investigated: fetal liver, placenta, and maternal blood serum. Sample collection occurred in 2015-16. To facilitate statistical comparison, women were of similar demographics to the previous studies conducted in 2008-9, 2011-12, and 2013-2014. The liver and placenta samples were analyzed for PBDEs using manual liquid-liquid extraction, while the serum samples were prepared via solid phase extraction utilizing RapidTrace® Solid Phase Extraction (SPE) Workstation. All extracts were quantitated using isotope dilution on a gas chromatograph coupled with high resolution mass spectrometer (GC-HRMS). A previous phase of this study reported a significant drop (39%) in PBDEs (sum of BDE-28, -47, -99, -100, and -153) between 2008-9 and 2011-12. We will investigate whether that trend has continued or has leveled off as observed with past persistent organic pollutants. Results from this study will add to collective biomonitoring data and help track the long term behavior of these pollutants in the human body and environment.

Climate Change and Water Resource Management: An Ever-Changing Challenge

WP001 Freshwater Rhodophyta and Climate Change: Assessment of photosynthetic performance by the chlorophyll a fluorescence method

L. Kortz Vilas Boas, R. de Campos Oliveira, C. Branco, Univ ESTADUAL PAULISTA – UNESP / Dept of Biological Sciences

Over the last decades there has been a growing concern on evaluating the human influence on Earth's climate. Considering that lotic ecosystems will also suffer effects from anthropogenic climate change, studies on the impact of temperature rise related to Climate Change on lotic primary producers are necessary to have a broader understanding of such effects in these ecosystems. Therefore, we evaluated the effects of temperature increase predicted by two scenarios (RCP 4.5 and RCP 8.5) from the Intergovernmental Panel on Climate Change (IPCC) on the photosynthetic performance of the macroalgae Sirodotia delicatula (Rhodophyta) and its respective "Chantransia" stage, which have been described as important primary producers in shaded tropical streams. We evaluated the photosynthetic performance by chlorophyll a fluorescence technique. Control treatment temperatures for summer (23ºC) and winter (20.8ºC) were determined based on direct measurements of streams from which algal samples were collected. Experimental temperatures were calculated based on seasons control temperatures and the projections proposed by the IPCC. Thus, the summer experimental temperatures defined for RCP 4.5 and RCP 8.5 treatments were, respectively, 25.3ºC and 27.4ºC, while the winter experimental temperatures were of 23.1ºC and 25.2ºC, respectively. S. delicatula showed that the projected increment in temperatures in both IPCC scenarios resulted in no significant change in photosynthetic yields (YII), with only a slight negative variation in nominal values for experimental temperatures in relation to control for both summer (RCP 4.5: -0.48% and RCP 8.5: -4,72%) and winter seasons (RCP 4.5: -15,04% and RCP 8.5: -15,44%). Despite few effects on YII, the RCP 8.5 summer treatment showed a significant increase in non-regulated energy loss (Y(NO)), suggesting that this scenario could cause damage in the photosynthetic apparatus. Although YII of "Chantransia" stage had showed narrow variation in all treatments of both IPCC scenarios, a very significant reduction in YII was observed under RCP 8.5 in summer (-95% in relation to control), indicating that this macroalgae could lose its photosynthetic efficiency in this temperature. From an ecological view, the results showed that the worst IPCC scenario tested could jeopardize the productivity of S. delicatula, both gametophyte and "Chantransia" stage, leading to a reduction in the autochthonous input of energy by this species in tropical streams.

Fate, Toxicology, or Risk Assessment of Materials of Interest to the Military

WP002 Risk Management of Perchlorate Is Influenced by Surface Water Properties That Mediate Amphibian Toxic Response

B. Mulhearn, Ensafe Inc.; P.N. Smith, Texas Tech Univ / Environmental Toxicology

As part of the investigations at the former Naval Weapons Industrial Reserve Plant (NWIRP) near McGregor, Texas and nearby offsite properties, an ecological risk assessment evaluated the risk from historical site contaminants to multiple species. Amphibians were identified as a critical species, and a literature-based screening concentration of 0.06 mg/L perchlorate was identified for surface water. Suitable breeding habitats were identified at and in the vicinity of NWIRP McGregor, so sublethal toxicity testing of Spea multiplicata, a species native to the region, was performed to determine the No Observed Adverse Effect Concentration in surface water. Using surface water collected from the vicinity of NWIRP McGregor and perchlorate concentrations of 0.06, 0.11, and 1 mg/L, no effect was observed (Brausch et al, Chemosphere, 2010). Follow-up toxicity testing using Xenopus laevis confirmed the mediating effects of the surface water. Concentrations above 1 mg/L may be more important when attempting to optimize remedial treatment systems. Native species, surface water collected from the vicinity of NWIRP McGregor, and perchlorate concentrations of 1.2, 1.7, 3.0, 5.1, and 8.0 mg/L are being tested to bound the initial study that will be used in optimizing the remediation system and in evaluating future surface water results.

WP003 Comparative toxicogenomics study on the three insensitive munitions constituents DNAN, NQ and NTO in the soil nematode Caenorhabditis elegans

P. Gong, K.B. Donohue, US Army Engineer Research and Development Center / Environmental Laboratory; A.M. Mayo, Badger Technical Services, Inc.; M.S. Wilbanks, US Army Engineer Research and Development Center / Environmental Lab; N.D. Barker, X. Guan, Bennett Aerospace, Inc.; K.A. Gust, US Army Engineer Research and Development Center / Environmental Laboratory

Ecotoxicological studies on the insensitive munitions IMX-101 and its components 2,4-dinitroanisole (DNAN), nitroguanidine (NQ) and nitrotriazolone (NTO) in various organisms (e.g., fathead minnow Pimephales promelas, the earthworm Eisenia fetida and the freshwater amphipod Hyalella azteca) showed that DNAN was the main contributor to the overall toxicity of IMX-101 and the three compounds might act independently. These results motivated this toxicogenomics study that aimed to discern toxicological mechanisms for these compounds at the molecular level. Here we used the soil nematode Caenorhabditis elegans, a well-characterized genomics model organism, as the test organism and a species-specific, genome-wide 44K-oligo probe microarray for gene expression analysis. In addition to the control treatment, C. elegans were exposed for 24 hours to 6 concentrations of DNAN (1.9-62 ppm) and NQ (83-2667 ppm) or 5 concentrations of NTO (187-3000 ppm) with ten replicates per treatment. The nematodes were moved to a clean environment after exposure. Reproduction endpoints (egg, larvae and offspring counts) were measured at three time points (i.e., 24-, 48- and 72-hr). Gene expression profiling was performed immediately after the 24-hr exposure for each chemical at the lowest, medium and highest concentrations plus the control with four replicates per treatment. Statistical data analysis suggested that chemical treatment did not significantly affect nematode reproduction but did induce 378, 2175 and 118 differentially expressed genes (DEGs) in DNAN-, NQ- and NTO-treated nematodes, respectively. Bioinformatic analysis indicated that the three compounds shared very few DEGs and Reactome-curated biological pathways. Gene set enrichment analysis further demonstrated that DNAN, NQ and NTO significantly altered 20, 84 and 7 unique pathways, separately. Despite the absence of significant reproduction effects, this study provided supporting evidence that the three chemicals, if mixed (e.g., in IMX-101), may exert additive toxicity by independently acting on distinct molecular targets and pathways. Our research findings may be extrapolated to other environmentally relevant species and hence have important implications on environmental risk assessment of materials of military interests.

WP004 Biotransformation of the insensitive munition 5-nitro-1,2,4-triazol-3-one (NTO) in soil

C.L. Madeira, S.A. Speet, Univ of Arizona / Chemical and Environmental Engineering; L.M. Abrell, Univ of Arizona / Soil Water Environmental Science; J. Chorover, Univ of Arizona / Soil Water and Environmental Science; R. Sierra-Alvarez, J.A. Field, Univ of Arizona / Chemical and Environmental Engineering

Insensitive munitions, such as 5-nitro-1,2,4-triazol-3-one (NTO), are being considered by the U.S. Army as replacements for conventional explosives due to their improved ability to withstand unintended detonations. Environmental emissions of NTO are expected to increase as the use of this new class of explosives becomes widespread. However, the fate of NTO in the environment is not well understood. In this study, the transformation of NTO in soil was investigated in batch bioassays under different redox conditions (i.e., anaerobic, aerobic and sequential anaerobic-aerobic). Under anaerobic conditions, NTO undergoes a microbial reduction to 3-amino-1,2,4-triazol-5-one (ATO) when utilizing pyruvate as a electron donor. However, ATO biodegradation was only observed after the redox condition was switched to aerobic. Abiotic controls using sterilized soil demonstrated that NTO persisted in the environment in the absence of microorganisms, indicating that biological activity plays an important role on NTO transformation in soil. ATO-degrading enrichment cultures were derived from an initial culture containing soil, mineral medium and ATO. After multiple transfers (10% v/v), ATO mineralization was investigated through measurements of CO_2 in the headspace and inorganic nitrogen ions in the liquid phase. The results indicate extensive mineralization of ATO, since approximately 100% of CO_2 and approximately 50% conversion of nitrogen to inorganic ionic N species were observed. The results obtained in this research suggest that NTO mineralization can be achieved through a sequential anaerobic-aerobic approach, decreasing the risks of this compound to the ecosystem and to public health.

WP005 Dissolution of insensitive munition constituents and their fate and transport in soils

K. Dontsova, Univ of Arizona / Biosphere; S. Taylor, Cold Regions Research and Engineering Laboratory; R. Pesce-Rodriguez, Army Research Laboratory / Weapons and Materials Research Directorate; M. Brusseau, Univ of Arizona / Soil Water and Environmental Science; J. Simunek, Univ of California, Riverside / Dept of Environmental Sciences; J. Arthur, N. Mark, Univ of Arizona / Soil Water and Environmental Science

Insensitive munitions (IM) were developed to prevent unintended detonations. 2,4-dinitroanisole (DNAN) and 3-nitro-1,2,4-triazol-5-one (NTO) are two new energetics which together with nitroguanidine (NQ), and hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) are used in IM formulations IMX-101 and IMX-104. Quantifying both their release from the formulation particles and their further environmental fate is critical for estimating risk for humans and ecosystems. We are presenting updates from our project where dissolution of IM particles and change in their structure was measured in the lab; their dissolution and phototransformation under different climatic conditions quantified, and products characterized; and adsorption measured for a wide array of soils. We also estimated transport of these compounds in soils by adding aqueous solutions or IM particles to the soils and measuring patterns of release and transport. We observed that IM constituents dissolved sequentially as predicted by solubility, first NTO, followed by NQ, and DNAN in IMX-101, and DNAN and RDX in IMX-104, a sequence that can be expected under field conditions. Fast removal of the soluble components resulted in porous particles that crumbled, further enhancing dissolution. About 65% of particle mass was dissolved in a little more than two years. The change in color of the particles exposed to sunlight and the detection of compounds not present in formulations indicated the occurrence of phototransformation. Due to the faster dissolution of IM formulations only about 19% of mass loss could be attributed to phototransformation, less than for traditional explosives. As NTO adsorption in soils was low when particles were dissolving very high peak concentrations of NTO were observed traveling through soils with little to no retardation. With time concentrations decreased and continued at a relatively constant rate. A similar pattern but lower concentrations were observed for NQ, while DNAN and RDX had lower concentrations in leachates that did not change over time and were delayed relative to NTO and NQ due to soil adsorption. The fast dissolution of NTO and its low attenuation in soils indicate high risk of its transport to the ground and surface waters, whereas DNAN slower dissolution and soil adsorption indicate lower potential for off-site transport.

WP006 Wash-off Coefficients of Chemical Warfare Agent (VX) from Foliar Surfaces of Living Plants

M. Simini, US Army Edgewood CB Center / Environmental Toxicology; M. Haley, R. Checkai, US Army Edgewood Chemical Biological Ctr / Molecular Toxicology Environmental; R. Lawrence, US Army Edgewood Chemical Biological Ctr; M. Busch, Excet Corporation

Defensive capabilities are needed to identify threats in the event of the release of Chemical Warfare Agent (CWA) into the natural environment. A CWA disseminated in the field can follow many pathways that affect its fate, which may ultimately result in exposure hazards. An important exposure pathway is the CWA–plant interface. Persistence, penetration (absorption), or evaporation of agent droplets on foliage depends on many factors including vapor pressure, the hydrophilic nature of the CWA, and the extent of hydrophobicity of foliar surfaces. Our objectives in the present study are to determine if rainfall reduces the exposure hazard to the warfighter by decreasing the amount of CWA available on the leaf surface for transfer by contact, and provide data for predictive models to estimate the environmental fate of CWA and related chemicals. We experimentally established wash-off coefficients (kw) for the CWA O-Ethyl-S-(2-diisoproylaminoethyl) methyl phosphonothiolate (VX) on grass (Echinochloa crus-galli), in separate replicated experiments utilizing 1 and 3 µL VX droplets, at 0.017 (1min), 1, and 4h post-dissemination. A 10mm (0.39”) rain event at 0.017h post-dissemination washed off 95% (1 µL droplets) and 83% (3 µL droplets) of the VX, respectively. However, VX readily absorbed into leaves, and at 1h post-dissemination, a 10mm rain event washed off 0.03 and 0.5%, respectively, of 1 and 3 µL VX droplets. The kw values for 1 and 3 µL droplets, respectively, at 0.017h post-dissemination are 0.095 and 0.083 mm-1. At 1 and 4h post-dissemination, kw values were approximately 3 orders of magnitude less than those at 0.017h. We also exposed grass contaminated with 3µL VX droplets to multiple (10x) light rain events (100µL) followed by multiple (10x) surface wipes, at 0.017, 0.5, 1, 4, and 24h post-dissemination. The cumulative proportions of 3 µL VX droplets washed off at 0.017 and 1h post-dissemination were 75.3 and 0.99%, respectively, whereas the respective cumulative proportions of VX that were wiped off following those rain events were 0.8 and 0.3%. Based on these results, the majority of the VX on grass (approx. 75-95%) can be removed by wash-off from a moderate rainfall (≥0.6mm), or with excess water, within minutes post-dissemination of VX; however, the hazard is then transferred to the water and soil. Results from these investigations provide functional information for Go/No Go decisions affecting Soldiers on CWA-contaminated battlefields.

WP007 Laboratory Hood Culture of Terrestrial Plants for Investigations Involving Highly Toxic Materials

R. Checkai, US Army Edgewood Chemical Biological Ctr / Molecular Toxicology Environmental; M. Simini, US Army Edgewood CB Center / Environmental Toxicology; M. Haley, US Army Edgewood Chemical Biological Ctr / Molecular Toxicology Environmental

Field investigations suffer from an inability to adequately control inherently unstable ambient variables. Standardized plant tests conducted under controlled environmental conditions allow investigation to focus on factors that directly affect critical parameters. However, it is necessary to maintain normal plant physiological responses in order to obtain results applicable to the field. We successfully sustained healthy living plants within laboratory hood constraints, and safely disseminated highly toxic compounds onto individual mature leaves of intact living plants. Traditional plant culture in growth chambers or greenhouses typically involves balancing heat loads with large chilling units too cumbersome for most laboratory hoods. Recent technological advances in blue light-emitting diodes (LED) now permit delivery of high-quality photosynthetically active radiation (PAR) in sufficient quantity to maintain plant physiology and sustain extended culture of healthy terrestrial plants. We installed and tested a lighting system consisting of improved LEDs to provide PAR in a laboratory surety hood. Environmental conditions in the hood were: PAR illumination >300 umoles cm^2 sec^{-1}, 16h-light/8h-dark;

22°C ±2; relative humidity >50% ±10; air flow 1.5mph ±0.09. We selected the grass E. crus-galli as the plant for method development and subsequent research. Grass is the most prevalent higher plant worldwide, and the natural distribution of E. crus-galli is one of the largest. We constructed stands with adjustable rings to hold plant containers in a fixed position, with petri dishes below each container for consistent bottom-up irrigation. Individual leaves were secured in a horizontal position onto rings by lengths of cellulose acetate tape folded onto itself, then placed across the leaf surface, thus preventing sticky contact, and tape ends were then secured. This prevented leaf damage by tape removal, yet ensured that the disseminated compound contacted the leaf surface at the points intended, and identified those locations for further investigation. Critical parameters successfully established include: characterization of droplet-spread, distribution within leaves as a function of time, coefficient of wash-off from measured rainfall, Effective Half-Life, Contact Transfer (exposure) from contaminated foliage. Results comport with those from field studies, thus allow standardized comparisons among compounds, plant effects, and respective corresponding hazards.

The Role of Stressors for Species Interactions and Food Webs

WP008 Stress response in round stingrays exposed to environmental PCBs along the southern California coast

K. Lyons, Univ of Calgary / Dept of Biological Science; M.M. Vijayan, Univ of Calgary / Biological Sciences

Stress response impairment due to environmental contaminant exposure has been documented in a variety of organisms; however, little research has investigated these types of effects in elasmobranch fishes. Round stingrays (Urobatis halleri) sampled from mainland California (Long Beach) had significantly higher hepatic PCB levels than stingrays from a nearby offshore island (Catalina). We tested the hypothesis that higher PCBs body burden will compromise the stress response in this species. Stingrays were collected via hook and line from these two locations and plasma was sampled either immediately or 15 min after a confinement stressor. Our results support the hypothesis that Catalina rays showed a corticosteroid response, while this conserved response was attenuated in the mainland rays. Also, liver glucose and glycogen content were lower in the stressed mainland stingrays compared to the Catalina rays. Overall, PCB contamination reduces the capacity to elicit a physiological stress response in the round stingrays. This study was supported by NSERC, Canada, Discovery Grant to MMV and a Vanier PhD Scholarship to KL.

WP009 Influence of Manatees' Diving on Their Risk of Collision with Watercraft

A. Smith, Ramboll E&H / Ecology and Sediment Management; H. Edwards, Florida Fish and Wildlife Conservation Commission / FWRI; J. Martin, USGS / Wetland and Aquatic Research Center; C. Deutsch, B. Muller, S. Kovslovsky, M. Barlas, Florida Fish and Wildlife Conservation Commission / FWRI

Collisions with watercraft account for approximately one quarter of Florida manatee (Trichechus manatus latirostris) deaths annually. Reducing the effects of this environmental stressor on this endangered subspecies is an important management goal. To assess risk factors that contribute to watercraft-related injury to manatees, we studied the dive behavior of nine manatees carrying GPS tags and time–depth recorders in Tampa Bay, Florida, during winters 2002–2006. We applied a Bayesian formulation of generalized linear mixed models to depth data to model the probability that manatees would be no deeper than 1.25 m from the water's surface as a function of behavioral and habitat covariates. Manatees above this threshold were considered to be within striking depth of a watercraft. Roughly three quarters of the depth records were within striking depth and strike risk was higher in shallow water, over seagrass, at night, or while stationary or slow-moving. They were less likely to be within striking depth when located 50 meters or less from a charted waterway. The probability of a manatee being within striking depth decreased as water depth increased. Strike probability was greater when the manatees were located within seagrass beds. Finally, in some circumstances, manatees made consecutive dives to the bottom while traveling, even in areas >14 m, possibly to conserve energy. This is the first documentation of potential cost-efficient diving behavior in manatees.

WP010 Monitoring changes in fish community composition relative to the occurrence of an extended harmful algal bloom/seagrass die-off event

D. Adams, Cape Canaveral Scientific, Inc.; R. Paperno, A. Sebastian, Florida Fish and Wildlife Conservation Commission/FWRI

A series of massive phytoplankton blooms (superbloom) beginning in early 2011 triggered habitat changes, most notably a loss of seagrass, throughout much of the Indian River Lagoon, Florida (IRL). The superbloom and subsequent habitat loss prompted a multi-agency effort to investigate and monitor the impacts of the resultant changes to the IRL ecosystem. The superbloom, which extended from southern Mosquito Lagoon to Ft. Pierce Inlet, had a significant impact on seagrass beds in subsequent years (up to 100% loss in some transects) in all three IRL sub-basins. Comprehensive and standardized fisheries data were used to compare with conditions prior to the superbloom as well as to analyze trends in relative fish abundance. In general, the observed decline in drift algal habitat, which was below the long-term average during the superbloom, has improved in post-bloom years. Fish health issues (e.g. lesions, parasites) increased during and after the superbloom. There were significant differences in community metrics among the pre-bloom, bloom, and post-bloom years. Relative abundance of most small-bodied/cryptic species and juveniles of several sciaenids (drums, croakers, etc.) declined during the bloom year. In contrast, sub-adult and adult relative abundance of these sciaenid species increased during the bloom year. A mixed response from certain planktivorous taxa was observed. Juveniles of some taxa (e.g., Spotted Seatrout, Pinfish) may have compensated for the loss of seagrass and drift algae habitat by utilizing tributaries and other alternate habitats in affected areas.

WP011 Bioaccumulation and trophic transfer of permethrin in pyrethroid-resistant Hyalella azteca

K. Huff Hartz, Southern Illinois Univ / fisheries; S. Nutile, Southern Illinois Univ Carbondale / Zoology; A. Derby, Southern Illinois Univ / Zoology; J. Heim, Southern Illinois Univ Carbondale / Zoology Fisheries; L. Muggelberg, Sage College of Albany / Dept of Biological Sciences; A. Harwood, Alma College / Environmental StudiesBiology; D.P. Weston, Univ of California / Dept of Integrative Biology; M.J. Lydy, Southern Illinois Univ-Carbondale / Center for Fisheries Aquaculture and Aquatic Sciences

Some field populations of the freshwater amphipod, Hyalella azteca, demonstrate resistance upon exposure to pyrethroid insecticides. Standard toxicity tests show that a resistant population is 53 times less sensitive to the pyrethroid, permethrin, than a non-resistant population, and that the resistance to permethrin is stable even after 16 months of pyrethroid-free culturing. One of the possible consequences of resistance is increased bioaccumulation, which increases the potential for transfer of pyrethroids from the resistant individuals to higher trophic level organisms. In the current study, resistant and non-resistant H. azteca were exposed to ^{14}C-labeled permethrin, and bioaccumulation and biotransformation were quantified. At lower permethrin exposure concentrations, the tissue concentrations and proportion of parent permethrin in resistant and non-resistant H. azteca were similar. As the exposure concentration was increased, the non-resistant H. azteca did not survive, while resistant H. azteca bioaccumulation increased with increasing permethrin concentration. The trophic transfer potential of permethrin via resistant H. azteca was demonstrated by daily feeding of permethrin-exposed H. azteca to fathead minnows (Pimephales promelas). After four days of feeding, the tissue concentrations in the fish reached 476 ng total permethrin/g lipid. Because resistant H. azteca can survive elevated permethrin concentrations, this subsequently increased the risk of permethrin bioaccumulation to fish through trophic transfer. The proportion of parent permethrin decreased from 47% in H. azteca to 33% in the fish tissue, which suggested that the acute toxicity to fish due permethrin is low. However, permethrin and its biotransformation products have sublethal toxic effects on some fish species. These results suggest that pyrethroid-resistance in H. azteca populations may increase fish exposure to permethrin and its biotransformation products, which may impact wild fish populations.

WP012 Mercury Contamination and Thermal Stress Combines to Have Detrimental Effects on Freshwater Mussel-Driven Ecosystems

B.N. Tweedy, C.C. Vaughn, Univ of Oklahoma / Biology

Modern freshwater ecosystems face an ever-growing array of threats and stressors. Among the most widespread are mercury (Hg) contamination, impoundment and flow alterations, and global climate change (GCC). Hg emitted from anthropogenic sources is converted into toxic methylmercury in aquatic ecosystems where it biomagnifies in the foodweb, threatening wildlife and humans, while impoundment, reduced in-stream flow, and GCC can contribute to increased thermal stress in many freshwater ecosystems. We conducted two experiments to test the combined effects of Hg and thermal stress modeled after the mussel-driven ecosystems of southeastern Oklahoma. A laboratory experiment examining the effects of Hg and thermal stress alone and in combination found decreased respiration and clearance rates in some mussel species and high mortality in a thermally sensitive species when exposed to both stressors. This study was followed-up with a mesocosm experiment examining the effects both stressors on communities with and without mussels. Increased mussel mortality was observed again in double stressor treatments for multiple species. Because freshwater mussels contribute significantly to the diversity and functioning of numerous rivers and streams across North America (including food web structure) these findings have important ramifications for management and conservation of these already stressed and imperiled ecosystems.

Toxicity Extrapolations in Aquatic Organisms and Wildlife

WP013 Toxicological estimation of mortality of oceanic sea turtles oiled during the Deepwater Horizon oil spill

C. Mitchelmore, Univ of Maryland Center for Environmental Science / Chesapeake Biological Laboratory; C. Bishop, Calliope Associates; T.K. Collier, Independent Consultant / Oceans and Human Health Program

During the Deepwater Horizon (DWH) oil spill hundreds of externally and internally oiled juvenile oceanic sea turtles were documented and rescued offshore and sent to rehabilitation facilities for treatment and observation. However, the entire Gulf of Mexico was not surveyed and the search effort for exposed turtles was limited to a period covering a few weeks after the spill and before the wellhead was capped. Therefore, the number of sea turtles dying in the wild during the spill or afterward is unknown. As part of the NRDA effort we employed multiple lines of evidence to estimate the mortality of oceanic sea turtles that were minimally to moderately oiled by the 2010 BP Deepwater Horizon (DWH) oil spill in the Gulf of Mexico (GoM). This included using estimates of the oil ingested by oceanic sea turtles that were rescued. As there is limited knowledge on the sensitivity of turtles to oil or the effects of oil spills on reptiles, the oil ingestion estimates were compared to toxic endpoints following oil ingestion in turtles and other vertebrate species so as to derived an estimated percentage of mortality for oil-exposed oceanic sea turtles. Oil ingestion in oceanic sea turtles was estimated based on extent of oiling categories assigned by the sea turtle technical working group (STTWG) (i.e. nonoiled (0); minimally oiled (1), lightly oiled (2), moderately oiled (3) and heavily oiled (4)). Because the STTWG concluded that 100% of heavily oiled turtles would have died from the physical effects of heavy oiling, we limited our assessment of mortality to turtles in categories 0-3, and estimated how many of these turtles would have died from ingestion of oil. We estimated mortality at 85% for category 3, 50% for category 2, and 25% for category 1. Visibly unoiled turtles (category 0) were assigned 0% mortality. To calculate the overall mortality for all turtles the mortality estimations for categories 0-3 were applied to the numbers of turtles observed with different degrees of oiling, as documented by direct capture operations during the DWH spill. We concluded that overall, approximately 30% of all oceanic turtles in the region affected by the DWH spill, that were not heavily oiled, would have died from ingestion of oil.

WP014 Modification in sensitivity of microalgae to 3,4-dichloroaniline. Comparison of exposure as single species or as assemblage of different species

F. Martínez-Jerónimo, Escuela Nacional de Ciencias Biológicas-I.P.N. / Laboratory of Experimental Hydrobiology; S. Guerra-Martínez, Instituto Politécnico Nacional – ENCB

The aromatic amine, 3,4-dichloroaniline (3,4-DCA), is used in the synthesis of azo dyes, bactericides, and herbicides; 3,4-DCA is also a byproduct of biodegradation of herbicides. This amine is very toxic to aquatic biota, being classified as dangerous for the environment. Toxic effects of pollutants in microalgae are frequently assessed in single species tests, but different effects could be expected when algal communities are exposed to toxicants. The aim of this study was to determine if growth inhibition caused by toxics in microalgae changes when algae are exposed collectively including species of different sensitivity. The 96-h median inhibitory concentrations (IC_{50}) for 3,4-DCA were determined in Ankistrodesmus falcatus, Chlorella vulgaris, Pseudokirchneriella subcapitata, and Scenedesmus incrassatulus. After this, 0, 2, 4, and 8 mg L^{-1} 3,4-DCA concentrations were tested in the assemblage of the four microalgal species. Four replicates for each treatment were incubated at 27°C, 83.25 µmol m^{-2} s^{-1} luminous energy, and 120 rpm orbital shaking during 9 days. Daily the cell density of each species was recorded, and for S. incrassatulus the phenotypic plasticity was also documented. The photosynthetic pigments concentration and the main macromolecules were quantified at the end of the assay; SEM and TEM images were also obtained. A. falcatus was the most sensitive species (IC_{50} = 0.38 mg L^{-1}), whereas the most tolerant was S. incrassatulus (IC_{50} = 5.58 mg L^{-1}); P. subcapitata and C. vulgaris showed a similar, intermediate tolerance (IC_{50} = 2.35 and 2.5 mg L^{-1}, respectively). In the algal assemblage (community) experiment, at the end of exposure, C. vulgaris predominated in the control whereas S. incrassatulus was dominant in all the 3,4-DCA concentrations. Toxicant exposure produced morphological changes and altered the structure of cell organelles, as revealed by SEM and TEM analyses. Concentration of photosynthetic pigments, protein, and lipids was also affected significantly. The morphology and number of cells per coenobium in S. incrassatulus was modified, depending on the exposure time and the toxic concentration. The structure of the assembled community provided protection to species and increased their tolerance, as compared to individual exposure. Results demonstrated that assessment of toxic effects of pollutants through single species assays could provide different sensitivity data to those potentially produced in an algal community.

WP015 Toxicity assessment of Congo Red dye using a battery of bioassays (Chlorella vulgaris, Daphnia magna, and zebrafish embryos)

M. Hernández, Instituto Politecnico Nacional / Zoology; F. Martínez-Jerónimo, Instituto Politécnico Nacional ENCB / Dept of Zoology

Azo dyes are widely employed in the textile and paper industries due to their low cost and easy use. Extensive consumption of synthetic dyes produces large volumes of wastewater discharged into aquatic ecosystems. Colored effluents produce toxic effects in the aquatic biota, reduce light penetration in water and alter the photosynthetic activity, causing oxygen deficiency, among other effects. Some dyes, such as Congo Red, are elaborated with benzidine, a known carcinogenic compound. Information regarding dye toxicity in aquatic ecosystems is reduced; therefore, our study was aimed at evaluating the toxic effect of Congo Red on a battery of bioassays: Chlorella vulgaris, Daphnia magna, and Danio rerio. C. vulgaris was exposed to 5, 10, 15, 20 and 25 mg L^{-1} Congo Red, (96 h at 25°C, continuous illumination of 120 µmoles m^{-2} s^{-1}). Daphnid neonates were exposed to 100, 200, 300, 400 and 500 mg L^{-1} Congo Red (48 h at 22°C, light intensity of 120 µmoles m^{-2} s^{-1}, and 16:8 h photoperiod). Zebrafish embryos were exposed to 6.25, 12.5, 25, 50 and 100 mg L^{-1} (96 h at 26 + 1°C, light intensity of 120 µmoles m^{-2} s^{-1},and 16:8 h photoperiod). C. vulgaris was the most sensitive species to Congo Red (IC_{50} = 5.14 mg L^{-1}). The cladoceran D. magna was tolerant to high concentrations of Congo Red, we determined the LC_{50} at non-environmentally relevant concentrations (322.88 mg L^{-1}), but we observed that the digestive tract of test organisms was remarkably red colored, hence toxic effects could be expected at sub-chronic exposures. On the other hand, no lethal effects were observed in Danio rerio embryos at 96 h (according to OECD guideline 236 criteria), but larvae were unable to break the chorion and hatch, even at times as long as 9 days, so they finally died at all tested concentrations. Results demonstrate that Congo Red dye affects diversely organisms of different trophic levels. Particularly, the effects observed in microalgae confirm the vulnerability of primary producers to colored wastewaters because dyes produce toxic effects and interfere with photosynthesis. Obstruction in fish larvae hatching is also a significant consequence that warns about the effects of Congo Red dye in fish. Azo dyes should be considered as emerging pollutants because they are continually discharged into the aquatic environment, and are not currently included in environmental monitoring and regulation programs.

WP016 Exposure to 3,3',4,4',5-pentachlorobiphenyl (PCB 126) Impacts Multiple Organ Systems in Developing Little Skate (Leucoraja erinacea)

R.R. Merson, C. Rei Mohammed, M. Lopes, C. Pendexter, K. Hughes, T.A. Bock, S. Lazar, Rhode Island College / Biology; S. Jayaraman, USEPA; B. Clark, D. Champlin, D.E. Nacci, USEPA / Atlantic Ecology Division

Effects of exposure to coplanar polychlorinated biphenyls (PCBs) and other dioxin-like chemicals on developing vertebrates involve many organ systems, including the skeletal and cardiovascular systems. Apex predators, including those from the class Chondrichthyes (sharks, skates, and rays), accumulate high body burdens of PCBs through biomagnification of chemicals moving through food webs. There are no published reports of the effects of dioxin-like chemicals on the development of sharks, skates, or rays. A study was undertaken to assess developmental effects of 3, 3', 4, 4', 5-pentachlorobiphenyl (PCB 126) exposure in little skate, Leucoraja erinacea, a model for oviparous elasmobranchs. Skate embryos cultured outside of their egg cases were exposed to 0.02 – 20 ng/ml PCB 126 for 6 days and then grown in clean seawater for up to 29 days. Gas chromatography was used to measure PCB 126 in the exposures water and quantify its accumulation in the embryo. Digital still and video imaging was performed to assess growth, identify developmental abnormalities, and cardiovascular function. Embryos accumulated approximately 50% of PCB 126 exposure mass in the embryonic tissues and yolk sac. All embryos in the control and 0.02 ng/ml treatment survived; mortality rates were 14, 52, and 40% of embryos exposed to 0.2, 2.0, and 20.0 ng/ml, respectively. PCB 126 exposure induced yolk sac edema, deformities of the jaw, cranium, and fins, and cardiovascular system failure in skate embryos at all concentrations. This study demonstrates that little skate embryogenesis is sensitive to the toxic effects of PCB 126. Many of the developmental effects of PCB 126 in skate embryos are similar to that observed in other vertebrates, however, the alteration in pectoral fin architecture is novel and may represent disruption of developmental pathways that differ between cartilaginous and bony fish appendages. The research continues to ascertain the no observable effects concentration for PCB 126 and identify sensitive developmental pathways using the little skate model.

WP017 Oxidative stress in the goodeid fish Chapalichthys pardalis induced by exposure to the herbicide glyphosate

L.A. Luna, Escuela Nacional de Ciencias Biologicas, IPN / Zoology; F. Martínez-Jerónimo, Instituto Politécnico Nacional ENCB / Lab de Hidrobiologia Experimental

In Mexico 900 pesticides are currently used, distributed over 260 brands, of which 24 are prohibited in other countries. Herbicides are the pesticides most frequently used in Mexico, being glyphosate the most common because it is cheap and easy to use. Glyphosate is normally mixed with different inert ingredients like haulers, antifreezes, antifoams, dyes and surfactants, which sometimes increase toxicity of the active ingredient. Michoacán is the seventh consumer of pesticides in Mexico, and also it is the habitat of the micro endemic goodeid Chapalichthys pardalis. This fish is distributed in a puddle surrounded by agricultural areas in Tocumbo, Mich. Yet the importance of Goodeidae as an endemic family that includes several endangered species, the effects of herbicides on the antioxidant response is poorly known. For this reason, the objective of this study was to determine the toxicity of glyphosate in the commercial formulation named FAENA^{MR}, and as active ingredient, assessing the effect on the oxidative stress levels in C. pardalis. Adults of C. pardalis were exposed to environmentally relevant concentrations of glyphosate both as the commercial formulation and as active ingredient. The concentration of carbohydrates and lipids, the antioxidant enzymatic activity of superoxide dismutase (SOD), glutathione peroxidase (GPx) and catalase (CAT) were determined; as well as oxidative damage measured as TBARS (related to lipid peroxidation), and protein oxidation; these biomarkers were analyzed in different tissues (gills, liver and muscle). Two-way ANOVA and Fisher LSD test for multiple comparisons were used for data analysis. Higher concentration of TBARS in the three organs was observed in the commercial presentation vs. pure glyphosate (gills 1.657 vs. 0.295, liver 1.597 vs. 0.297 and muscle 0.522 vs. 0.111 nM mg^{-1} of tissue), but no significant differences among concentrations were observed. Gills, liver and muscle showed protein oxidation among treatments ($p < 0.001$) and concentrations ($p < 0.001$). High concentrations of glyphosate in the commercial formulation (>180 mg L^{-1}) increase the protein carbonylation (oxidation). Obtained results confirm that the commercial formulation FAENA^{MR} is more toxic than the pure active pesticide. This herbicide provokes oxidative stress by lipid and protein oxidation in different organs of C. pardalis. The present results warn about the damage associated with the use of this herbicide on endemic fish species.

WP018 Exposure to silver nanoparticles produce effects in physiological biomarkers and modifies the antioxidant response in Chapalichthys pardalis

R.V. García, Instituto Politécnico Nacional-ENCB / Zoology; F. Martínez-Jerónimo, Instituto Politécnico Nacional ENCB / Lab de Hidrobiologia Experimental; A.C. Hernández, Instituto Politécnico Nacional-ENCB / Zoología; E. Martínez Ruíz, Instituto Politécnico Nacional ENCB / Zoology; V. Jarquín Díaz, Instituto Politécnico Nacional ENCB / Dept of Zoology

In recent years, the industry of nanomaterials has become very important in various areas and its applications are still growing in all fields. This has created a great concern about their impacts on the environment. Is expected, that the high production of nanomaterials could increase the levels of its discharges on water bodies, causing adverse effects on the biota. Moreover, it has been documented that metal nanoparticles may represent a potential risk to aquatic organisms since previous studies have reported their capability to cause oxidative stress and morphological alterations in hydrobionts. In Mexico, silver nanoparticles (AgNP) are the most produced and commercialized due to its antibacterial properties; however, no information about its aquatic toxicity, specifically with native species, is available. in this study we evaluated the 96-h acute toxicity of AgNPs (LC_{50}) in adults of Chapalichthys pardalis; after this, subchronic toxicity during 21 days to two sublethal concentrations (equivalent to the LC_1 and LC_{10}) was evaluated through quantification of an array of biomarkers: activity of antioxidant enzymes (SOD, CAT and GPx), lipid peroxidation inferred from the concentration of thiobarbituric acid reactive substances (TBARS), concentration of macromolecules (protein, lipids and carbohydrates), and metabolic parameters (glucose and lactate), on liver, gills and muscle of the goodeid endemic fish Chapalichthys pardalis. The results were analyzed with the Integrated Biomarker Response (IBR). The LC_{50} was 10.32 mg L^{-1}. Results of sub-chronic exposure showed that AgNPs produced oxidative stress in adults of C. pardalis, since decreased activity of antioxidant enzymes, increased levels of TBARS, proteins oxidation, and increased energy consumption were documented. The analysis of IBR evidenced that the greatest effect occurred in organisms exposed to LC_{10}. The gills (IBR = 10.07) and liver (IBR = 5.37) were the tissues that suffered further damage, and the muscle was the less affected (IBR = 2.73). We conclude that the AgNPs are potentially risks to endemic aquatic biota, which could be exposed to xenobiotics because of water pollution.

WP019 Antioxidant and metabolic maternal-embrionary response of Chapalichthys pardalis exposed to 3,4-dichloroaniline

A.C. Hernández, Instituto Politécnico Nacional-ENCB / Zoología; F. Martínez-Jerónimo, Instituto Politécnico Nacional ENCB / Lab de Hidrobiologia Experimental; R.V. García, E. Martínez Ruíz, Instituto Politécnico Nacional ENCB / Zoology; V. Jarquín Díaz, Instituto Politécnico Nacional ENCB / Dept of Zoology

Goodeinae are endemic viviparous fish distributed in the Mexican Central Plateau. The habitat of these fish has been transformed, mainly as result of chemical pollution, but the effect of chemical stress in wildlife has been poorly documented. All Goodeinae fish have evolved an exceptional reproductive mechanism characterized by intra-ovarian gestation, internal fertilization, matrotrophy and the development of trophotaeniae in embryos. The great maternal-embryonic interaction during gestation could increase the risk to the progeny, when adults are exposed to toxicants. The aim of the present study was to determine the maternal-embryonic antioxidant and metabolic response in C. pardalis exposed to 3,4-dichloroaniline (3,4-DCA), a reference toxicant used for the synthesis of common herbicides, and byproduct of herbicide degradation. The median lethal concentration was determined (LC_{50}); after this, gravid females were exposed to sublethal concentrations of 3,4-DCAduring 21 days. The antioxidant enzymes activity (superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GPx)) was assessed in different organs of the exposed gravid females, and in the embryos. Concentration of macromolecules (protein, lipids and carbohydrates), glucose, lactate, thiobarbituric acid reactive substances (TBARS), and protein oxidation were also measured. All results were analyzed using the “Integrated Biomarker Response” (IBR) for a whole interpretation of toxicity effects. The LC_{50} was 5.18 mg L^{-1}(confidence limits: 4.8-5.5 mgL^{-1}). All the embryos were aborted ingravid females exposed to 3.3 and 2.5mg L^{-1}. Females exposed to 0.5 mg L^{-1} showed antioxidant activity alterations and oxidative damage, being the most affected the liver of adults and the embryos (IBR of 10.8 and 9, respectively). Macromolecules concentration was significantly affected in embryos and adults’ liver (IBR= 14.36 and 8.44, respectively). We can conclude that maternal exposure to environmental xenobiotics, such as 3,4-DCA,constitutea risk for embryo development and for the survival of C. pardalis.

WP020 Comparison of pharmaceutical and signaling pathway inhibitor effects on expression of genes related to swim bladder inflation in Japanese medaka

Z.P. Pandelides, Univ of Ontario Inst of Tech; M. Overturf, Univ of Louisiana at Monroe / Biology; E. Ussery, Univ of Ontario Inst of Tech / Faculty of Science Biology; J. Guchardi, Univ of Ontario Inst of Technology / Faculty of Science Aquatic Toxicology; D.A. Holdway, Univ of Ontario Inst of Tech / Science

Inadequate swim bladder inflation can have serious long term effects on many larval fish populations. Many different environmental contaminants including pharmaceuticals have been shown to inhibit swim bladder inflation. Understanding how this occurs and developing biomarkers for this effect are thus important. This study first established that embryonic exposure to 5µM cyclopamine, a Hedgehog (Hh) signaling inhibitor, as well as 1µM IWR-1, a wnt signalling inhibitor, resulted in >95% inhibition of swim bladder inflation of Japanese medaka (Oryzias latipes) larvae. The effects of these inhibitors on the expression of medaka genes related to the Hh and wnt pathways, as well as genes involved in the formation of the three cell layers that make up the swim bladder (epithelial, mesenchyme and outer mesothelium) were determined at 80, 96, 101, 144, 180 and 216 hours post fertilization. The effects on expression of key genes related to swim bladder formation and inflation were measured following exposure to 17α-ethinylestradiol, levonorgestrel, and diclofenac to determine if these pharmaceuticals act on similar targets or pathways related to Hh or wnt signaling.

WP021 Effects of Dicofenac on the Expressions of Genes Related to Detoxification System in Mugilogobius Abei

P. Ku, Dept of Ecology,Jinan Univ; X. Nie, Dept of Ecology,Jinan Univ / Dept of Ecology Jinan Univ

An increasing number of pharmaceuticals and personal care products (PPCPs) have been found in the aquatic environment and the issue has become a global environmental health concern. Dicofenac is a widely used non-steroidal antiinflammatory drug (NSAID) and is frequently detected in the various aquatic environments, such as wastewater effluents, surface waters, groundwaters and even drinking water due to its relative long half life periods. With the increase of consumption of the pharmaceuticals and subsequent their discharge into the aquatic environment in recent years, they are present at detectable levels in most sewage effluents. Now information available is still not enough about their potential impacts on aquatic organisms, especially on responses of genes related to fish detoxification metabolisms. In this study, real-time quantitative PCR was used to investigate the effects of dicofenac on aquatic fish Mugilogobius Abei. First, we cloned PXR, CYP3A and Alpha-GST of Mugilogobius Abei and established a stable and believable method to test the mRNA and microRNA alterations. The transcriptional expressions of PXR, P-gp,CYP3A and GST as well as the alterations of their corresponding microRNAs (miR-148a, miR-27a, miR-27b, miR-34a, miR-34b and miR-34c) related to detoxification system were determined. The results showed that there existed significant dose-effect relationship between GST, P-gp and dicofenac concentrations. A similar trend between PXR mRNA expression and P-gp, CYP3A and GST genes was observed in the exposure of dicofenac, suggesting PXR-CYP3A, PXR-Pgp and PXR-GST pathway for the DCF detoxification exists in Mugilogobius Abei. No significant changes were observed in all microRNAs tested. However, the genes and microRNAs were more sensitive in the exposure of 5 µg L-1 dicofenac, a negative correlation between miR-148a, miR-27a, miR-27b, miR-34a, miR-34b and miR-34c with P-gp was observed. It is a complex process in the detoxification of xenobiotics, in which nuclear receiptors-regulated and miRNA-mRNA pathways may play an critical role.

Activated Carbon as a Remedial Alternative for Management of Risks in Contaminated Sediments

WP022 Activated Carbon in Sediment Remediation – Experiences from laboratory and field studies

S. Abel, Univ of Eastern Finland / Dept of environmental and biological sciences; I. Nybom, Univ of Eastern Finland; K. Maenpaa, Univ of Eastern Finland / Dept of environmental and biological sciences; S.E. Hale, Norwegian Geotechnical Inst / Environmental Engineering; G. Cornelissen, Norwegian Geotechnical Inst; J. Akkanen, Univ of Eastern Finland / Dept of environmental and biological sciences

In-situ treatment of contaminated sediments can be an effective, uncomplicated and less invasive method than traditional approaches, such as dredging. Activated carbon (AC) has quickly become one of the most promising tools for this purpose, as it is capable of binding large amounts of persistent organic contaminants, thus rendering them unavailable for the uptake by organisms or release into the water phase. While the high contaminant binding potential has been shown in both field and laboratory trials, the adverse effects of AC amendments seem to be more pronounced in the latter. For this reason, we are utilizing both approaches and aim at a direct comparison from laboratory-based predictions and observations in the field. The field trial was set up in the PCB contaminated Lake Kernaalanjärvi, Finland. A 300m^2 plot was amended with an AC thin layer cap (1.66 kg AC/m^2) in 2015. The PCB bioaccumulation and the ecological condition of the benthic fauna on the plot and several adjacent reference sites will be monitored. In addition, sediment traps were used to determine the amount, composition and PCB-content of newly deposited sediment. Passive samplers (coated vials and PE strips) were used to determine freely dissolved aqueous concentrations of PCB's. Laboratory studies were executed to predict the effectiveness and risks of AC amendments, including scenarios with ongoing sedimentation of contaminated material (as it is the case on the studied field site). In microcosms, AC thin layer caps were covered with an additional layer of natural, PCB contaminated sediment in varying thicknesses to simulate different sedimentation rates. First results using Chironomus riparius larvae show that PCB bioaccumulation is reduced significantly even if the AC cap is covered by contaminated sediment, although the remediation efficiencies reduce rapidly with increasing top layer thicknesses. Additionally, adverse effects, such as reduced growth and survival of larvae and a delayed larval development, remain a problem until thicker sediment layers have formed atop the AC cap. In combination with the data from the field trial, these experiments can give valuable information necessary as a basis for the improvement of AC based remediation methods.

WP023 Assimilation Efficiency of Sediment-Bound PCBs Ingested by Fish Is Reduced after Activated Carbon Amendment

H. Fadaei Khoei, Univ of Maryland Baltimore County / Civil and Environmental Engineering; E. Williams, Inst of Marine and Environmental Technology; A. Place, Inst of Marine and Environmental Technology, UMCES / Columbus Center; J.P. Connolly, Anchor QEA, LLC; U. Ghosh, Univ of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering

Uptake of polychlorinated biphenyls (PCBs) by fish is controlled by bioavailability of the ingested PCBs in the gut as well as the freely dissolved concentration in the water. Prediction of bioaccumulation in fish relies on models which are often oversimplified. It is also unclear how mitigation strategies affect these models in terms of consumption of PCB contaminated sediment particles. To test the bioavailability of PCBs from treated and untreated sediments, dietary assimilation efficiencies (AEs) were measured for 16 polychlorinated biphenyl (PCB) congeners in mummichogs (Fundulus heteroclitius) that were fed four experimental diets. Diets consisted of PCB-spiked earthworms, untreated sediment mixed with earthworms, activated carbon (AC)-treated sediment mixed with earthworms, and AC mixed with earthworms. AEs were determined by calculating the ratio of PCB mass in the fish tissue to the PCB mass in the food. Fish that were fed the PCB-spiked untreated sediment and those fed AC particles exhibited the highest and lowest AEs over a wide K_{OW} range, respectively. AEs of sediment-bound PCBs were significantly reduced (31 to 93% reduction for different congeners) upon amendment with AC. AEs of PCBs associated with earthworm diet were similar to the values reported in the literature. The present study indicates that assimilation of PCBs can be reduced by enhanced affinity of PCBs to black carbon. The empirical AE-K_d correlations derived in the present study can help improve predictions of sediment contribution to PCB uptake by fish prior to and after addition of carbonaceous sorbents to sediments.

WP024 Effectiveness of activated carbon in reducing the bioavailability of organochlorine contaminants in high organic carbon sediments

V. Dang, K.J. Kroll, Univ of Florida / Physiological Sciences; S.D. Supowit, Arizona State Univ / Dept of Civil and Environmental Engineering; R.U. Halden, Arizona State Univ / Biodesign Center for Environmental Security; N.D. Denslow, Univ of Florida / Physiological Sciences

The north shore muck farms of Lake Apopka, FL are contaminated with legacy organochlorine pesticides (e.g., p,p'-DDE, dieldrin, toxaphene, and chlordanes). Sediments at these muck farms have very high total organic carbon content (39%, w/w). The current remediation strategy is to mix the top 15-20 cm of contaminated sediments with the lower 1.2 m of muck soils. This strategy appears to reduce the effective concentrations, but contaminants remain present in the sediments and bioavailable for bioaccumulation into biota. In this study, we assessed the application of activated carbon (AC) as an alternative treatment for the north shore muck farms around Lake Apopka. Sediments from the least contaminated muck farms were spiked with a mixture of 5 chemicals (p,p'-DDE, dieldrin, triclosan, triclocarban, and fipronil) at a nominal concentration of 2 mg/kg chemical, incubated for 7 days to reach a steady state level, and washed unbound chemicals. The spiked sediments were amended with either granular activated carbon (GAC; Fritz) or powdered activated carbon (PAC) pellets (SediMite™) at a dose of 5% of sediment dry weight, mixed with clean water, and incubated for up to 30 days prior to use in exposure experiments. A 7-day sediment bioaccumulation study was conducted using Lumbriculus variegatus (blackworm). The sediments used in the spiking experiments also still contained additional measurable concentrations of weathered pesticides (i.e., p,p'-DDT, p,p'-DDD, and p,p'-DDE). Worm body burdens did not decrease in bioaccumulation experiments with GAC amended sediment and were similar to the concentrations in worms in un-amended sediments after 7 days of exposure. In the experiments using PAC amended sediments, the body burdens in worms of p,p'-DDT, p,p'-DDD, p,p'-DDE, and dieldrin decreased by < 30%, and those of triclosan, triclocarban, and fipronil decreased by >50%, which corresponded to their degree of hydrophobicity (K_{OW} value). These data suggest that the PAC pellets tested here might be an excellent material for in situ remediation of contaminated sediments containing very high background levels of total organic carbon.

WP025 PCB Tissue Concentrations and Benthic Community Impacts at a Carbon Amendment Pilot Study in the Intertidal and Subtidal Zone of San Francisco Bay

C.A. Irvine, CH2M / Ecosystem Services; S.L. Clark, Pacific EcoRisk; T. Himmer, A. Salter-Blanc, R. Zajac, G. Hicks, J. Eby, CH2M; D. Janda, Navy Base San Diego

Historical site activities at the Hunters Point Naval Shipyard (HPNS) in South San Francisco Bay resulted in the release of chemicals, including PCBs, to offshore sediments. To inform remedy selection at this urban site, activated carbon (AC) amendments alternatives were evaluated in a pilot treatability study. Two 0.4 acre plots extending from the intertidal to the subtidal zone were treated with either AquaGate + PAC™ or SediMite™ were assessed for their potential to reduce ecological risks associated with PCB-contaminated sediment. Previous treatability studies indicated that AC may be effective at reducing the bioavailability of PCBs to the bent-nose clams (Macoma nasuta) in shallow intertidal sediments when aided by mechanical mixing. This study assessed the effectiveness of AC placements without mechanical mixing in deeper water that is more representative of conditions where full-scale remediation is expected. Tissue bioaccumulation, benthic invertebrate community composition, and chemical analyses were measured as indicators of remedy effectiveness. Comparisons were made between baseline, reference, and post-amendment conditions (6 months and 12 months post-placement). PCB tissue concentrations in Macoma sp. were measured in situ and ex situ (bench-top) after 28-day exposures. Developing field exposure chambers that allowed sediments to infiltrate the chambers and expose clams upon deployment and then retrieve the sediment and exposed organisms for chemical analyses was a challenge. Modifying a chamber design used in previous studies by Luthy et al. (2009) proved successful. Test organisms were another challenge. Tissue bioaccumulation was planned to be conducted with M. nasuta but instead, initial measurements were made with M. secta (white sand clam) collected at a nearby reference location where M. nasuta had been previously found. The species have a similar appearance and life histories but M. secta had low survival in the field (< 20%), lab exposures (< 60%), and lab controls (10%). Additional field pilot testing led to the use M. nasuta from a supplier for post-amendment monitoring. PCB tissue concentrations were reduced by approximately 60% in both pilot amendment areas after 6 months and survival in the field and lab exposures were greater than 90 percent. Benthic invertebrate communities in test plots were not significantly different from baseline conditions or among treatments 6 months after AC deployment.

Developments and Barriers in the Adoption of Amendments for Soil and Sediment Remediation

WP026 Bring contaminated sediment back to life: application of zeolite-amended sediment in soil

J. Wen, Hunan Univ / College of Environmental Science and Engineering; G. Zeng, Hunan Univ / College of Environmental Science and Engineering

Lake sediment is a crucial composition in lake ecosystem for its role as the storage bank for organic and inorganic nutrients, and for toxics and hazards (i.e. heavy metals) simultaneously. A conventional way of utilizing the lake sediment is to apply it on land to increase soil fertility. However, if the sediment is highly contaminated or not properly managed, heavy metals within the sediment will lead to soil contamination and subsequently cause harmful effects on human beings and organisms. To make such sediment recycled and reusable, a modified zeolite amendment was added to sediment in order to minimize the mobility/bioavailability of heavy metals. The natural zeolite was first modified by chitosan to increase metal adsorption/exchange capacity. The amended sediment was then subjected to BCR sequential extraction scheme. By thorough mixing, the amended sediment was incorporated into soil and impacts of the sediment on soil property were evaluated by water soluble heavy metals (i.e. Cd, Cu, Pb, and Zn), microbial biomass carbon and enzyme activity. The modified sediment had a decreased exchangeable fraction of Cd, Cu, Pb, and Zn, indicating a reduced direct toxicity and effective heavy metal stabilization upon zeolite addition. The soil receiving the stabilized sediment had a reduced water soluble Cd, Cu, Pb, and Zn. In addition, increased total soil microbial biomass carbon and carbon/nitrogen ratio were found in the soil of such treatment. Soil dehydrogenase activity, as a microbial endpoint, was also improved in the soil treated with the modified sediment. Results show the addition of chitosanmodified zeolite as an amendment for contaminated lake sediment was an effective remediation solution. Incorporation of the stabilized sediment into the soil improved soil biological property, and facilitated the recycling and reuse of the sediment at no cost of bringing potential risks associated with the heavy metals.

WP027 Characterizing the partitioning of mercury and methylmercury to activated carbon in the presence of dissolved organic matter

J.P. Sanders, U. Ghosh, Univ of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering; A. McBurney, C.C. Gilmour, Smithsonian Env. Research Center

Mercury in aquatic sediments can pose a significant human health risk when it is converted by microorganisms to the more toxic and bioaccumulative methylmercury (MeHg). MeHg is introduced to aquatic food webs near the sediment-water interface, and can biomagnify to dangerous levels at higher trophic levels. Common remediation strategies for mercury-contaminated sites, including capping and dredging of sediments, can be costly and disruptive and may increase risk by resuspending contaminants or altering redox conditions in a way that favors methylation. Amendment of sediments with activated carbon (AC), an established strategy to decrease the bioavailability of hydrophobic organic contaminants, has shown promise for mercury and methylmercury remediation at the lab scale. AC has the potential to increase solid-phase partitioning and reduce the bioavailability both of inorganic Hg to methylators, and of MeHg to benthic organisms. Quantitative predictions of this partitioning are needed for dose calculations aimed at achieving a target pore water concentration. To date, such AC-water partitioning constants have only been published for the chloride complexes of Hg and MeHg. However, in many estuarine waters, dissolved organic matter (DOM) is much more likely than chloride to control Hg and MeHg speciation, with potentially critical implications for AC remedy effectiveness. We measured the AC-water partitioning of Hg and MeHg complexed to Suwannee River Humic Acid, a well-characterized DOM isolate. Measured logarithmic partitioning constants (L kg^{-1}) were between 3.8 and 4.4, more than two orders of magnitude lower than those published for the chloride complexes. Partitioning was less than 1% similar to that of the chloride complexes, and more than 99% similar to that of DOM alone, in agreement with equilibrum speciation calculations. The results indicate that DOM, a strong and bulky ligand for mercury, can control (and greatly reduce) the overall partitioning of mercury species to AC. At present, we have only a limited understanding of the bioavailability of various Hg and MeHg species and their potential to be attenuated by AC. Nonetheless, in light of this finding, we argue that the effectiveness of an AC amendment will depend heavily on sediment pore water chemistry, and that mercury speciation calculations can be used in combination with partitioning data to improve remedy design and facilitate model predictions of site treatability.

WP028 Decreasing bioavailability of organochlorine pesticides in historical orchard soils

M. Anderson, Univ of Maryland / Civil and Environmental Engineering; C.J. Hapeman, D. Jackson, USDA-ARS; L. McConnell, Univ of Maryland; N. Beyer, USGS / Patuxent Wildlife Research Center; R. Chaney, USDA-ARS; T. Centofanti, Univ of Maryland; C. Green, C. Jennings, A. Nguyen, USDA-ARS; T. LaChance, A. Torrents, Univ of Maryland / Civil and Environmental Eng

Repeated applications of organochlorine (OC) pesticides to historical orchard soils pose a continued risk to local ecosystems and fauna. Quantifying this risk, however, has typically focused on total concentration of the contaminant as opposed to its bioavailability. Assessing risk based on bioavailability as opposed to concentration will allow implementation of more economic and practical remediation strategies. For example, various soil amendments have been considered for soils contaminated with the persistent OC pesticides, DDT and dieldrin. In our previous work, locally-sourced composts were shown to reduce the bioavailability of these contaminants to earthworms in contaminated soils from a local historical orchard which is now a CERCLA site. Thus, we expanded this work to examine the changes in the bioavailability of these OC pesticides under field conditions. A small scale plot study was conducted to examine two promising composts under environmental conditions, as well as the long-term effectiveness of the amendments on the bioavailability of these legacy contaminants. Samples of soil and earthworms were collected periodically over three years, and concentrations in both matrices were determined, producing bioavailability data. All earthworms were naturally present in the historically-contaminated site, allowing for real-world bioavailability to be examined. Results showed that although substantial variability due to sampling season and field management were observed, aged-compost was more effective in decreasing bioavailability. These results have lead to the implementation of a 1.5-ha field study. Because this is a long term project, sampling of the field plots will continue in order to meet CERCLA requirements. Finally, the soil sample bank acquired from the plot and field studies will allow for examination of new and developing non-biological methods to determine bioavailability.

Making Your Research Relevant to Regulatory Science and Supportive of Decision-Making

WP029 Activities of the Federal Interagency Workgroup on Pharmaceuticals in Water

O. Conerly, B. Behl, USEPA; D.M. Eignor, USEPA / Office of Water; J.M. Lazorchak, USEPA / Office of Research and Development; J. Rogers, J. Strong, USEPA; R.A. Bloom, J.P. Laurenson, USFDA / Center for Drug Evaluation and Research; H. Zahner, USFDA; C.F. Williams, USDA / Lead Research Soil Scientist; K.E. Lee, USGS; W. Backe, Minnesota Dept of Health / Public Health Laboratory; H. Vesper, CDC; B. McIntyre, NIEHS; M.H. Fulton, NOAA / National Centers for Coastal Ocean Science; L. Baetz, L. Strutz, USAPHC; A. Gebhart, J. Martin, Cadmus

In 2012, four federal agencies signed a Memorandum of Understanding (MOU) establishing a formal mechanism to improve and sustain federal coordination and collaboration on issues related to pharmaceuticals in water. The MOU is in response to the Government Accountability Office recommendation in its August 2011 report "Action Needed to Sustain Agencies' Collaboration on Pharmaceuticals in Drinking Water." The signatories are the US Environmental Protection Agency (EPA), US Department of Agriculture/Agricultural Research Service (USDA), US Department of Health and Human Services/Food and Drug Administration (FDA), and US Department of Interior/Geological Survey (USGS). As a result of this agreement, an interagency workgroup (EPA, USGS, FDA, USDA, Army Public Health Center (Provisional), National Institute of Environmental Health Sciences, National Oceanic and Atmospheric Administration, and Center for Disease Control and Prevention) was formed to address issues related to the occurrence of pharmaceuticals in water. This Workgroup provides a forum for the exchange of information on pharmaceuticals in the environment, supports coordination of joint studies on pharmaceuticals in the environment, and facilitates interagency consultation on implications of research and analyses derived from shared information. The Workgroup is currently developing a product that will summarize ongoing federal efforts in this area and describe the process for monitoring, evaluating, and reporting to the public the results of these efforts. The Workgroup has created a database describing known federal research activities related to pharmaceuticals in water. Potential data gaps were identified and grouped based on the Boxall et al. "Big Questions" paper (2012). Examples of current interagency collaboration to address such data gaps include: developing human health benchmarks for pharmaceuticals, which may help identify pharmaceuticals of greatest risk to humans via the environment; identifying classes of drugs that need to undergo an environmental assessment under the National Environmental Policy Act regulations; studying the effects of chemical mixtures and monitoring pharmaceuticals and other chemicals of emerging concern in water; and developing USDA's five-year project plan. Disclaimer: The views expressed in this poster are those of the authors and do not necessarily represent the views or policies of the U.S. government.

WP030 Development of a practical risk assessment tool for assessing the environmental safety of consumer product ingredients in China (Chera 2.0)

M. Fan, The Procter & Gamble Company / Global Product Stewardship; S.D. Dyer, The Procter & Gamble Company / Environmental Stewardship and Sustainability Organization; Z. Liu, Chinese Research Academy of Environmental Sciences / State Key Laboratory of Environmental Criteria and Risk Assessment; W. Schecher, Environmental Research Software; D.C. McAvoy, Univ of Cincinnati / Environmental Engineering

An environmental risk assessment (ERA) framework and model for consumer product ingredients has recently been developed for China (Chera 2.0). The framework involves an exposure methodology using conditions specific to China including physical setting, infrastructure, and consumer habits and practices. China's current regulatory screening and prioritization schemes are also incorporated as part of a tiered risk assessment approach. The ERA methodology starts with Tier Zero, which utilizes the existing Chinese regulatory qualitative method, whereas Tiers One and Two use deterministic and probabilistic methods respectively, that account for per capita residential water use, wastewater treatment capability, and receiving water dilution factors. Due to major differences in wastewater treatment infrastructure and water usage between urban versus rural regions in China, two scenarios are included for assessing environmental exposure: (1) Urban with wastewater treatment, and (2) Rural without wastewater treatment (i.e., direct-discharge of wastewater). The newly upgraded modeling framework was developed with a Graphical User Interface (GUI) platform that incorporates probabilistic parameters and functionalities. Several ERA case studies will be presented for a variety of consumer product ingredients (e.g., fragrance materials and surfactants) that are widely used in China. These case studies will be used to demonstrate the conservative nature of the Tier 0 assessment and greater environmental realism associated with higher tier methodologies. Future considerations will include enhancing the model's capability with additional GUI features and the inclusion of monitoring network data. The intent of this risk assessment tool is to increase the efficiency for decision-making, which is critical for the management of chemicals in China.

WP031 Integrating weight of evidence into toxicity benchmark development

M.S. Johnson, US Army Public Health Center / Toxicology; P.D. Guiney, Retired- S C Johnson & Son, Inc / Molecular and Environmental Toxicology Center

Developing toxicology benchmarks for applications in risk assessment is rarely straightforward. Often, interpreting an abundance of toxicology data can be more daunting than dealing with a limited data set. Differences in study design, animal models, methods of administration, variability in response and statistical error all contribute to variations in interpretation. Current methods often assume equivalent quality between studies and available data and use the most sensitive outcome to be protective of others. This is logical for a screening approach; however, when more predictive benchmarks are needed, other methods must be employed. Here we present methods to better assess variability in results and study quality through integration of a semi-quantitative analysis of toxicology data sets. This approach allows for developers to assess the relative value of negative data in an objective manner and begin to assess the influences of false negative and false positive relationships.

WP032 Life Cycle Management on Energy, Water and Material Resources

H. Poremski, co2online Foundation / Energy and Climate Protection

Increasing scarcity of material and fossil resources, environmental impacts from sourcing through production and uses, the global competition on limited and high valued materials for the high technology sectors and the increasing costs are urgent drivers for improving sustainable production, reducing emissions and pollution and supporting environmental protection startegies. The working conditions of employees are challenged through sourcing processing on limited raw materials, increasing competitive production in well-developed countries but also the need to stimulate economic and social development in transition and developing countries. Life Cycle Assessment (LCA) and Life Cycle Costing (LCC) will be used for setting Sustainability criteria of products. Special focus will be addressed to Energy, Material and Water Resources during the life stages sourcing, production and uses. LCC assessment will determine the performance criteria of achievable BAT and BEP of products. Re-use and recycling is of growing importance for limited and and high value materials such as noble earths. LCA-based methodology is being used as management tool for decision-making. This Life Cycle Management (LCM) serves as an instrument to make LCA and LC-Tools operational. LCA studies were developed more than 80 priority product groups. The selected products are characterized by high market volume, environmental relevance and potentials for improvement. Management Systems on Resource Efficiency such as Energy, Materials and Water Resource Management procedurally follow the same systematic and operational approach of LCA and LCM. Typically, data measurement, compilation, analysis and assessment of data as well as improvement recommendations are main components of these Management Systems. But also training and qualification of personnel, organization, communication and a continual improvement process are important elements to reach a sustainable processes,improved technologies and products. Holistic approaches provide transparency and credibility for assessments. There is a number of cases where Life Cycle Management (LCM) provided knowledge-based and scientifically defendable decision options. The political decision OSPAR on the Decommissioning of Offshore Oil/Gas Installations in 1995/98 were based on extensive LCA studies and the application of LCM tools.

WP033 Policy Shaping Flame Retardant Use and Regulation: the Role of States and Future under TSCA Reform

E. Schreder, Washington Toxics Coalition

At the federal level in the United States, the U.S. Environmental Protection Agency (USEPA) has had very limited authority to restrict chemicals under the Toxic Substances Control Act (TSCA) of 1976. Therefore, since 2003 when California passed the first state-level restrictions on the use of flame retardants, states have taken the lead in the United States in identifying and acting to restrict flame retardants that pose a hazard to human and environmental health. State legislatures have passed laws to restrict primarily focused on two classes of flame retardants, PBDEs and chlorinated organophosphates. As these laws have come into effect, a pattern has emerged in which one to several states restricts a flame retardant, then manufacturers announce voluntary withdrawal of that chemical from the market. In some cases, this has involved agreements made with the USEPA and federal rules restricting future production. The June 2016 passage of TSCA reform by the U.S. Congress is likely to change this dynamic somewhat: the USEPA will now be required to adhere to a schedule to assess chemicals, but the new law places constraints on the ability of states to restrict chemicals. USEPA has started the process of scoping risk assessments for four types of flame retardants: chlorinated phosphate esters, hexabromocyclododecanes, tetrabromobisphenol A, and brominated phthalates. The history of state policy action on flame retardants was reviewed and an analysis developed of the expected effect of new authority and actions at the federal level.

WP034 Strategy and development of direct-discharge assessment methodology for consumer product chemicals

M. Fan, The Procter & Gamble Company / Global Product Stewardship; S.D. Dyer, The Procter & Gamble Company / Environmental Stewardship and Sustainability Organization; D.C. McAvoy, Univ of Cincinnati / Environmental Engineering

The direct disposal of untreated wastewater (or very limited treatment) into the environment is a common practice in many regions around the globe, particularly in rural areas of Asia, Central and Eastern Europe, and Latin America. Elevated levels of organic wastes from untreated wastewater cause an increase in oxygen demand due to the concomitant increase in biological decomposition. The zone of impact can be characterized by relatively high total suspended solids (TSS), and biochemical oxygen demand/chemical oxygen demand (BOD/COD), resulting in low dissolved oxygen and high ammonia concentrations, which itself can be inhibitory to aquatic organisms. Thus, risk assessments for consumer product ingredients under these exposure scenarios should take into account such conditions with reduced DO and increased ammonia due to conventional pollutants. In our risk assessment framework, we: (1) used a mechanistic modeling scheme for estimating water quality to delineate the zone of impact and subsequent risk level for chemicals of interest; and (2) compared our approach to more traditional and established methods. In particular we evaluate whether our approach can be used under broad or specific conditions. Furthermore, chemical and fate properties (e.g., biodegradability and sorptivity) and environmental factors (cold, temperate or tropic regions and effluent/receiving water dilution) where consumer products are used and disposed of will be analyzed to assess their interactions for affecting the size of the impact zone and risk assessment outcomes. A series of case studies using commonly used consumer product ingredients (e.g., fragrances, surfactants) illustrate this proposed assessment strategy with representative scenarios for China, South America, and Eastern Europe. Comparison of these case studies will provide an opportunity to recommend guidance in appropriately assessing the impact of down-the-drain consumer product ingredients in direct discharge scenarios globally.

Microplastics in the Aquatic Environment: Fate and Effects

WP035 State of the Science Overview: Effects of Plastics Pollution on Aquatic Life and Aquatic-Dependent Wildlife

C. Bergeron, USEPA / Office of Water; J.R. Beaman, USEPA / Office of Water; A. Cook, Environmental Protection Agency / Region; K. Gallagher, USEPA / Office of Water; K.T. Ho, USEPA / Atlantic Ecology Division

Plastic production is increasing globally, with the volume of plastics entering marine and freshwater ecosystems increasing by several orders of magnitude since mass production began in the 1940s. The adverse physical impacts to organisms from plastic debris in aquatic environments, including ingestion and entanglement, have been well documented, and the ingestion of plastics may establish an exposure pathway for chemical contaminants sorbed from the water column or incorporated into the plastics during manufacture. The U.S. Environmental Protection Agency (EPA) Office of Water developed a state-of-the-science review of the chemical effects associated with plastic pollution and potential impacts on aquatic life and aquatic-dependent wildlife. Based on a review of the literature, available research from field and experimental studies suggests invertebrates, fish, and birds can accumulate chemicals associated with ingested plastics. Toxicological studies with invertebrates and fish have shown sublethal effects from chemicals associated with plastics as well as the plastic itself. However, bioaccumulation modeling under environmentally realistic exposure scenarios provides indirect evidence that plastics serve as a relatively minor contaminant exposure pathway compared to other natural pathways. Based on the current state-of-the-science, there are significant opportunities for research to further our understanding of the potential toxicological impacts of plastic ingestion throughout the food web. In addition, EPA's Trash Free Waters program may be a catalyst for proactive plastics reduction by helping states and localities reduce the volume of plastics, trash, and debris that enters both freshwater and coastal ecosystems.

WP036 Microplastics as Vectors of Polycyclic Aromatic Hydrocarbons (PAHs) via Chemical Adsorption and Desorption

C.B. Crawford, C. Ewins, Univ of the West of Scotland / Inst of Biomedical and Environmental Health Research; M. Russell, Marine Scotland Science; B. Quinn, Univ of the West of Scotland / Inst of Biomedical and Environmental Health Research

With an approximate degradation time of 450 years, plastic is one of the most durable and persistent environmental contaminants in the modern world. Production since the 1950s has increased prodigiously. In the marine environment, photooxidative degradation and the abrasive action of waves progressively degrade larger pieces of plastic into tiny polymer particles less than 5 millimetres in diameter, termed microplastics. As a consequence of their small size, microplastics are inadvertently ingested by ocean dwelling biota, particularly susceptible filter feeders such as Mytilus edulis and many species of fish. This can result in detrimental effects such as inhibition of gastrointestinal function and feeding impairment. However, it has emerged fairly recently that microplastic polymers collected from the marine environment have been found to have hydrophobic organic chemicals (HOCs), such as polycyclic aromatic hydrocarbons (PAHs), adsorbed onto their surface. Since marine organisms ingest microplastics, it can be proposed that microplastics have the potential to act as a transporter for the conveyance of persistent organic pollutants (POPs), such as PAHs, into marine biota. PAHs are formed from incomplete or inefficient combustion of organic material, diagenesis and biosynthesis. While there is a consistent background level from forest fires and volcanic activity, a significant fraction of PAHs present in the environment is due to anthropogenic activities, such as internal combustion engines. Consequently, PAHs reach the marine environment via sewage and industrial discharges, oil spillages and deposition from the atmosphere. One particular characteristic of PAHs is their susceptibility to ultra-violet light. However, pericondensed PAH structures are more centrally condensed allowing them to withstand higher ultraviolet fluxes. This results in a decrease in susceptibility to photodecomposition by ultraviolet light and thus, resistance to degradation in the marine environment. Consequently, microplastics can then adsorb these contaminants. Since many of the susceptible organisms that ingest microplastics are located at the bottom of the food chain, chemical adsorption provides a potential mechanism for the bioaccumulation of contaminants in marine organisms and the potential trophic transfer of these contaminants up the food web to larger organisms, and possibly humans. Consequently, it is necessary to investigate this potential mechanism.

WP037 Microplastics and nanoplastics in South African Aquatic Systems: Occurrence and Distribution

S.L. Sebata, ERWAT/UNISA / Nanotechnology and water sustainability; B. Mamba, UNISA / Nanotechnology and water sustainability; T. Msagati, Univ of South Africa / Nanotechnology and water sustainability

Microplastics and nanoplastics water pollution research in South Africa should be in the forefront of water research, as they represent a basket of aquatic system contaminants which has been classified as emergent and has proved to have entered into the food chain. The utilisation of the South African coastal areas to boost the much required economic development, through trade ports; tourism; fish; and seafood industries makes it imperative to investigate the abundance, occurrence, distribution and accumulation of microplastics and nanoplastics pollution in rivers, dams, lakes, ocean, sea, estuaries and beach environments. Almost all publicly provided potable water in South Africa originates from rivers, dams, and groundwater. Unfortunately the associated environmental risks including comprehensive data on microplastics and nanoplastics' occurrence and distribution including biological effects are currently lacking in South Africa just as it may be the case for other countries. The objective of this paper is to presenton the status of research and literature generated in South Africa from a quantitative and qualitative data's perspective in demonstrating the abundance, occurrence and distribution of microplastics in the South African oceans, beaches, estuaries and freshwater systems. The other objective is to improve knowledge on the occurrence, distribution and possible accumulation in South African freshwater system. The South African historical political situation and the current migration trends towards urban areas has created unintended problems that manifest themselves though the mismanagement of a large quantity of urban litter that includes microplastics and nanoplastics. Plastics, microplastics and nanoplastics research in South Africa started in the late 80's, with a lot of work focused on the coastal areas, but work on freshwater systems is lacking and this fragmentation of knowledge reduces the chances of achieving a transdisciplinary directed risk assessment for freshwater systems. One major challenge in microplastic research is the lack of general definitions and convergence in methodology. The majority of South African researchers have utilised similar methodology for sample processing, however, the methodology utilised for sample collection was different. This might be of concern because, differing methodologies may sometimes lead to data interpretation divergence. A compromise interpretation model has been proposed in this review.

WP038 Ecological investigations of microplastics and microparticles in environmental matrices-environmental science is now in the second (not first) wave

S.E. Belanger, The Procter & Gamble Company / Environmental Stewardship and Sustainability Organization; J. Brill, The Procter & Gamble Co. / Environmental Stewardship and Sustainability; J.M. Rawlings, The Procter & Gamble Company / Environmental Stewardship and Sustainability; K.A. Connors, Procter & Gamble / Global Product Stewardship

Investigations of the environmental fate and effects of microplastics and microparticles is now in vogue. Small, insoluble polymeric particles are implicated by scientists in a wide variety of studies that are used to suggest potential for wide-spread impacts in freshwater and marine pelagic and sediment environments. In the past 7 years, the annual rate of publications regarding environmental fate, exposure, bioaccumulation and ecotoxicity of microplastics has grown nearly 50-100 fold. This literature has ignored deep and important literature on the use of microplastic (microsphere) particles to understand the feeding biology, behavior, and ecology of zooplankton, epibenthic invertebrates and early life stages of fish. Much of this rich literature is found in limnological and marine biology and ecology studies of invertebrates in the 1970's to early 1990's. The types of research that was performed in this arena includes studies to develop an understanding of size selectivity of filter-feeding zooplankton, clams, mussels, early development stages of echinoids; evaluation of particle sorting efficiency and ingestion rates of zooplankton; determination of filtering ability of organisms as a surrogate for classic chronic toxicity endpoints for zooplankton; use of functionalized particles tagged with flavors to address taste discrimination by zooplankton; investigation of microplastics as potential mosquito larvicides when applied as a physical barrier on pond surfaces; understanding the movement of microparticles in sediment matrices following bioturbation. In this paper, we review this literature and what it can do to inform scientists on the currently emerging information on microparticle/microplastic ecotoxicity as a comparison.

WP039 Zooplankton exposure to microplastic at estuarine tidal fronts in Charleston Harbor, SC

T. Payton, College of Charleston / Marine Biology; B. Beckingham, College of Charleston / Environmental Geosciences; P. Dustan, College of Charleston / Biology

The Charleston Harbor in Charleston, SC receives input from three main river systems and the Atlantic Ocean, generating tidally-driven frontal aggregation zones for semi-buoyant particulates. Microplastics are found in Charleston Harbor and have entered the estuarine trophic system as evidenced by fragments and fibers found in the guts of shrimp, the feces of local birds, and the gills of Eastern oysters, Crassostrea virginica. The present study examined whether aggregation zones at flood tidal fronts in the Ashley and Cooper River present a pathway of increased exposure for microplastics to enter the estuarine trophic system via ingestion by zooplankton. Fluorescence and bright-field microscopy were used to enumerate microplastics in filtered surface water samples and melting point analysis confirmed the identification. The increased relative abundance of microplastics in flood tidal fronts compared to the surrounding water suggests these systems concentrate microplastics similarly to phytoplankton and thus may be an important conduit for microplastic to enter the food web. Additionally, each front and associated river system may be characterized by different relative abundances of microplastic fibers verses fragments. Future analysis will examine zooplankton populations collected at tidal fronts to provide a better understanding of the movement of microplastics into the lower trophic feeding guilds in a dynamic estuarine environment.

WP040 Microplastics in a surface water environment receiving treated wastewater effluent

S. Lasee, Texas Tech Univ / Dept of Environmental Toxicology The Inst of Environmental and Human Health; J. Mauricio, Texas Tech Univ-The Inst of Environmental and Human Health / Dept of Environmental Toxicology The Inst of Environmental and Human Health TIEHH; A. Karnjanapiboonwong, Texas Tech Univ / Dept of Environmental Toxicology The Inst of Environmental and Human Health; J. Kasumba, S. Subbiah, Texas Tech UnivThe Inst of Environmental and Human Health; T.A. Anderson, Texas Tech Univ / Environmental Toxicology

The large global production and use of plastics has led to the presence and accumulation of plastic particles in aquatic environments. The presence and impact of plastic debris, particularly in the oceans, has been highly publicized; it has been proposed that plastic debris can adversely affect marine organisms physically and chemically. Plastic polymers show little environmental degradation, although over time the size of plastic particles decreases. These small plastic fragments (microplastics or solid particles less than 5 mm in size) accumulate in surface water environments. In addition, microplastics or "microbeads" used in personal care products and cosmetics may ultimately find their way into aquatic environments. Ingestion of microplastics by filter feeding organisms has been observed, but the significance of this exposure is unclear. A recent paper (Lönnstedt and Eklöv, 2016) indicated impacts of microplastics on larval fish behavior and development. Microplastics are also present in freshwater environments where they may have similar impacts. We measured the presence of microplastics (53 – 106 µm) spatially and temporally in a series of connected urban lakes fed by treated wastewater effluent. The lakes also serve as urban drainage during storm events. We used wet sieving of water similar to methods described by NOAA. A sample of treated wastewater effluent feeding Lake 1 (3.75 L) contained 10 mg of microplastics. A near-surface sample of similar volume from the dam at Lake 1 contained 7 mg of microplastics. A sample of water flowing into the 7th lake in the series contained 15 mg of microplastics. These results suggest that urban runoff contributes microplastics to the system in addition to the treated wastewater effluent. Recent legislation has been proposed that would ban microbeads in personal care products and cosmetics by July, 2017. Our preliminary data suggest that additional monitoring would help to better understand such regulation, the potential impacts of historic use, and the input to aquatic environments of other sources of microplastics beyond personal care products.

WP041 Identifying Point Sources of Microplastic Debris in Charleston Harbor, SC

R. Leads, College of Charleston / Biology; J.E. Weinstein, The Citadel / Dept of Biology

Plastic marine debris has been identified as a high-priority research area due to the worldwide prevalence of plastic debris in the marine environment. Of particular interest is the occurrence of small plastic particles measuring less than 5 mm in diameter. These particles, termed microplastics, are considered an emerging contaminant of concern. Accordingly, there is a growing effort to determine the origin and fate of microplastics in aquatic ecosystems. In order to identify point sources of microplastic pollution entering Charleston Harbor, South Carolina, industrial effluent discharged into the Cooper River, a tidal river emptying into Charleston Harbor, was analyzed for the presence of microplastics (63-500 µm). In addition, the distribution and abundance of microplastics in the Cooper River was determined. These data help to elucidate the role of riverine input as a source of microplastic in Charleston Harbor, and can help us to understand the fate of microplastics in an estuarine ecosystem.

WP042 Contribution of Plastic Debris to Microplastic Abundance in Charleston Harbor

J.E. Weinstein, The Citadel / Dept of Biology; C. Holt, The Citadel; A.D. Gray, Univ of North Carolina at Greensboro / Biology; R. Leads, College of Charleston / Biology

To mitigate the problems associated with microplastic in the environment, it is important to understand their sources and the pathways by which they gain entry into various habitats. Previous studies in our laboratory have demonstrated that the major type of microplastic particle found in Charleston Harbor are fragments consistent with the degradation of plastic debris. To understand the mechanisms involved in the formation of these particles and to identify possible sources, three studies were conducted. First, plastic strips composed of high density polyethylene, polypropylene, and polystyrene were deployed in a salt marsh, and monitored for 32 weeks. A laboratory mechanical fragmentation test demonstrated that the production of microplastic particles from these strips was evident following 8 weeks for all three polymers. SEM images suggested that the production of these microplastic particles resulted from the delamination of the surface layer. To validate these initial findings, a second study was conducted examining microplastic production from eight discarded plastic debris items found in situ in a salt marsh. In each case, there was significantly more microplastic particles produced in the laboratory mechanical fragmentation test by the field-collected, discarded plastic debris relative to the non-discarded control material. To identify possible sources of black microplastic fragments, the major type of fragment found within the harbor, a third study was conducted examining microplastic production from field-deployed strips of common black plastic items (oyster reef restoration bags, silt fencing, monofilament fishing line, fishing net, and grocery bags). At 16 weeks, monofilament fishing line and the fishing net produced the greatest number of microplastic particles, and silt fencing produced the least. These results suggest that nylon fishing gear may be a major contributor to the microplastic litter in Charleston Harbor.

WP043 An estimation of plastic debris and persistent and bioaccumulating toxic riders in the Tijuana River Estuary

H. Allen, USEPA Region 9 / Superfund Division; A. Cook, Environmental Protection Agency / Region

Accumulation of plastic debris in aquatic environments is a growing concern. Recent research has demonstrated that small plastic beads, fragments and particles, or "microplastics," can pose chemical exposure hazards as well as physical hazards to aquatic animals. Microplastics have been found to attract, harbor and hyperaccumulate Persistent and Bioaccumulating Toxins, thereby acting as another exposure media to birds, fish and macroinvertebrates, including species we consider seafood. We separated plastic debris pieces from sediments at the Goat Canyon Retention Basin (GRCB) at the Tijuana River Estuarine Natural Resource Reserve. We estimated plastic quantities in sediment samples and analyzed sediments and plastic fragments for PBTs using a Gas Chromatography/High Resolution Mass Spectroscopy (GC/HRMS). We compared chemical concentrations between sediments and co-located plastic fragments. Concentrations of PBTs on plastics far exceeded concentrations in sediments from the same sample location. PCB results on plastics also exceeded sediment contamination threshold criteria. A "back-of-the-envelope" calculation yielded an estimate of 21.3 to 41.3 metric tons of plastic in the GCRB alone with a total PCB load of 4 to 7 kg. These findings suggest that typical PBT risk assessments performed on sediments may be confounded by the presence of contamination on entrained microplastic media. Further exploration of this phenomenon could have significant impacts on contaminated sediment risk assessment methodology and decisions regarding cleanup and management decisions such as invasive sediment exaction activities.

WP044 Assessment of environmental fate of solid polymers in wastewater treatment plant

J. Hu, J.W. Davis, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; Y. Zhang, D. Meunier, Y. Li, The Dow Chemical Company / Core RD Analytical Science

Over the last several years there have been a range of scientific and non-technical articles reporting the presence of microplastics in rivers, lakes, and oceans. Although the direct source for input of these particles into waterways is not clear, it has been suggested that the ability of these micron and sub-micron particles to pass through wastewater treatment may contribute towards microplastic's input into the environment. However, most well-functioning municipal wastewater treatment plants (WWTP) remove solids from the wastes stream by sedimentation during both primary and secondary treatment. Sedimentation simply entails the physical settling of matter, due to its density, buoyancy, and the force of gravity. Chemical coagulants and flocculants are often used to improve the efficiency of this process by facilitating the aggregation of particles. To address the environmental fate of two solid polymers, SunSpheres™ and Opulyn™ 301, we initiated a laboratory study to evaluate whether these materials can be removed from wastewater during sludge settling. This laboratory study was not meant to directly simulate the operating conditions in WWTPs, but to provide preliminary first tier screening level estimates on the removal potential of SunSpheres™ and Opulyn™ 301 during sludge settling in a typical municipal WWTP. Wastewater containing activated sludge was collected from the oxidation ditch bioreactor at a Municipal Wastewater Treatment Plant one day prior to the initiation of the test, and was continuously aerated until use. Aliquots of SunSpheres™ PGL Polymer and Opulyn™ 301 were added at a range of concentrations into the wastewater. The dosed wastewater was mixed at 100 rpm for ~ 2 hr, and subsequently settled for 3 – 4 hr. The mixing and settling time was chosen to reflect the actual retention/detention time of an aeration tank and a secondary clarifier in a typical municipal WWTP. After settling, the upper aqueous phase was analyzed by pyrolysis coupled with GC/FID for SunSpheres™ PGL Polymer and Opulyn™ 301. Removal of SunSpheres™ and Opulyn™ 301 from wastewater was ~ 99%. This laboratory study was not meant to directly simulate the operating conditions in WWTPs, but the results clearly demonstrated that SunSpheres™ and Opulyn™ 301 have great potential to be removed during sludge settling in a typical municipal WWTP.

WP046 Differential bioavailability of PCBs associated with environmental particles: microplastic in comparison to wood, coal and biochar

B. Beckingham, College of Charleston / Environmental Geosciences; U. Ghosh, Univ of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering

Microplastic particles are increasingly being discovered in diverse habitats and a host of species are found to ingest them. Since plastics are known to sorb hydrophobic organic contaminants (HOCs) there is a question of what risk of chemical exposure is posed to aquatic biota from microplastic-associated contaminants. We investigate bioavailability of polychlorinated biphenyls (PCBs) from polypropylene microplastic by measuring solid-water distribution coefficients, gut fluid solubilization, and bioaccumulation using sediment invertebrate worms as a test system. The results are compared to several natural and anthrogenic particles, including wood, coal, and biochar, placing microplastic-associated PCBs in a differential bioavailability framework. PCB distribution coefficients for polypropelene were higher than natural organic materials like wood, but in the range of lipids and sediment organic carbon, and much smaller than for black carbons like coal and biochars. Gut fluid solubilization potential increased in the order: coal < polypropylene < biochar < wood. Interestingly, lower gut fluid solubilization for polypropylene than biochar infers that PCBs at the biochar surfaces were accessible to gut fluid micelles while bioaccessibility is limited by diffusion from the interior of the microplastic. Biouptake in worms was lower by 76% when PCBs were associated with polypropelene compared to sediment. The presence of microplastics in sediments has an overall impact of reducing bioavailability and the transfer of HOCs to sediment-ingesting organisms. Since the vast majority of sediment and suspended particles in the environment are natural organic and inorganic materials, pollutant transfer through particle ingestion is going to be dominated by these particles and not microplastics. Therefore, these results support the conclusion that in most cases the transfer of organic pollutants to aquatic organisms from microplastic in the diet is likely a small contribution compared to other natural pathways of exposure.

WP048 Plastic Pollution as a Transport Mechanism for PCB Loadings in the Hawaiian Monk Seal at Tern Island/French Frigate Shoals

A. Cook, USEPA Region 9 / Superfund Emergency Response; S. Goldsmith, USEPA Region 9 / Office of Regional Counsel; S. Murray, USEPA Region 9 / Superfund Site Assessment; L. Woodward, USFWS / Marine National Monumnets of the Pacific; M. Duhr-Schultz, USFWS / Hawaiian Islands National Wildlife Refuge; W. Robberson, USEPA Region 9 / Superfund Emergency Response; S. Gray, Weston Solutions Inc; H. Allen, USEPA Region 9 / Superfund Emergency Response

Tern Island/French Frigate Shoals (FFS) is designated critical habitat for the endangered Hawaiian monk seal and is also the largest pupping grounds in the Northwestern Hawaiian Islands (NWHI) for the monk seal. Approximately 95% of the threatened Hawaiian green turtle population is known to nest in the FFS, including Tern Island. FFS is also home to approximately 6% of the world's population of the endangered black footed albatross and is a long-term monitoring site for 18 breeding seabird species – numbering approximately 500,000 birds – making Tern Island the most species-rich rookery in the NWHI. Studies conducted on Tern Island and its immediate vicinity have concluded that there is clear evidence of bioaccumulation through the aquatic food chain of high concentrations of PCBs and other lipophilic contaminants in organisms that occupy high trophic levels. In response to a December 2012 petition from the Center for Biological Diversity, EPA in partnership with FWS conducted an evaluation of releases, or threats of release, of hazardous substances from Tern Island that may adsorb to plastic marine debris in the surrounding surface water. Microplastic particles may provide a mechanism to concentrate and transport hazardous substances to marine species via the food chain. High levels of PCBs in the blood and blubber of the Hawaiian monk seal are a likely stressor contributing to the precipitous decline of the species. Microplastic ingestion via the food chain is a likely pathway for PCBs to enter the bodies of the monk seal and EPA is committed to understanding the role and relative threat posed by marine plastic pollution on the health of this endangered mammal. Initial steps to conduct a remedial investigation and risk assessment have begun, with special focus on the toxicological impacts, including PCB uptake, from contaminated plastic ingestion on the prey which make up the monk seal diet. The information gleaned from determining the risk posed by plastic particle pollution to the US' most endangered marine mammal may be transferrable to the effects and impacts expected on other mammals who eat seafood, such as humans.

WP049 Predicting the Ecological Implications of Leachates from North Pacific Gyre Plastics using In Vitro and In Vivo Models

S.L. Coffin, Univ of California, Riverside / Environmental Toxicology; E. Lemaire, Université de la Sorbonne / Ecotoxicologie Ecophysiologie marine; G. Xu, Univ of California Riverside; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences

Marine plastics are one of the most common and persistent pollutants in ocean waters and beaches worldwide and are estimated to be present between 60-95% in the marine environment. Plastic marine debris may pose a threat to aquatic life as many plastics contain endocrine-disrupting compounds including nonylphenol, bisphenol A and various phthalates, and have been shown to adsorb common persistent organic pollutants. Plastic samples recovered from the North Pacific Gyre along with UV-irradiated virgin plastic and non-irradiated virgin plastic were extracted and concentrated using solid phase extraction (in methanol) and nitrogen evaporation. In vitro assays using luciferase-reporter estrogen receptor-dependent (ER) agonist cells (VM7Luc4E2) revealed significantly higher activity in UV-irradiated virgin plastic leachates than gyre plastics and virgin plastics (EEQ= 159.0, 7.7 and < 0.1 ng/L , respectively). Beta-lactamase-reporter GeneBLAzer® CYP1A1-Bla (aryl hydrocarbon-receptor or AhR) assays revealed greater activity in gyre-recovered plastics than in virgin plastic and UV-irradiated virgin plastic (TEQ= 2, < 0.1 and < 0.1 ng/L, respectively). Oryzias latipes (Japanese medaka) fish were used as an endocrine-disruption in vivo model for these plastic leachates. To better understand the in vivo responses of plastic leachates and adsorbents, larval Japanese medaka (1-5 dph) were exposed to 0.01% methanol plastic extracts for 5 days. Induction of vitellogenin mRNA (VTG; an estrogen-dependent yolk precursor) and cytochrome P450-1A mRNA (CYP1A; an aryl-hydrocarbon-dependent enzyme) were measured using quantitative real-time polymerase chain reaction (q-RT-PCR). Delta-Ct values for CYP1A showed a significant difference between control and ocean plastic-treated fish (p=0.033, dunnett test), with an expression fold change of 10.7. Irradiated virgin plastic-treated fish showed no significant differences for either gene tested.

WP050 Ingestion of experimentally contaminated microplastics causes changes in biomarker responses in three-spine stickleback Gasterosteus aculeatus

G. Asmonaite, Univ of Gothenburg / Dept of Biological and Environmental Sciences; E.J. Sturve, Univ of Gothenburg; G. Limonta, Univ of Gothenburg / Dept of Biological and Environmental Sciences; B. Carney Almroth, Univ of Gothenburg / Biology and Environmental Sciences

Microplastics (MPs) raise great environmental concerns due to the wide distribution in aquatic environment and its known capacity to absorb and concentrate environmental contaminants. As potential threats of MPs are greatly unknown, research oriented towards understanding of biological fate of MPs in organisms and their effects, is greatly needed. A two-tier experimental study was conducted to study vector effects of MPs following different environmentally relevant exposure scenarios. Unplasticized polyvinyl chloride (uPVC) microscopic pellets were exposed to either model compounds, such as bisphenol A and crude North Sea oil, as well as to environmental mixtures (sewage effluent and industrial harbor's water). Consequently, long-term dietary exposures utilizing pre-exposed particles (incorporated in fish diet) were performed on three-spine sticklebacks (Gasterosteus aculeatus). The dietary toxicity of MPs and associated chemicals on fish was assessed using biomarkers' approach in two subsequent feeding experiments. Findings of the study provided strong evidences of MPs as vectors for environmental pollutants, transferring desorbed chemicals into fish. Results revealed that uPVC MPs may not be toxic alone, but when co-exposed to environmental hazards, mediate hepatotoxicity and act as endocrine disruptors. It was demonstrated that experimentally contaminated MPs cause changes in EROD activity and gene expression in liver, specifically altering gene expression of detoxification enzyme CYP1a, metallothionein (MT), estrogen receptor α (ER-α), vitellogenin (VTG) and androgen receptor β (AR- β). Changes in enzymatic biomarker responses were detected in gills, suggesting gills to be an important site for MPs-related toxicant exposure.

WP051 Effects of acute exposure of microplastics on the physiology of blue mussels

J. Ward, Univ of Connecticut / Marine Sciences; C. Herrick, Sacred Heart Academy; M. Rosa, Univ of Connecticut; V. Haynes, Univ of Connecticut / Marine Sciences; B. Holohan, Univ of Connecticut

As sedentary organisms, suspension-feeding bivalves are particularly vulnerable to anthropogenic contaminants that enter coastal environments. To understand the full range of impacts that contaminants such as microplastics have on these animals, sub-lethal effects must be assessed. In this study we exposed the blue mussel, Mytilus edulis, to microspheres composed of polystyrene divinylbenzene (ca. 3-30 µm; 1500 microspheres ml^{-1}, Bangs Labs) for a period of 12 hours. Prior to exposure, mussels were delivered a microalgal diet for 1 day and then divided into two groups: a microplastic-exposed group and an unexposed control group. Mussels in each group were then placed in individual feeding chambers supplied with the microalgal diets and microspheres as appropriate. After exposure, three physiological parameters were measured including diet absorption efficiency (AE; Conover 1966), oxygen consumption, and ammonium excretion (phenolhypochlorite method). Each mussel was then sacrificed and soft tissues isolated and dried to a constant mass. All physiological parameters were then standardized to a 1-g dry tissue mass using appropriate allometric equations. Absorption efficiency of mussels exposed to microplastics (55.6%) was significantly lower than AE of control mussels delivered only the microalgal diet (73.6%). No significant differences were found between treatments for mussel oxygen consumption or ammonium excretion. Results indicate that acute exposure of mussels to polystyrene-divinylbenzene microplastics can have significant impacts on digestive processes, but not on respiration or ammonium excretion rates.

Advances in Exposure Modeling: Bridging the Gap Between Research and Application

WP052 Human exposure to household cleaning products: Application of a two-field model

G. Wang, Univ of Michigan / Environmental Health Sciences; L. Huang, Univ of Michigan / Dept of Environmental Health Sciences; O. Jolliet, Univ of Michigan

Indoor cleaning is a common household activity, and cleaning products contain volatile organic compounds that constitute a potential threat to indoor air quality and occupants' health. This study aims 1) to establish a dynamic modeling framework which accounts for the near-person inhalation and dermal exposure to indoor cleaning products; 2) to determine the evolution of chemical mass and concentration associated with the activity, and to determine the factors affecting chemical fate and exposure in indoor environment; and 3) to determine the short-term human intakes and product intake fractions. We modify a two-zone model to describe the indoor environment where cleaning products are applied, identifying four transfer compartments, i.e. near-person surface, near-person air, far-person surface, and far-person air. Mass transfers between compartments are described by first-order transfer rate constants structured in the K matrix. The exposure matrix, XP matrix, relates the mass in a given compartment to the intake by human. Three exposure pathways are considered: inhalation exposure to near-person air, inhalation exposure to far-person air, and dermal exposure during application. The model is applied to 20 common ingredients in surface cleaning products, with a focus on two representative chemicals, n-hexane (high volatility) and 2-butoxyethanol (low volatility). The application of cleaning product is assumed to last for 1.5 hours (Phase 1) and a time period of 200 hours after application (Phase 2). For both representative chemicals, mass in each compartment continues increasing during Phase 1 and reaches its peak at the end of Phase 1. However, for n-hexane the two air compartments have higher chemical masses after the application, whereas the masses in the two surface compartments are higher for 2-butoxyethanol. Dermal intake during Phase 1 dominates exposure for n-hexane, while inhalation exposure during Phase 2 dominates for 2-butoxyethanol. Among the studied chemicals, inhalation intake dominates the total product intake in most cases and is driven by the chemical's air-water partition coefficient. The adapted dynamic two-zone model describes with parsimony the dynamic of chemical mass and near-field intakes during the application of household surface cleaning products. The results will be compared to exposure estimates for application of other cleaning products to elucidate the relative importance of various transfer pathways in near-field exposures.

WP053 A spatial approach for estimating the national distribution of sewer residence times for wastewaters in the US

K.E. Kapo, Waterborne Environmental, Inc.; M. Paschka, The Procter & Gamble Company; R. Vamshi, Waterborne Environmental, Inc.; M.L. Sebasky, Waterborne Environmental; K. McDonough, P&G / Environmental Stewardship

Sewer residence time can have a significant influence on the environmental fate and transport of wastewater constituents, including down-the-drain household consumer product ingredients. In this study, best-available data resources and geoprocessing tools were used to develop a spatial approach for estimating the national distribution of sewer residence times for wastewaters in the U.S. Case studies estimating sewer residence times for two municipalities demonstrated that road networks could be used as a spatial proxy for sewer networks when the latter data is not available. The approach was then extrapolated to a national dataset of >3,400 wastewater treatment plant (WWTP) facilities across the U.S. to estimate the national distribution of sewer residence times, with an estimated national median sewer residence time of 3.3 hours. Sewer residence times for smaller WWTP facilities (< 1 million gallons per day) were comparatively shorter than larger facilities, however the latter comprised a greater proportion of the overall national wastewater volume. The sewer residence time distributions derived in this study can be combined with in-sewer biodegradation data to estimate WWTP influent concentrations of down-the-drain household consumer product ingredients as part of a national-scale probabilistic risk assessment.

WP054 Global-Scale Multimedia Chemical Fate Modeling in High Spatial Resolution: Introducing BETR-Research 3.0

R.K. Goktas, kocaeli Univ / Dept of Environmental Engineering; H. Wöhrnschimmel, ETH Zurich / Inst for Chemical and Bioengineering; S. Schenker, ETH Zurich / Safety and Environmental Technology Group; H. von Waldow, Eawag; M. MacLeod, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry

BETR-Research is a framework to create spatially resolved multimedia fate and transport models for chemical contaminants. The first version of BETR-Research was based on BETR-Global 2.0, which is a well-developed and tested global fate model implemented in Visual Basic for Applications (MacLeod et al., 2011). BETR-Research was developed by re-implementing BETR-Global 2.0 in the Python programming language. The purpose of this re-implementation was to create a more flexible modeling platform using BETR-Global's model structure and taking advantage of efficient numerical packages in Python. In recent years, the BETR-Research model source code has gone through several important modifications. Some of the chemical fate process descriptions have been modified, a new algorithm for tracking chemical mass transfer fluxes throughout the simulations has been added, and a fast differential equation solver library to be used in dynamic model simulations has been integrated to the model code. Also, the databases that describe global atmospheric and oceanic flows, and climate properties have been updated; and now interannual variability can be accounted for. Further, there are options for quantifying the contribution of secondary emissions to atmospheric concentrations. The new version of BETR-Research can run global model simulations in spatial resolutions of 7.5°×7.5° and 3.75°×3.75°, in addition to the 15°×15° base resolution of BETR-Global. Here, we demonstrate BETR-Research 3.0 by simulating the global distribution of two polychlorinated biphenyls (PCB28 and PCB153) in 3.75°×3.75° spatial resolution. This application is a high-resolution upgrade of a previous modeling study using BETR-Global (Lamon et al., 2009). This model application was used to verify the implementation and new process descriptions, and to establish that the high-resolution environmental data set is reliable for use in future BETR-Research global modeling studies. The model results were compared with updated monitoring data sets and the model performance was evaluated. The source code of BETR-Research 3.0 will be publically available through an updated website which will also include the new high-resolution global environmental input data sets.

WP055 Geospatial Modeling of Particulate Matter Pollution from Post-Panamax Ships in Charleston Harbor, SC

M. Cains, Indiana Univ / School of Public and Environmental Affairs; D. Henshel, Indiana Univ / Public and Environmental Affairs; D. Good, Indiana Univ / School of Public and Environmental Affairs

The US Army Corps of Engineers (USACE) has been selected by South Carolina State Ports Authority to dredge the Charleston Harbor (CH) to a depth of 52 feet from the current depth of 45 feet (i.e. Post 45 Project). The completion of the Post 45 Project will make CH the deepest harbor on the East Coast which enhances the economic efficiency of commercial navigation and the local economy. The deepening of the port will allow for the passage and docking of Post-Panamax (PP) container ships which can carry ~1,000 additional cargo containers as compared to Panamax containers ships. The USACE environmental impact statement air quality assessment only calculated the emissions at four terminal locations and stated that total terminal emissions would be less than the status quo due to the use of larger and more efficient container ships. As part of the larger Integrated Risk Assessment and Vulnerability Assessment project, the presented work details the models and analysis used to conduct a geospatial comparative release and exposure assessment of particulate matter (PM) from Panamax and PP container ship traffic in CH. Our analysis extends beyond that of the USACE EIS as it includes the use of geographic information system software to determine potentially impacted populations by overlaying the container ships' funnel plume PM dispersion with population data and other sociodemographic data. The analysis is organized into four sections: pre-dredge PM emissions modeling of Panamax container ships moving through the harbor to the shipyard, pre-dredge PM emissions modeling of Panamax container ships idling at the shipyard, post-dredge PM emissions modeling of Panamax and PP container ships moving through the harbor to the shipyard, and post-dredge PM emissions modeling of Panamax and PP container ships idling at the shipyard. Various atmospheric dispersion models are employed in an effort to find the model or set of models (e.g. Eulerian, Lagrangian, and Gaussian dispersion models) that best represents the characteristics of the container ships' emissions and atmospheric profile of CH. Future work includes modeling the dispersion of other criteria pollutants and pollutants of interests emitted by the container ships. The goal of this research is to understand the potential geospatial air pollution and human health impacts of the Post 45 Project on Charleston Harbor and compare the findings to the results presented in the USACE environmental impact statement.

WP056 Sorption of non-ionic and anionic surfactants to three stationary phases as parameters for QSAR models

J. Hammer, Univ of Utrecht / IRAS; J. Haftka, P. Scherpenisse, J. Hermens, Utrecht Univ / Inst for Risk Assessment Sciences; P. de Voogt, Univ of Amsterdam / IBED

Anionic and non-ionic surfactants are high-production volume chemicals which are found in many consumer products and consequently also in the environment. The octanol-water partition coefficient (K_{ow}) is often used in QSAR studies as a measure of hydrophobicity to predict the environmental fate and exposure of neutral organic compounds. However, K_{ow} is not meaningful for surface-active compounds because sorption to environmental matrices is not only driven by their hydrophobicity, but also by specific interactions with the sorbent (hydrogen-bonding and electrostatic interactions). Furthermore, experimental K_{ow} values of both non-ionic and anionic surfactants are difficult to determine because of their surface active properties and ability to emulsify the octanol-water system. Alternative approaches to quantify and predict the environmental behavior of surfactants are therefore required. Our research is focused on developing and testing new approaches and parameters that can be applied in models to predict sorption and bioaccumulation of different surfactant classes. To this end we studied the interactions between surfactants and different stationary phases with liquid chromatography: C_{18}, mixed-mode hydrophilic interaction (HILIC), and mixed-mode weak anion exchange (WAX). To quantify the contribution of hydrophobic, hydrogen-bonding and electrostatic interactions to the environmental behavior of surfactants, capacity factors were derived from the different stationary phases. The affinity of surfactants for the C_{18} phase increased with carbon chain length for both anionic and non-ionic surfactants. The non-ionic surfactant class of alcohol ethoxylates showed increased affinity with the mixed-mode HILIC phase when increasing the number of ethoxylate units in the molecule. The logarithmic capacity factors determined for alcohol ethoxylates with both C_{18} and mixed-mode HILIC phases were used in a multilinear regression to determine the contribution of the hydrophobic and hydrogen-bond components to their environmental properties (e.g., bioconcentration, toxicity, sorption to clay minerals, and partitioning to membranes and dissolved organic carbon). Using the current approach, it is possible to predict the environmental behavior of alcohol ethoxylates with only two stationary phases. Retention on liquid chromatographic phases can therefore aid in the understanding of the driving partition mechanisms of alcohol ethoxylates in the environment.

WP057 Quantifying the Equilibrium Partitioning of Substituted Polycyclic Aromatic Hydrocarbons in Aerosols and Clouds using COSMOtherm

B. Awonaike, Univ of Toronto Scarborough / Physical and Environmental Science; C. Wang, Univ of Toronto / Dept of Chemistry; K. Goss, Helmholtz centre for environmental research – UFZ / Analytical Environmental Chemistry; F. Wania, Univ of Toronto at Scarborough / Physical and Environmental Sciences

Functional groups attached to polycyclic aromatic hydrocarbons (PAHs) can significantly modify the environmental fate of the parent compound, making it important to assess the behavior of these substituted polycyclic aromatic hydrocarbons (SPAHs) in the environment. However, equilibrium partition coefficients, which are essential for describing a compound's distribution between environmental compartments, are largely unavailable for SPAHs. In this study, COSMOtherm, a quantum chemical software is used to estimate atmospherically relevant partition coefficients for naphthalene, phenanthrene, benz(a)anthracene and benzo(a)pyrene and 66 of their substituted counterparts. The resulting partition coefficients between the gas phase, the aqueous bulk phase, the water surface and the water insoluble organic phase, as well as the salting-out coefficients, served as input parameters for the calculation of phase partitioning of these compounds in atmospheric aerosols and clouds. The predictions showed the influence of compound properties (number of rings, nature of attached functional group) and environmental conditions (size of aerosol/cloud, liquid water content, salting-out effect) on the atmospheric phase distribution of SPAHs. While highly polar substituents such as hydroxyl, nitro and dione are expected to significantly influence the partitioning properties of the parent compounds, the non-polar alkyl substituents showed much less of an effect.

WP058 Development and Validation of Biota-Sediment Accumulation Factors for the Lower 8.3 Miles of the Lower Passaic River using Log-linear Regression

E.A. Garvey, X. Wang, Louis Berger, Inc.; J.W. Kern, Kern Statistical Services, Inc.; J. Atmadja, Louis Berger, Inc.; N. Richardson, Battelle / Environmental Monitoring Assessment

The Lower Passaic River, part of the Diamond Alkali Superfund Site, is a highly impacted tidal urban estuary located in northern New Jersey that has been the focus of intense study, leading to the recent Record of Decision (Mar-2016) by the USEPA for the lower 8.3 miles. An important component of this investigation was the development of quantifiable site-specific relationships between sediment and fish tissue concentrations for the major contaminants, including 2,3,7,8-TCDD, PCBs, DDT, dieldrin, PAHs, copper, lead and mercury. The data for the analyses came from the Superfund investigation as well as NYC harbor studies including CARP and NOAA RE-MAP programs. These relationships were developed for 3 fish and one invertebrate species, representing a range of trophic levels. For organic compounds, the BSAFs were developed based on lipid-normalized and organic carbon-normalized concentrations in fish and sediment, consistent with EPA guidance. For metals, only sediment concentrations were normalized, to iron content. Concentrations in both media often spanned orders of magnitude, with sample-specific BSAF and BAF estimates apparently varying with sediment concentration. To address this non-linearity, the data were fit with a log-linear regression of the form: C_{fish} = $?_0$+ $?_1$*Ln [C_{sed}/f_n]+ $?_2$Ln(f_{Lipid})where f_n is the fraction of organic carbon or fraction of iron in the sediments, for organics and metals, respectively. The $?_i$ are coefficients in the regression. Thef_{Lipid} term was excluded for metals. This formula reverts to the standard BSAF when the $?_i$ equal 1. Individual tissue concentrations were matched to area-weighted average surface sediment concentrations based on animal home range. The regressions achieved statistically significant relationships for most species-contaminant pairs, often spanning orders of magnitude; maximum R^2 was 0.92 for 2,3,7,8-TCDD. Subsequent to the original work described in the 2014 proposed plan, an additional data set collected in 2012 above the head-of-tide on the Passaic was used as a validation data set for the original BSAF regression approach. In 6 of the 8 contaminant-species pairs reviewed, the new data validated the original regression analysis, and confirmed the extrapolation of the 2,3,7,8-TCDD regressions to sediment concentrations 10 times lower than those in the original analysis. This relatively simple but robust empirical approach was used to develop the site-specific sediment remedial goals for the ROD.

WP059 Monitoring Toxicity of Complex Mixtures in the Savannah River using Passive Sampling Devices

D. Wyker, Clemson Univ ENTOX / Environmental Toxicology; P. van den Hurk, Clemson Univ / Biological Sciences; O. Flite, Phinizy Center for Water Sciences; C.M. Lee, Clemson Univ / Environmental Engineering and Earth Sciences Dept

Previous biomarker research measuring the exposure of fish to a range of compounds, including endocrine disrupting compounds and polycyclic aromatic hydrocarbons, produced significant responses at multiple locations along the Savannah River. This justified a broader investigation into the chemical mixture present in the river and the components responsible for the observed biological effects with the use of passive sampling devices (PSDs). PSDs concentrate contaminants and act as biological surrogates, without the metabolism or depuration of living organisms, allowing for detection of dilute analytes that may fluctuate over time. Two PSDs that complement one another, LDPE (low density polyethylene) strips for nonpolar compounds and POCIS (polar organic compound integrated sampler) disks for polar compounds, were deployed in triplicate along the Savannah River to monitor environmental mixtures both temporally and spatially. Samplers were deployed at three river surface water sites around and below the Augusta (GA) area as well as two locations within Hartwell and Strom Thurmond Dams, which create reservoirs in the Savannah River upstream of Augusta. River surface water sampling sites all possessed continuous river monitoring probes maintained by the Phinizy Center for Water Sciences, measuring pH, specific conductance, DO, and temperature. Chemical analyses were performed on concentrated extracts for each site and time weighted average (TWA) concentrations calculated using compound-specific uptake rates and USGS river discharge data. LPDE extracts were analyzed for 16 priority pollutant PAHs using GC-EI/MS and PCB congeners from Aroclor mixtures 1016 and 1254 using GC-ECD. Select pharmaceuticals and personal care products (PPCPs) were extracted from the POCIS disks and analytical methods were developed using UPLC-MS/MS. Differences in surface water mixture compositions were evaluated for differences in season, site characteristics, and usage patterns. Combined PSD extracts were used in small volume bioassays including the YES assay and zebrafish embryo developmental toxicity assay to link the measured chemical pollutants with observed biological effects in the field.

Contaminant Flux Across Environmental Compartments and Implications for Global Distribution

WP060 Prediction of soluble release of PCBs from contaminated sediment using measured sediment pore water distribution coefficients and DOC

A. Martinez, K.C. Hornbuckle, Univ of Iowa / Civil and Environmental Engineering IIHRHydroscience and Engineering

The release of dissolved hydrophobic organic contaminants (HOCs) from contaminated sediments is often a major source to the aquatic environment. However, quantifying the release in specific environments is challenging because the physical and biological processes involved in this release are diverse, variable, or otherwise difficult to characterize in a quantitative way. Here, we develop and evaluate four approaches to predict the soluble release of PCBs from the sediment bed. These models include the processes of bioturbation and transport across the benthic boundary layer (BBL), assess the importance of using measured rather than modeled sediment pore water concentration, and consider the role of dissolved organic carbon (DOC). Results indicate that the mass transfer coefficient is most dependent on the sediment pore water distribution coefficient, which is obtained from the sediment pore water concentration, and variables that affect the transport across the BBL. DOC in the sediment pore water and water column did not greatly affect the mass transfer coefficient. We applied our findings to the Indiana Harbor and Ship Canal (IHSC) of Lake Michigan and show that deeper sediment section from IHSC will significantly increase ($p < 0.05$) the current release of PCBs from the sediment to the above water by a factor of at least 9.

WP061 Predicting the Airborne Polychlorinated Biphenyl Emissions from the Contaminated Waters of New Bedford, Massachusetts

B.N. Hadnott, The Univ of Iowa; A. Martinez, K.C. Hornbuckle, Univ of Iowa / Civil and Environmental Engineering IIHRHydroscience and Engineering

New Bedford Harbor (NBH) is a 70 km^2 urban estuary in Massachusetts with sediment contaminated with polychlorinated biphenyls (PCBs) and heavy metals. Aroclor 1242 was the primary commercial PCB mixture used in New Bedford until 1971 when Aroclor 1016 became available for use in the manufacture of electronic capacitors. The usage of PCBs in New Bedford peaked at about 1 million kg per year from 1973 to 1975. Due to this contamination, the harbor was placed on the U.S. Environmental Protection Agency (USEPA) federal list of Superfund cleanup sites in 1982 and is considered to be one of the nation's largest PCB contaminated sites. An environmental dredge of sediment in the harbor is ongoing, with plans to contain the sediment in a confined aquatic disposal (CAD) cell located in the lower harbor. USEPA Region I has been monitoring water concentrations of PCBs since 2006 and significant concentrations have been measured ranging from 10 to 10^5 ng L^{-1}. Using these water data, we have predicted gaseous fluxes as well as emissions of PCB congeners from NBH water, on days when water samples were collected, as a function of the meteorological conditions (e.g. wind speed, air and water temperatures) and individual PCB physical-chemical properties (Henry's law constant, internal energy, etc.). For example, gaseous flux of PCBs (expressed as the sum of the 18 NOAA measured PCB congeners) on June 24th, 2009 was 1.05 X 10^6 ng m^{-2} day^{-1} and a total PCB emissions from the upper Harbor, with an area of 550,000 m^2, was 600 g day^{-1}. These predicted values are at least one order of magnitude higher than other known PCB contaminated water systems, such as the Indiana Harbor and Ship Canal (IHSC), East Chicago, Indiana. Our findings indicate that NBH could be considered as one of the largest sources of airborne PCBs, which could not only affect the local PCB airborne concentration, but may impose a regional impact as well.

WP062 Evaluation of Air-Water Exchange of Polychlorinated Biphenyls at the Lower Duwamish Waterway Superfund Site

J. Apell, MIT / Civil Environmental Engineering; P. Gschwend, MIT / Dept of Civil and Environmental Engineering

Air-water exchange can be an important sink of PCBs in contaminated tidal estuaries. To determine the flux of PCBs across the air-water interface at the Lower Duwamish Superfund site, passive samplers were deployed in the surface waters and in the air above the water to measure the freely-dissolved and truly gaseous PCB concentrations. The error introduced by the use of passive sampling and several transfer velocity relationships found in the literature are evaluated. Di- through octa-chlorobiphenyls were detected in both the air and water, and the flux was from the water to the air even considering the uncertainty. Although the average flux of 67 ng PCBs/m^2/day is comparable to the flux calculated at other contaminated sites, it proved to not be a major sink of PCB contamination for the Lower Duwamish Waterway.

WP063 Air-water Exchange and Health Risk of PAHs and OPAHs at a Superfund Mega-site

L.G. Tidwell, Oregon State Univ / Environmental Molecular Toxicology; L. Paulik, K.A. Anderson, Oregon State Univ / Environmental and Molecular Toxicology

Chemical fate is a concern at environmentally contaminated sites, but characterizing that fate can be difficult. An important component of characterizing fate is identifying and quantifying the movement of chemicals at the air-water interface. Superfund sites are often suspected sources of air pollution due to legacy sediment and water contamination. A quantitative assessment of polycyclic aromatic hydrocarbon (PAH) and oxygenated PAH (OPAH) diffusive flux in a river system that contains a Superfund Mega-site, and passes through residential, urban and agricultural land, has not been reported before. Here, passive sampling devices (PSD) were used to measure 60 polycyclic aromatic hydrocarbons (PAHs) and 22 oxygenated PAHs (OPAHs) in the air and water. Human health risk associated with inhalation of vapor phase PAHs and dermal exposure to PAHs in water were assessed. Excess lifetime cancer risk estimates show potential increased risk at sites within and in close proximity to a Superfund Mega-site. Specifically, estimated excess lifetime cancer risk associated with inhaling PAHs was above 1 in 1 million within the Superfund Mega-site. We show the majority of PAHs and some OPAHs in the water are from airborne sources. The majority of PAHs detected in both environmental compartments, 16 out of 26, the direction of mass transfer at all five study sites was deposition. This suggests that the river water in this Superfund site is predominantly a sink for airborne PAHs and OPAHs, rather than a source.

WP064 Measurement of anthropogenic and natural polybrominated diphenyl ethers on atmospheric particles: Potential for long-range transport & health effects

J. Bautista, CJY group / Dept of Chemistry; C. Young, Memorial Univ / Dept of Chemistry

The usage of polybrominated diphenyl ethers (PBDE) as fire retardants in furniture and electronics have become a health concern. These species are known to act as endocrine disruptors. Recently, natural PBDE analogues produced from phytoplankton, blue mussels and sponges have been discovered which may contribute to a greater PBDE pool. Methoxy- and hydroxy-PBDEs found in marine environments are identifiable among other environmental PBDEs and may have more significant health impacts than anthropogenic PBDEs. Previous work has assumed the impact of natural PBDE analogues is limited to ocean environments; however PBDEs may also be transported into the atmosphere through the formation on marine aerosols. Hence, long range transport may also be possible through the atmosphere, leading to exposure far from the ocean. The atmospheric fate and potential health impacts of these species depends on the aerosol size on which they are found. Size-selected marine aerosols were collected with a nano-Micro Orifice Uniform Deposition Impactor (nano-MOUDI) setup from a rooftop atmospheric site in St. John's, NL. Aerosols ranging from 10 nm to 18 um in diameter were sampled over a year to capture any impacts of seasonal phytoplankton blooms. Samples were solvent extracted and analyzed using gas chromatography coupled to mass spectrometry (GC-MS). Temporal trends will be discussed, as well as implications of aerosol concentrations to human exposure and long-range transport for both anthropogenic and natural PBDEs.

WP065 Bioaccumulation of Substituted Diphenylamine Antioxidants and Benzotriazole UV Stabilizers in an Urban Creek in Canada

A.O. De Silva, Environment and Climate Change Canada; Z. LU, Environment and Climate Change Canada / Water Science Technology Directorate; T.E. Peart, C. COOK, G. TETREAULT, Environment and Climate Change Canada; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; M.R. Servos, Univ of Waterloo / Dept of Biology

Substituted diphenylamine antioxidants (SDPAs) and benzotriazole UV stabilizers (BZT-UVs), previously under reported classes of organic contaminants, were determined in sediment, water, and freshwater biota in an urban creek in Canada. SDPAs and BZT-UVs were frequently detected in all matrices including upstream of the urban area in a rural agricultural/woodlot region, suggesting a ubiquitous presence and bioaccumulation of these emerging contaminants. Spatial comparisons were characterized by higher levels of SDPAs downstream compared with the upstream, implying a possible influence of the urban activities on the antioxidant contamination in the sampling area. In sediment, 4,4'-bis(α,α-dimethylbenzyl)-diphenylamine (diAMS), dioctyl-diphenylamine (C8C8), and dinonyl-diphenylamine (C9C9) were the most dominant congeners of SDPAs, with concentrations up to 191 ng/g (dry weight, d.w.). Benthic invertebrates (crayfish (Orcoescties spp.)) had larger body burdens of SDPAs and BZT-UVs compared to pelagic fish (hornyhead chub (Nocomis biguttatus) and common shiner (Luxilus cornutus)) in the creek and partitioning coefficients demonstrated that sediment was the major reservoir of these contaminants. This is the first report of bioaccumulation and partitioning behaviors of SDPAs and BZT-UVs in freshwater environments.

Assessing Contaminant Effects in Multi-Stress Ecosystems

WP066 Integrated presentation of ecological risk from multiple stressors

B. Goussen, Univ of York / Environment; C. Rendal, O. Price, Unilever / Safety and Environmental Assurance Centre SEAC; R. Ashauer, Univ of York / Environment

The lack of ecological realism is widely recognised as a limitation in current prospective environmental risk assessment (ERA), as is the failure of making variability and uncertainty explicit and transparent. While these aspects are currently covered by assessment factors, our growing understanding of the chemical, biochemical, and ecological interactions governing adverse effects have the potential to enable next generation ERA to explicitly account for complex interactions. A step toward capturing more ecology and relevance is the use of environmental scenarios that represent biotic and abiotic parameters required to characterise direct and indirect exposure as well as effect and recovery of species. Prevalence plots area new way of presenting ecotoxicological data whilst accounting also for multiple stressors and ecologically relevant parameters. They provide an indication of the maximum population-relevant impact of an effect of interest and the prevalence of this impact. Essentially they answer two related questions: How strong is the effect? In how many locations will we see the effect? We discuss some of the challenges and opportunities involved in bringing these new concepts into everyday risk assessment. One of the key questions revolves around understanding and definition of the protection goal in specific environmental scenarios, and indeed whether certain scenarios require specific modified protection goals. Once the specific protection goal has been established, a metric to suit both the specific environmental scenario and protection goal needs to be defined and agreed. The selection of this endpoint must be carefully considered as different options will lead to different interpretation. We present a framework to integrate probabilistic approaches with mechanistic effect models to assess variable stressors and environmental scenarios. We present a hypothetical case study risk assessment and illustrate the potential benefits of the framework. To do so, we use an individual based model integrating a dynamic energy budget model to assess the potential impact of chemicals associated with local environmental characteristics. We then illustrate on potential policy makers' decisions of the maximal ecologically acceptable impact and the maximal prevalence of this impact. This new framework has the potential to better present ecologically relevant risk by using integrated biological endpoints and to aid more transparent risk communication.

WP067 Driver-response relationships in multi-stressor watersheds: findings from a long-term, integrated assessment of four US streams

C. Flinders, W. Arthurs, J. Ikoma, R. Ragsdale, NCASI; D.L. Cook, NCASI / Dept of Chemistry; W. Streblow, NCASI

To understand the effects of anthropogenic stressors in multi-stressor environments, managers must consider biota patterns in the context of natural environmental conditions (e.g. flow, temperature), point- and non-point discharges, and taxa-and end-point specific responses (i.e. physiological biomarkers vs. assemblage-level metrics). These assessments benefit from an integrated, weight-of-evidence framework that considers effluent toxicity, exposure relationships, and in-stream response in the context of spatial and temporal variation. Measurements made during a long-term receiving water study (LTRWS) assessed effluent toxicity, and examined patterns relative to non-point source run-off, and point-source inputs from tributaries and pulp and paper mill effluent discharge. Evaluations included effluent toxicity (Whole Effluent Toxicity (WET) tests, life cycle studies), and habitat and water quality relationships to biota (fish, macroinvertebrates, periphyton diatoms and chlorophyll a [chl a]) from multiple sites (n=5-7) in four streams (Codorus Creek, PA; Leaf River, MS; McKenzie and Willamette Rivers, OR). In all streams, most measured water quality parameters were variable across seasons and years, although annual patterns were generally consistent across sites. Statistically significant increases in some parameters (COD, color, conductivity, hardness) were seen at sites downstream of the effluent discharges relative to upstream sites, but at all four study streams some tributary stream parameters were similar or substantially greater than those at main channel sites regardless of effluent exposure. In WET tests (n>100) using effluent from the mills on each of the four streams, fathead minnow growth and Ceriodaphnia dubia reproduction was typically unaffected in 100% effluent exposures. Fathead minnow life cycle tests examining effluent-exposed fish at key life stages showed that eggs/female/day was the most sensitive endpoint measured, with effects not seen until 3-40x the instream effluent concentrations. In the larger rivers (Leaf, McKenzie, Willamette), fish, macroinvertebrate, and periphyton assemblage patterns were driven more by seasonal and annual variation than by differences among sites, while spatial patterns were more prevalent in Codorus Creek biota. The integrated, multi-facetted study design of the LTRWS enables driver-response relationships to be evaluated to disentangle the effects of in-stream stressors and guide management decisions.

WP068 Assessment of seasonal occurrence and risks of antibiotic residues in multi-impacted surface water and groundwater of Jianghan Plain, central China

L. Yao, China Univ of Geosciences (Wuhan) / Environmental Science; Y. Wang, China Univ of Geosciences, Wuhan

Jianghan Plain is one of the major regions of aquaculture production in China, meanwhile, antibiotics as therapeutic and growth promoters have been widely used in the aquaculture and animal husbandry. In this study, four categories antibiotics (macrolides, tetracyclines, fluoroquinolones and sulfonamides) were detected over three seasons in the aquatic environment at Jianghan Plain, central China. Anthropogenic activities

including fishery and livestock breeding were highly concentrated in the study area, and both of manure and fertilizer were used for crop planting. Besides, the shallow groundwater table and frequent precipitation derived intensive interaction between surface water and groundwater. The detection of target compounds in water samples were conducted by using the high performance liquid chromatography-tandem mass spectrometry. The average concentrations of total antibiotics in groundwater samples were with the value of 130.98, 20.27 and 33.65 ng/L in the spring, summer and winter sampling campaigns respectively, and that for surface water samples were with the value of 2.15, 0.98 and 0.71 µg/L in the foregoing three seasons respectively. The results suggested that the highest accumulation of detected antibiotics in the aquatic environment were occurred in spring, and the lowest concentrations of antibiotics were detected in summer and winter in groundwater samples and surface water samples respectively. Norfloxacin as the most predominant compound in groundwater samples, with concentration values ranging from 2.78 to 142.47 ng/L in spring, from 1.19 to 10.76 ng/L in summer and from 4.65 to 45.04 ng/L in winter. The concentrations of erythromycin accounted for the great proportion of the total antibiotic residues in surface water samples, ranging from 0.57-2.91µg/L (spring), 0.08-1.18 µg/L (summer) and 0.03-1.05 µg/L (winter). The method of risk quotient was used to assess the ecological risk posed by target compounds in both groundwater and surface water, and aquatic organisms in three different trophic levels (algae, daphnids and fish) were chosen to conduct the risk assessment. The results of assessment indicated that the overall order of susceptibility was algae > daphnids > fish, and during all of the measured antibiotics, erythromycin and ciprofloxacin were found to be the most harmful to the algae in surface water and groundwater respectively.

WP069 Assessment of immunotoxicity in fish based on the chemical effects on a natural host-pathogen interaction

K. Nakayama, Ehime Univ / Center for Marine Env Studies; S. Kitamura, Ehime Univ

In order to assess chemically-induced immunosuppressive effects in fish, we have developed a test method for evaluation of the chemical effects on a natural host-pathogen interaction. As host, we selected common carp (Cyprinus carpio), a species well studied in fish immune system, and tested pathogenicity of three bacterial species, Aeromonas hydrophila, A. salmonicida, and A. veronii against carp. An experimental infection of A. salmonicida by immersion caused high mortality in carp without any additional stressor, while bath infection of others did not show pathogenicity; therefore we chose A. salmonicida as a natural pathogen. In a preliminary test, 90% mortality was observed after 9 days post-infection, when fish were exposed to 1.0 x 10^6 colony forming unit (CFU)/mL A. salmonicida for 1 h. Based on these results, we decided to infect A. salmonicida at < 1.0 x 10^6 CFU/mL, when analyzing the chemical effects on the host-pathogen interaction. For validation of the test method, we used an immunosuppressive agent, dexamethasone as a positive control. Carp were exposed to 1 mg/L dexamethasone for whole experimental period, and fish in unexposed groups were received only 0.01% acetone. One week after the exposure test started, fish from each group were bath infected in 20 L water containing 2.9 x 10^3 (low) or 2.9 x 10^4 (high) CFU/mL A. salmonicida overnight. Unexposed and uninfected fish were set as control. After 7 days post infection, fish in the dexamethasone-exposed and high dose of A. salmonicida infected group started to die, and 40% mortality was observed in the group after 21 days post infection. The dexamethasone-exposed and low dose of A. salmonicida infected group showed 10% mortality after 13 days post infection. On the other hand, bacterial infection-associated mortality was not observed in A. salmonicida infected fish without dexamethasone exposure. These results clearly indicated that exposure to high concentration of dexamethasone suppressed the immune system of common carp, and caused subsequent mortality. Thus, the test method introduced in the present study is thought to be useful to evaluate chemically-induced immunomodulatory or immunosuppressive effects in fish.

WP070 In situ exposures in an agricultural area in Southern Brazil promote osmoregulatory disturbances in the freshwater fish Prochilodus lineatus

C.D. Vieira, W.E. Risso, Univ Estadual de Londrina / Departamento de Ciências Fisiológicas; C.B. Martinez, Univ Estadual de Londrina / Ciencias Fisiologicas

Aquatic ecosystems in agricultural areas may be affected by trace elements such as metals, as they are present in the composition of many fertilizers and fungicides. In areas with a historical and intensive agricultural production, metals may accumulate in the environment over time and represent severe threats to water bodies. Among metal effects, the disruption of osmoregulatory processes is well known. Thus, the objective of this work was to assess osmoregulatory parameters in fish Prochilodus lineatus subjected to in situ tests in an agricultural area in northern Paraná (Southern Brazil) and evaluate organism responses over time. Juvenile fish were confined in large cages (6000 L) at two different sites: the control group (CTR, n = 500) was confined at a fish farming station; the experimental group (EXP) was confined in a lake located inside an area of intense agricultural activity. During the caging period fish remained in contact with the sediment, so they could feed the substrate, but commercial food was also supplied. After 5, 15, 30, 60, 90 and 120 days of exposure a number of fish (n = 50) was removed from the cages and immediately transported to the laboratory where sampling took place. The gills and kidneys were removed for the determination of the activities of Na^+K^+- ATPase (NKA), H^+-ATPase (HA), and carbonic anhydrase (CA) activity, and plasma was collected for the determination of ions (Na^+, K^+, Cl^-, Ca^{2+} and Mg^+). Metal concentrations (Cu, Pb, Cr, Mn, Ni, Zn, Cd and Al) were determined in sediment samples collected in both sites, along the exposure period. In general, EXP site showed higher concentrations of Cu, Ni, Zn and Cd, in comparison to CTR site. When compared to CTR group, EXP fish showed a significant decrease in the branchial NKA activity, after 120 days of exposure, while in the kidney, an increased activity of this enzyme was observed after 60 and 120 days. The activity of renal HA increased significantly after 60, 90 and 120 days of confinement. Changes in the concentrations of certain ions were also seen, with significant reductions of Ca^{2+}, after 90 and 120 days, and Na^+, after 60 and 90 days; conversely, Mg^+ showed a significant increase after 90 days. These results show the in situ exposure of P. lineatus in an agricultural area changed osmoregulatory processes in different ways, and the metals present at these locations are the potential cause of these changes.

WP071 Toxicity and fitness costs in PAH-resistant and non-resistant Fundulus heteroclitus exposed to creosote-contaminated sediment extract and hypoxia

C.D. Lindberg, N. Jayasundara, J.S. Kozal, R.T. Di Giulio, Duke Univ / Nicholas School of the Environment

Chronic creosote pollution at sites along the Elizabeth River (VA, USA) has resulted in the evolution of toxicant resistance in populations of Atlantic killifish (Fundulus heteroclitus) inhabiting those areas. Specifically, these fish are resistant to the acute toxicity induced by exposures to polycyclic aromatic hydrocarbons (PAHs), the primary components of creosote. We have found that a population of killifish that resides at the site Republic, which contains approximately 113,886 ng PAH/g dry sediment (Vogelbein & Unger, 2008), is recalcitrant to both in ovo CYP1A induction and developmental deformities after exposures to simple and complex PAH mixtures compared to the reference site Kings Creek (York River, VA, USA). This adaptation is protective against the acute lethality and teratogenesis associated with PAH exposures. However, we have found that there are trade-offs of PAH-resistance. Our goals for this study were to evaluate how multiple stressor exposures affect wild-caught populations of killifish and how evolved resistance against PAH toxicity influences the tolerance of fish populations to other environmental stressors. To do so, we exposed killifish embryos starting at 24hpf to non-teratogenic doses of a sediment extract that contains a complex, real-world mixture of PAHs along with diurnal hypoxia, an environmental condition common to the Chesapeake Bay and many other estuaries in the United States. Preliminary data in other fish species suggests that this type of co-exposure results in more-than-additive toxicity in developing embryos. Endpoints to be tested further include mortality, hatch rates, gross morphological deformities, CYP1A activity, embryo bioenergetics, and oxidative stress analyses. Our work identified bioenergetic costs of PAH-related adaptations, evidenced by reduced active metabolic rates and subsequent reduced aerobic scopes (both $p < 0.05$) in Republic F1 juveniles and an increased basal oxygen consumption rate Republic F1 embryos throughout development ($p < 0.05$). These fitness costs and others could result in an increased vulnerability of Republic killifish to additional anthropogenic or environmental stressors. This work was supported by NIEHS T32-ES021432 and the Superfund Research Program P42ES010356.

WP072 An ecotoxicological approach to oil sands

D. Nunes Cardoso, CESAM, Univ of Aveiro / Dept of Biology and CESAM Centre for Environmental and Marine Studies; J. Pestana, S.F. Goncalves, Univ of Aveiro / Dept of Biology and CESAM; F.J. Wrona, Alberta Environment and Parks / Environmental Monitoring and Science Division; A.M. Soares, Univ de Aveiro / Dept of Biology and CESAM; S. Loureiro, Univ de Aveiro / Biology

The oil sands deposits in northern Alberta (Canada) are one of the world's largest oil reserves that have unique geochemical, ecological and eco-toxicological characteristics to address. A key issue in the oil sands region is the discrimination of natural versus anthropogenic sources of oil sands-related contamination of surface and groundwater and the resulting cumulative effects on aquatic ecosystem structure and function. Since the the lower Athabasca River and many of its major tributaries flow through natural bitumen deposits, the challenge is to distinguish between the types and levels of hydrocarbon-associated contaminants that occur naturally from those arising from anthropogenic activities related to oil sands mining and subsequent upgrading of oil. The main objective of this study was to evaluate the acute and chronic ecotoxicological effects associated with the slumping of river bank material that is comprised of oil sands deposit that naturally enters the river systems through fluvial geomorphological processes. Ecotoxicological tests were conducted using parental geological material collected from the river banks near the oil exploitation area (Alberta, Canada), in 4 different locations. Samples differ each other mainly in terms of texture and proportional bitumen content due to the differences in the specific geological formations in each river basin. The solid samples (treated as soils), sediment and water-based exposure tests were carried out, using standardized ecotoxicological tests with representative terrestrial (Folsomia candida), sediment dwelling (Chironomus riparius) and aquatic (Daphnia magna, Physa acuta) organisms. Preliminary results confirmed that a suite of methodologies were needed to derive an accurate assessment of possible ecotoxicological and related environmental effects. The use of both soil and aquatic organisms provided complementary knowledge on the possible ecotoxicological effects related to exposure to oil sands materials arising from bank erosion-related processes. Different patterns of toxicity were observed based on the location of the different samples' collection areas and types of slumping material (i.e., % content of bitumen), suggesting that the geological context of the area must be taken into consideration when assessing both reach-specific and regional ecological effects.

Global Non-Point Source Aquatic Contamination Mitigation Strategies: Success and Failures

WP073 An Integrated Vegetated Ditch System Reduces Chlorpyrifos Loading in Agricultural Runoff

B.M. Phillips, Univ of California-Davis / Environmental Toxicology; B.S. Anderson, Univ of California – Davis / Dept of Environmental Toxicology; J.P. Voorhees, Univ of California Davis / MPSL Environmental Toxicology; K. Siegler, R.S. Tjeerdema, Univ of California – Davis / Environmental Toxicology; M. Cahn, Univ of California Davis / UC Cooperative Extension; R. Budd, California EPA / Dept of Pesticide Regulation; K. Goh, California Dept of Pesticide Regulation

Agriculture runoff containing toxic concentrations of the organophosphate pesticide chlorpyrifos has led to impaired water body listings and Total Maximum Daily Load restrictions in California's central coast watersheds. Chlorpyrifos use is now tightly regulated by the Central Coast Regional Water Quality Control Board. This study evaluated treatments designed to reduce chlorpyrifos in agricultural runoff. Initial trials evaluated the efficacy of three different drainage ditch installations individually: compost filters, granulated activated carbon filters, and native grasses in a vegetated ditch. Treatments were compared to bare ditch controls, and experiments were conducted with simulated runoff spiked with chlorpyrifos at a 1.9 L/s flow rate. Chlorpyrifos concentrations and toxicity to Ceriodaphnia dubia were measured at the input and output of the system. Input concentrations of chlorpyrifos ranged from 858 ng/L to 2840 ng/L. Carbon filters and vegetation provided the greatest load reduction of chlorpyrifos (99% and 90%, respectively). Toxicity was completely removed in only one of the carbon trials. A second set of trials evaluated an integrated approach combining all three treatments. Three trials were conducted each at 3.2 L/s and 6.3 L/s flow rates at input concentrations ranging from 282 ng/L to 973 ng/L. Chlorpyrifos loadings were reduced by an average of 98% at the low flow rate and 94% at the high flow rate. Final chlorpyrifos concentrations ranged from non-detect (< 50 ng/L) to 82 ng/L. Toxicity to C. dubia was eliminated in three of the six integrated trials. Modeling of the ditch and its components informed design alterations that are intended to eventually remove up to 100% of pesticides and sediment. Future work includes investigating the adsorption capacity of granulated activated carbon, costs associated with carbon disposal, and real-world field trials to further reduce model uncertainties and confirm design optimization. Trials with more water-soluble pesticides such as neonicotinoids are also recommended.

WP074 An Overview of Risk Mitigation of Agricultural Pesticides in the Lourens River, South Africa

J. Dabrowski, CSIR South Africa; R. Schulz, Univ of Koblenz-Landau / Inst for Environmental Sciences

The aquatic fate, transport, risk and mitigation of pesticides have been intensively studied in the catchment of the Lourens River (Western Cape, South Africa). The catchment supports intensive deciduous fruit and vineyard production and runoff and spray drift are the most important routes of entry of pesticides into the aquatic ecosystem, with short-term peak concentrations resulting in deleterious effects on macroinvertebrate community assemblages. The importance of runoff and spray drift as a source of contamination is highly dependent on spatial scale with spray drift being more important at a field scale, and runoff being more important at a larger catchment scale. A major focus in the catchment has been to characterise landscape features that influence contamination with an emphasis on identifying suitable mitigation options. Wetlands constructed in tributaries and drainage canals are highly effective in reducing runoff and spray drift associated particle bound and aqueous dissolved pesticide concentrations entering the mainstream Lourens River. These reductions in concentrations have also resulted in reductions in toxicity to aquatic macroinvertebrates. Aquatic macrophytes in tributaries and drainage canals are effective in reducing the downstream transport of spray drift associated pesticide concentrations. The effectiveness of these

in-stream measures is however highly dependent on prevailing hydrological conditions, as runoff associated pesticide concentrations were not as effectively reduced due to increased flow velocity. Furthermore, emergent in-stream aquatic vegetation acted as an effective physical barrier, intercepting spray drift and reducing in-stream deposition of pesticides. While many of the tributaries in the catchment have a relatively wide vegetated buffer strip adjacent to orchards, intensive surveys of the catchment revealed that in almost all cases, preferential flow paths led to the development of erosion rills, providing an unhindered route of entry for runoff into water bodies. The results obtained from the research conducted in the Lourens River have direct implications for the global risk assessment and mitigation of pesticides. Regulation of pesticides in South Africa is however not well developed and research results are discussed within this context, with the aim of providing future research and development opportunities relevant to both South Africa and the rest of the world.

WP075 Mitigation of fungicide pollution in detention ponds and vegetated ditches within a vine growing area in Germany

M. Bundschuh, Dept of Aquatic Sciences and Assessment Swedish Univ of Agricultural Sciences / Dept of Aquatic Sciences and Assessment; D. Elsaesser, Univ of Koblenz; C. Stang, Univ of Koblenz-Landau; R. Schulz, Univ of Koblenz-Landau / Inst for Environmental Sciences

Large amounts of fungicides are commonly applied to agricultural fields, particularly vineyards. Following their application, fungicides may accidentally be introduced into agricultural surface waters posing a potential risk for the integrity of aquatic ecosystems. In this context, the present study characterized the aquatic fungicide exposure at base flow and during rainfall-related runoff events in viticulture in Southern Palatinate (SW-Germany) between 2006 and 2009. The mitigation performance of three vegetated ditches (VD) and five vegetated detention ponds (DP) was assessed. The measurements uncovered the presence of four to eleven different fungicide compounds in each of the 81 samples. During runoff events, the ecotoxicological potential – expressed as the sum of toxic units calculated based on the acute toxicity towards algae, Daphnia and fish– of some of the mixtures detected at the inlet of the VD or DP exceeded the Uniform Principle threshold set by the European Union. Both the VD and the DP systems reduced the median fungicide concentrations and thus their associated ecotoxicological potential by 56% and 38%, respectively. This fungicide mitigation efficiency was mainly explained by the plant density and size-related properties of the vegetated systems. Although VP and DP are promising tools to mitigate fungicide exposure, a better mechanistic understanding of the factors triggering the remediation potential finally feeding back into policy decision making is required.

WP076 Non-Point Source Aquatic Contamination Mitigation Strategies: A Global Perspective

E.R. Bennett, Univ of Windsor; K.G. Drouillard, Univ of Windsor / Great Lakes Inst for Environmental Research; D. Haffner, Univ of Windsor / GLIER; J. Struger, Environment and Climate Change Canada / Water Quality Monitoring Surveillance; A. Dove, B. Bass, Environment and Climate Change Canada; S. Yu, Chinese Academy of Sciences; C.D. Metcalfe, Trent Univ / Water Quality Centre

With increased global demand for fuel and food production, a major intrinsic cost may be damage to downstream aquatic ecosystems due to non-point source contamination. Implementation of natural landscape features or bioengineered structures are part of the solution in reducing toxicological or biological effects caused by potential upstream contamination. The aim of this presentation is to highlight what mitigation strategies are in place, working or failing, to reduce concentrations of pesticides and nutrients in receiving waterbodies. This main focus will be to highlight some of the best management practices that are currently being implemented in different locations around the world. The latter portion of the presentation will focus on what approaches are being applied in southern Ontario, Canada to reduce loadings in Lake Ontario and Lake Erie.

WP077 Potential use of Japanese Sweetflag (Acorus gramenius) for Remediation of Contaminated Surface Water

N. Abdel-Mottaleb, Univ of Florida / Soil and Water Science; P.C. Wilson, Univ of Florida / IFAS / Soil and Water Science

Acetaminophen, carbamazepine, sulfamethoxazole, and estradiol are often detected in wastewater treatment effluent and surface waters receiving wastewater and reclaimed water. Conventional remediation techniques are often impractical for non-point sources and for compounds with no water quality regulations. One possible remediation technique under evaluation is the use of floating islands established with ornamental wetland plants. Mass balance studies were conducted to characterize the potential uptake of 14C-labelled acetaminophen, carbamazepine, sulfamethoxazole, and estradiol by the ornamental wetland plant, Acorus gramenius (Japanese Sweetflag). Over a 14 day exposure period, there was a 20% reduction of atrazine, 26% reduction of carbamazepine, 40% reduction of perfluorooctanoic acid (PFOA), 60% reduction of sulfamethoxazole, 60% reduction of estradiol, and 100% reduction of acetaminophen. Preliminary results suggest that A. gramenius may be a good candidate for removing acetaminophen, PFOA, carbamazepine, sulfamethoxazole, and estradiol from contaminated surface water. Future research will evaluate the uptake potential of other contaminants with differing hydrophobicity to identify optimal properties for uptake.

WP078 Reducing nutrients and organic micropollutants in a rural wastewater effluent with subsurface filtration treatment technology

L.G. Chaves-Barquero, Univ of Manitoba / Dept of Chemistry; K. Luong, Univ of Winnipeg / Richardson College for the Environment; M.L. Hanson, Univ of Manitoba / Dept of Environment and Geography; C.S. Wong, Univ of Winnipeg / Richardson College for the Environment

To better understand the efficacy of wastewater treatment in rural Canada, we characterized the occurrence of wastewater contaminants (i.e. pharmaceuticals and nutrients) from lagoon to release at a treatment facility in Dunnottar, Manitoba. Wastewater treatment in this community is performed by the use of a two-lagoon system with subsequent subsurface filtration and ultraviolet treatment. Grab samples were collected during the summer of 2015 to measure pharmaceuticals along the wastewater path and Polar Organic Integrative Chemical Samplers (POCIS) were deployed at the input, output and post-UV treatment on the filtration system. Nutrients concentrations were measured at the input and output of the filter. Significant attenuation was observed for nutrients between the input and the output of the subsurface filter (19-42% ammonia; 55-71% total phosphorus). A total of five pharmaceuticals were consistently detected throughout the filter: atenolol, sulfamethoxazole, metoprolol, propranolol and carbamazepine. Of these five, most were mainly removed between the primary and secondary lagoons (56% carbamazepine; 86% metoprolol; 73% sulfamethoxazole), likely due to photolysis and microbial degradation, with little attenuation being observed for these compounds within the filter, which is consistent with previous studies done by our research group at this facility. The detected concentrations at the output of the treatment system were below levels of concern for aquatic life. Our results suggest that the constructed sub-surface treatment filtration system can provide a low-cost and low-maintenance means to reduce nutrient loadings commonly found in wastewaters.

WP079 Savannah River Site's A-01 Constructed Wetland System: A Model for Sustainable Aquatic Risk Mitigation

G.M. Huddleston, SynTerra Corporation; C. Gulde, Chevron Environmental Management Co.; S.M. Harmon, Univ of South Carolina Aiken / Biology and Geology; J. Rodgers, Clemson Univ / Forestry and Env Conservation

In October of 2000, a constructed wetland treatment system began receiving a combination of stormwater and wastewater from the A-01 outfall located at the U.S. Department of Energy's Savannah River Site (SRS) in South Carolina. The constructed wetland treatment system was designed to treat one million gallons per day of stormwater from a 200-acre watershed (42% of total flow) and effluent from research laboratories (58% of total flow) at SRS. The A-01 outfall is an NPDES permitted discharge, and prior to construction of the wetlands, contained copper at levels toxic to aquatic organisms. The conceptual design of the wetland treatment system was developed from pilot mesocosm studies to identify key aspects of wetland function and performance. The pilot studies determined specific design parameters such as physical/chemical characteristics of hydrosoil, appropriate hydraulic retention time, and selection of wetland vegetation effective for copper attenuation. The full-scale constructed wetland system consisted of an upstream retention basin that provided consistent flow via gravity to eight one-acre wetland cells planted with giant bulrush (Schoenoplectus californicus). The A-01 outfall has consistently achieved compliance for copper, mercury, and toxicity since the wetlands came on line 16 years ago. The constructed wetland system has provided numerous research opportunities from conceptual design through long-term operation. Much of the research will be highlighted here. The A-01 constructed wetland system received recognition from the U.S. Department of Energy and U.S. Environmental Protection Agency Region 4 as a model application of sustainable technology, having saved SRS over $60 million over the life of the system.

WP080 When you wish upon a ditch: Twenty years of bioengineering for agroecosystem services

M. Moore, USDA-ARS National Sedimentation Laboratory / Water Quality and Ecology; E.R. Bennett, Univ of Windsor; J.L. Farris, Arkansas State Univ / Univ Distinguished Professor; J.M. Taylor, USDA-ARS National Sedimentation Laboratory; R. Kroger, Covington Civil and Environmental; D.L. Denton, USEPA Region 9 / co SWRCB; M.A. Locke, USDA-ARS National Sedimentation Laboratory / Water Quality and Ecology Research Unit

Throughout history, agricultural drainage ditches have served to move excess water from production acreage to nearby rivers, lakes, and streams. Research, however, has indicated these unique structures are capable of providing vital ecosystem services such as pesticide and nutrient mitigation. Early studies on vegetated drainage ditches in the Mississippi Delta demonstrated their substantial ability to sorb several different pesticides and transfer them out of the water column. These studies led to further confirmation across the United States, culminating in the Natural Resource Conservation Service's California state office recognizing vegetated agricultural drainage ditches as a modified conservation practice (607A). More recent drainage ditch research has focused on denitrification, carbon sequestration, and ditch metabolism involved with nutrient mitigation. Successful pesticide mitigation results will be briefly highlighted before presentation of the challenges faced in nutrient mitigation, along with results from current mesocosm studies showing the capability of Leersia oryzoides (rice cutgrass) to denitrify and immobilize nitrate.

Thinking Outside the Laboratory Box: An Ecological Approach in Tackling Ecotoxicological Problems

WP081 Bifenthrin causes trophic cascades in aquatic food webs and alters subsidies to terrestrial food webs

T.S. Schmidt, USGS / Colorado Water Science Center; H. Rogers, USGS / Fort Collins Science Center; B. Dabney, Colorado State Univ / Fish, Wildlife, and Conservation Biology; M.L. Hladik, USGS / California Water Science Center; B.J. Mahler, USGS / Water Mission Area; P.C. Van Metre, U. S. Geological Survey / Texas Water Science Center

Direct and indirect ecological effects of the widely used insecticide bifenthrin on stream ecosystems are largely unknown. To investigate such effects, a 30-d experimental stream test was conducted by exposing macroinvertebrate communities to a single dose of bifenthrin-contaminated sediment; results were interpreted in the context of a regional-scale assessment of Midwestern (USA) streams. At bifenthrin-sediment concentrations previously thought safe for aquatic life, direct effects of exposure included reduced larval macroinvertebrate abundance, richness, and biomass; whereas, indirect effects included a trophic cascade in which periphyton abundance increased after macroinvertebrate scrapers decreased. Adult emergence dynamics and corresponding terrestrial subsidies were altered at all tested bifenthrin concentrations. Extrapolating these results to the regional stream assessment suggests pervasive ecological effects in Midwestern streams with altered emergence dynamics likely in 39% of streams and a trophic cascade in 7% of streams. We provide new evidence that a common pyrethroid can alter aquatic and terrestrial ecosystem function at the regional scale.

WP082 Multi-Stressor Impacts on Fish Energetics: A Comparison between Lab and Field Studies

H. Mehdi, E.C. Laidley, P. Craig, Univ of Waterloo / Biology

Aquatic organisms face numerous stressors simultaneously in their environments. While each of these stressors pose great threats to aquatic life, studying each stressor individually is not sufficient, as these stressors are not independent, but work cumulatively and synergistically to alter aquatic ecosystems. The objective of this study was to compare and contrast the impacts of multi-stressors under lab and field conditions using two fish species, zebrafish (Danio rerio) and rainbow darters (Etheostoma caeruleum). Under lab conditions, the study examined the impacts of chronic exposure to environmentally relevant concentrations of venlafaxine, an antidepressant pharmaceutical contaminant found abundantly in wastewater treatment plant effluents, in combination to elevated water temperatures on zebrafish. Under field conditions, rainbow darters were collected from two sites, upstream and downstream of a wastewater treatment plant, which served as control and contaminated sites respectively. Muscle tissue was sampled from both lab and field species to measure enzyme activity of major metabolic enzymes and metabolites involved in regulating energetics in fishes. Circulating levels of stress hormone, cortisol, were measured from holding water of fishes. Oxygen consumption was measured using respirometers to assess the effects of stressors on standard metabolic rate, active metabolic rate, and aerobic scope, all of which can be used as ecological performance indicators. The results of this study will contribute to the recognized importance of including multi-stressor approach assessments to make predictions regarding the impact of stressors on fish health and abundance.

WP083 Eutrophication and nanopesticide contaminants interact to reduce ecosystem productivity and microbial functioning in a wetland mesocosm experiment

M. Simonin, Duke Univ; B.P. Colman, Univ of Montana / College of Forestry and Conservation; M.R. Ruis, Duke Univ / Biology; B.G. Perrotta, Baylor Univ / Biology; S.M. Anderson, Duke Univ / Biology; R.S. King, Baylor Univ / Dept of Biology; E. Bernhardt, Duke Univ / Biology

Engineered nanomaterials have now been considered pollutants of emerging concern for almost a decade. The recent development of nanopesticides is resulting in widespread application of engineered nanoparticles to agricultural fields. Nanopesticides are likely to become increasingly common components of agricultural runoff, with significant potential for environmental impact in downstream ecosystems. We examined the impacts of chronic 0.05 mg L^{-1} weekly addition of an agricultural copper hydroxide nanoparticle ($Cu(OH)_2$-NP) containing fungicide (Kocide 3000) on wetland mesocosms (small ecosystems). Because we anticipate that nanopesticide exposures will often co-occur with fertilizer enrichment, we crossed our nanopesticide exposure treatment with a nutrient enrichment treatment (Oligotrophic or Eutrophic). We hypothesized that resource availability may have a major effect in driving the resistance and resilience of organisms to the potentially toxic effects of nanomaterials, with nutrient rich (eutrophic) ecosystems having a greater capacity for mitigating stress than nutrient poor (oligotrophic) ecosystems, given the elevated nutrient and energy demands of dealing with toxins. Testing this hypothesis necessitates an emphasis on the "eco" part of ecotoxicology with the focus less on mechanisms of toxicity and more on community and ecosystem level endpoints. As such, we assessed the impact of the nanopesticide on: productivity, respiration and biomass of the macrophyte and periphyton; and microbial activities (C, N, P, S enzyme activities, respiration, nitrification, denitrification) in the surficial sediments and periphyton. After 3 months of chronic exposure to the nanopesticide, there have been observable impacts on primary productivity and microbial functioning in the wetland mesocosms, but contrary to our hypothesis they have only been observed in the eutrophic conditions. Significant decreases of macrophyte and periphyton photosynthesis and respiration were observed, as well as 50–70% decrease in periphyton and sediment microbial enzyme activities. These global effects lead to an increase of the buildup of available N and P in the watercolumn and an increase in greenhouse gas emissions (CO_2 and CH_4). Thus this work highlights both the importance of characterizing the impact of nanomaterials in environmentally relevant conditions and in different ecological contexts, such as trophic status.

WP084 Trait-based approach to detect the impact of chemicals on fish in multi-stress condidions

S. Sipos, Univ of Novi Sad / Faculty of Sciences; V. Jovanovic, IBISS – Inst for Biological Research; I. Teodorovic, Univ of Novi Sad / Faculty of Sciences

The impairment of overall ecological status of aquatic ecosystems is generally attributed to multi-stress conditions, mainly hydromorphological alterations, eutrophication, biological invasions and to a certain extent, chemical pollution. Monitoring programs relying on classical taxonomy-based approach typically failed to distinguish between individual stressors, quantify the overall impact of chemical pollution and identify key toxic pollutants, or rather, key type of chemical mixtures which significantly affect aquatic communities and contribute to ecological status impairment. The aim of the present study was to assess the applicability of the trait-based approach in detection and quantification of the impact of the pollutants and their mixtures on fish communities, with the overall objective to contribute to regulatory – driven process of identification of key or river basin specific pollutants and mixtures which is a main focus of EU FP 7 SOLUTIONS project. The study is based on a large dataset acquired during Joint Danube Survey 3 (JDS 3) in 2013 at 32 sampling sites along the River Danube, which includes biological, hydromorphological (CORINE) and large chemical dataset. Fish taxonomical data (132,498 fish specimens, 67 species, 17 families) were converted into six major traits with a number of states. Taxonomical and trait variation of fish communities along the river was checked by correspondence analysis (CA), chemical composition (255 chemicals) at 32 sites was analyzed by principal component analysis (PCA) and ordination techniques, two canonical correspondence analysis (CCA) – PCA coordinates/CORINE scores were used to explore variation of fish taxonomical and trait-based community structure and in the end, fish data (species, traits /states) were correlated with chemical data by general linear model (GLM). Some of the interesting results include: no significant correlation between any species (taxonomical approach) and any chemical or chemical mixture; no significant negative correlation between any trait / state and any chemical or chemical mixture; high positive correlation of non-feeding adults state with a cocktail of ubiquitous chemicals (metals, PAHs) and high positive correlation (established for the subset of 8 sampling sites) of catadromous, rhithral, lithophilic, speleophilic, brood hiders and rheophil species to a cocktail of 11 chemicals typical for sewage waters –nitrogen, pharmaceuticals and personal care products.

WP085 The Qatari Pearl Oyster: Their reproductive biology, in vitro fertilization, sensitivity to local contaminants for environmental management program

S. Saeed, ExxonMobil Research Qatar / Environment and Water Reuse Program; N. Deb, ExxonMobil Research Qatar / Environmental; C.S. Warren, ExxonMobil Research Qatar / Environment and Water Reuse Program

The marine species Pinctada radiata is the most abundant pearl oyster found in Qatari waters; however, little is known about its reproductive biology, ecological importance and life cycle. Oysters filter prodigious volumes of water, capturing particles down to 5 microns in size and ingesting algae, zooplankton, bacteria and detritus. They are therefore exposed to both dissolved and suspended contaminants. Consequently, they are likely to be excellent indicators of potential contaminants in the Arabian Gulf and can be used for risk assessment and monitoring as part of an effective environmental management program. To investigate seasonal variation in gonad maturation a total of 300 oysters were collected from intertidal habitat from March 2014 to May 2016. Upon collection individuals were weighed, shell length and width recorded and sex determined under light microscope. About 30 oysters were selected from different sizes for histological investigations to determine maturation stage of gonads. The rest of the oysters were used for in vitro fertilization and were exposed to widely used reference toxicants and to local contaminants of concern. Another experiment was carried with 120 oysters collected from the same site to determine the optimum diet for best growth. The oysters were kept in a flow-through system. They were divided into three equal groups and were placed every day into a feeding tank for 2 hours. One group was fed with a combination of microalgae and rice powder, the second group was fed the microalgae alone and the third group was fed rice alone. The results showed that there was no correlation between length and width with sex of oysters. Comparing between field and lab-cultured oysters, there were clear differences between the ratios of males to females as well as differences in sexual maturity. Successful fertilization was achieved with gametes obtained from oysters fed with mixtures of algae and rice (80%), rice alone (60%) and microalgae alone (20%). Data from acute and chronic toxicity tests showed that embryo mortality to be dose-dependent and different sensitivity towards various toxicants were obtained. The protocol for successful in vitro culture and fertilization as shown in the present study provides both oyster embryos and adults throughout the year for performing acute and chronic toxicity studies. Future work will focus on using P. radiata for monitoring contaminants of concern in the Arabian Gulf region.

WP086 Individual-based and system dynamic modeling frameworks to explore a complex energetic process in aquatic communities

A. East, Towson Univ / Environmental Sciences; C.J. Salice, Towson Univ / Biological Sciences/ Environmental Science

Advancing the predictive capacity of mathematical models that inform ecological risk assessments necessitates improving the connection between single species toxicity tests and multiple species systems. To this end, models that focus on community level interactions are of particular interest. Specifically, a focus on lower trophic level organisms that function as energetic mobilizers or recyclers would likely improve effectiveness of community models that have typically focused more on predation or competition. A core addition required to expand single species energetic stressor effect models to community levels is the facilitation that occurs due to waste recycling or energetic mobilization by one organism to the benefit of other organisms. In an effort to explore the potential system effects of facilitation, we have constructed two models that mimic experimental aquatic communities of Daphnia magna, Lymnaea stagnalis, generic 'algae,' and lettuce. These are common arrangements of single species toxicity tests, but also represent a potentially common freshwater system of two functionally and behaviorally different invertebrates, a phytoplankton, and a macrophyte. The modelling approaches are (1) an individual-based model centered on Dynamic Energy Budget Theory models of growth and reproduction (DEB-IBM) and (2) a system-dynamics model parameterized by the consumption rate and waste generation of compartments and the corresponding network that defines potential connections of mobilization and recycling for facilitation processes. The DEB-IBM incorporates facilitation processes and their magnitude through a manipulation of the functional response parameter (f) of receiving organisms (D. magna) as a function of output magnitude from providing organisms (L. stagnalis). Both models suggest a wide variety of responses to facilitation, driven not only by the increased complexity of increased connections but also on the magnitude of facilitation. Of particular importance is the observation that facilitation can potentially explain differential toxicity responses in multiple species toxicity tests; this was confirmed in both models under similar scenarios of energetic stressor exposure. Our results suggest that models designed to explain stressor effects at community levels require a framework for inclusion and exploration of facilitating energetic pathways.

WP087 Biofilm in Large-Scale Stream Mesocosms as a Tool to Assess the Efficacy of Advanced Wastewater Treatment Technologies

J. Rodriguez Gil, Univ of Calgary / Biological Science; L. Jackson, Univ of Calgary / Biological Sciences

An increasing number of studies have shown, with certainty, that current wastewater treatment processes and technologies fail to remove many chemical compounds we use in our everyday lives. Numerous studies have also shown that some of these compounds affect, among others, endocrine function and can cause dramatic changes in the biological communities of receiving ecosystems. Development of advanced wastewater treatment technologies has closely followed this realization and new technologies are more effective at removing these compounds. Increasing pressure on water resources, with water re-use becoming a real need in many places around the world makes progress in this field ever more important. Evaluation of the biological effects of these compounds on receiving ecosystems, however, remains limited by difficulties associated with field studies, such as lack of true replication and difficulty selecting reference conditions (even in up-stream downstream designs), which limits our understanding of the true biological/ecological effects of these compounds in aquatic communities. These limitations become even greater when attempting to assess and compare differential effects, typically in single systems, from effluents of new wastewater treatment technologies. Now, the 12, 320 m artificial streams of the Advancing Canadian Wastewater Assets (ACWA) facility (Calgary, Alberta, Canada) provide a unique platform to answer these questions. Here we present results of biofilm growth in streams that were divided into 4 treatment groups (n=3) representing a negative reference treatment (14 L s^{-1} of adjacent Bow River water) or one of 3 exposure treatments where Bow River water received a 5 % (v/v) influx of either final effluent (positive reference) from the Pine Creek Wastewater treatment plant (where ACWA is embedded), or the same volume of this effluent after treatment via in-line ozonation or reverse osmosis. Structural (biomass, chlorophyll-a and algal community composition) and functional (community respiration, gross primary production, transformation of organic phosphorus and photosynthetic efficiency) endpoints were assessed in the biofilm communities of the streams to evaluate the effect of the positive reference treatment (Pine Creek final effluent) and whether dosing with effluent from advanced treatment technologies led to any observable changes.

Advanced Analytical Methods for Contaminant Discovery

WP088 Application of non-targeted analysis approaches to assess input of organic micropollutants to San Francisco Bay

N. DeStefano, Duke Univ; J. Sun, R. Sutton, San Francisco Estuary Inst; L. Ferguson, Duke Univ / Dept of Civil and Environmental Engineering

Input of emerging contaminants (EC) such as pharmaceuticals, personal care products, pesticides, and consumer/industrial chemicals to San Francisco (SF) Bay through stormwater or wastewater discharge is of concern due to potential impacts on environmental quality and effects on wildlife. Although proactive efforts have been directed toward monitoring for ECs within the Regional Monitoring Program for Water Quality in San Francisco Bay (RMP), there still remains much uncertainty regarding the identity and fate of the most relevant ECs in SF Bay water, along with their source. We have thus conducted a broad spectrum, non-targeted analysis of polar, water-soluble organic micropollutants in SF Bay using high resolution/accurate mass (HR/AM) mass spectrometry approaches, in order to assess occurrence and establish prioritization of ECs for further fate and effects assessment. In 2016, Polar Organic Chemical Integrative Samplers (POCIS) were deployed at three locations in the San Francisco Bay watershed influenced by different contaminant pathways: urban stormwater runoff (San Leandro Bay), agricultural runoff (Napa River), and wastewater effluent (Lower South Bay). These passive samplers were used to provide an integrated, semi-quantitative assessment of pollutants entering the Bay over the course of approximately three weeks. Grab samples were collected before and after deployment to provide a quantitative snapshot of contaminants for comparison. 24-hour composite samples of wastewater effluent were also collected from several wastewater dischargers. Samples were analyzed using HR/AM Orbitrap liquid chromatography high resolution mass spectrometry and resulting data were analyzed using a custom workflow designed for high-fidelity componentization, prioritization, identification, and semi-quantitation of detected molecular features. Compounds identified through this method include, but are not limited to, detergents and other surfactants, pesticide and pharmaceutical breakdown products, and plastic additives. Preliminary results from the non-targeted analyses of SF Bay water will be presented in context of pathways and (where possible) estimated loadings of ECs to the SF Bay ecosystem.

WP089 Exposure Profile Comparison and Screening of Unknown Contaminants Using LC-QTOF: A Cat Hyperthyroidism Study

M. Wang, ECL California Dept of Toxic Substances Control / Dept of Toxic Substances Control Environmental Chemistry Laboratory; E. Parry, California Environmental Protection Agency / Dept of Toxic Substance Control Environmental Chemistry Laboratory; S. Anand, S. Salihovic, California Environmental Protection Agency / Dept of Toxic Substance Control; W. Guo, DTSC-ECL; M. Petreas, California Environmental Protection Agency / Dept of Toxic Substance Control Environmental Chemistry Laboratory; J. Park, California Environmental Protection Agency / Dept of Toxic Substances Control Environmental Chemistry Laboratory

Targeted analytical methods using GC- or LC-MS/MS have been widely employed to study the presence of emerging compounds in various matrices. Recently, use of high resolution mass spectrometry (HR-MS) aimed at examining the human exposome has been rapidly growing. In this study we explore the cat exposome via chemical profiles comparison, identify unknown chemicals of potential health concern, and compare the levels of those unknowns in normal and hyperthyroid cats to examine their possible links to the disease. Pet cats share humans' exposure to household contaminants, albeit with certain differences, including metabolic rates. Nevertheless, cats can be sentinels of human exposure, particularly for toddlers with frequent hand-to-mouth activities. Serum samples from 10 San Francisco Bay Area cats (5 hypothyroid and 5 non-hyperthyroid) were analyzed using an Agilent 6550 quadrupole time of flight (QTOF) MS. Using molecular feature extraction (MFE) algorithm, approximately 2500 distinctive molecular features were extracted from all the samples. Further multivariate analysis using the Mass Profile Professional (MPP) software allowed us to identify 131 features that were statistically different between the two groups ($p< 0.05$). Among them, 76 were upregulated and 55 were down regulated in the hyperthyroid group. Using a compiled database on chemicals found in consumer products, groups of antidepressants, pesticides, PPCP, PFASs and others were tentatively identified based on exact mass, isotope distribution, and isotope spacing. Further identification efforts are underway for those unidentified features that have halogenation patterns. This study will help to better understand not only the cat exposome, but possible body burden changes under hyperthyroidism conditions. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

WP090 Identifying Poly- and Perfluoroalkyl Substances (PFAS) Transformation Products in A Wastewater Treatment Plant

E. Houtz, Arcadis North America, San Francisco; M. Wang, ECL California Dept of Toxic Substances Control / Dept of Toxic Substances Control Environmental Chemistry Laboratory; W. Duong, J. Park, California Environmental Protection Agency / Dept of Toxic Substances Control Environmental Chemistry Laboratory

Recently, poly- and perfluoroalkyl substances (PFASs) derived from aqueous film forming foams (AFFF) were measured at relatively high levels in effluent in some San Francisco Bay Area wastewater treatment plants. A follow-up study was commissioned to investigate the fate of PFASs at an airport wastewater treatment plant before, during, and after a major AFFF introduction event. In addition to routine analysis of PFASs by LC-MS/MS, additional transformation products were identified using high resolution quadrupole time of flight mass spectrometry (QTOF/MS). Using a combination of targeted and non-targeted approaches, molecular features that were extracted from the raw total scan chromatography were tentatively identified with compounds from an in-house PFAS database. For compounds without a database match, chemical formulas were generated based on exact mass, isotope distribution, isotope spacing, and retention time (if available). We preliminarily identified the presence of various PFASs in AFFF formulations, such as 6:2 fluorotelomermercaptoalkylamido sulfonate (FtTAoS), 6:2 fluorotelomer sulfonamide alkylbetaine (FTAB), and two transformation products from the biological oxidation of 6:2 FtTAoS. The integrity of the analysis was validated by standardized sample analysis procedures using Agilent MassHunter Qual and Mass Profiler Professional (MPP) software for multivariate analysis, and high match scores (>90) for the assignments. Available isotope labeled and natural PFAS standards were used as positive controls. This is the first study to examine real time, microbially-mediated transformation reactions in a full scale system. The use of unknowns analysis is critical in establishing transformation reactions and their rates because there are only a few commercially available analytical standards that are applicable to the PFASs present in AFFF. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

WP091 Thermal Desorption of Silicone Wristband Passive Sampling Devices to Assess Fuels, Lubricants, and Coolant Exposure

R. Scott, Oregon State Univ / EMT; G. Wilson, Oregon State Universtity / Environmental Molecular Toxicology; P. Hoffman, K.A. Anderson, Oregon State Univ / Environmental and Molecular Toxicology

The coupling of thermal desorption gas chromatography mass spectrometry with silicone wristbands (WB) as passive sampling devices was utilized to assess volatile organic compounds (VOCs), organophosphates, and poly-α-olefins (PAO). Advantages to this methodology include the ability to examine all three of these chemical classes with the use of only one passive sampling device – reducing sampling costs and effectively eliminating the use of organic solvents – during laboratory processing. Standard-infused wristbands were thermally desorbed in a Markes Micro-Chamber/Thermal Extractor (M-CTE 250) onto Markes Tenax (TA) carbograph 5 (TD) tubes and analyzed with a Markes Thermal Desorption (TD) system interfaced to an Agilent 6890N gas chromatograph / 5975B mass spectrometer (GC/MS). This technology enabled the quantitative assessment of 42 VOCs with detection limits ranging from 0.04-1.35 ng/g WB. Three organophosphates, tributyl phosphate, triphenyl phosphate, and tricresyl phosphate, along with the PAO Xceltherm 500M with detection limits of 0.54 ng/g WB and 54.54 ng/g WB respectively.

WP092 Large Volume In-Vial Extraction Gas Chromatography Mass Spectrometry for Suspect Screening of Semi-Volatile Polyfluoroalkyl Substances in Textiles

J. Rewerts, Oregon State Universtity / Dept of Chemistry; J. Cochran, Restek; S.L. Massey Simonich, J. Field, Oregon State Univ / Dept of Environmental and Molecular Toxicology

Traditional extraction of per- and polyfluoroalkyl substances (PFASs) in consumer products is typically a complex and multi-step process. Reducing the complexity of analysis may reduce the potential loss of the volatile, short-chained fluorotelomer alcohols. For this reason, a simple screening method was optimized for ten volatile classes and 34 individual volatile polyfluorinated chemical species including: fluorotelomer alcohols, acrylates, and methacrylates, and olefins; perfluoroalkyl sulfonamido (N-ethyl and N-methyl) alcohols, acrylates, and methacrylates. Samples were analyzed by gas chromatography mass spectrometry (GC-MS), coupled with concurrent solvent recondensation-large volume splitless injection (CSR-LVSI), to increase method sensitivity. Textiles were prepared by cutting 1x1 cm^2 sections of material and placing them into 1.5 mL autosampler vials with ethyl acetate that were then spiked with stable-isotope labeled internal standards. Vials were then sonicated in a heated water bath (50°C) and analyzed by a GC-CSR-LVSI-MS approach with a 40 µL injection volume that was optimized in preliminary experiments. This methodology was paired with suspect screening to scout for potential homologues within each family of volatile polyfluorinated species. Preliminary data indicated that C4-C7 homologs are present for N-methyl sulfonamidoethanols, while C2-C10 homologs are present for N-ethyl sulfonamidoethanols. The screening methodology is rapid, with the capability of quantifying a large array of volatile polyfluorinated chemicals, with little to no sample preparation and requiring only small sample size.

WP093 What's the bottom line?

S.T. Glassmeyer, USEPA / Office of Research and Development; A. Batt, USEPA / SED; D.W. Kolpin, USGS / Iowa Water Science Center; E.T. Furlong, USGS / National Water Quality Laboratory

Advances in analytical instrumentation have not only increased the number and types of chemicals measured, but reduced the quantitation limits, allowing these chemicals to be detected at progressively lower concentrations in various environmental matrices. Such analytical advancements have been a particular benefit to pharmaceuticals, hormones, personal care products and other contaminants of emerging concern (CECs). Nevertheless, even as specific methods for CECs are being developed concentrations of many CECs are still near or below the threshold of these improved detection limits. The complexity of these analyses is further compounded by the fact that many CECs are so pervasive in that they may be present in the environments in which samples are collected, processed, or analyzed and may contaminate samples. To ensure confidence in data being generated, an integrated suite of quality assurance (QA) procedures and quality control (QC) samples are necessary. These QA procedures and QC samples prevent or address potential for contamination or loss in both the field and the laboratory, and discriminate between field or laboratory introduction of these artifacts. These QC samples include, but are not limited to, field and laboratory blanks, replicate samples, matrix fortified samples, fortified laboratory samples and instrument blanks. This presentation will examine the QA protocols implemented in and QC sample results from a recent national study of drinking water treatment plants across the United States jointly conducted by the USEPA and the USGS. The QA/QC implemented in this project resulted in nearly a third of the measurements demoted to qualitative instead of quantitative detections, and another third completely censored due to contamination or method performance issues. The presentation will also examine how the handling of detections hovering near the threshold of detection influences the data set.

WP094 Identification of Manufactured Nanoparticles in Soil at Trace Levels with Single-Particle Multi-Element ICP-TOF-MS

F. Von der Kammer, Vienna Univ / Dept of Environmental Geosciences; A. Praetorius, Univ of Vienna / Dept of Environmental Geosciences; A. Gundlach-Graham, E. Goldberg, D. Guenther, ETH Zurich; T. Hofmann, Univ of Vienna / Dept of Environmental Geosciences

Analytical methods to detect, quantify and characterise manufactured nanoparticles (MNP) in soils and surface waters are urgently needed to assess environmental exposure and risk of these materials. The main challenge in the detection of i.e. manufactured CeO_2 NPs in environmental matrices is the presence of natural Ce-containing minerals of similar size range at concentrations several orders of magnitude above expected levels for manufactured CeO_2 NPs. To identify manufactured CeO_2 NPs against the high natural background we take advantage of the different elemental composition and impurities of natural and manufactured Ce-containing NPs. For example, the Ce to La ratio is expected to be relatively stable at about 2:1 in natural environments, while manufactured CeO_2 NPs show a Ce:La ratio of about 4000:1. However, due to the much higher natural Ce-levels compared to manufactured CeO_2 NP concentrations in the environment, the sensitivity gained from the element ratio alone is insufficient to yield any detectable results when performing conventional bulk analysis on soil samples. We therefore propose an assessment of the elemental composition on an individual particle level by using an ICP-TOF-MS instrument.,This new instrument enables the simultaneous measurement of multiple elements at high sensitivity and time resolution. The applicability of this method for the detection of manufactured CeO_2 NPs in complex samples is demonstrated on a series of natural soils spiked with different concentrations of CeO_2 NPs. Our results show, that we can clearly differentiate between Ce- and La-containing natural particles and Ce-only containing engineered nanoparticles using the ICP-TOF-MS in single-particle mode. Furthermore, a more advanced data analysis method based on a Machine Learning approach and using a multi-element analysis, makes it possible to improve our detection by establishing elemental "fingerprints" of natural and engineered Ce-containing NPs based on 30 selected elements. This provides a more reliable analysis, especially for particle signals close to the particle size detection limit. In this way we are able to confidently detect, identify and quantify manufactured CeO_2 NPs at ppb concentration levels on a 70 ppm natural background. The new method represents a breakthrough for the detection of MNPs in complex matrices at environmentally relevant concentrations and can likely be applied to a wide range of other MNPs in the future.

WP095 Hyphenation of field-flow fractionation and single particle ICP-MS for the assessment of number-based particle size distributions at ultratrace levels

R. Reed, Postnova Analytics Inc.; T. Pfaffe, Postnova Analytics GmbH; S. Tadjiki, Postnova Analytics Inc; E. Moldenhauer, F. Meier, T. Klein, Postnova Analytics GmbH

One of the challenges in characterization of complex nanomaterials in the environment is to obtain number based information such as particle concentration and size distribution at environmentally relevant concentrations, typically predicted to be in the ng/L or µg/L range in surface waters. The combination of field-flow fractionation and inductively coupled plasma mass spectrometry (FFF-ICP-MS) has been proven to be a powerful analytical technique for characterization of environmental samples, but it lacks a direct measurement of particle number concentration since the ICP-MS is used in the traditional "bulk" analysis mode. Single particle ICP-MS (spICP-MS) is a relatively new and rapidly advancing analytical technique which can provide number based information for monodisperse metal and metal oxide nanoparticles at ng/L concentrations. This presentation reports direct hyphenation of spICP-MS to both asymmetrical flow FFF and centrifugal FFF systems. The spICP-MS was utilized as an online particle number detector for characterization of gold, silver, silica and titania nanoparticles as well as different mixtures thereof. The hyphenated technique was able to measure the number-based concentrations and size distributions of the nanoparticles by counting and sizing the respective nanoparticle mixtures in one single run. In general, the ability of spICP-MS to discriminate particle pulses from background is diminished when there is a large amount of dissolved analyte present. Dissolved Ag (µg/L levels) was added to a mixture of Ag nanoparticles (ng/L levels) prior to separation by asymmetrical flow FFF. The semi-permeable membrane (10 kDa cut-off) in the FFF channel allowed the removal of dissolved Ag during the focusing step, thereby improving the ability of the coupled spICP-MS detector to discriminate particles from background.

WP096 Venlafaxine and its major degradation products determination in algae samples

O. Amarante Jr, IFMA / PACA; S. Rodriguez-Mozaz, Catalan Inst for Water Research ICRA / Water Quality; F. Van de Heuvel, Hortimare Projects & Consultancy; D.A. Muñoz, N. Caceres, Catalan Inst for Water Research ICRA / Water Quality; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry

Emerging contaminants are substances that have been reported recently as anthropogenic compounds that cause damage to the environment even at very low concentrations. Several drugs are within that classification, ending up in the environment through industrial and wastewater discharges, or inadequate disposal. Among pharmaceuticals, venlafaxine, an antidepressant from the class of serotonin-norepinephrine reuptake inhibitors, is usually found in wastewater and contaminated natural water bodies. A analytical method based on liquid chromatography coupled to mass spectrometry (LC-MS/MS) was developed for the determination of this compound and its main degradation products in macroalgae samples. Recovery studies were performed using two species of macroalgae (Laminaria digitata and Saccharina latissima). Freeze-dried samples were weighed (5 g) in Falcon tubes. Three different solvents were tested for the extraction, by adding 10 mL of (i) methanol + formiate buffer 10 mmol L^{-1} (1: 1, v / v); (ii) NaOH 0.1 mol L^{-1}; (iii) acetonitrile + citrate buffer 10 mmol L^{-1} (1: 1, v / v). Tissues were disrupted using and ultrasound pointer for 5 min. Clean up of the extract was performed by Oasis HLB cartridge (60 mg, 3 mL). The extracts were analyzed by LC-MS/MS. Venlafaxine showed a linear response between 0.2 to 20 ng mL^{-1} whereas O-desmethylvenlafaxine (ODV) and N-desmethylvenlafaxine (NDV) showed a linear response from 0.01 to 100 ng mL^{-1}. Instrumental limits of detection (LOD) and limits of quantification (LOQ) for all studied contaminants were 0.01 and 0.2 ng mL^{-1}, respectively. Extractions with acetonitrile + citrate buffer showed the best recovery: between 87 and 111% for venlafaxine, 93 and 105% for ODV, and 108-132% for NDV in spiked algae samples at a concentration of 10 ng g-1 dry weight; and between 80 and 110% with fortification level of 40 ng g-1. In order to verify the efficiency of the method, the method will be applied for the analysis of venlafaxine and target metabolites at environmental levels in macroalgae samples.

WP097 Determination of Nitrate and Phosphate Concentration in Sediment of the Lagos Lagoon

A.A. Olufolajimi, Univ of Lagos, Nigeria / Chemistry

Eutrophication is a state of nourished water body or sediment as the case may be, this has continued to be a major environmental problem. This study was aimed at determining the nitrate and phosphate concentration in the Lagos lagoon, hence the nutrient availability in the sediment. Sediment samples were at six different locations from the lagoon in the months of March, June and August 2015. The physicochemical properties were determined in the laboratory by titrimetry, colorimetry, Phosphates and nitrates were determined spectrophotometrically; pH, 2.78-7.38 (5.79±1.57); organic matter, 0.76-2.96 (1.97±0.64) bio-available Phosphates, 7.85-20.9 mg/kg (12.2±4.34) Nitrates, 0.495-4.227µg/kg (2.71±1.25). High concentrations of Nitrates and Phosphates in the sediment samples from the Lagoon indicated that the waters flowing into the Lagoon were highly polluted, it is highly contaminated and therefore not suitable for drinking purpose in man. In conclusion, this study is baseline data towards future ecological study, setting guidelines and standards for the conservation and management of resources in economically important wetland in Nigeria.

WP098 Determination of gliphosate and its degradation product in surface water

O. Amarante Jr, IFMA / PACA; G.H. Pinheiro, N. Mesquita Brito, Inst Federal of Maranhao (IFMA) / DAQ

This work aimed to evaluate the quality of water resources in Maranhao state with respect to the presence of the herbicide most widely used in the world and its major degradation product. The glyphosate and aminomethylphosphonic acid are of great concern pollutants currently just due to the wide use of this pesticide on crops, mechanical weeding in gardens and family production. The research considered also the parameters established by the National Water Agency (ANA), which manages the National Program for Water Quality Assessment (PNQA) and those established in Resolution 357/05 of CONAMA. The collection points established by PNQA were analyzed for the concentration of glyphosate and AMPA, determined by ion chromatography (IC), and amperometric detection. The analysis was performed using Dionex Ion Chromatograph of ICS3000-DUAL, Thermo Scientific, Term Scientific IonPac AS19, 2x250 mm / AG19 2x50 mm; flow 0.35 ml min -1; 30 oC; GMA; injection volume of 50 uL with autosampler; gradient generated in situ by Thermo Scientific Sionex III EGC-KOH cartridge. Observed the results, it was noted that some cromatrogramas detected glyphosate and AMPA, some just left glyphosate, others only AMPA, others neither compounds; so having a divergent results and realizing that some regions the practice of herbicide use is being made and there is no other records.

WP099 Development of method for analysis of 17α-ethinyl estradiol

N. Mesquita Brito, Inst Federal do Maranhao-IFMA / DAQ; L.G. Silva, Inst Federal of Maranhao (IFMA); O. Amarante Jr, IFMA / PACA

Bisphenol-A (BPA) is an extensively used chemical in industrial processes. It can be used as a monomer in the production of polycarbonates, polymers, epoxy resins and unsaturated polyester-styrene resins. BPA is also presented as lining in food and beverage aluminum cans and as dental sealant. The 17α-ethinyl estradiol (EE2) is an estrogen hormone often used in contraceptive pills with very similar effects of BPA. It leads to great potential hormonal disorders capable to cause adverse health effects on animals and humans. This study developed an efficient extraction method to identify and quantify BPA and EE2 chemicals in tadpoles used in ecotoxicological studies. The high-performance liquid chromatography (HPLC) was used for the analysis. Four extraction assays were performed in order to optimize the processes. They had variations according to reports in the literature. Of all tests performed, the most effective had a recovery of 52% and 32% for BPA and EE2, respectively. This test was conducted in four stages using solid-phase dispersion with hexane and liquid-liquid extraction with acetonitrile. The Amphibians that undergone ecotoxicological tests with BPA were analyzed through the developed procedure performed in this study. No animal presented the compound. The test 4 was the best procedure for extraction and recovery of BPA. Despite the complexity of the analyzed samples, the assays T1, T2 and T3 had lower recovery rates for biological samples (< 1%). No procedure tested in this study was efficient for EE2. The solvents and the correct handling of the samples influenced notably the efficiency of extraction, taking into consideration the specificities and interactions in the analyzed matrices. The solvents for extraction of animal tissue were chosen according to intrinsic characteristics (chemical and physical) of the matrix. Biological samples should be analyzed within few hours after exposure of amphibians in order to detect and quantify the presence of the analytes. Furthermore, the optimized extraction method performed in this study may be an efficient tool for monitoring urban sewage and environmental impact assessment.

Canadian Oil Sands: Advancing Science in Chemical and Toxicological Characterization, Reclamation and Monitoring

WP100 The Effects of Diluted Bitumen (dilbit) on the Hatching Success and Embryonic Development of Sockeye Salmon (Oncorhynchus nerka)

F. Lin, Simon Fraser Univ / Dept of Biological Sciences; S.L. Alderman, T.E. Gillis, Univ of Guelph / Dept of Integrative Biology; C.J. Kennedy, Simon Fraser Univ / Dept of Biological Sciences

Diluted bitumen (dilbit) is a crude oil blend produced by mixing heavy crudes and/or bitumen with diluents, typically natural gas condensate, naphtha or a mix of other light hydrocarbons. Current (and proposed) pipelines carrying dilbit traverse the coastal watersheds of British Columbia, where Pacific salmon are at risk of exposure. Sockeye salmon (Oncorhynchus nerka) embryos were exposed to 4 concentrations (0, 13.7, 34.7 and 124.5 μg/L) of the dissolved fraction (DF) of a Northern Alberta dilbit blend immediately following fertilization in a flow-through exposure system for 72 d. TPAH concentrations declined with time and the composition of the DF shifted towards larger and more substituted PAHs. The mortality of embryos and alevins were recorded through the exposure. At the end of the exposure, a subset of individuals from each treatment group were sacrificed for deformity and biochemical analysis. Validation of the exposure and biological availability of hydrocarbons were confirmed by a significant induction of CYP1A gene expression. Cumulative mortality was 6.1% higher in embryos exposed to the highest concentration of dilbit compared to controls. The incidence of the four types of deformity examined (skeletal, craniofacial, finfold, and presence of edema) was generally low, and exposure to the DF of dilbit did not significantly affect deformity rates. The time to hatch was significantly delayed (control group reached 50% hatching at 55 d post-fertilization; the two highest dilbit concentrations achieved 50% hatch by 58 d and 59 d post fertilization) in exposed embryos. Total body lipid content and whole body triglyceride concentrations were significantly increased by 2.2- and 2.7-fold, respectively, in the high exposure group. Whole body protein concentrations in the two higher exposure concentration groups were also affected (31.4% and 28.7% lower than controls). These results suggest that exposure to dilbit at low ug/L total PAH concentrations may cause increased mortality, delayed hatching, and altered biochemistry in sockeye salmon embryos.

WP101 The Effects of Diluted Bitumen (dilbit) on Stress Responses, Iono- osmoregulatory and Immunological Performance of Sockeye Salmon (Oncorhynchus nerka)

F. Lin, Simon Fraser Univ / Dept of Biological Sciences; S. Balfry, Vancouver Aquarium; C.J. Kennedy, Simon Fraser Univ / Dept of Biological Sciences

Bitumen is a major type of crude oil extracted from the Oil Sands in Alberta, Canada. Current (and proposed pipelines) carrying diluted bitumen (dilbit) traverse the coastal watersheds of British Columbia, potentially putting populations of Pacific salmon at risk of exposure. Juvenile sockeye salmon (Oncorhynchus nerka, age 1+) were exposed both acutely (24 h, 96 h) and sub-chronically (21 d) to 4 concentrations (0, 13.7, 34.7 and 124.5 μg/L) of the dissolved fraction (DF) of a Northern Alberta dilbit blend in a flow-through exposure system; toxicity was assessed using a suite of morphological, physiological and biochemical endpoints. Total PAH concentrations declined with time and the composition of the DF shifted towards larger and more substituted PAHs. Significant induction of liver ethoxyresorufin-O-deethylase (EROD) activity was observed in DF-exposed fish, indicating hydrocarbon bioavailability. Dilbit was not acutely toxic to sockeye at these concentrations. Plasma cortisol concentrations and gill Na^+/K^+-ATPase (NKA) activity were found to be the most sensitive endpoints; NKA activity was significantly reduced at all 3 concentrations of dilbit after 96 h and 21-d exposures. Plasma cortisol in all treatment groups was higher than in control fish at all time points. Plasma

osmolality, [Cl$^-$], and [Na$^+$] were lower in the two high concentration groups at 24 h and continued to decrease with time. Hematocrit decreased significantly in the two high concentrations after 21 d, while [hemoglobin] increased significantly. Plasma glucose was significantly elevated in the two higher concentrations of dilbit at all time points. Liver glycogen content was significantly reduced at 96 h and 21 d at the highest concentration. Fry (8 month) were exposed (24 h and 42 d) to 124.5 µg/L of the DF of dilbit and then challenged with a seawater pathogen, Vibrio (Listonella) anguillarum. Compared to controls, cumulative mortality in exposed fry was 3.8% and 8.7% higher in the 24 h and 42 d exposure groups. This study suggests that acute and subchronic exposure to low concentrations of the DF of dilbit affects the ability of ELS sockeye salmon to maintain ion homeostasis, reduces immunological performance, and causes a significant organismal stress response.

WP102 Effects of Diluted Bitumen on Hematological Parameters in Exposed Juvenile Sockeye Salmon

F. Lin, Simon Fraser Univ / Dept of Biological Sciences; H. Osachoff, BC Ministry of Environment / Land Remediation Section; C.J. Kennedy, Simon Fraser Univ / Dept of Biological Sciences

Current (and proposed) pipelines carrying diluted bitumen (a crude oil blend produced by mixing heavy crudes and/or bitumen with diluents) traverse the watersheds of British Columbia, potentially putting populations of Pacific salmon at risk of exposure. To mimic exposures realistic to fish in an oil spill scenario, a bitumen blend sourced from Northern Alberta, Canada, was equilibrated in an aqueous mixture; sockeye salmon (Oncorhynchus nerka) were exposed to the dissolved fraction of this mixture acutely (24 h, 96 h) and sub-chronically (21 d). Four concentrations of the diluted bitumen dissolved fraction (dilbit-DF) were used: 0, 13.7, 34.7 and 124.5 µg/L total polycyclic aromatic hydrocarbons ($PAHs_{total}$). These treatment concentrations were not acutely lethal to sockeye as < 1% mortality was observed. Hematological parameters in sockeye salmon whole blood were evaluated, including: erythrocyte, leukocyte, and hemoglobin concentrations; hematocrit; and secondary indices including mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). At all concentrations and timepoints, erythrocyte concentrations were not significantly altered by dilbit-DF treatment; however, hemoglobin, MCH and MCHC were significantly elevated after 96 h and 21 d in the 34.7 µg/L and 124.5 µg/L $PAHs_{total}$ dilbit-DF treatments. Changes in these parameters indicate erythrocyte hemoglobin became more concentrated, which can occur as a result of lowered blood oxygen levels (increased oxygen demand) and stress. Leukocyte concentrations were significantly decreased in the 34.7 µg/L and 124.5 µg/L $PAHs_{total}$ dilbit-DF treatments after 96 h of exposure. This indicated the potential for reduced immunological performance, which was confirmed in a related pathogen challenge study by increased susceptibility of dilbit-DF exposed sockeye to Vibrio (Listonella) anguillarum. These results show the importance of understanding the effects of diluted bitumen on salmonid immunological performance. Reductions in immune status and alterations in hematological functions could have major consequences on juvenile sockeye salmon viability as individuals or as a population.

WP103 Fluorescence methods for quantitative analysis of oil toxicity test solutions and assessment of diluted bitumen toxicity to fish embryos

J. Adams, Queens Univ / School of Environmental Studies; M. Leedham, K. Charbonneau, Queens Univ; R. Brown, P.V. Hodson, Queens Univ / School of Environmental Studies

Valid toxicity tests require the measurement of the concentrations of test substances in test solutions, so that toxicity can be expressed as a function of actual exposure concentrations. However, for complex mixtures of hydrophobic compounds such as crude oil, many publications report toxicity only in terms of nominal oil loadings, largely because access to sophisticated analyses by gas chromatography/mass spectrometry (GC-MS) is limited by cost. As a consequence, there is little or no information on the rate and extent of decline in hydrocarbon concentrations during toxicity tests, and toxicity is significantly under-estimated. In tests of the toxicity of conventional crude oils and of diluted bitumens (dilbits), we developed methods to chemically characterize and quantify oil in water by fluorescence spectrometry (FS). The method involves a 50:50 dilution of water samples with ethanol, scanning the sample at excitation and emission wavelengths of 300 nm and 310 to 460 nm respectively, and comparisons of the area under the emission spectrum with a standard curve, after correction for blanks. Compared to analysis of water samples by GC-MS, FS is low cost (~$1/sample), rapid (under 2 minutes/sample), can be done “in-house”, and with a lower detection limit. The FS technique has been used to quantify the amount of oil in water with different oils, including crude oils, heavy fuel oils, and dilbit. Fluorescence analyses show excellent correspondence to other analytical methods, including measurement of total polycyclic aromatic hydrocarbon measurements (TPAH) by GC-MS. In combination with a limited number of analyses by GC-MS, FS can be used for high frequency analysis of test solutions to generate immediate and detailed chemical characterization of hydrocarbon exposures.

WP104 A proposed whole ecosystem study to examine fate, behavior, and toxicity of a diluted bitumen spill in a Canadian boreal lake catchment

V. Palace, IISD-Experimental Lakes Area; J.M. Blais, Univ of Ottawa / Dept of Biology; M.L. Hanson, Univ of Manitoba / Dept of Environment and Geography; M.J. Paterson, IISD-Experimental Lakes Area

Despite constantly improving safety measures when transporting petroleum products, whether by pipelines, rail, or truck, there will always exist the possibility of accidental releases (spills). In North America, recent reviews by the Royal Society of Canada and the National Academies of Science have highlighted knowledge gaps regarding the fate and behaviour of oil in freshwater environments. These reports also identified the need for ecosystem-level studies to examine the efficacy of first response strategies, clean-up procedures, and the effects of residual oil on the ecosystem following completion of spill recovery efforts. The feasibility of conducting controlled oil release experiments at the Experimental Lakes Area (IISD-ELA) field station in Northwestern Ontario, Canada will be presented and model scenarios for examining responses related to a dilbit (diluted bitumen) release proposed. The authors are soliciting input from the research community regarding, but not limited to, the most significant knowledge gaps to address, experimental design options, and effects endpoint identification as they relate to oil entering boreal ecosystems, aquatic and terrestrial.

WP105 Longitudinal Patterns of Metal Concentrations in Fine Sediments, Surface Water and Aquatic Invertebrates in Tributaries of the Lower Athabasca River

C. Suzanne, Univ of Calgary / Biological Sciences; F. Wrona, Alberta Environment & Parks / Science Division; J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; C. Cooke, Alberta Environmental Monitoring, Evaluation and Reporting Agency

One of the largest landscape perturbations in Canada is the result of mining the Athabasca Oil Sands Region (AOSR) in northern Alberta, Canada. The oil sands bitumen deposit in the Lower Athabasca River basin is the largest in North America and covers an area of 42,000 km^2, surrounding the city of Fort McMurray. A significant portion of the bitumen in the AOSR occurs within fluvial deposits of the McMurray Formation (McMF) which outcrop in many of the surrounding rivers catchments, creating natural oil seeps into regional watersheds. Heavy and major metals that co-occur with petroleum hydrocarbons have been found in tributary surface water in the lower reaches, where the river flows through the oil sands deposit of the McMF. Recent studies have suggested that the extensive nature of the current oil sands operations could also have potential consequences on water quality and aquatic ecosystem structure and function in regional rivers. In this study, metal concentrations in fine sediments, surface water and aquatic invertebrates were quantified in two tributaries of the Lower Athabasca River using an environmental disturbance gradient sampling design spanning from upper to lower reaches of the catchments. Both catchments have comparable geomorphology but differ in non-point source geochemical inputs as a result of landuse disturbance from nearby land clearing and related oil sands extraction. Results indicate that among-site differences within catchments in fine sediment, surface water and aquatic invertebrate metal concentrations could be attributed primarily to natural variation and gradients in catchment-related geochemical inputs in both rivers. This study highlights the high natural geochemical complexity of tributary ecosystems in the Lower Athabasca River. Furthermore, we emphasize the importance of defining appropriate baseline/reference conditions against which to assess change in environmental endpoints and the need for monitoring designs and related evaluations to discriminate sources of natural variation from potentially confounding effects related to anthropogenic factors.

WP106 Evaluation of toxicity and contaminant concentration of lake sediments from the Peace-Athabasca Delta, downstream of oil sands deposits

A.J. Farwell, Univ of Waterloo / Dept of Biology; J. Thienpont, Univ of Ottawa / Dept of Biology; C. Lu, Univ of Waterloo / Biology; I. M'Hiri, X. Chen, C. Remmer, Univ of Waterloo / Dept of Biology; J.M. Blais, Univ of Ottawa / Dept of Biology; B. Wolfe, Wilfrid Laurier Univ / Dept of Geography and Environmental Studies; R. Hall, D. Dixon, Univ of Waterloo / Dept of Biology

The Peace-Athabasca Delta in northern Alberta, Canada is the largest freshwater inland delta (321,200 ha) in North America with ecological, historical and cultural significance at local, national and international (recognized as UNESCO World Heritage Site) scales. The ecosystem services of the Peace-Athabasca Delta may be threatened by multiple stressors such as oil sands production, climate change and hydroelectric development. A key concern is the potential for contaminants from oil sands to enter the delta by floodwaters from the Athabasca River. Here we evaluate the spatial distribution of contaminants (metals and polycyclic aromatic compounds) in surficial sediments and their toxicity for 60 delta lakes and link results to hydrological pathways. The assessment of toxicity of the delta lake sediments included a Hyalella azteca survival and growth test (14 day) and a fathead minnow (Pimephales promelas) embryo-larval survival, growth and development test (5-7 day). Toxicity tests showed high rates of survival for Hyalella azteca and Pimephales promelas (between 80-100% survival) indicating low sediment toxicity for the majority of lake surficial sediments from the Peace and Athabasca sectors of the delta. Data on toxicity tests and contaminant concentrations for delta lake sediments will be used to identify potentially vulnerable lakes for further study and monitoring, as needed to improve environmental risk assessment associated with the oil sands activity.

WP107 The impact of atmospheric pollutants on regional fresh waters: An assessment of winter-time deposition in the Athabasca oil sands region

V. Wasiuta, Univ of Alberta / Earth and Atmospheric Science; C. Cooke, Alberta Environmental Monitoring, Evaluation and Reporting Agency; A. Alexander, Univ of New Brunswick / Biology and Canadian Rivers Inst; P. Chambers, Environment and Climate Change Canada / Watershed Hydrology Effects Research Division; J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division

The mining and upgrading of the Athabasca oil sands releases nutrients and trace elements to the atmosphere. Sources of these atmospheric emissions include the open-pit mines themselves, regional upgrading facilities, exposed coke piles, deforested areas, as well as volatilization from tailings ponds, and vehicle emissions. Regional snowpack chemistry reveals high winter-time loading of pollutants, including key limiting nutrients and EPA priority pollutants. Winter atmospheric loads to six tributary watersheds were calculated using measured snowpack loads and interpolation using geospatial software. Atmospheric deposition maps show a bullseye pattern of contaminant deposition for pollutants of concern with the highest loadings between the Muskeg and Steepbank Rivers. Here we present the results from a three-year intensive sampling effort to understand the fate of winter-time pollutant deposition on regional freshwaters. We focused on those pollutants most enriched in snowpack chemistry, relative to background atmospheric deposition (Al, La, Fe, Co, Cr, Cu, C, Mg, Pb, U, PO^{3-}_4, V, Cl, Na, Sn, Ni, Mo, Sr, Be, As). Concentrations of pollutants of concern in stream water were evaluated from intensive monitoring of six tributary streams during the 2013–2015 open-water seasons. Here we will present the results of these analyses and comment on the fate and impact of atmospheric deposition on regional freshwaters.

WP108 One-pot conversion of petroleum-derived carboxylic acids to hydrocarbons to facilitate compound identification and source tracking

M. Ross, MacEwan Univ / Physical Sciences; T. Hynes, M. Litchfield, J. Withey, MacEwan Univ

Oil sands process-affected water (OSPW) contains a complex mixture of petroleum-derived organic acids, which, as whole, have been identified as the acutely toxic components of OSPW. Although a number of individual acids have been identified, the molecular structures of the majority of species remain uncharacterized. However, an increased understanding of the molecular composition of these organic acids in OSPW and natural waters is necessary to enable both a greater awareness of their toxicity, sources, environmental fate, and a more accurate assessment of their risk. The objective of this work was to develop methodology for the simple and efficient conversion of mono- and poly-carboxylic acids, hydroxylated acids, and aromatic acids to their hydrocarbon analogues to facilitate characterization by gas chromatography-mass spectrometry (GC-MS). The developed methodology utilizes n-butyl silane in the presence of a Lewis acid catalyst (tris(pentaflurophenyl)borane, $B(C_6F_5)_3$) to reduce the carboxylic acid and alcohol moieties to their corresponding hydrocarbon groups. The "one-pot" reaction was carried out in 5 mL reaction vials and the resulting products were analyzed by GC-MS without further clean-up. The method was developed and optimized using a series of structurally diverse standard compounds chosen to represent acids previously identified in OSPW. No carboxylic acid or alcohol functional groups were detected following the developed procedure, indicating substantial conversion of the acids to hydrocarbons. Conversion yields were compound dependent, but were typically greater than 65%, with losses likely due to volatilization, rather than incomplete conversion. Once optimized, the methodology was applied to characterize commercially available petroleum-derived acids (Refined Merichem, Aldrich, and Acros) and the acid fraction of OSPW. Initial screening and comparison revealed that fingerprints of C_1-C_4 alkylated polyaromatic hydrocarbon (PAH) homologues (naphthalene, phenanthrene, dibenzothiophene, fluorene), and paraffins, differed amongst samples, confirming source specific differences in petroleum-derived acid composition and suggesting that the developed methodology may be applicable to future environmental forensics studies. Future work will investigate fingerprints of other compound classes and incorporate the developed methodology into environmental fate and toxicological studies.

WP109 Deconvolution of the complex environmental mixture: chemical and biological strategies

H. Peng, Univ of Saskatchewan / Toxicology Centre; W. Christena, Univ of Saskatchewan; D.M. Saunders, Univ of Saskatchewan / Toxicology; J. Sun, Univ of Saskatchewan – Toxicology Centre / Toxicology Centre; S. Tang, Univ of Saskatchewan; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre; S.B. Wiseman, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; P.D. Jones, Univ of Saskatchewan; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre

Characterization of toxicological profiles of environmental mixtures is challenging due to the complex components. Here we proposed a hybrid platform by combining chemical analyses and affinity based pull down to deconvolute the toxicity and chemical components of environmental mixtures. Using oil sands as a case study, we developed a pull-down assay combined with untargeted chemical analyses (PUCA) to identify the peroxisome proliferator-activated receptor gamma (PPARγ) agonists. A total of 30 ligands were identified in OPSW extracts by PUCA assay. For chemical strategy, using halogenated compounds as a case study of prioritized chemicals, we developed a data-independent precursor isolation and characteristic fragment (DIPIC-Frag) method to identify halogenated compounds in different environmental matrices. e.g., 2,052 brominated and 4,238 iodinated compounds were identified in Lake Michigan sediments; 1,303 brominated disinfection by-products (Br-DBPs) and 1,637 I-DBPs were identified in drinking water samples; 1,008 brominated compounds were identified in house dust. These results revealed numerous unidentified halogenated compounds in environment, which provided a basic mass spectrometric database of prioritized chemicals. Especially, in house dust, by using correlation matrix analysis, we found brominated azo dyes, rather than brominated flame retardants (BFRs), contributed to the majority (85%) of the total brominated compounds in house dust. This study introduced a hybrid platform to deconvolute the environmental mixtures: for chemical strategy (DIPIC-Frag), we could establish and narrow down a list of prioritized chemicals; for biology strategy, the toxic components in complex mixture could be robustly identified.

WP110 A methodology comparison study for quantitative measurement of naphthenic acid in surface water in the Alberta oil sands region

L. Fu, B. Leung, Government of Alberta / Environment; A. Pereira, J. Pretorius, Alberta Innovates Technology Futures

Naphthenic acids (NAs) occur naturally in Northern Alberta in the oil sands region. It is also found and concentrated in oil sands process-affected water (OSPW), generated from the bitumen extraction process. The quantification and characterization of NAs in surface water for the oil sands region have been challenging especially since NAs are a complex mixture with mostly unknown structures. Water samples from different sources and locations have different statistical profiles. This makes the determination and production of standard reference materials difficult for method development and calibration. A GC-MS method was developed in the 1990s and was used in the NA monitoring program for the oil sands region. With the advance of high resolution mass spectrometry technology, weaknesses and deficiencies of GC-MS have been identified. In a recent expert workshop in Edmonton Alberta, it was agreed that the GC-MS method should be replaced with more suitable technologies, taking advantage of the latest development of analytical instrumentation. At the workshop, a simple NA definition was agreed to by workshop participants – simple carboxylic acids with two oxygen atoms detected using ESI negative-ion mode; R group can be multi-cyclic and aromatic, but does not include heteroatoms, nor any other functionalities. To support the transition to new monitoring methodologies, a comparison study was carried out using the following three methods: Fourier transform infrared spectroscopy (FTIR), high resolution mass spectrometry (HRMS) and GC-MS. Surface water and OSPW samples were used to generate test samples for the comparison study. The performance of the analytical methods was tested using various naphthenic concentrations, extraction and sample preparation processes. The results confirmed the deficiencies of GC-MS method and indicated good correlation between data from FTIR and HRMS. This study also revealed further insight into the complex nature of NA monitoring and will inform the final development of the standard operating procedures for future NA monitoring in Alberta.

WP111 Passive Sampling Advances Knowledge of Water Chemistry in Rivers of Canada's Oil Sands Region

L. Levesque, Environment and Climate Change Canada; N. Glozier, C. Epp, K. Pippy, Environment and Climate Change Canada

Passive water quality monitoring was implemented in the oil sands region of Alberta, Canada in 2012 as a part of the Joint Oil Sands Monitoring program. Semi-permeable membrane devices (SPMDs) were deployed in the Athabasca River upstream, within and downstream of the oil sands minable area (OSMA) and mining activities. Polycyclic aromatic compounds (PACs) in water quality grab samples were for the most part below method detection. Although concentrations in water samples were typically orders of magnitude greater than those estimated from SPMDs (e.g., perylene grab = 100 ng/L, SPMD = 0.40 ng/L), this was not always the case (e.g., C4-phenanthrenes/anthracenes grab = 3.4 ng/L, SPMD = 9.3 ng/L). In contrast, PAC detections in SPMD samples had substantially higher frequencies, allowing for PAC profiling and comparisons between sites and over time. Typical of bitumen within the region, SPMDs deployed in the water contained high concentrations of alkylated PACs, dominated by naphthalenes, fluorenes, phenanthrenes/anthracenes, fluoranthenes/pyrenes and dibenzothiophenes. These included measurable concentrations of compounds with 5 and 6 benzenoid rings (e.g., benzofluoranthenes, benzopyrenes, dibenz[a,h]anthracene, perylene, benzo[ghi]perylene and indeno[1,2,3-cd]pyrene], which are identified as priority pollutants by the United States Environmental Protection Agency. Concentrations were highest within the OSMA and in the open water season, decreasing with distance downstream and under-ice. This work shows that long-term water quality monitoring programs that apply SPMDs will acquire information on trace level organic compounds that is of higher spatial and temporal resolution that that generated from conventional water quality grab samples.

WP112 Survey of PAH concentrations and composition in predatory and forage fish in the Fort McMurray oil sands area with comparisons to environmental regime

M. Evans, Environment and Climate Change Canada; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate Aquatic Contaminants Research Division; H. Keith, Hatfield Consultants; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Keating, Environment and Climate Change Canada; G. Tetreault, Enviroment Canada / Water Science and Technology Directorate

The Fort McMurray region is rich in natural sources of polycyclic aromatic hydrocarbons (PAHs) from exposed bitumen beds; anthropogenic sources have increased with oil sands industry expansion. Here we report on results of a broad survey of PAHs (47 compounds) in eight fish species conducted during 2012-2014 fish health investigations in the oil sands area; results are compared with sediment data collected under the Regional Aquatics Monitoring Program and the Joint Oil Sands Monitoring Program. Athabasca River walleye had average fillet ΣPAHs concentrations of 12.4±5.4 ng/g (72.2±14.1% alkylated) with higher liver (75.6±98.9 ng/g; 82.0±14.0% alkylated) concentrations; white sucker fillet (17.0±8.0 ng/g; 89.3±5.1% alkylated) and liver (64.3±61.7 ng/g; 70.6±15.0% alkylated) concentrations were slightly higher. ΣPAHs in lake trout fillet (12.8±4.7 ng/g; 77.6±7.0% alkylated) and liver (68.6±22.2 ng/g; 63.9±14.0% alkylated) and lake whitefish fillet (13.2±5.9 ng/g; 78.6±6.9% alkylated) from Namur Lake also were low. ΣPAHs were higher in forage fish averaging 105.8±33.2 ng/g (68.2±4.8% alkylated) in trout-perch from the Athabasca River, 277.8±267.3 ng/g (75.5±13.4% alkylated) in slimy sculpin from the Steepbank, Firebag, and Dunkirk rivers, and 125.1±21.9 ng/g (63.8±6.22% alkylated) in pearl dace from the Ells River. ΣPAHs in sediments over this study area were substantially higher (4,745±10,652 ng/g) and more alkylated (91.8±5.9%). Fish ΣPAHs were dominated by low-molecular weight PAHs, particularly naphthalenes, fluorenes and biphenyls whereas medium and heavy PAHs such as dibenzothiophenes, fluoranthenes, pyrene and chrysene, common in sediments, were minor contributors. Burbot (liver) from western Lake Athabasca had the highest ΣPAH concentrations (728±534 ng/g; 95.9±8.3% alkylated) and C4-phenathrene dominated, presumably because of their high lipid content. The European Commission has set fish consumption guidelines of 2.0 ng/g for benzo(a)pyrene and 12 ng/g for the sum of PAHs benzo(a) pyrene, benz(a)anthracene, benzo(b)fluoranthene, and chrysene; neither guideline was exceeded for any species, tissue or location. There were no obvious spatial gradients in PAH concentration and composition although the small number of samples (generally 3-4) examined at each location and time and the shortness of the record limited the statistical sensitivity of such investigations. Apart from mercury, there were no obvious gradients in metals concentrations.

WP113 Assessment of Athabasca River tributaries in the oil sands mining region of Alberta, Canada, using in situ exposures of Hyalella azteca

A.J. Bartlett, Environment and Climate Change Canada / Aquatic Contaminants Research Division; L.R. Brown, Environment and Climate Change Canada / Aquatic Contaminants Research Division; R. Frank, Environment and Climate Change Canada / ACRD; M. Hewitt, Environment and Climate Change Canada / National Water Research Inst; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate Aquatic Contaminants Research Division; J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division

As part of the Joint Canada-Alberta Oil Sands Monitoring Program, in situ (caged) exposures with the freshwater amphipod, Hyalella azteca, were conducted in Athabasca River tributaries to assess differences between environmental exposures in areas likely influenced by both natural and anthropogenic sources (sites near mining activity) versus areas likely influenced primarily by natural sources alone (sites in the natural deposit but upstream from mining activity). In situ exposures were coordinated with wild fish and benthic community studies, as well as with laboratory exposures using fish and invertebrates, with the intention to link field assessments and laboratory studies conducted at the same sites. Exposures were conducted in the fall (September-October) of 2010, 2012, 2013, and 2014. Amphipods were collected from a wetland within the Athabasca River watershed but outside the area of mining activity, and deployed in cages at 3 sites on the Ells River, 3 sites on the Firebag River, and 4 sites on the Steepbank River. Cages were removed after 2 weeks, and survival and size of amphipods were assessed before freezing amphipods for subsequent analysis of metals bioaccumulation. Survival was greater than 90% for all years and sites, with the exception of 2 sites in 2012 where high water flows resulted in burial of caged amphipods and reduced survival to 85 and 67%. Average size of amphipods at all sites showed less than 10% difference within the same exposure year. Bioaccumulation of 45 metals revealed that although some metals were present at higher concentrations at some sites when compared to amphipods that were not caged, there were no consistent patterns between years for each river. Toxic units were calculated for the 9 metals for which bioaccumulation data associated with amphipod toxicity were available; no consistent trends were observed between years for each river, and the summed toxic units of the 9-metal mixture were 0.6 or less for all years and sites. The results of these in situ exposures indicate that no differences in amphipod survival, size, or bioaccumulation of metals were attributable to natural and/or anthropogenic sources of oil sands chemicals.

WP114 Relationships between parasites and plasma proteins in male white sucker (Catostomus commersonii) from the Athabasca River

D. Simmons, Univ of Waterloo / Biology; J. Sherry, Environment and Climate Change Canada / Water Science Technology Directorate; P. Braicovich, D. Marcogliese, Environment and Climate Change Canada

Shotgun proteomics can be used to assess the health of animals, to determine protein biomarkers that are specific to environmental exposures, and also to characterize unique mechanisms of action of contaminants. As part of a larger wild fish health assessment for the Athabasca River under the Joint Oil Sands Monitoring Program, we successfully developed and applied shotgun proteomics to generate protein profiles from plasma of mature male white sucker taken from three sites along the main stem of the Athabasca River in 2011. The study sites were located within the oil sand deposit including a site downstream of Fort McMurray but above the oil sands operations, and two sites downstream of the oil sands extraction facilities. On average, 376 ± 96 proteins were identified in plasma from each location. Gene names corresponding to those identified proteins were analyzed using interactive pathway software (Ingenuity Systems, Inc.) to determine their core functions and to compare the datasets by location, year, and sex. There were 478 proteins identified in plasma from fish across all sampling locations that were related to immunological functions. The following parasites were enumerated in the same fish samples: Diplostomum spp. (eye fluke), Ichthyocotylurus sp. (fluke), Phyllodistomum sp. (bladder fluke), Dactylogyrus sp. (gill flukes), and Polyopisthocotylea gen. sp. (flatworm). Linear discriminant analysis (LDA) was performed on the parasite counts for each species and the count of proteins related to various immunological functions. Principal component analysis (PCA) was performed on the relative expression (total intensity counts) of each protein related to immune functioning for all individuals. Both of the multivariate approaches revealed strong differences (based upon protein expression, function, and parasite counts) among the three sampling locations.

WP115 Development of wood frog (Lithobates sylvaticus) tadpoles in a natural wetland after embryonic exposure to naphthenic acids: Preliminary findings

D. Orihel, J.M. Blais, Univ of Ottawa / Dept of Biology; M. Galus, Univ of Ottawa; J.V. Headley, Environment and Climate Change Canada; J. Hughes, USGS / Columbia Environmental Research Center; B.D. Pauli, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate; K.M. Peru, Environment and Climate Change Canada; S.A. Robinson, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate; A. Salat, V.L. Trudeau, Univ of Ottawa / Dept of Biology

Due to their unique life history, amphibians are sensitive models for understanding the toxicity of process waters produced by bitumen extraction from Canadian oil sands. Naphthenic acids (NAs) are one of the most toxic constituents of oil sands process-affected water (OSPW). Our research team is conducting a series of lab and field-based studies to understand the effects of naphthenic acids (extracted from OSPW) on the health of amphibians at different life stages. In this experiment, we assessed whether a naïve population of wood frogs (Lithobates sylvaticus) exposed to NAs during the embryonic stage display abnormal growth and development as tadpoles that could affect their survival in the wild. In April 2016, we collected wood frog egg masses from a wetland at the Queen's University Biological Station in Elgin, Ontario. Egg masses were then randomly assigned to 15 outdoor microcosms containing 10 L of natural pond water. Following a regression-based design (12 treatments, 3 controls), we added NAs to microcosms at nominal concentrations ranging from 1 to 50 mg/L, representing 1 to 100% of NAs typically found in OSPW. After 5 weeks, tadpoles (Gosner stage 25) were transferred to floating cages (35 cm diameter x 60 cm height) in their wetland of origin. Tadpoles are being examined weekly to monitor their growth, development, and survival. Once tadpoles reach Gosner stage 42, metamorphs will be analyzed for gene expression (RNASeq) to identify possible genetic biomarkers from exposure to NAs. Findings from this study will help improve wildlife monitoring programs in Canada's oil sands region. Additionally, the development of biomarkers may help reduce the reliance on traditional vertebrate test methods to monitor for toxicity.

WP116 Impairment vs local adaptation: Physiological scope of forage fish affected by natural and anthropogenic bitumen sources in Alberta oil sands region

S. Chow, Univ of Lethbridge / Biological Sciences; G.G. Pyle, Univ of Lethbridge

The lower Athabasca River basin of northern Alberta, Canada is home to fish species that reside within bituminous rich deposits of the McMurray geologic formation. Within the same area, the oil sands industry has increasingly developed in the last fifty years. However, the potential and extent of local adaptation of these indigenous fish species to natural and anthropogenic bituminous sources are not well known. Following a reciprocal cross transplant between sites containing natural bitumen and downstream of industry, a 28 day chronic exposure experiment was conducted using a small forage fish, the fathead minnow (Pimephales promelas). Reference fish olfactory acuity in response to social cues such as conspecific alarm cues and taurocholic acid was impaired to levels that were similar to fish downstream of industry after they were transplanted to either the natural bitumen site or the site downstream of industry. Similarly, respiration rates were observed to decrease to levels that were detected in fish that resided in bituminous-toxicant containing waters prior to experimentation. Downstream and natural bitumen fish had lower olfactory acuity and respiration rates than upstream fish which did not change after the chronic exposure at either site. Fish without pre-existing contact with bitumen – natural or otherwise – displayed impairment in olfaction and respiration to levels comparable to fish from within the oil sands region. Biomarker for toxicant exposure increased in both fish populations from bitumen-containing tributaries. Fish from populations inhabiting bitumen-rich environments did not exhibit local adaptation in the measured physiological traits as was previously hypothesized. Physiological scope of fish from natural bitumen and downstream-of-industry waters may be limited in comparison to reference fish without previous bitumen exposure, which may explain the lower survival rates observed in the former. Data in this current study illustrate how differing toxicant loads will affect the ability of a forage fish population to cope with particular environmental stressors. Although no evidence of local adaptation was observed, the differences in physiological responses indicate an effect of oil sands related toxicants on these fathead minnow populations. Understanding that these forage fish populations exhibit a limited physiological scope can inform reclamation and remediation efforts.

WP117 Regulation of cyp1a, cyp3a, abcb1, and abcc2 genes in northern pike (Esox Lucius) population from different locations on the Athabasca River, Canada

H. Alharbi, J.A. Doering, Univ of Saskatchewan / Toxicology Centre; P.D. Jones, Univ of Saskatchewan / School of Environment and Sustainability; B. Tendler, Univ of Saskatchewan / Toxicology Centre; E. Ohiozebau, Univ of Saskatchewan / School of Environment and Sustainability; S. Wiseman, Univ of Lethbridge / Biology; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre

There is evidence that organic chemicals, including naphthenic acids and polycyclic aromatic hydrocarbons (PAHs) that result from extraction of bitumen from oil sands might enter the Athabasca River and its tributaries. Therefore, identification of molecular biomarkers of exposure to these organic chemicals would be useful for monitoring exposure to these chemicals and potential impacts on organisms. Cellular defence against accumulation of toxic xenobiotics includes metabolism by phase I and II enzymes and export of toxicants and their metabolites via ATP-binding cassette (ABC) transporters. In this study, mRNA abundances of genes that encode two phase I enzymes (CYP1A and CYP3A) and two phase III proteins (ABCB1 and ABCC2) were quantified in livers from northern pike (Esox lucius) collected in Spring of 2012 from three locations on the Athabasca River in Alberta near Fort McMurray, Fort McKay, Fort Chipewyan, and two downstream locations (Fort Smith and Fort Resolution) on the Slave River in the Northwest Territories.. Compared to reference sites, expression of CYP1A, CYP3A ABCB1 and ABCC2 were significantly greater in fishes collected from the two sites in the vicinity of Fort McKay, Alberta, which is the site closest to oil sands activities. Correlation analysis was used to determine the relationship between the expression of target genes, concentration of PAHs in bile and location using Pearson's Correlation and principle component analysis (PCA). Concentrations of 2 and 3 ringed PAHs were correlated with expression of CYP1A but concentrations of 4 and 5 ringed PAHs were correlated with expression of CYP3A ABCB1, and ABCC2. Moreover, PCA revealed site-specific differences in both gene expression and PAHs concentrations. While CYP1A is well established as a biomarker for monitoring the exposure to PAHs, quantification of expression of CYP3A, ABCB1 and ABCC2 might be a promising approach to assess exposure to specific classes of PAHs. Additional research is needed to determine whether other chemicals, including organic chemicals in the aqueous phase of OSPW, that might enter the Athabasca river form tailings ponds, contribute to these effects.

WP118 Effect of dissolved organic fractions from OSPW on toxicity of hydrophobic organic compounds to early life-stages of Japanese medaka

H. Alharbi, Univ of Saskatchewan / Toxicology Centre; G. Morandi, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; S. Wiseman, Univ of Lethbridge / Biology; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre

Toxicity of water soluble organic fraction from oil sands process-affected water (OSPW) to aquatic organisms has been studied, but effects of co-exposure to OSPW and hydrophobic organic contaminants such as polycyclic-aromatic hydrocarbons (PAHs), which are an important class of chemicals in tailings ponds used to store OSPW has not been investigated. This study was conducted to determine if dissolved organic compounds (containing mainly basic and neutral compounds) extracted from the aqueous phase of relatively fresh OSPW from Base-Mine Lake (BML-OSPW) or aged OSPW from Pond 9 experimental reclamation pond (P9-OSPW) modulate toxic potency of the model alkyl-PAH, retene to early life-stages of Japanese medaka (Oryzias latipes). The exposure was performed using a partition controlled delivery (PCD) system made of polydimethylsiloxane (PDMS) until day of hatch. Larvae exposed to only BML-OSPW had no significant change in the incidences of pericardial edema compared to control but were significantly greater in larvae exposed only to retene. Expression of CYP1A and incidences of pericardial edema were significantly greater in larvae co-exposed to retene and dissolved organic compounds from BML-OSPW compared to retene alone at 5 × equivalent of dissolved organic compounds from BML-OSPW . However, co-exposure to retene and a 1 × equivalent of dissolved organic compounds from BML-OSPW, and 5 × equivalent of dissolved organic compounds from P9-OSPW were not significant. Although the exposure to 5 × equivalent of dissolved organic compounds from BML-OSPW caused oxidative stress, larvae exposed only to retene or co-exposed to retene and a 5 × equivalent of dissolved organic compounds from BML-OSPW had no significant oxidative stress. These results suggest that water soluble organic fraction from Base Mine Lake might influence toxicity of alkylated-PAHs to early life stages of fishes but this effect would not be expected to occur at current concentrations of OSPW and aging of OSPW can attenuate the observed effects.

WP119 Assessing the toxicity of naphthenic acid mixtures in the clawed frog Silurana (Xenopus) tropicalis embryos

J. Gutierrez Villagomez, Univ of Ottawa / Dept of Biology; J. Vázquez Martínez, E. Ramírez Chávez, CINVESTAV IPN UNIDAD IRAPUATO / Biotecnología y Bioquímica; S.A. Hughes, Shell Health – Americas / Shell Health Risk Science Team; K. Peru, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Headley, Environment and Climate Change Canada / Watershed Hydrology and Ecology Resarch Division; J. Molina Torres, CINVESTAV IPN UNIDAD IRAPUATO / Biotecnología y Bioquímica; J.M. Blais, Univ of Ottawa / Dept of Biology; V. Trudeau, Univ of Ottawa / Biology

Naphthenic acids (NAs) are carboxylic acid mixtures considered to be emerging contaminants of concern. They are detected in Canada's Oil Sands Process-affected Water (OSPW) generated during bitumen extraction at concentrations up to 120 mg/L total NAs. The aim of this study was to assess the toxicity and teratogenic effects of commercial NA extracts (NA1 and NA2) and one Acid Extractable Organic (AEO) from OSPW, using Silurana (Xenopus) tropicalis embryos. Following the Frog Embryo Teratogenesis Assay Xenopus (FETAX), Nieuwkoop and Faber stage 9-10 (early organogenesis) embryos were exposed for 96 hours to NA1 and NA2 (11 treatments) to concentrations up to 24 mg/L, and to the AEO extract (13 treatments) to concentrations up to 96 mg/L (n=7 replicates). The nominal concentrations used covered OSPW relevant concentrations. Embryos were photographed for analysis of abnormalities. The estimated lethal toxicity (LC50) was 9 mg/L (R^2=0.99, 95% CI [8, 10]), 12 mg/L (R^2=0.96, 95% CI [12, 13]), and 45 mg/L (R^2=0.97, 95% CI [44, 47]) for NA1, NA2 and the AEO extract, respectively. The main abnormalities observed were smaller size, edema, gut abnormalities and heart abnormalities, and especially evident in the 8, 12 and 48 mg/L groups of the NA1, NA2 and AEO extracts, respectively. The number and severity of the abnormalities increased with increasing NAs concentration in the test solutions. Our results suggest that NAs from commercial sources are significantly ($p< 0.05$) more toxic than those from OSPW. Efforts are underway to identify causative agents in the very complex mixtures of NAs and to understand whether or not effects observed in the lab may occur with NA exposures in native frog species in the wild.

WP120 Identifying the toxic organic components within bitumen-influenced groundwaters

A. Bauer, Univ of Waterloo / Biology; J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division; R. Vanderveen, M. Rudy, J.W. Roy, G. Bickerton, Environment and Climate Change Canada; D. Dixon, Univ of Waterloo / Dept of Biology; M. Hewitt, Environment and Climate Change Canada / National Water Research Inst; R. Frank, Environment and Climate Change Canada / ACRD

Surface mining operations in the region surrounding Ft. McMurray, AB are employed where bitumen deposits are relatively shallow. The by-products of surface mining are stored in large tailings ponds, and have been accumulating for decades with increases in oil sands extraction. Investigations have identified the presence of oil sands process-affected water (OSPW) in nearby groundwater due to tailings seepage. However, these same groundwater systems often flow through bitumen deposits, potentially mobilizing water-soluble bitumen components leading to natural bitumen inputs to the Athabasca River watershed. Current research is focussed on chemically profiling natural and anthropogenic bitumen-derived compound influences to groundwaters, and also on toxicity investigations designed to prioritize compound classes of interest for monitoring initiatives. The present study assessed the toxicity of isolated groundwater soluble organic fractions through exposure to two freshwater fish; fathead minnow (Pimephales promelas) and Japanese medaka (Oryzias latipes). Four samples representing natural bitumen only (two samples) and anthropogenic plus natural bitumen (two samples) sources (>100 L each) were fractionated using a preparative solid phase extraction methodology. This protocol produced three fractions of the soluble organics separated using a range in polarity. Both fish bioassays displayed distinct toxicological differences between fractions within sites and between sites. Generally, the fish bioassays results were very similar but distinct from invertebrate bioassays conducted in parallel. Coupled with high resolution chemical characterization data, this study will aid in guiding future comprehensive fractionation studies intent on better elucidating the bioactive components within bitumen-influenced waters. The present study is important for the development of water quality criteria in future water monitoring programs in the Athabasca region.

WP121 Nrf2-mediated Oxidative Stress Responses of Oil Sands Process-Affected Water and Causative Chemicals Identification

J. Sun, Univ of Saskatchewan – Toxicology Centre / Toxicology Centre; H. Peng, Univ of Saskatchewan / Toxicology Centre; H. Harbi, Unviersity of Saskatchewan; J. Giesy, S.B. Wiseman, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre

There is evidence that dissolved organic chemicals in OSPW might cause oxidative stress, but definitive studies linking the adverse effect of oxidative stress with corresponding chemicals in OSPW have not been performed. In this study, a reproducible in vitro bioassay was incorporated to effect directed analyses (EDA) approach to identify oxidative chemicals in OSPW. Activation of nuclear receptor erythroid 2-related factor 2 (Nrf2), was 2.9 ± 0.1-fold greater in cells exposed to a total extract (TE) of OSPW. Among the five fractions of OSPW from HLB cartridges, activation of Nrf2 was 2.7 ± 0.1-, 1.2 ± 0.1-, and 1.7 ± 0.1-fold greater in cells exposed to F2, F1 and F5. Further HPLC fractionation of F2 found the Nrf2 activity centered in F8 (1.30-fold, $\rho < 0.001$), F16 (1.34-fold, $\rho < 0.001$) and F25 (1.28-fold, $\rho < 0.001$).The Nrf2 was not activated in cells exposed to either F3 or F4. Untargeted chemical analysis and a semi-quantitative data mining strategy were developed to enhance the performance of EDA approach. Among >30,000 chemicals detected, only 54 chemicals were predicted to be potential causative components by the two-step EDA approach. By use of exact mass and predicted formula, polyoxygenated heteroatomic chemicals, rather than naphthenic acids, were found to be the major causative chemicals for oxidative stress effects in OSPW.

WP122 Transcriptional responses of embryonic zebrafish exposure to raw and ozonated OSPW and recovery post-exposure

D. Lyons, Univ of Alberta; D. Philibert, Univ of Alberta / Biological Sciences; M. Meshref, R. Huang, N. Klamerth, Univ of Alberta / Civil and Environmental Engineering; M. Gamal El-Din, Univ of Alberta / Cival and Environmental Engineering; K. Tierney, Univ of Alberta / Biological Sciences

Oil sands process water (OSPW) is water that is stored in tailings containment structures to ensure it can be recycled for various uses including bitumen extraction, material hydro transport, and process cooling. Progressive aquatic reclamation efforts require increasing OSPW quality to permit hydrological integration of the landscape. Ozone treatment is being studied as a potential tool to assist in remediation efforts, as it has been shown to reduce effects such as cardiotoxicity and neurotoxicity to embryonic fish induced by OSPW exposure. This study provides further insight on the potential benefits of ozonation as a remediation technique through toxicity reduction. In this study we exposed zebrafish embryos to both raw and ozone-treated OSPW from 0-7 days post fertilization (dpf). At 7dpf the embryos were transferred to clean water for recovery. Transcript levels were measured immediately after exposure at 7dpf and again at 9dpf to characterize the gene expression changes induced by embryonic OSPW exposure and to monitor recovery post-exposure. OSPW exposure significantly altered the expression levels of certain biotransformation (CYP1a/b) and neurodevelopment (NeuroD) genes. After two days of recovery, the expression levels of these genes were closer to those of the control than those immediately after exposure, which indicates that fish partially recovered from exposure within two days. This study demonstrates for the first time that embryonic fish recover relatively quickly after exposure to OSPW. By studying recovery time post-exposure we can determine the length of time that OSPW-induced effects persist and whether ozonation ameliorates the time required for recovery.

WP123 Airborne polycyclic aromatic hydrocarbons (PAHs) induce the tumor-related p53 pathway in wild double-crested cormorants living in the Great Lakes area

S.J. Wallace, Royal Military College of Canada / Chemistryand Chemical Engineering; S. de Solla, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; P.J. Thomas, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; V.S. Langlois, Royal Military College of Canada / Dept of Chemistry and Chemical Engineering

Polycyclic aromatic hydrocarbons (PAHs) are known and probable carcinogens that are found in oil products and can be emitted into the environment as a by-product through the incomplete combustion of fossil fuels. Studies have shown that exposure to PAHs in the environment can induce both epigenetic toxicity and genotoxicity, but few studies have related PAH exposure to changes in the putative molecular pathways in free ranging wildlife. Previous work has suggested that double-crested cormorants (Phalacrocorax auritus) had a higher incidence of genetic mutations at sites in Hamilton Harbour, ON, Canada, where higher PAH concentrations in the air and sediment occur. The aim of this project was to determine if airborne PAHs further affected cormorants by altering global DNA modification and/or the tumour-suppressing p53 pathway. Liver and lung tissue samples were collected from cormorants at sites in Hamilton Harbour and Lake Erie with differing levels of PAH exposure.

PAHs have been shown to decrease global methylation (5-methylcytosine) in humans and fish, but here we found only a slight increase in 5-methylcytosine in lung tissue of cormorants living at sites with low compared to high PAH exposure. Furthermore, the tumour-suppressing protein (p53) regulates the pathway that conserves genetic stability by activating DNA repair or by inducing the apoptosis, among others, and it is also known to be mutated in over 40% of cancer cases. Our results from real-time RT-PCR show that expression of genes related to DNA repair in both liver and lung tissue were increased with higher exposure to PAHs. Likewise, mRNA levels of genes involved in cellular apoptosis were also increased in the liver, while expression of genes involved in the regulation of p53 decreased in lung tissue at the site with highest PAH exposure. Further western-blot analysis of p53 and p53r2 indicated that post-transcriptional modifications were also affected by exposure to PAHs.Altogether, data suggest that PAHs activate the p53 pathway, which allows birds to cope with increased exposure to mutagens.

Fate and Effects of Metals: Biogeochemical Perspective

WP124 Effect of pH and natural organic matter on heteroaggregation of CeO2 nanoparticles with clay

S. Bae, Korea Inst of Toxicology (KIT); Y. Hwang, Korea Inst of Toxicology / Future Environmental Research Center

Heteroaggregation of nanoparticles and natural clay minerals in aquatic environment plays an important role in determining their environmental fate and mobility. We studied the heteroaggregation of CeO_2 nanoparticles (NPs) with montmorillonite as well as homoaggregation of CeO_2 NPs and montmorillonite under various conditions, including pH and natural organic matter (NOM). Time-resolved dynamic light scattering (TR-DLS) measurements were used to investigate the aggregation kinetics. CeO_2 NPs and montmorillonite had ionic strength (IS) and pH-dependent surface charge. For this reason, the aggregation kinetics of CeO_2 NPs and clay increased in low pH and high IS. At single system, the critical coagulation concentration (CCC) of montmorillnonite increased with increasing pH. At low pH, montmorillonite aggregated due to electrostatic attraction between positive charged clay edge and negative charged clay face. At high pH, both face and edge were negative charge and therefore montmorillonite was more stable than at low pH. On the other hand, the CCC of CeO_2 NPs was lower at pH 6 than at low or high pH. At pH 6, it was close to pH_{pzc} of CeO_2 NPs, and the stability of CeO_2 NPs decreased considerably, resulting in an extensive aggregation. In binary system (montmorillonite-CeO_2 NPs mixture), the CCC of mixture increased with increasing pH. At low pH, the surface charge of CeO_2 NPs was positive while that of montmorillonite was negative. Because there had oppositely charged surface between CeO_2 NPs and clay, the interactions of CeO_2 NPs and montmorillonite could accelerate aggregation. Whereas, at high pH, both CeO_2 NPs and clay had negative charged surface and heteroaggregation was not increased. However the presence of NOM increased stability of CeO_2 NPs irrespective of pH or the presence of clay. Consequently, particularly low aggregation kinetics of mixture was observed even at over 0.1 M NaCl concentrations due to the steric interruption of NOM. This study suggests that these environmental factors should be carefully considered in assessing the environmental impact of metal oxide nanoparticles.

WP125 The role of metal oxide minerals in nickel bioavailability in field-contaminated sediments

R.M. Mendonca, Kent State Univ / Biological Sciences; C.E. Schlekat, NiPERA; E.R. Garman, NiPERA / Ecotoxicologist; J.M. Daley, M. Hudson, Univ of Michigan / School of Natural Resources and Environment; A. Burton, Univ of Michigan / School of Natural Resources Environment; D. Costello, Kent State Univ / Biological Sciences

In freshwater ecosystems the bioavailability and toxicity of nickel (Ni) can be modified by its partitioning to metal ligands. In anoxic sediment, reduced sulfur (AVS) is the primary metal ligand, whereas iron (Fe) oxide minerals can be important binding fractions for Ni under oxic conditions. Lotic sediments are often vertically stratified with thin oxic layers overlying anoxic horizons, and the distinct physicochemical conditions in these sediment layers (i.e., redox, pH) modify their metal binding capacity. Current sediment quality criteria consider AVS as the major binding phase for Ni, but have not yet incorporated ligands that are present in oxic sediments. Our research goal is to assess the role of Fe oxides in Ni bioavailability in lotic sediments. In streams exposed to effluent from Ni mining operations in Thompson, MB, Canada, we assessed Ni bioavailability by coupling spatially-explicit sediment geochemistry with the indigenous macroinvertebrate community composition. Benthic macroinvertebrates, intact sediment cores and overlying water samples were collected in two pairs of reference and effluent-exposed sites. Sediment cores were separated into surface (0–2 cm, “oxic”) and deep (2–4 cm, “anoxic”) samples for geochemical characterization. Effluent-impacted sites contained high concentrations of sediment Ni and AVS, though roughly 60% less AVS was observed in surface sediments. Fe oxide mineral concentrations were elevated in surface sediments and bound a substantial proportion of sediment Ni. Redundancy analysis of the invertebrate community showed surface sediment variables significantly explained shifts in community abundances, and indicated that total sediment Ni and amorphous Fe oxide concentrations were the main environmental variables driving community variation. Relative abundance of the dominant mayfly (Ephemeridae) was reduced in sites with greater total Ni, but accounting for Fe oxide-bound Ni greatly decreased intersite variation in effect thresholds between the two mine sites. Our results provide evidence that solid-phase ligands in oxic sediment, most notably Fe oxides, may be playing a critical role in nickel bioavailability.

WP126 Environment monitoring for trace elements in Hawaii Islands using the small Indian mongoose (Herpestes auropunctatus)

S. Horai, Y. Nakashima, Tottori Univ; I. Watanabe, Tokyo Univ of Agriculture and Technology; S. Abe, Ministry of the Environment / Naha Nature Conversation Office; R. Sugihara, US Dept of Agriculture Animal & Plant Health Inspection Service Wildlife Services / National Wildlife Research Center Hawaii Field Station

Concentrations of 27trace elements (Li, Mg, Cr, V, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Rb, Sr, Mo, Ag, Cd, Hg, Pb and Bi) in the livers, kidneys, brains, hairs, muscles, stomach contents of the small Indian mongooses inhabiting Hawaii Islands were determined. Cadmium concentration from Macnut orchard was relatively higher than other areas in Hawaii. Although Pb concentrations in the liver and kidney from Hawaii were not significant differences from other countries, the concentration in the brain was observed significantly higher than the others. As the results of area analysis, it found out that Pb levels in the brains of the individuals collected from the firing range were relatively and/or significantly higher than the other areas, moreover, Pb concentration from the firing range showed positive correlations between the concentrations of As and Sb which are included Pb pellets. Median of Pb concentration from the firing range 2.68 $\mu g\ g^{-1}$ WW (min: 0.395 $\mu g\ g^{-1}$ WW -1510 $\mu g\ g^{-1}$ WW). There were three individuals from Ukumehame firing range which exceeded 3.79 $\mu g\ g^{-1}$ WW which was the mean cerebral Pb level in the rats exposed Pb-acetate, and showed the significantly decreases of the number of total erythrocyte, monocytes and neutrophils, and cellular necrosis, diffused oedema and encephalomacia were observed in the rat brain. Furthermore, two fetuses exhibited elevated Pb concentrations than each mother. These results prompted us to express our concern on possible exposure and health effects in the small Indian mongooses and other animals by Pb derived from firing range.

Fate and Effects of Metals in the Environment: Modeling and Interpreting Effects of Metals Mixtures

WP127 It doesn't always add up: A new approach for statistical determination of non-additive toxicity in metal mixtures that have multiple interactions

E.M. Traudt, Colorado School of Mines; J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry; J.S. Meyer, Applied Limnology Professionals LLC

Surface waters often contain mixtures of metals that may cause aquatic toxicity. We investigated acute toxicity to Daphnia magna in binary (Cd-Cu, Cd-Ni, Cd-Zn, Cu-Ni, Cu-Zn, Ni-Zn) and ternary (Cd-Cu-Zn, Cd-Cu-Ni, Cd-Ni-Zn) mixtures and demonstrated that the toxicity can be less-than-additive, additive, or more-than-additive, depending on the metals and their concentrations. When metals having non-additive effects are included in a ternary mixture, a complicated combined effect of those interactions can arise. For example, the toxicity of Cd-Cu and Cd-Ni mixtures is, to differing extents, less-than-additive, but the toxicity of Cu-Ni mixtures is generally more-than-additive. Therefore, ternary Cd-Cu-Ni mixtures could exhibit a somewhat complicated combined effect of those three interactions. We present a method to statistically test for additivity that accounts for uncertainty in both the predicted and the observed mixture-toxicity results, when response-addition is assumed. This method uses toxicity data from "titration" experiments, in which the concentration of one metal in the mixture is varied through an exposure series while the concentrations of the other "background" metals are held constant; and then the concentrations of the background metals are sequentially changed in separate experiments. By plotting the ratio (observed mixture mortality/predicted response-additive mixture mortality) versus concentration of the varied metal, the non-additive and/or additive mixture toxicity are visualized across that metal gradient. Using a Monte-Carlo type randomization method, uncertainty associated with the observed mortality in each combination of metal concentrations and uncertainty in predicted response-additive mortality in each of those mixture combinations are concurrently taken into account to then test for non-additivity on a point-by-point basis. The uncertainty in predicted response-additive mortality is computed from the standard deviations of the EC50 and slope of each individual-metal concentration-response curve that was tested concurrently with a given mixture. When feasible, nonlinear regression curves are fit to the "global" mortality ratio versus concentration relationships. To demonstrate this approach, we provide examples of binary and ternary mixtures that exhibit a variety of additive/non-additive toxicity patterns.

WP128 Genotoxicity produced by Fe and Al mixture on liver and gills of the common carp (Cyprinus carpio)

M. Galar-Martinez, K. Ruiz-Lara, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional / Laboratory of Aquatic Toxicology Dept of Pharmacy; L. Gómez-Oliván, Universidad Autonoma del Estado de Mexico / Farmacia; S. Garcia-Medina, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional / Laboratory of Aquatic Toxicology Dept of Pharmacy; R. García-Rodríguez, Universidad Veracruzana; Y. Márquez-Flores, Dept of Pharmacy

Unlike many organic pollutants, heavy metals have been identified as the most dangerous in aquatic ecosystems because these are not biodegradable, so they can be accumulated in different aquatic compartments, thus enhancing its toxicity. It has been shown that they can generate oxidative stress, so they may act as genotoxic agents, and in turn cause damage to the fish, reducing their population or promoting their disappearance from a body of water. The objective of this project was to evaluate the genotoxic damage produced by the interaction of Fe and Al in liver and gill of Cyprinus carpio. For this, organisms (juvenile stage) were exposed to Fe (1 ppm) and Al (0.05 ppm) individually and in mixtures, the concentration used was the maximum allowable limit for the protection of aquatic life, established in México (DOF, 1989). The exposure time was 12, 24, 48, 72 and 96 h, after this, the liver and gills extraction was performed with PBS and homogenized. To assess the damage to genetic material, single cell electrophoresis and micronucleus assays were used. The results showed significant differences ($P < 0.001$) at 12 h in liver and gills of organisms exposed to Al and Fe with respect to control group in comet assay and micronucleus test, and a tendency to recover before 48 h for both organs. However, in organisms exposed to the mixture no recovery is observed, and instead the damage remains throughout the study for both organs ($P < 0.005$). In conclusion, aluminum and iron cause damage to genetic material, this being higher in organisms exposed to the mixture of metals in both organs.

WP129 Development of biotic ligand model for prediction of arsenic toxicity to Aliivibrio fischeri: 1. Effects of pH and major ions

B. Jeong, Seoul National Univ; J. An, K. Nam, Seoul National Univ / Dept of Civil and Environmental Engineering

Arsenic is known as one of most hazardous metalloid that could have a toxic effect to organisms. The importance of methodology to assess its toxicity has been emphasized and as a suggestion, biotic ligand model (BLM) was introduced to provide toxicity assessment of arsenic. This study was conducted to develop the BLM to predict arsenic toxicity to luminescent bacteria, Aliivibrio fischeri and aimed to investigate effects of pH and major ions to its toxicity. Also arsenate, a pentavalent inorganic form of arsenic abundant in aquatic and terrestrial systems, was used along with Microtox®, a toxicity testing system, to perform the experiment observing light intensities emitted by A. fischeri before and after the toxicant was injected. When tested arsenate, its major species were hydrogen arsenate ($HAsO_4^{2-}$) and dihydrogen arsenate ($H_2AsO_4^-$) which varied with pH values. As pH increased there were mostly $HAsO_4^{2-}$ ions in the solution and the toxicity also increased. It demonstrates that the change of arsenic species with pH should be considered when modeling and the methodology to incorporate pH effect into the BLM was also discussed in this study. Besides the effect of pH, some cations and anions were also tested in order to analyze their effects on the arsenic toxicity. Increased activities of SO_4^{2-}, HPO_4^{2-}, NO_3^- and HCO_3^- resulted in decreased arsenic toxicity by having competing effect between anions and arsenate ions to the binding site (i.e., biotic ligand) in the following order: $HPO_4^{2-} > SO_4^{2-} > HCO_3^-$. However, cations such as Ca^{2+}, Mg^{2+}, and K^+ did not have significant effects on its toxicity. Overall, the advanced BLM for prediction of arsenate toxicity was proposed to reflect the arsenic species variation, the competition effect of major anions, and the change of strength in competition effect of pH.

WP130 Development of biotic ligand model for prediction of arsenic toxicity to Aliivibrio fischeri: 2. Effects of humic and fulvic acids

B. Jeong, Seoul National Univ; J. An, K. Nam, Seoul National Univ / Dept of Civil and Environmental Engineering

Arsenic is a hazardous metalloid that is generated not only from anthropogenic reasons but also from natural environment such as mineral sources. Pentavalent inorganic arsinic acid (arsenate) is a major species in aquatic and terrestrial environment. As a methodology to assess its toxicity, a biotic ligand model (BLM) can be effectively applied. In this study, effects of humic acid (HA) and fulvic acid (FA) as surrogates of dissolved organic carbon on arsenate toxicity were investigated to develop the accurate and reliable BLM. Toxicity tests were performed using the Microtox® with luminescent bacteria Aliivibrio fischeri. The research studied arsenate toxicity depending on the HA and the FA concentrations, a bridging effect of cations including Ca^{2+}, Mg^{2+}, and K^+, contact time between the HA or FA and arsenate (5 min, 1 h, 1 d, and 7 d), and the effect of pH values. Possible formation of complexes (through the interaction between FA or HA and arsenate) was also observed with high performance liquid chromatography linked to inductively coupled plasma mass spectrometry (HPLC-ICP-MS) instrumentation. The results of changing toxicity will be reflected to the BLM in order to design a model predicting the arsenate

toxicity. By studying the effect of HA and FA on the arsenate toxicity, the BLM is expected to be applied in various sites and provide more accurate toxicity assessment considering the site characteristics.

WP131 Estimating acute toxicity of metal mixtures to Daphnia magna: A multiple evaluation approach

T. Boloori, Trent Univ / Environmental and Life Sciences; D. Evans, Trent Univ / Chemistry Dept; T. Backhaus, Univ of Gothenburg / Dept of Biology and Environmental Sciences

The simultaneous exposure of aquatic organisms to multiple metals in real-world environments creates a need for increased evaluation of the toxicity of metal mixtures. Due to the lack of systematic approach to determination of multiple metals toxicity in the literature, many hypotheses can be postulated about the potential interactions of metals in both aqueous and biological media. In this regard, interactions among metals and water constituents in the water medium, as well as competitive binding of metals to receptors on biological surfaces can impact the toxic effects. To assess the toxicity of multiple metals, acute toxicity tests of mixtures of metals, including Cd, Cu, Ni, and Zn, to Daphnia magna were performed in this study. The background test medium was modified filtered river water (Otonabee River, Peterborough, ON. Canada) with 3 mg DOC/L. After multiple runs of individual metal exposures, the binary mixtures were assessed using different total toxic units (TU) based on 1TU = EC50 value of individual metal. A complex series of interactions was observed in binary metals exposures. In the binary mixtures of Cd-Cu, Cd-Zn, and Ni-Zn, an antagonism can be observed in low total TUs equal to 0.5; whereas it turned to synergism in higher total TUs of 2. Further, to identify possible synergism or antagonism interactions between metals, a multiple metal toxicity evaluation program was compared to our empirical data.

WP132 From single to metal mixture exposure: Effects on Plationus patulus population dynamics

J.V. Rios Arana, Universidad Autónoma de Cd. Juárez / Chemical and Biological Sciences; E.J. Walsh, Univ of Texas at El Paso / Dept of Biological Sciences; M. Ortiz, Univ of Texas Houston School Public health at El Paso

Although it is recognized that some heavy metals (Cu, Cr, Ni, and Zn) are essential for life, it is also known that at certain concentrations their presence can cause even death. Many studies have determined toxicity of single metals and some have addressed the interactive effects of multiple elements at diverse concentrations on aquatic populations. We were interested in determining if consequences caused by two or more metals on rotifer population dynamics were due to element interactions or their individual effects. The rotifer, Plationus patulus, a basal freshwater consumer, was exposed to singly to six elements (As, Cr, Cu, Ni, Pb, Zn) and specific metal mixture combinations (As-Ni, As-Pb, Cr-Cu, as well as As-Cr-Cu-Ni-Pb-Zn) at environmentally determined concentrations. Effects on six population parameters (intrinsic rate of increase (r), relative cumulative reproduction, mortality ratio, mictic ratio, fertilization ratio and number of deformed offspring) were assessed. Occurrence of metal interactions was determined by linear regression analyses. Mictic and fertilization ratio as well as mortality were affected during single element exposures, mostly by Cr and Cu (20X higher than control in both cases), Cu (2X>control), and As (2X>control). Significant negative effects due to As-Ni and As-Pb interactions were observed in r and Cr interacted with a combination of all other elements negatively affecting, r and mortality ratio. Although rotifer population dynamics were altered by metal mixtures, the effects produced by mixtures were not always more detrimental than those caused by single metal exposures. Interactions among elements may contribute to the reduced the toxicity of single elements, which may occur in nature, where organisms are exposed to mixtures of pollutants. This research provides insights on effects of metal mixtures on freshwater organisms, which are not always predictable.

From Phosphates to Food Webs: A Tribute to David Schindler's Legacy in Aquatic Sciences

WP133 Will climate change exacerbate pollutant bioaccumulation in marine food webs? Perspectives from an ecosystem modelling approach

J. Alava, Inst for the Oceans and Fisheries, Univ of British Columbia / School of Resource and Environmental Management; A. Cisneros-Montemayor, W.W. Cheung, Univ of British Columbia / Inst for the Oceans and Fisheries

Anthropogenic climate change and chemical pollution are amongst the major stressors on marine ecosystems in the 21st century, posing substantial ecological and human health risks. Understanding the combined effect of climate change and pollutant impacts is crucial for those tasked with managing ecological and human health risks in the long-term. However, the combined effects of these two stressors on marine foodwebs are still not clear. Several studies suggest that climate change is already changing pollutant fate and transport in the atmosphere, and affecting exposure and accumulation of pollutants in marine organisms that can subsequently be affected by adverse health effects. Top predators and humans with high rates of seafood consumption such as marine mammals and First Nations communities in the Northeastern Pacific (Canada and US), may be most vulnerable to such impacts. To test this hypothesis, we developed a trophodynamic model (Ecopath with Ecosim) to examine the impact of climate change and acidification on the bioaccumulation of organic chemical pollutants, including polychlorinated biphenyls (PCBs) and organic mercury (MeHg), in the Salish Sea marine food web in the Northeastern Pacific Ocean. The ecosystem model is driven by projected climate change variables, including temperature, pH, dissolved oxygen and primary production under a 'strong mitigation' (low emission) and 'business-as-usual' (high emission) scenarios (Representative Concentration pathways, or RCP 2.6 and 8.5). The model also tracks and predicts the bioaccumulation of pollutants (PCBs and MeHg) with the Ecotracer module. We then examine the effects of different potential pathways of climate-pollutant interactions on the biodiversity and fisheries in the ecosystems. This study improves our understanding of the interactions of climate and pollution impacts, contributing to a more comprehensive understanding of the risks of multiple human stressors, and highlights key areas for concerted research and potential mitigation policies.

WP134 Validation of in ovo embryo microinjections using selenomethionine to simulate maternal transfer in the fathead minnow (Pimephales promelas)

T. Lane, Univ of Saskatchewan; D.M. Janz, K. Liber, L. Doig, Univ of Saskatchewan / Toxicology Centre; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

Selenium (Se) is a developmental toxicant of increasing concern because it can be released into the aquatic environment in significant amounts from industrial and natural processes. Inorganic Se released into surface water is biotransformed and bioaccumulated by microorganisms and algae as selenomethionine (SeM). SeM is then transferred to higher trophic levels, such as aquatic invertebrates and fish. Early life-stages of fish are highly sensitive to SeM exposure and are primarily exposed via maternal transfer. Developmental deformities (e.g. spinal curvature, craniofacial, edema) might occur as a result of embryo exposure to maternally transferred SeM. However, maternal transfer is difficult to study in native species of concern in Canadian ecosystems, especially for those species that are long-lived or endangered. This study will be the first step in developing an embryo injection model to help interpret maternal transfer of SeM. The fathead minnow was selected as a model organism based on its wide distribution throughout North America and its extensive use in previous regulatory testing and research. Fathead minnow embryos will be injected with graded concentrations of (9, 18, or 36 µg SeM/g d.m – egg) and developmental endpoints will be compared with those from a parallel maternal transfer study. Establishing an embryo injection model for predicting toxicity of SeM through maternal transfer will make testing a broader range of species more feasible. Future research using this model will aim to determine Se sensitivity in early life stages for native species of concern (e.g. white sturgeon and rainbow trout).

Aquatic and Terrestrial Plants in Ecotoxicology and Risk Assessment

WP135 Ability of cupric ion activity to predict growth and survival of individual plants and community-level parameters

C.B. Meyer, J. Iannuzzi, ARCADIS; M. Buonanduci, Arcadis US, Inc.; M. Barkley, A. Thatcher, ARCADIS

High copper concentrations in soils with depressed pH can be phytotoxic. Cupric ion activity, measured as pCu = $-\log Cu^{2+}$, integrates effects of copper and pH and can be used to evaluate potential phytotoxicity of soils. We developed dose-response curves of pCu against terrestrial plant endpoints measured in a greenhouse (emergence, survival, shoot height, shoot weight, and root length) and field (percent canopy cover, species richness) in semi-arid mining sites to assess if pCu is strongly predictive of phytotoxicity. Covariates were added to the model to account for other soil parameters that affect plant survival and growth, including organic matter, chemistry, and soil type. The laboratory plant species evaluated included the agricultural species, alfalfa, and two species native to the study sites, sideoats grama (Bouteloua curtipendula) and tansyleaf tansyaster (Machaeranthera tanacetifolia). The two native species were further split into seeds collected from the study sites and seeds obtained from nurseries to evaluate if plants growing in mineralized areas have evolved more tolerance to high copper than plants growing in non-mineralized areas. The dose-response model that combined all five seed types evaluated in the greenhouse fit the data well with $R^2 > 0.74$, showing a sigmoid response of reduced plant performance with lower pCu (= higher toxicity). Site-collected seeds of native species were not more tolerant of low pCu than agricultural or nursery acquired seeds when median effect concentrations (EC50) were compared. Soil location type (in bedrock, steep slopes, or level areas with or without topsoil), iron, and clay content of soils were covariates that significantly shifted the dose-response curves as follows: Topsoil present in flat areas and more extractable iron were protective, whereas higher clay content was detrimental to plant growth and survival. A linear model best fit the richness data collected in the field when separated by soil type ($R^2 = 0.83$). The pCu did not predict plant cover well for steep slopes or flat areas lacking topsoil but was predictive for bedrock and flat areas with topsoil. The effect levels were generally consistent between the greenhouse phytotoxicity and field community studies after accounting for natural variability in reference areas without high copper. The results show that pCu is a good predictor of individual and community parameters, better than either copper or pH alone.

WP136 Exposure Assessment Modelling Approach to Non-Target Plants Through Runoff from Agricultural Fields

A. Ritter, M. Cheplick, D. Desmarteau, N. Snyder, Waterborne Environmental, Inc.

The USEPA uses the screening model, TerrPlant, to estimate exposure to non-target terrestrial plants from a single application of pesticide. Audrey III is a higher tier exposure model that has been developed by USEPA to estimate exposure to plants in a Plant Exposure Zone (PEZ). The objective of this study was to investigate the magnitude and likelihood of exposure of non-target plants to pesticide residues through runoff from agricultural field to an adjacent PEZ. TerrPlant and AUDREYIII will be compared to two vegetative filter models: PRZM-Buffer and VFSMOD. PRZM-Buffer is a modified version of the Pesticide Root Zone Model (PRZM), a rainfall-runoff simulation model, to simulate pesticide fate and transport in a PEZ. VFSMOD is a vegetative filter strip (VFS) model designed to simulate VFS processes to remove sediment and pesticides from field runoff/erosion. Current EPA Tier II scenarios for PRZM were used to represent main field simulations. Movement of pesticide through the PEZ and the concentrations for the segments were modeled with the PRZM-Buffer model and VFSMOD. Results from these two models will be compared to each other and to USEPA models TerrPlant and AUDREYIII. Multiple widths of buffers were assessed to determine distance required for soil concentrations to drop below level of concern for non-target crop.

WP137 Glyphosate and Dicamba Inhibit Flowering of Native Willamette Valley Plants

D. Olszyk, U.S EPA / NHEERLWED; T. Pfleeger, USEPA NHEERLWED / Western Ecology Division NHEERL; E. Lee, USEPA NHEERLWED; T. Shiroyama, Senior Environmental Employment Program; M. Plocher, CSS-Dynamac Inc.

Successful flowering is essential for reproduction of native plants and production of food for herbivores. It is also an important alternative endpoint for assessment of ecological risks from chemical stressors such as herbicides. We evaluated flowering phenology after herbicide drift treatments for nine native Willamette Valley plant species grown together in small (0.45 x 0.45 m) field plots. Study taxa were: Eriophyllum lanatum (ERLA, Oregon sunshine), Iris tenax (IRTE, toughleaf iris), Prunella vulgaris var. lanceolata (PRVU, lance selfheal), Camassia leichtlinii (CALE, large camas), Festuca roemeri (FERO, Roemer's fescue), Elymus glaucus (ELGL, blue wildrye), Ranunculus occidentalis (RAOC, western buttercup), Fragaria virginiana (FRVI, Virginia strawberry), and Potentilla gracilis (POGR, slender cinquefoil). Research was conducted during the summer growing season at two Oregon State University farms in Corvallis, OR in 2010 and 2011. The effects of glyphosate and dicamba alone, and in combination, were determined for simulated drift rates of 0.01 to 0.2 x field application rates (FAR) of 1119 g ha^{-1}active ingredient (AI) for glyphosate and 560 g ha^{-1} AI for dicamba. Flowering phenology was rated by presence of buds (1), buds turning into flowers (2), flowers (3), flowers deteriorating and seeds beginning to form (4), and mature seeds (5); with data analyzed statistically for treatment (n=8 for each treatment) vs. control plots (n=8). Flowering patterns varied by species, farm and year; but, in general, herbicides alone or in combination reduced the number of plants with flowers on a sampling date and/or delayed the onset of full flowering for 3 species in 2010, and for 6 species in 2011. For example, the number of flowering plants was reduced with dicamba and/or glyphosate at 0.1 x FAR for ERLA and PRVU, with dicamba and/or glyphosate at 0.2 x FAR for CALE, with glyphosate at 0.1 x FAR for IRTE and RAOC, and with glyphosate at 0.2 x FAR for POGR. Results of this study provide evidence that herbicide drift can affect flowering phenology of native plants.

WP138 Is the Tier-1 effect assessment for herbicides protective for aquatic algae and vascular plant communities?

G. Arts, R. van Wijngaarden, Alterra Wageningen Univ and Research Centre / Environmental Risk Assessment

For the admission of plant protection products on the European market, the environmental risk assessment (ERA) follows a tiered approach. In the first tier of the risk assessment scheme, experiments are required with standard test species. If plant protection products fail the first tier of the risk assessment, higher tier assessments may be applied including microcosm and mesocosm studies. In the aquatic Tier-1 effect assessment for plant protection products with a herbicidal mode of action, algae and/or vascular plants usually trigger the environmental risks. This 1st tier effect assessment includes chronic tests with at least two algae and one macrophyte (usually Lemna). Although considered of a chronic nature based on the duration of the test, the measurement endpoints derived from the laboratory tests with plants and that are used in the 1st tier effect assessment for plant protection products are effect concentrations to 50% of the test organisms (EC_{50}'s). In other European legislative frameworks (e.g. underlying the Water Framework Directive) effect concentrations to 10% of the test organisms (EC_{10}'s) are used. This paper contributes to a validation of the tiered herbicide risk assessment approach by validating the standard first-tier effect assessment with results of microcosm and mesocosm studies. We evaluated the protective value of the Tier-1 effect assessment using EC_{50} and EC_{10} values of standard test algae and macrophytes based on either the growth rate endpoint or the lowest available endpoint for growth rate or biomass/yield. These values were compared to the Regulatory Acceptable Concentrations (RACs) for the threshold option as derived from microcosm and mesocosm studies. A dataset of 14 herbicides was compiled based on regulatory data approved for inclusion in the risk assessment underlying the admission of pesticides in Europe. The Tier-1 RACs based on respectively ErC_{50} (9 cases) and EC_{50} (12 cases) values for algae and macrophytes resulted in 80% and 75% of the cases in a sufficient protection level when compared with the higher-tier RACs derived from microcosms and mesocosms. The Tier-1 RACs based on NOErC/ErC_{10} (6 cases) and NOEC/EC_{10} (7 cases) values were in all cases protective when compared with RACs from microcosms and mesocosms.

WP139 Occurrence and behaviour of emerging organic contaminants in a large-scale constructed wetland in Singapore

Q. Wang, National Univ of Singapore / Civil and Environmental Engineering; B.C. Kelly, Barry C Kelly / Civil Environmental Engineering

Constructed wetlands are commonly used to simulate the wetland process in a more controlled environment. These nature-assisted water treatment systems may be used as substitutes or supplements for conventional wastewater treatment systems. Constructed wetlands have proven effective for removal of COD, BOD, nutrients and heavy metals. There are relatively few studies on emerging organic contaminants (EOCs) in constructed wetland systems. The objective of the present study is to assess the occurrence, distribution and bioaccumulation behavior of several EOCs in a large-scale constructed wetland in Singapore. This constructed wetland was designed to treat landfill leachate and consists of a pretreatment system (equalization tank, aeration lagoons and sedimentation tank), five constructed reed beds and five polishing ponds. Three plant species are grown within the reed beds, including cattail (Typha angustifolia) vetiver grass (Chrysopogon zizanioides) and papyrus (Cyperus papyrus). The current study focused on assessing the occurrence and behaviour of synthetic musks, triclosan and methyl-triclosan, as well as several halogenated flame retardants. The majority of the target EOCs were detected in the different compartments of the wetland, raw leachate, equalisation tank, sedimentation tank, reed beds and polishing ponds. Polycyclic musks (galaxolide and tonalide) and the chlorinated flame retardant, Dechlorane Plus, exhibited the highest concentations in water and planty samples. The translocation factors (TFs) of the compounds ranged between 0.22 and 7.23. TFs tended to drop for very hydrophobic compounds with log Kow > 5. The root concentration factors (RCFs) and leaf concentration factors (LCFs) varied substantially among chemicals. LCFs were typicall higher than RCFs for these compounds. The results help provide a better understanding of the key determinants and mechanisms governing transport, bioaccumulation and phytoremediation of these contaminants in constructed wetlands.

WP140 The effects of the aquatic herbicide diquat on native and invasive macrophytes

R.L. Dalton, Univ of Ottawa / Dept of Biology; C. Boutin, S.A. Robinson, Environment and Climate Change Canada; A.J. Bartlett, Environment and Climate Change Canada / Aquatic Contaminants Research Division; V. Sesin, Univ of Koblenz-Landau; F.R. Pick, Univ of Ottawa / Dept of Biology

Invasive aquatic plant species are a significant threat to the health of aquatic ecosystems and demand for chemical control options are likely to increase as invasive species spread and reach nuisance levels. Currently, data on the effects of chronic, ecologically relevant concentrations of current-use aquatic herbicides on non-target biota are lacking. The objective of our study was to assess the effects of the aquatic herbicide diquat on target and non-target biota using outdoor mesocosms (300 L) to simulate natural systems. The experiment consisted of a control and five treatments reflecting environmentally relevant concentrations of diquat, each with five replicates. Biota included a) native and invasive macrophytes collected from nearby waterbodies (Myriophyllum spicatum, Myriophyllum sibiricum, Elodea canadensis and Ceratophyllum demersum), b) natural communities of phytoplankton and periphyton, c) juvenile amphipods (Hyalella azteca) and d) northern leopard frog tadpoles (Lithobates pipiens). The effects of diquat on invasive and native macrophyte communities in semi-natural conditions will be discussed. The relative sensitivity of individual species to diquat when grown in mesocosms will be compared with their sensitivity when grown individually in laboratory conditions. Overall, results from this study will assess the potential risks versus benefits diquat poses to the aquatic environment.

WP141 The impact of nano copper oxide and arsenic on the seeds germination and seedling growth conditions of the rice plant (Oryza Sativa)

J. Liu, Baylor Univ; P.S. Watkins, Baylor Univ / Dept of Environmental Science; B. Dhungana, Baylor Univ / Chemistry and Biochemistry; G.P. Cobb, Baylor Univ / Dept of Environmental Science

nCuO and As altered seed germination and seedling growth for an important rice species (Oryza Sativa). 1/5th strength of Hoagland solution was used as nutrient. Five treatments of nCuO (0.1, 1.0,10, 50, and 100mg/L) were made with the nutrient solution. As (18 ppm) was added to the sand medium as As treatment. Forty replicates of rice seeds were exposed to each of the following 12 treatments: control, As treatment, five nCuO treatments and five As+nCuO treatments. The seed germination and seedling growth test was proceeded in an incubator for 18 d. The temperature was set at 25 ? during the day (16h), and 20 ? at night (8h). Results showed that: seeds started germinating on day 4; both time and treatment significantly affected the germination rate (time p-value < 0.001, time*treatment p-value =0.007); according to the germination curve, from day 4 to 8, seeds germination was boosted with higher concentration of nCuO (10,50 and 100 mg/L), while those treated with lower concentrations of nCuO and with As showed lower germination rates compared with control; However, on day 18, the germination rate with all nCuO treatments except 0.1mg/L was higher than or equal to the control, while it's higher for As with 1.00mg/L nCuO, and lower for the seeds with the rest of As + nCuO treatments. Moreover, all the seedling length and whole dry biomass were significantly different with different treatment groups($p< 0.05$). As treatments decreased the length and dry weight of both shoots and roots. Lower concentration of nCuO (0.10 mg/L and 1.00 mg/L) alone enhanced the seedling growth with increasing length and dry weight of both shoot and root while the higher concentration of nCuO inhibited the seedling growth. Seedlings growth in As treatments were more inhibited than in treatments receiving As+nCuO. On day 18, the seedling survival rate in the nCuO treatments were consistent with the germination rate rank, whereas the results for As treatments were more consistent with the whole dry biomass. The activity of antioxidant enzymes, superoxide dismutase (SOD) and catalase (CAT), and GSSG/GSH ratio will be measured to compare the oxidative stress caused by different treatments, which will help explain the potential mechanism of the different impacts on the seedling growth conditions. EDS-TEM will be used to identify the distribution and speciation of the chemicals of interests, in order to determine the uptake and transportation of nCuO and As in the seedlings.

Bringing Probabilistic Risk Assessment into Criteria Development

WP142 Application of a Lead Shot Ingestion Model for Waterfowl at a Former Shooting Range Site

S. Thakali, B.J. Reese, AECOM; C. Mancini, AECOM / Environmental Services; R.G. Stahl, E.I. DuPont de Nemours and Company / Corp Remediation

Intentional ingestion of residual lead shot as grit can be a critical exposure pathway for waterfowl species at former shooting range sites. A quantitative understanding of this exposure pathway at a site can support risk and/

or remedial decisions for lead shot. Despite its availability since the early 2000, the general framework for modeling lead shot ingestion by birds has not be widely applied for waterfowl species. At a former shooting range site near a coastal estuary, the ingestion of lead shot from sediment by waterfowl species has been identified to be the exposure pathway of greatest ecological concern. Historically, remediation was performed at this site to remove lead shot from the sediment in the intertidal and shallow subtidal areas, primarily to mitigate this critical exposure pathway for the waterfowl species using the site. Subsequent erosional impacts to the sediment and winnowing effects have resulted in limited sporadic patches of high shot concentration in these remediated areas. A lead shot ingestion model has been applied to estimate the probability that an American black duck (Anas rubripes) will ingest a given number of residual lead shot during its lifetime. The approach, results, and discussion of the waterfowl lead shot ingestion model, including model assumptions, input parameters (receptor-specific and site-specific), and uncertainty evaluations, in the context of on-going and future remedial and/or risk decisions at the site, will be presented.

WP143 Exposure analysis of alkylphenol ethoxylates and their metabolites in US surface waters: combining deterministic and distributional analyses

C.A. Staples, Assessment Technologies, Inc.; K.K. Coady, The Dow Chemical Company / Toxicology Environmental Research and Consulting; B. Losey, RegNet Environmental Services

C8 and C9 alkylphenol ethoxylates (APnEO, where n = 4-40) are widely used surfactants mainly in a variety of industrial applications since their use in consumer cleaning products has declined over the last decade. In most uses, spent APnEO are sent to wastewater treatment plants for treatment. During treatment, APnEO break down to low-mole AP1,2EO, AP and a variety of low-mole carboxylated APnEC. These degradation intermediates are released via effluent discharges into receiving waters in which they are routinely detected. Due to their aquatic toxicity, the USEPA developed a chronic water quality criteria for freshwater organisms of 6.6 µg/L for the most toxic degradation product, nonylphenol. This criteria was developed using mainly acute toxicity data and acute-to-chronic ratios. Sufficient chronic aquatic toxicity data now exist such that various statistical techniques can be used to assess toxicity including probabilistic, species sensitivity distributions, and distributional analyses. This presentation follows up on an exposure analysis of AP and APnEO in US surface waters that was conducted in 2007 in which the authors compared aggregated concentrations to the USEPA WQC for NP. More recent monitoring data shows some reductions in both environmental occurrence and concentrations of APnEO degradation products. Results of traditional deterministic assessments (hazard quotients) and analyses that compare the distributions of recent measured concentrations and chronic ecotoxicity data are presented and compared to previous findings. The results show that more recent concentrations of AP/AP1,2EO are mostly non-detected in US surface waters, and nearly all aggregated detected concentrations are well below the WQC and lower 5th centile of the chronic toxicity data. The aggregated concentrations that do exceed the WQC are found in streams comprised of nearly 100% effluent.

WP144 Human Inter-individual Versus Population Level Dose-Response Curves Induced by 2,3,7,8-Tetrachlorodibenzo-p-dioxin in Primary B Cells: Linear or Not?

S.L. Hession, Michigan State Univ / Center for Statistical Training Consulting; P. Dornbos, J. LaPres, Michigan State Univ / Dept of Biochemistry and Molecular Biology

The effect of inter-individual variability within the human population is not typically assessed in traditional toxicological studies. However, populations within which chemical exposures occur are heterogeneous. Understanding how population dynamics and inter-individual variability impact dose response relationships (DRRs) is critical for accurate risk assessment and protection of human health. A recent report from the National Research Council (NRC) suggests that, when accounting for inter-individual variation in responses, traditionally assumed nonlinear DRRs for non-cancer endpoints would better be explained with a linear model in the low-dose region. While the NRC has acknowledged potential differences between individual and population-level responses, the assumption of low-dose linearity has not been adequately assessed empirically. With the potential to cause undue harm to public health and industrial and municipal finances, such an assumption warrants scientific proof. To address this, we utilized TCDD-induced inhibition of primary human B cells as a model. B cells were isolated from 51 unique human donors and exposed to increasing concentrations of the environmental contaminant 2,3,7,8-tetrachlordibenzo-p-dioxin (TCDD) on a logarithmic scale. Two endpoints were assessed: 1) number of IgM secreting B-cells and 2) amount of IgM secreted. Two approaches were taken to model DRRs. First, EPA's Benchmark Dose (BMD) software was used to assess the DRR between TCDD concentration and average population response at each dose. Second, multilevel modeling was conducted to directly address the issue of individual versus population level DRRs and their corresponding shapes. As such, the model accounts for unequal variances, obviating the need for variance stabilizing transformations of the response. Initial results using BMD indicate that TCDD has a significant suppressive effect in the number of B cells secreting IgM and the concentration of IgM secreted ($p< 0.05$). BMD model comparisons of population-averaged DRRs indicate that the low-dose region is best fit to a nonlinear model, suggesting the presence of a threshold in the population response to TCDD. Multilevel modeling supports these findings, yielding greater clarity regarding the population DRR. Based on initial findings, our study suggests the need to retain an assumption of nonlinearity in the low-dose region of the DRR during risk-management decision-making for non-cancer endpoints.

WP145 Idaho's Experience Using PRA for Human Health Criteria

D. Essig, Idaho DEQ / Water Quality

In March of 2016 Idaho concluded three and one-half years of rulemaking to adopt updated Clean Water Act criteria to protect human health from exposure to toxins through ingestion of water and consumption of fish. Early on in the effort it was decided to pursue probabilistic risk assessment (PRA) to develop the new criteria and a fish consumption survey was mounted with the aim of producing distributions of fish consumption in Idaho. Criteria were proposed based on PRA, but ultimately the criteria adopted were based on traditional deterministic calculations. This presentation will address reasons why Idaho chose to go down the PRA path, bumps along the way, why this path was ultimately abandoned, and some recommendations for smoothing the way for future use of PRA in water quality standards.

WP146 Probabilistic Ecological Risk Assessments – Are they worth your time?

G.I. Greenberg, Gradient Corporation; D.G. Skall, Gradient

Ecological risk assessments evaluate risks to likely receptors exposed to media potentially impacted by site activities. Typically, a deterministic ecological risk assessment (DERA) is conducted for representative receptors with upper-end exposure assumptions (e.g., 100% diet, home ranges equal to site) and central tendency values (e.g., body weight) that ignore the variability of the available data. In a DERA, the inputs for the exposure models and effects concentrations are single values which are used to calculate a simple ratio of effect (i.e., hazard quotient [HQ]). Alternatively, probabilistic ecological risk assessments (PERA) reduce the uncertainties associated with limited data and the variabilities associated with modeling by characterizing risks based on the magnitude of risk as well as the probability of occurrence. We conducted ecological risk assessments for five terrestrial receptors exposed to metals in surface soils, surface water, and associated prey items using both deterministic and probabilistic methods. To simplify the process, the same exposure point concentrations and toxicity reference values were used. The two methods differed in exposure parameters (i.e., body weight, home range, percentage of diet). For the PERA, we also compared two methods of calculating ingestion rates (diet-specific field metabolic rates [FMR] vs. FMRs for representative animal groups). We compared DERA HQs to PERA HQ ranges and determined which input parameters contributed the most to the overall risk results. We determined that in addition to producing more realistic mean HQ values compared to the DERAs, the PERAs can also provide more conservative estimations of risk for receptors with large home ranges. For receptors with small home ranges, the percentage of terrestrial invertebrates in the diet impacted the PERA mean HQs by up to a factor of 4. When comparing PERA HQs using the two different ingestion rates, risks using the diet specific FMRs resulted in lower HQs, but with more variability than HQs using FMRs for representative animal groups. While performing PERAs requires more time, PERA HQs provide information on the magnitude of risk and the probability of occurrence. DERA HQ values only note that the values are conservative, but provide no information on how conservative they are. Consequently, information regarding the probability of occurrence could vastly improve remediation goals and decisions.

WP147 Probabilistic Human Health Water Quality Criteria Calculator

M. Buonanduci, G. Houck, P.D. Anderson, Arcadis US, Inc.

Arcadis has a developed publicly available risk assessment calculator that States and other interested parties can use to derive State-specific human health water quality criteria (HHWQC). The calculator is designed to be transparent but allow States the flexibility to employ the State-specific assumptions that they believe are appropriate. This flexibility allows States to use either point estimates or distributions for any or all of the parameters included in the equations employed by the United States Environmental Protection Agency (EPA), including trophic level-specific fish consumption rates and bioaccumulation factors. In addition to the parameters explicitly listed in the EPA equations, the calculator also includes the ability for users to input distributions for implicit parameters that affect the outcome of the equations but are not listed specifically in the equations (e.g., exposure duration, loss of chemicals from fish tissue during cooking, fraction of fish consumed that are caught within the state, fraction of fish consumed that reside within the water body for their entire life cycle). This presentation will introduce the calculator, which is available on the Idaho Department of Environmental Quality website, and demonstrate how it can be used to derive ambient water quality criteria using probabilistic risk assessment methods. This derivation process uses an iterative approach in which a water concentration is selected and the resulting risk distribution is compared to risk management goal(s). If one or more goals is exceeded, the process is repeated using alternative chemical concentrations until a concentration is identified that results in a risk distribution that meets all risk management goals. That concentration is the HHWQC.

Adverse Effects of Chemicals on the Microbiome

WP148 Analysis of Animas Watershed Sediment Bacterial Communities after the Gold King Mine Breach

K. Thompson, Texas Tech Univ / Environmental Toxicology; P.N. Smith, G.D. Mayer, Texas Tech Univ / Dept of Environmental Toxicology

On August 10, 2015 a tailing pond at the Gold King Mine near Silverton, CO was breached when workers attempted to add a tap to aid in restoration efforts. As a result, approximately three million gallons of water containing elevated concentrations of cadmium, lead, arsenic, zinc, copper, iron, beryllium and other toxicants were released into the Animas watershed. Presumably, deposition of metals in sediments along the watershed present a selective pressure for sediment-borne bacteria inhabiting these niches. Here we report on the structure of sediment bacterial communities along the path of the waste outflow from the mine through Cement Creek, the Animas River, and proximal regions of the San Juan River. In the absence of baseline data collected before occurrence of the breach, samples upstream of the confluence of Cement Creek with the Animas River and the confluence of the Animas with the San Juan River were collected to serve as unaffected controls. Analysis of 16S marker genes was used to determine diversity metrics and population structure within the sediment-borne communities and these were compared with communities from unaffected sites. Additionally, abundance of metal resistance determinants was analyzed to garner information regarding how native bacterial communities adapt to mixed metal stressors.

WP149 Evaluating changes in the gastrointestinal microbiome of rainbow trout (Oncorhynchus mykiss) as a consequence of pollutant exposure

A.R. Moate, Univ of Saskatchewan – Toxicology Centre / Toxicology Centre; T. Jardine, Univ of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; S. Wiseman, Univ of Lethbridge / Biology; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

The gastrointestinal microbiome plays a critical role in organism health as it influences metabolic processes, plays a key role in host nutrition, and contributes to intestinal and immune system development in vertebrates, including fish. Many factors can affect the composition of the intestinal microbiome in fish including diet and host phylogeny. While a number of studies have shown that microorganisms are sensitive to low concentrations of pollutants, to date little information is known about the effects of contaminants on the bacterial community composition of the intestines. Any changes in gut microbiome composition have the potential to negatively influence fish health, and due to the essential role of bacteria in the gut, research is needed in this area. To further explore the impacts of contaminants on the intestinal microbiome of fish, this study investigated the potential effects of two pollutants (triclosan and benzo(a)pyrene), representing two chemical classes of environmental concern, namely antimicrobials and polycyclic aromatic hydrocarbons (PAHs) on microbial composition in the gut of rainbow trout. Antimicrobial compounds are extensively used in aquaculture, as well as in humans and animals, to treat bacterial diseases, which can lead to residues entering the aquatic environment and possible subsequent microorganism toxicity. PAHs are ubiquitous in the environment and can elicit a variety of deleterious effects on a wide range of organisms, including bacteria. Gastrointestinal microbiome composition was determined by next generation sequencing of the 16S rRNA gene using an in house Illumina MiSeq system. This research aims to provide insight into novel aspects of toxicity and chemical metabolism in fish, and further our understanding of the important role played by gut flora in host well-being and adaptation to changing environmental conditions. Furthermore, information generated from this study may be used in identification of bioindicator taxa present in the gut microbiome that are sensitive to certain contaminant classes, and development of biomonitoring strategies around known pollutant sources.

WP150 Linking contaminant induced microbiome shifts to host health in fishes

N. Ortell, The Univ of Southern Mississippi; K.M. Bayha, USEPA / American Association for the Advancement of Science; R. Takeshita, Abt Associates; R.J. Griffitt, Univ of Southern Mississippi / Coastal Sciences

Host-associated mucosal surfaces (gill and intestine) are important sites for normal development of host immune response, homeostasis, nutrient uptake and overall health. Impacts on a healthy microbiome following exposure to an environmental contaminant are not well-characterized, specifically in non-aquaculture teleosts. Typically, few microbes dominate the limited niches available in healthy tissues. Imbalances in these communities can have detrimental physiological effects. Contaminant exposure may allow rare taxa to compete for resources and dominance. In this study, multiple species of fish were challenged with a known pathogen (Vibrio anguillarum) following exposure to oiled sediment. Using 16S rRNA high-throughput sequencing, short-term microbiome responses were examined in lower gill and intestinal tissue from oil-exposed and pathogen challenged fishes. Two alpha indices, Chao 1 and Shannon, were used to determine changes in species richness and evenness. The gill microbiome was rapidly and significantly altered by oiled exposure;

while no significant difference in alpha diversity metrics were found in intestines (One-way ANOVA, Tukey HSD $p < 0.05$). The gill microbiome from Oil/Pathogen-challenged fish saw the greatest species richness and evenness compared to No Oil/No Pathogen-challenge exposures. Oil exposure resulted in Alcanivorax (a known PAH degrader) and Shewanella (implicated in fish spoilage), dominating the gill microbiome. A complete loss of members of the Photobacterium, occurred in both oil-exposed intestine and gill tissues. Lower levels of contaminant exposure induced significant changes to the gill microbiome, demonstrating an immediate sensitivity of gill fauna to environmental toxicant challenge, suggesting an important link between environmental contamination, microbiome function and host health.

WP151 Phthalates in the gastrointestinal system: Impacts on host-microbiome function

A. Buerger, Univ of Florida / Environmental and Global Health; J. Schmidt, Univ of Florida / Physiological Sciences; A. Tiblier, Univ of Florida / Environmental and Global Health; C.J. Martyniuk, Univ of Florida / Physiological Sciences; J. Bisesi, Univ of Florida

Phthalate esters, a class of chemicals used as plasticizers in polyvinyl chloride products such toys, water bottles, and medical supplies, are ubiquitous in aquatic environments. These chemicals are also classified as obesogens, or chemicals thought to be involved in metabolic disorders like obesity. However, the mechanisms by which phthalates affect metabolic function are largely unknown. During diet and waterborne exposures, the gastrointestinal system acts as a first line of defense, and consequently may be impacted by phthalate contaminants. As a result, the delicate balance of host-microbiota function may be disrupted. Alterations in the gut microbiome and host gastrointestinal system may disrupt nutrient processing, which can result in downstream phenotypic impacts. In this study, we examine whether low-level chronic exposure to a diethyl-hexyl phthalate (DEHP) alters the microbiome and gastrointestinal function of zebrafish (ZF). ZF were separated into three treatments: (1) a control group fed 2.5 mg food/fish/day, (2) an overfed group fed 20 mg food/fish/day and (3) an overfed group fed 20 mg food/fish/day with 3 mg DEHP/kg food. Following a 60 day exposure, fish were euthanized, and the gut and fecal matter were excised. Fecal DNA was extracted and 16S conserved regions were sequenced, matched to known sequences from bacterial phyla, and analyzed using QIIME. RNA was extracted from the host gut and analyzed for differential gene expression using RNAseq. Preliminary results indicate that treatment with DEHP alters the β diversity of the gut microbiome. Specifically, this study noted an increase in Bacteriodetes phylum in the overfed with DEHP group alone, and decreases both Fusobacteria and Tenericutes phyla in both the overfed and overfed with DEHP groups. Such changes in the abundance of Bacteriodetes and Fusobacteria of the gut microbiome have previously been associated with obesity and colorectal cancer in humans. These data support the hypothesis that environmental exposure to phthalates may negatively impact fish species by altering the gut microbiome, which may subsequently alter the ability of the organism to process nutrients, leading to metabolic disruption.

WP152 Suitability of frog skin microbiomes as sentinels of endocrine disrupting compounds

T. Van Rossum, Simon Fraser Univ / Dept of Molecular Biology and Biochemistry; E.J. Griffiths, Simon Fraser Univ; F. Brinkman, Simon Fraser Univ / Molecular Biology and Biochemistry; C.C. Helbing, Univ of Victoria / Dept of Biochemistry Microbiology

Municipal wastewater effluents introduce a variety of pharmaceuticals and personal care products (PPCPs) into the aquatic environment, which can perturb diverse biological processes by disrupting hormone function. Effective, environmentally-relevant methods to detect the activity of endocrine disrupting compounds (EDCs) are lacking, particularly for thyroid hormone (TH)-disruption. One model to test for EDCs is based on TH-dependent tadpole metamorphosis: tadpoles exposed to TH will become froglets, but this effect is blocked if TH-disrupting chemicals are present. Because this model relies on a binary outcome, it lacks sensitivity. Further, it looks at a single animal outcome instead of evaluating the impact of contamination on the whole community. While evaluating changes across a macrobiotic community is difficult, microbial communities provide an opportunity to profile population-level community changes. Bacterial communities can be taxonomically profiled by DNA-sequencing a phylogenetic marker gene (16S rRNA amplicon sequencing). Such profiling has already revealed that frog skin associated bacterial communities can reflect host changes. Therefore, we are investigating whether a microbiome-targeted assay would enhance existing tadpole-based tests for EDCs and TH-disruption. In order to investigate the effect of PPCPs on frog skin microbiomes, we are profiling their bacterial composition across chemical exposures and life stages. Skin microbiome samples were collected from Rana (Lithobates) catesbiana tadpoles exposed to TH, a cocktail of PPCPs, and suitable controls, all under conditions similar to those used for regulatory monitoring. Samples were also collected from unexposed animals across pre- and post-metamorphic life stages. Preliminary results suggest that frog skin bacterial communities vary by life stage and with exposure to TH. Experiments to evaluate the effect of PPCPs are currently underway. This study will provide fundamental baseline data for lab-reared frogs under controlled laboratory conditions, describing the variability of skin microbiomes over life stages and chemical exposures. The results of the present study will contribute to the evaluation of bacterial communities as sentinels of environmental contamination.

Strategies to Manage Contaminants in Urban Stormwater Runoff

WP153 Concentration and Forms of Carbon in a Longitudinal Gradient from Freshwater to Estuarine Ecosystem

G. Baysal, Univ of Florida IFAS; G.S. Toor, Univ of Florida / Soil Water Science Dept

Urbanization affects water resources and carbon (C) is one of the indicators to determine the effects of urbanization in coastal waters. We investigated the concentrations and forms of C in a longitudinal gradient from freshwater to estuarine ecosystem in Florida. Monthly water samples were collected (December 2015–May 2016) from 10 freshwater sites located in the upper (n=3), middle (n=4), and lower (n=3) reaches of a river and 3 estuarine sites. Water samples were analyzed for dissolved organic C (DOC), total organic C (TOC), and total C (TC). Other C forms were calculated as follows: particulate organic C (POC) = TOC–DOC; total inorganic C (TIC) = TC–TOC. Across freshwater and estuarine sites, TC was 10.0–47.8 mg/l, of which TOC was 8.2–65.1%, and TIC was 34.9–91.8 % during April–May 2016. Among organic C, DOC was the dominant form at all sites (>98%), whereas POC was < 2%. Concentrations of all C forms were lowest at the most upstream site, which continued to increase till middle reach of the river and then declined in the lower reach and estuarine system. The increase in C in the upper parts of the river is attributed to the increase in the urban land use. However, in the lower reach of the river, a part of the water is impounded in a reservoir to provide drinking water for local municipality. We suggest that water impoundment increased the residence time of water, which likely resulted in utilization of C as an energy source resulting in lower C concentrations. After water left the reservoir, another river added low C water resulting in dilution of C concentrations in the estuarine sites. The dominance of TIC across all sites is attributed to the geologic sources such as limestone in the watershed that likely contributed carbonates and bicarbonates. Among organic C, the dominance of DOC in this subtropical ecosystem is not surprising due to the abundance of organic sources such as plant materials and sediments. We conclude that concentrations and forms of of C were affected by urbanization, water impoundment, and dilution–where urbanization increased the concentrations in the freshwater system, whereas water impoundment and dilution decreased the concentrations in the estuarine system.

WP154 Evaluation of Turfgrass Variety and Management Practices to Mitigate Off-site Transport of Pesticides and Nutrients with Runoff from Golf Course Turf

P. Rice, USDA-ARS; B. Horgan, Univ of Minnesota / Dept of Horticulture; J. Hamlin, USDA-ARS

Managed turfgrass is found in both private and public settings; as residential, commercial and public lawns, on golf courses and athletic fields, along roadsides, and in parks and cemeteries. Turfgrass offers protection from soil erosion, provides habitat for wildlife, and offers ecosystem services including aesthetics promoting mental health and safe playing surfaces for children and athletes. Strategies used to maintain managed turfgrass often involve multiple applications of pesticides and fertilizer at rates that exceed application rates of cultivated farmland. Pesticides associated with the turfgrass industry have been detected in storm runoff and surface waters of urban watersheds; inferring contaminant contributions from residential, commercial, and recreational sources. Excess nutrients in surface waters result in enhanced algal blooms, promotion of eutrophication, and negative impacts on sensitive aquatic ecosystems. We evaluated the influence of turf variety and effectiveness of management practices to reduce runoff volume and quantity of pesticides and nutrients transported with runoff from turfgrass managed as a golf course fairway. The overall goal is to eliminate or minimize risk of adverse impacts to aquatic ecosystems receiving turfgrass runoff as well as improve efficacy of plant protection products at their site of application. Hydrographs and chemographs revealed both turfgrass variety and turf management practices influence runoff volume and off-site loads of applied chemicals. This information is useful to grounds superintendents when selecting best management practices and as data for watershed-scale modeling evaluating the effect of land management practices on surface water quality.

WP155 Nitrogen in Freshwater and Estuarine Ecosystems: Longitudinal Distribution, Source Characterization, and Bioavailability

J. Jani, Univ of Florida / Gulf Coast Research and Education Center; G.S. Toor, Univ of Florida / Soil Water Science Dept

Urbanization accelerates nitrogen (N) loss from land resulting in excess N in coastal waters, which leads to harmful algal blooms, hypoxia, and loss of essential habitat. Our objectives study were to (1) investigate longitudinal distribution of inorganic and organic N forms, (2) identify sources of nitrate (NO_3-N), and (2) determine dissolved organic nitrogen (DON) bioavailability in freshwater and estuarine ecosystems. Monthly water samples (December 2015–May 2016) were collected from 13 sites along a longitudinal gradient from freshwater (10 sites) to estuarine (3 sites) ecosystem. Samples were analyzed for various N forms [ammonium (NH_4), NO_3, DON, particulate organic nitrogen (PON)] and stable isotopes of N and O of NO_3. Bioassay experiments were conducted for 5 days to determine the bioavailability of DON. Mean concentrations of total N in freshwater sites were 0.5–1.2 mg/L and estuarine sites were 0.5–0.6 mg/L; these values were lower than EPA numeric criteria for freshwater (1.65 mg/L) and estuarine (1.125 mg/L) ecosystems.Organic N forms were dominant at all sampling sites (DON: 64%, PON: 22%) as compared to inorganic N forms (NO_3-N: 7%, NH_4-N: 7%). Stable isotope data showed that NO_3-N in urban waters originated from mixing of multiple sources and biotic processes (i.e. nitrification). The bioavailability of DON ranged from 13 to 65% across all sites, with highest bioavailability in the estuarine sites. We conclude that although the estuarine ecosystem had low inorganic N (< 15% TN), the higher bioavailability of DON will meet the N requirement of algae and bacteria, which may result in onset of algal blooms.

WP156 Sources and Transport of Nitrate-Nitrogen in Urban Residential Runoff

Y. Yang, Univ of Florida; G.S. Toor, Univ of Florida / Soil Water Science Dept

Urban development increases fluxes of water and pollutants in urban watersheds. We investigated the sources and transport of nitrate-nitrogen (NO_3-N) in urban residential stormwater runoff using N and oxygen stable isotope of nitrate ($\delta^{18}O-NO_3^-$ and $\delta^{15}N-NO_3^-$). Water isotopes ($\delta D-H_2O$ and $\delta_{18}O-H_2O$) measurements were used to determine the source of water in stormwater runoff. Stormwaer runoff were collected during 2014 wet season (June-Auguest) that received ~33% of ~130 cm annual rainfall from six medium- to high-density residential catchments located in Tampa Bay, Florida. Concentrations of NO_3-N in stormwater runoff varied from 0.07 to 0.29 mg/L, of which NO_3-N was < 40% and organic N was >60% across six residential catchments. Our results showed that atmospheric deposition (35-64%), followed by chemical N fertilizers (1-39%) were the dominant sources of NO_3-N in stormwater runoff. This study will discuss the source identified and importance of developing correct best management practices to reduce N export in urban water systems.

WP157 Longitudinal distribution of phosphorus fractions along an urban river

S. Asal, Univ of Florida IFAS / Gulf Coast Research and Education Center; G.S. Toor, Univ of Florida / Soil Water Science Dept

Phosphorus (P) is a limiting nutrient in freshwater ecosystems. Excess P in water bodies lead to eutrophication and can impact the economy. Our objective in this study was to determine the longitudinal distribution of various P forms in an urban river that drains to an estuary. Monthly water samples were collected along a longitudinal gradient (13 sampling sites) in three reaches of Braden River – upper, middle, and lower – and Manatee River in Florida from December 2015 to May 2016. Samples were separated into dissolved (≤0.45 µm) and particulate (≥0.45 µm) P forms using a phsicochemical fractionation method, which resulted in four P forms: dissolved reactive P (DRP), dissolved unreactive P (DUP), particulate reactive P (PRP), and particulate unreactive P (PUP). Among all P fractions, the most dominant P form at all sites over six months was DRP (mean: 99 ug/L; 46% of TP), followed by PRP (mean: 59 ug/L; 27% of TP), DUP (mean:39 ug/L; 19% of total P), and PRP (mean:15 ug/L; 8% of total P). However, the concentrations and proportions of P forms varied over time at different sampling sites. For example, the proportion of inorganic P forms were more variable (DRP: 25-57%; PRP: 5-59% of total P) as compared to organic P forms (DUP: 12-33%; PUP: 3-14% of total P). Total P concentrations at all sampling locations over six months did not exceed the US Environmental Protection Agency Numeric Nutrient Criteria thresholds (330−490 µg/L). Results suggest that understanding the sources of different P forms in water bodies is needed and will be a key to devising strategies to control P losses from land to water.

EDCs and Pharmaceuticals in the Environment

WP158 Quantification of Human Pharmaceutical Conjugates in Municipal Wastewaters

A. Brown, Univ of Manitoba / Chemistry; C.S. Wong, Univ of Winnipeg / Richardson College for the Environment

Recent data suggests there are non-trivial amounts of human pharmaceutical conjugates potentially entering environmental surface waters. These compounds could contribute to eliciting toxic effects either directly or indirectly (via de-conjugation) on aquatic biota. The need for developing a single method for quantifying both parents and conjugates is necessary. Propranolol (PRO), sulfamethoxazole (SMX), and their respective major conjugates 4-OH-propranolol sulfate (PRO-Sul) and sulfamethoxazole-β-glucuronide (SMX-Glc) were successfully simultaneously extracted through weak anion exchange solid phase extraction cartridges from primary and secondary clarification wastewaters from the North End

Winnipeg Water Pollution Treatment Plant in Winnipeg, Manitoba, Canada. Subsequent separation and quantification was achieved by reversed-phase C_{18} chromatography coupled to positive electrospray ionisation tandem mass spectrometry. Linearity was > 0.99, and recovery RSD ranges across all matrices for PRO, SMX, PRO-Sul, and SMX-Glc were 2.14-13.21%, 2.32- 10.18%, 9.79- 19.22%, and 2.01- 10.32% respectively. Primary and secondary filtrates respectively showed a significant increase of PRO from 0.039 to 0.045 µg/L (P= 0.0457); SMX showed a significant decrease from 1.56 to 0.58 µg/L (P< 0.0001); PRO-Sul showed a significant decrease of 0.050 to 0.020 µg/L (P= 0.0172); and SMX-Glc showed a significant decrease from 0.41 to 0.019 µg/L (P< 0.0001). To the best of our knowledge this is first study that simultaneously separated and quantified two different classes of parent compounds and two different kinds of human transformation product conjugates (glucuronide and sulfate) from a major urban wastewater treatment plant in Canada.

WP159 Pharmaceuticals and Personal Care Products in an Effluent-Dominated Stream: Seasonal Variability and Downstream Fate

B. Boswell, W.J. Doucette, Utah State Univ / Utah Water Research Laboratory

Wastewater treatment plants (WWTPs) are major sources of pharmaceuticals and personal care products (PPCPs) in the environment, particularly in effluent-dominated streams (EDSs). EDSs likely represent worst-case scenarios for exposure of PPCPs to aquatic organisms. Dilution often decreases concentrations of PPCPs in streams downstream from WWTP effluents but other attenuation mechanisms such as degradation, sorption to streambed sediments, and plant uptake may also be important for some PPCPs. However, data quantifying the impact of these mechanisms is generally lacking in most EDSs. Environmental conditions such as weather, temperature, precipitation and snowmelt can also impact seasonal PPCP concentrations in EDSs. The objective of this study was to investigate the attenuation and yearly concentration variability of PPCPs in the East Canyon Creek, an EDS in Park City, Utah. Not surprisingly, water samples collected from the East Canyon Creek show that PPCP concentrations below the East Canyon Water Reclamation Facility (ECWRF) discharge point are much higher than upstream concentrations. In addition, the variability of PPCP in the concentrations as a function of season, downstream location and physical-chemical properties of the PPCPs will be described.

WP160 The occurrence and fate of parabens and their metabolites in wastewater treatment plants in India

K. Rajendiran, Wadsworth Center, NY State Dept of Health; A. KV, K. Kannan, Wadsworth Center, New York State Dept of Health

Parabens (p-hydroxy benzoic acid esters) are antimicrobial agents, used widely as preservatives in personal care products (PCPs), pharmaceuticals, foods and beverages. Parabens are endocrine-disrupting chemicals (EDCs). The use of products that contain parabens results in continuous release of these EDCs into sewage treatment plants (STPs), which is a cause for concern. A few studies have demonstrated the occurrence of parabens in wastewater and indicated that conventional treatment plants are not adequate to remove parabens from water cycle. This is the first study to measure parabens in Indian wastewater and sewage samples. We focused on the occurrence and fate of six parabens, viz., MeP, EtP, PrP, BuP, HpP and BzP and their metabolites (4-HB, 3,4-DHB, OH-MeP, OH-EtP and BA) in influent, effluent and sludge samples collected from five sewage treatment plants and 6 raw sewage collected from sewerage channels in India. The sum of measured concentrations of parent parabens (∑parent parabens) were significantly lesser than the concentrations of their metabolites. The concentrations of parent parabens (∑parent paraben) in five STPs ranged between 16.8 and 222 ng/L in influent; 36 and 58.3 ng/L in effluent and 96.7 and 1090 ng/g, dry weight, in sludge samples. Similarly, the concentrations of paraben metabolites (∑paraben metabolites = 5) in five STPs ranged between 2650 and 32800 ng/L in influent; 1660 and 3690 ng/L in effluent and 1220-36000 ng/g, dry weight in sludge samples. We calculated the mass loadings, removal efficiency and the amount released into the environment based on the measured concentrations of parabens and their metabolites in influent, effluent and sludge samples.

WP161 Levels of PCBs and PBDEs in the liver of dolphins from the Brazilian southeastern coast

I. Moreira, R. Lavandier, Pontifical Catholic Univ of Rio de Janeiro / Chemistry; R.C. Montone, Instituto Oceanografico – Univ de Sao Paulo / Departamento e Oceanografia Fisica Quimica e Geologica; S. Siciliano, ENSPFIOCRUZ; N. Quinete, Medical Faculty, RWTH Aachen Univ / Inst for Occupational and Social Medicine; S. Taniguchi, Univ of São Paulo / Physical Oceanography Dept

Dolphins are very sensitive to environmental changes and have been considered a good bioindicator of contaminants. Persistent organic pollutants (POPs) are able to bioaccumulate in fat tissues and biomagnify through the food web. Some of them, like PCBs and PBDEs can act as endocrine disrupters (EDCs). Marine mammals are top predators and may accumulate high concentrations of organic pollutants through bioaccumulation and biomagnification processes. Despite the concern over the widespread distribution of PCBs and PBDEs few studies have reported their occurrence in South America. The objective of the present work was to determine the levels of PCBs and PBDEs in liver of two species of dolphins (Tursiops truncatus and Stenella frontalis) stranded and accidentally caught in the Brazilian southeastern coast in 2012. Only fresh carcasses were used in this study. About 1.0 g of sample was used in this work. The analytical procedure was performed based on an Ultra Turrax extraction followed by clean-up and chromatographic analysis (GC/MS). ? PCBs ranged from 3078 ng g^{-1} to 15306 ng g^{-1} (lipid wt.) in Tursiops truncatus and from 6091ng g^{-1} to 29138 (lipid wt.) in Stenella frontalis. ? PBDEs varied from 330.79 ng g^{-1} to 864.92 ng g^{-1} (lipid w) in Tursiops truncatus and from 397,20 to1685,81ng g^{-1} (lipid w) in Stenella frontalis. PCB 153, 138 and 180 were the major PCB congeners detected in both species. Furthermore, BDE 47 was the major PBDE congener found in both species. The contamination patterns suggest the previous use of Aroclor 1254, 1260 and Penta –BDE mixtures in Brazil. PCBs and PBDEs were never produced in Brazil. However, the concentration found in this study, are of great concern, suggesting the presence of a source contamination in the Brazilian southeastern coast and representing a risk to these cetacean species.

WP162 Human pharmaceuticals in fillet of fish species of interest for consumption in the Uruguay River

M.G. Rojo, Centro de Investigaciones del Medio Ambiente, Universidad Nacional de la Plata – CONICET / Centro de Investigaciones del Medio Ambiente CIMA; D. Alvarez-Muñoz, Catalan Inst for Water Research ICRA; A. Dománico, Subsecretaría de Pesca y Acuicultura de la Nación – Comisión de Investigaciones Científicas de la Provincia de Buenos Aires – Comisión Administradora del Río Uruguay; S. Rodriguez-Mozaz, Catalan Inst for Water Research ICRA / Water Quality; D. Barceló, Catalan Inst for Water Research ICRA – Dept of Environmental Chemistry, IDAEA-CSIC / Dept of Environmental Chemistry; P. Carriquiriborde, Centro de Investigaciones del Medio Ambiente, Universidad Nacional de la Plata – CONICET – Comisión Administradora del Río Uruguay / Centro de Investigaciones del Medio Ambiente CIMA

The Uruguay River, is an important South American river that flows from north to south along 1,838 km and form part of the boundary of Brazil, Argentina, and Uruguay. CARU is a binational Commission created to administrate the shared sector of the river between Argentina and Uruguay and, among other responsibilities, it is aimed to protect the fisheries and living resources. Several cities are located along this sector of the river that receive its wastewater, raw or poorly treated. Human pharmaceuticals are excreted by the urine and feces through the sewage drain, and are unable to be fully degraded by treatment plants. Then, concern has raised on the potential accumulation of these compound on fish species that are usually consumed. In the present study the concentration of 20 pharmaceuticals were measured by ASE-GPC-HPLC-MS/MS in the muscle of three emblematic fish species: Prochilodus lineatus (sábalo), Leporinus obtusidens (boga) and Salminus brasiliensis (dorado) caught in 10 localities under the CARU jurisdictional area. Only 9, 6 and 3 of the 20 compounds were detected at least once in boga, sabalo and dorado, respectively. Carbamazepine was ubiquitous, but always below quantification levels. Atenolol, clopidogrel and metoprolol followed it in occurrence frequency. Maximum total concentration of the studied pharmaceuticals was found in boga (20.9 µg/Kg) and significantly higher values were observed for boga and dorado collected from the sites located in lower sector of the river compared with the intermediate and upper sectors. The highest concentrations were observed for propranolol (6.44 µg/Kg) and atenolol (5.49 µg/Kg) in boga. Although not specific regulation exist for this family of compounds in Argentina, the observed concentrations were below the maximum residues limits (MRL) established for pharmaceuticals by the European Union in food stuffs from animal origin (Commission regulation (EU) No 37/2010). This was the first report on bioaccumulation of pharmaceuticals of fish in the Uruguay River, and despite values are low and they should not pose a risk for human health, its presence would deserve more detailed studies and consider them in the monitoring programs.

WP163 Patterns and instream attenuation of select contaminants of emerging concern: Predicted and observed therapeutic hazards to fish respond to snowmelt

S. Haddad, Baylor Univ / Environmental Science; W.C. Scott, Baylor Univ / Dept of Environmental Science; S.R. Burket, Baylor Univ / Environmental Science; S.C. James, Baylor Univ; G. Saari, Baylor Univ / Environmental Science; L.A. Kristofco, Baylor Univ / Dept of Environmental Science; K. Chambliss, Baylor Univ / Dept of Chemistry; M. Luers, Snyderville Basin Water Reclamation District; C. Rogers, Carollo Engineers; B.W. Brooks, Baylor Univ / Dept of Environmental Science

Pharmaceuticals and other contaminants of emerging concern (CECs) are increasingly reported in the peer-reviewed literature. However, instream attenuation and seasonal dynamics of such observations are rarely studied, particularly for semiarid streams with flows influenced by seasonal snowmelt and municipal effluent discharges. Herein, fish plasma modeling appears to provide a useful approach to identify concentrations of pharmaceuticals in surface water that may increase risk to fish when internal fish plasma levels approach human therapeutic (Cmax). We selected East Canyon Creek, located in Park City, Utah, USA, because it experiences yearly snowmelt and thus has higher flows in spring, which dilutes reclaimed wastewater discharge, but experiences lower and increasingly effluent-influenced flows during summer and fall months. The primary objective of the current study was to evaluate longitudinal gradients of select pharmaceuticals and other CECs in surface waters upstream and at incremental distances downstream (0.15, 1.44, and 13 miles) from an effluent discharge to East Canyon Creek. This gradient was then sampled during spring, summer and fall 2014 to determine whether contaminant levels were differentially attenuated and responded to seasonally variable instream flows. A secondary objective was to examine potential risks of pharmaceutical exposure to brown trout (Salmo trutta). Isotope dilution LC/MSMS was used for the quantitation of target analytes in surface water, effluent and fish plasma samples. Preliminary data for the attenuation rate of target analytes suggests that caffeine, benzolecgonine (cocaine metabolite), and carbamazepine have the lowest attenuation rates and are recalcitrant. Further preliminary data suggests that amitriptyline, methylphenidate, and diphenhydramine had the highest attenuation rates. Amitriptyline, fluoxetine and norfluoxetine were generally predicted from water concentrations within an order of magnitude of the observed internal dose levels in S. trutta. Several antidepressants were observed to accumulate in plasma of S. trutta above a previously proposed safety factor. Levels of amitriptyline were specifically observed within one order of magnitude of its corresponding human Cmax in fish plasma during lower flows associated with the fall sampling event. Unfortunately, the bioaccumulation dynamics or toxicological implications of such observations are not understood but warrant additional study.

WP165 Multiclass Endocrine Disrupting and Pharmaceutical Chemicals in Sediments and Surface Water near a Potomac River Wastewater Treatment Facility

T.B. Huff, Z. Kassahun, A. Godfrey, George Mason Univ / The Potomac Environmental Research and Education Center; G.D. Foster, George Mason Univ / Dept of Chemistry

As awareness of the multiple classes of endocrine disrupting (EDCs) and pharmaceutical chemicals found in the environment grows, wastewater treatment plant operators look to determine what impact if any that their effluent has on the aquatic ecosystems and drinking water sources in the vicinity. This begins with the determination of fate and transport data. Water, sediments, and suspended-sediment samples were collected from the Potomac River in Alexandria, Virginia as well as from Hunting Creek, a small tidal tributary into which treated municipal wastewater is discharged. Water and suspended sediment samples were collected in 20 L stainless steel kegs. The water was pressure filtered with 145 mm diameter 0.2 um clean glass-fiber filters held in a stainless steel filter stand using high-purity nitrogen. The filtrate water was aliquoted into 1 L amber glass bottles and was extracted using mixed-mode solid phase extraction cartridges for EDCs or with a combination strong-anion and strong-cation exchange SPE method for pharmaceutical compounds. Sediment samples were ground and desiccated with anhydrous sodium sulfate and solvent extracted by a microwave assisted reaction system (MARS). Suspended sediment containing glass fiber filters were extracted by MARS as well. Sediment and filter extracts were cleaned either by florisil columns for EDCs or by SPE following dilution in UHP water for pharmaceuticals. Samples were analyzed by GC-MS or by LC-MS for estrogens, corticosteroids, sunscreen agents, antibiotics, over-the-counter pharmaceuticals, antidepressants, and household products. Notable detected water concentration ranges (ng/L) were bisphenol A 33 – 1632, prednisone 335 – 1255, diclofenac 126 – 372, sulfamethoxazole 26 – 206, naproxen 82 – 101 and caffeine 35 – 70. Mean concentrations (ng/L) for Hunting Creek versus the Potomac River were higher with 575/205, 1469/208, 463/83, 300/11, for bisphenol A, prednisone, diclofenac, sulfamethoxazole, naproxen and caffeine respectively. The experimental K_{oc} partition coefficient values for sediments and suspended sediments generally gave mixed results when compared with their theoretical values.

WP166 Transport of Steroidal Hormones from Cattle Feedlot Pens via Simulated Rainfall Runoff

S. Sura, Agriculture and AgriFood Canada AAFC / Research; C. Sheedy, F.J. Larney, T.A. McAllister, Agriculture and AgriFood Canada AAFC

Growth promoters including steroidal hormones such as trenbolone acetate and melengestrol acetate are routinely administered to cattle in commercial feedlots to improve feed efficiency and promote growth. Trenbolone acetate (TBA) is a synthetic androgenic steroid used as an anabolic growth promoter administered via implants while melengestrol acetate (MGA) is a synthetic progestogen administered orally to heifers to improve feed conversion, promote growth, and suppress estrus. TBA, MGA and their metabolites are excreted by cattle in feces and urine. These contaminants could be introduced into the environment when the corresponding manure is applied as fertilizer to agricultural fields or through leaching or runoff from manure storage locations (feedlots, stockpiles, windrows, lagoons). These steroids and their metabolites have been detected in manure, feedlot runoff, catch basin water, and manure-amended soils. Runoff after major precipitation events appear to be major transport pathways by which these steroidal hormones from manure eventually contaminate surface water. A study is being conducted at the Agriculture and Agri-Food Canada Research Centre, Lethbridge, AB to investigate the transport in simulated rainfall runoff of TBA and MGA from feedlot pens. Cattle were administered the following steroidal hormone treatments according to Compendium of Veterinary Products: (1)

0.4 mg of MGA head^{-1} d^{-1} via feed, (2) 200 mg of TBA head^{-1} for every 84 d via implants, (3) no MGA or TBA (control). After manure accumulation in the pens, cattle were relocated and rainfall simulation experiments were conducted in situ using a portable Guelph Rainfall Simulator II. Composite manure samples were collected from the pen floor prior to rain simulations. Manure and runoff samples will be extracted and the extracts analyzed for MGA and TBA using LC/MS/MS analysis. The residue data will be used to determine the amount of each steroidal hormone that would potentially be transported to the catch basin adjacent to the feedlot in the event of a major rainfall.

WP167 Fate and Transport of Bisphenol A, F and S in Soil Irrigated with Wastewater

A. Mawof, S. Prasher, E. ElSayed, McGill Univ / Bioresource Engineering

There is a growing concern about the occurrence of bisphenols in the environment. They are widely used in the synthesis of polycarbonate plastics and epoxy resins. Therefore, they are commonly found in consumer goods and containers. Bisphenols have the ability to disrupt the endocrine system and cause harmful effects. The potential uptake and distribution of bisphenol A and bisphenol F in edible crops and their transport in soil needs to be closely examined. Therefore, the focus of this study is to (1) investigate the fate and transport of bisphenol A, F and S in potato tubers in soil irrigated with untreated wastewater; (2) Examine the effect of three amendments, plantain peel biochar, super absorbent polymer (SAP) and the combination of biochar and SAP, in reducing plant uptake and pollution. A four-month study in a field lysimeters, grown with potatoes, was conducted to investigate the abovementioned goals. Results showed that none of the tested bisphenols was found in the flesh of potato tubers after harvest. However, the concentration of bisphenols in topsoil increased over the growing season, indicating the cumulative effect in the soil. The biochar treatment indicated higher removal efficiency (45%) of bisphenols compared to other treatments.

WP168 Reproductive and general health assessment of fathead minnow populations inhabiting an effluent-dominated stream, Wascana Creek, SK, Canada

S. Hanson, Univ of Saskatchewan / Toxicology Centre; T. Bagatim, Univ of Saskatchewan / School of Environment and Sustainability; K.B. Steeves, Univ of Saskatchewan / Toxicology Centre; S. Wiseman, Univ of Lethbridge / Biology; N.S. Hogan, Univ of Saskatchewan / Toxicology Centre; A. Hontela, Univ of Lethbridge / Dept of Biological Sciences; P.D. Jones, Univ of Saskatchewan / School of Environment and Sustainability; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

The province of Saskatchewan is experiencing a dramatic increase in population growth, resulting in a greater release of municipal wastewater effluents (MWWEs) into local water bodies. There is concern regarding the impact of contaminants in this effluent, particularly endocrine disrupting compounds (EDCs), to resident wildlife as conventional wastewater treatment technologies are often incomplete or inefficient at removing such compounds. Waterbodies in the southern Canadian Prairies may be at particular risk of exposure to EDCs due to the uniqueness of prairie surface water systems. For example, during low flow periods, Wascana Creek, a small stream in southern Saskatchewan can consist of over 90% treated effluent originating from the City of Regina's outdated lagoon based treatment facility. The aim of this study was to characterize the potential endocrine disrupting effects of municipal waste-water effluents on wild fathead minnow (Pimephales promelas; FHM) populations in an effluent dominated stream, Wascana Creek, SK. Field studies were conducted on spawning FHMs (2014 and 2015) to assess responses in terms of overall health (condition factor, somatic indices), reproduction (secondary sexual characteristics, sex steroids in blood plasma, gonad histopathology, gene expression), and sex ratios. Fish collected downstream of the effluent fallout had lower gonadosomatic indices and significantly greater hepatosomatic indices compared to fish from upstream populations. There was significant disruption of regulation of key genes along the hypothalamus-pituitary-gonad-liver axis that are associated with reproductive processes. Additionally, in both male and female FHMs gonadal degradation and delayed maturation was observed histologically. Exposed males displayed lower scores of secondary sexual characteristics. This case study highlights the potential ecological risks of EDCs associated with MWWEs, and the need for implementing more effective and affordable measures to remove them at wastewater treatment plants.

WP169 Degradation Pattern of pharmaceutical and personal care products (PPCPs) mixture and its effect on Soil Microbial diversity

E. Osuji, Texas Tech Univ / Biological Science; D.L. Carr, Texas Tech Univ / Biological Sciences

Pharmaceutical and personal care products (PPCPs) associated with land farming of municipal wastewater effluent may potentially, persist in the soil and alter soil microbial community processes. Estrone (E1) and the anti-microbial agent, Triclosan, were examined for their potential to persist and disrupt soil microbial community function. Soil with 7 decades-long exposure to these chemicals (conditioned soil) and naive soil, which has not been previously exposed (unconditioned soil), was spiked with estrone, triclosan, or a 1:1 mixture of estrone: triclosan, and incubated for 90 days in the dark at 27°C. Control samples consisting of unspiked conditioned and unconditioned soil were included in the analysis. The community level physiological profile was examined using BIOLOG® EcoPlates™ for the ability of their microflora to utilize ecologically relevant carbon sources. There was a significant increase in substrate activity and substrate richness in all treatments. Principal component analysis (PCA) of the data showed the microbial community utilized different carbon substrates by day 90 whereas they had exhibited similar substrate utilization at day 0. Microbial degradation rates were compared over the 90 days incubation period using high performance liquid chromatography (HPLC). Estrone and Triclosan showed the same pattern of biological degradation in both conditioned and unconditioned soils. Half-lives were determined to range between 5.9-6.8 days for the estrone treatments and 24.1-26.9 days in the triclosan treatments. The rate of degradation of the estrone:triclosan mixture was the same as the individual compound.

WP171 Microsomal metabolism of trenbolone acetate metabolites: Transformation product formation and bioactivity

B. Michalsen, Univ of Iowa / Civil and Environmental Engineering; A. Kupsco, Univ of California-Riverside / Dept of Environmental Sciences; E. Uwimana, Univ of Iowa / Dept Occupational and Environmental Health; N. Pflug, Univ of Iowa / Chemistry; N. Evans, USEPA / RTB TAD NHEERL; E.P. Kolodziej, Univ of Washington Tacoma / Center for Urban Waters Interdisciplinary Arts and Sciences Civil and Environmental Engineering; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences; V.S. Wilson, USEPA / Reprodcutive Toxicology; H. Joachim-Lehmler, The Univ of Iowa / Occupational and Environmental Health; D.M. Cwiertny, Univ of Iowa / Dept of Civil and Environmental Engineering

Trenbolone acetate (TBA) is a synthetic growth promoter widely used in animal agriculture, and its metabolites are suspected endocrine disrupting compounds in agriculturally impacted receiving waters. However, beyond the three widely recognized TBA metabolites (17b-trenbolone, 17a-trenbolone and trendione), little is known about other metabolites formed in vivo and subsequently discharged into the environment, with some evidence suggesting these unknown metabolites may comprise a majority of the TBA mass administered to the animal. Here, we explored the metabolism of the three known TBA metabolites using rat liver microsome studies. All TBA metabolites are transformed into a complex mixture of monohydroxylated products. Based on transformation product characterization, the majority are more polar than the parent metabolites but maintain their characteristic trienone backbone. A minor degree of interconversion between known metabolites was also observed, as were higher order hydroxylated products with a greater extent of reaction. Notably, the distribution and yield of products were generally comparable across a series of variably induced rat liver microsomes, as well as during additional studies with human and bovine liver microsomes. Bioassays conducted with mixtures of these transformation products suggest that androgen receptor (AR) binding activity is diminished as a result of the microsomal treatment, suggesting that the transformation products are generally less potent than the parent TBA metabolites from which they were generated. Outcomes of this work are beneficial in attempting to more confidently assess the environmental occurrence and ecosystem risks associated with TBA use in animal agriculture.

WP172 Triclosan is a proton ionophore mitochondrial uncoupler super-resolution microscopy reveals disrupted mitochondrial ultrastructure

L. Weatherly, The Univ of Maine / Graduate School of Biomedical Sciences and Engineering Dept of Molecular and Biomedical Sciences; A. Nelson, The Univ of Maine / Dept of Physics and Astronomy; J. Shim, The Univ of Maine / Molecular and Biomedical Sciences; A. Riitano, H. Hashmi, The Univ of Maine / Dept of Molecular and Biomedical Sciences; R. Sher, The Univ of Maine / Graduate School of Biomedical Sciences and Engineering Dept of Molecular and Biomedical Sciences; S. Hess, The Univ of Maine / Graduate School of Biomedical Sciences and Engineering Dept of Physics and Astronomy; J.A. Gosse, The Univ of Maine

Triclosan (TCS) is an antimicrobial used so ubiquitously that seventy-five percent of the U.S. population is likely exposed to TCS via consumer goods and personal care products that contain concentrations up to 10mM TCS. TCS is readily absorbed into human skin and has been found in urine and in the plasma and milk from nursing mothers. Detectable levels of TCS have also been found in a wide range of aquatic and terrestrial wildlife. We found that non-cytotoxic, µM levels of TCS inhibit both adenosine triphosphate (ATP) and oxygen consumption rate (OCR), from rat (RBL-2H3) and human (HMC-1.2) mast cells, NIH-3T3 mouse fibroblasts, and primary human keratinocytes. Primary human keratinocytes yield the most pronounced decrease in ATP with an EC_{50} of 3.0-4.1 µM (95% CI). This effect is due to TCS's proton ionophore structure. The reduction in ATP with no change in plasma membrane integrity in multiple cell types, including primary human cells, indicates that TCS is a mitochondrial toxicant. Known mitochondrial uncouplers have been shown to disrupt mitochondrial morphology. We have successfully imaged mitochondrial ultrastructure using the super-resolution microscopy technique fluorescence photoactivation localization microscopy (FPALM) with the outer mitochondrial membrane marker dendra2-TOM20 and have shown that TCS changes mitochondrial morphology without causing apoptosis. TCS also decreases mitochondrial membrane potential. TCS increases reactive oxygen species (ROS) production in RBL-2H3 cells, in contrast to the effects of the known uncoupler CCCP, which decreases ROS production. These data show that TCS disrupts mitochondrial and cellular functioning in diverse cell types.

WP173 Triclosan is a mitochondrial uncoupler in live zebrafish

J. Shim, The Univ of Maine / Molecular and Biomedical Sciences; L.M. Weatherly, R.H. Luc, M. Dorman, Univ of Maine; A. Neilson, R. Ng, Agilent Technologies-Seahorse Bioscience; C.H. Kim, P.J. Millard, Univ of Maine; J.A. Gosse, The Univ of Maine

Triclosan (TCS) is a synthetic antimicrobial agent used in many consumer goods at millimolar concentrations. As a result of exposure, TCS has been detected widely in humans. We have recently discovered that TCS is a proton ionophore mitochondrial uncoupler in multiple types of living cells. Here we present novel data indicating that TCS is also a mitochondrial uncoupler in a living organism: 24 hour post fertilization zebrafish embryos. These experiments were conducted using a Seahorse Bioscience XF^e 96 Extracellular Flux Analyzer modified for bidirectional temperature control, using the XF96 spheroid plate to position and measure one zebrafish embryo per well. Using this method, following acute exposure to TCS, basal oxygen consumption rate (OCR) increases, without a decrease in survival or heart beat rate. TCS also decreases ATP-linked respiration and spare respiratory capacity and increases proton leak: all indicators of mitochondrial uncoupling. Our data indicate, for the first time, that TCS is a mitochondrial uncoupler in vivo, which should be taken into consideration when assessing the potential toxicity and/or pharmaceutical uses of TCS. To our knowledge, this is the first example of the Seahorse 96-well Extracellular Flux Analyzer being used to measure bioenergetic flux of a single embryo per well in a 96 well assay format. The method developed in this study provides a novel high-throughput tool to identify previously-unknown mitochondrial uncouplers in a living organism.

WP174 Interactions among diverse endocrine disrupting chemicals: Tetrabromobisphenol A modulates estradiol and bisphenol A concentrations in mice

T. Pollock, McMaster Univ / Psychology Neuroscience Behaviour; D. deCatanzaro, McMaster Univ / Psychology Neuroscience and Behaviour

Many toxicological studies examine the effects of a single chemical, whereas people are commonly exposed to multiple toxicants that may interact. Here we studied interactions of a flame retardant, tetrabromobisphenol A (TBBPA), with two other environmental chemicals: bisphenol A (BPA; the monomer of polycarbonate plastics) and triclosan (an antimicrobial agent). These chemicals are found in numerous consumer products and are absorbed into the body through the skin, lungs, and gastrointestinal tract. Whereas only BPA shows affinity for estrogen receptors, all three chemicals interact with key metabolic enzymes, including sulfotransferase and UDP-glucuronosyltransferase. We hypothesized that TBBPA may compete with estradiol and BPA for access to these enzymes, thereby elevating estradiol and BPA concentrations. We subcutaneously injected mice with TBBA, administered 50 ug/kg 14C-BPA in a dietary supplement, and subsequently measured levels of radioactivity in serum and tissues. A single injection of TBBPA magnified ^{14}C-BPA concentrations in serum and reproductive organs in a dose-dependent manner. Moreover, concurrent treatment with TBBPA and triclosan resulted in higher concentrations of ^{14}C-BPA than either chemical given alone. Administration of TBBPA also elevated urinary concentrations of endogenous estradiol in female mice. These data are consistent with a proposed adverse outcome pathway in which the molecular initiating event for TBBPA is the binding and inhibition of sulfotransferase. These data also provide convincing evidence of an in vivo interaction between environmental chemicals and steroid hormones. These findings demonstrate the importance of considering studies of multiple toxicants when determining regulatory exposure limits.

WP175 Characterization of the contribution of a major hospital in Central America to the load of pharmaceutical to urban wastewaters and receiving waters

A. Ledezma, Instituto Tecnologico de Costa Rica / Chemistry; C.S. Wong, Univ of Winnipeg / Richardson College for the Environment; F. Roa, Instituto Tecnologico de Costa Rica / Chemistry Departament; J.K. Challis, Univ of Manitoba / Chemistry; K. Luong, Univ of Winnipeg / Richardson College for the Environment

Many studies around the world have shown the presence of pharmaceuticals as emerging organic contaminants in surface waters and wastewaters. However, there is very limited knowledge about the occurrence and hence effects of these chemicals in the Central American tropical aquatic environment. In this study, passive sampling was used to determine time-weighted averages and fluxes of a suite of pharmaceuticals in the effluent of a major urban hospital in the metropolitan area of San Jose, Costa Rica. Concentrations and fluxes were also measured at the intake of San Jose's wastewater treatment plant, to ascertain the contribution of hospitals to the amount of drugs that could be attributed to releases from hospital compared to use by the urban population served by the treatment facility. Use and prescription records of the hospital were correlated with levels observed in hospital effluent, suggesting that these data could be used to predict the contribution of hospitals to pharmaceutical contamination in urban wastewaters. Key words: Pharmaceuticals, emerging contaminants, hospital, Costa Rica

WP176 The estrogen potency and reproductive impairment of equine estrogens on Japanese medaka (Oryzias latipes)

K. Arizono, Prefectural Univ of Kumamoto / Faculty of Env Symbiotic Science; H. Ishibashi, Ehime-Univ / Faculty of Agriculture; M. Uchida, Mizuki Biotec; N. Tominaga, Ariake National College of Technology / Dept of Chemical and Biological Engineering

The objective of this study was to investigate endocrine-disrupting potentials of equine estrogens (EQs) on Japanese medaka (Oryzias latipes). Our gene expression analysis with DNA microarray representing 6000 medaka genes revealed that 24-h exposure of 100 ng/L equilin (Eq) up-regulated the expression of 6 genes in male liver, and 24-h exposure of 100 ng/L equilenin (Eqn) also up-regulated the expression of 34 genes. The genes up-regulated by Eq included estrogen-responsive genes, such as vitellogenins (vtgs) and choriogenins (chgs), and among the up-regulated genes by Eqn exposure were cancer-related genes, such as mediator complex subunit 16 and RAS oncogene family members. We further investigated the gene expressions of vtgs, chgs, and estrogen receptor (ER) subtypes in male liver by qRT-PCR after exposing medaka to six different EQs (1-300 ng/L each) for 3 days. As a result, the estrogenic potentials of the chemicals were in the order of Eq > 17β-estradiol (17β-E_2) > Eqn > 17β-dihydroequilin > 17β-dihydroequilenin > 17α-dihydroequilin > 17α-dihydroequilenin, which showed the higher estrogenic potential of Eq than that of 17β-E_2. We were also interested in reproductive impairment in paired medaka that were exposed to 10, 100, and 1000 ng/L of Eq for 21 days, and an observation was noted that Eq (100 and 1000 ng/L) adversely affected the reproduction (fecundity and fertility) of adult medaka and hatchability in F1 generation fertilized eggs.

WP177 Effects of full-scale ozonation of treated effluent – Environmental impact in a receiving river

J. Fick, Umeå Univ / Dept of Chemistry; T. Brodin, Umeå Univ / Dept of Ecology and Environmental Science; J.D. Larsson, The Sahlgrenska Academy at the Univ of Gothe / Dept of Infectious Diseases Inst of Biomedicine; L. Norrgren, Swedish Univ of Agricultural Sciences / Biomedical Sciences and Veterinary Public Health; B. Björlenius, KTH Royal Inst of Technology

One class of new emerging contaminants that have received a lot of attention lately are the pharmaceuticals. Pharmaceuticals are a diverse group of chemicals used in large quantities and are, in contrast to most chemicals used in society, designed to cause a specific pharmacological effect in biological systems. Pharmaceuticals have been found in aquatic systems globally, due to a combination of worldwide usage and low removal efficiency in wastewater treatment plants (WWTPs), or a complete lack of WWTPs (1). In surface waters, concentrations of pharmaceuticals usually range from low $\mu g\ l^{-1}$ close to point sources to low $ng\ l^{-1}$, and are correlated to human population density in the drainage area, volume of the receiving water body and technologies used in WWTPs. One technique to increase the removal of pharmaceuticals in WWTPs is to add a tertiary treatment step based on the addition of ozone. Ozonation is a cost efficient way to degrade chemicals and several studies have shown that most pharmaceuticals are readily degraded in the presence of ozone (2). However, several oxidized degradation products are formed during ozonation and the environmental impact of these are largely unknown. The aim with this study was to evaluate the removal of pharmaceuticals in a WWTP, when adding ozonation as an additional tertiary treatment step and also to investigate the environmental impact of this effluent on the receiving river. All treated effluent from a minor WWTP (10000 PE) were treated by an addition of 8 mg h^{-1} ozone during 6 months. Removal rates in the WWTP as well as levels of pharmaceuticals in the receiving river (both in water and biota) were monitored. Ecological status was also determined before, during and after the time period when the ozonation treatment step was used. Several methods were used including invertebrate inventories, microbial community composition, etc. 1) Lindberg RH, Östman M, Olofsson U, Grabic R, Fick J. 2014. Occurrence and behaviour of 105 active pharmaceutical ingredients in sewage waters of a municipal sewer collection system. WP178 A meta-analysis of parabens in sewage sludge

J. Chen, Arizona State Univ / Biodesign Center for Environmental Security; R.U. Halden, Arizona State Univ / Center for Environmental Security

Parabens are a group of compounds extensively used as preservatives in pharmaceutical and personal care products (PPCPs), food, beverages, and industrial products. They also are considered to represent emerging endocrine disruptors and have raised concerns for human and animal health. Parabens are known to be toxic to aquatic organisms and also potentially may cause immune dysfunctions and adverse reproductive outcomes in humans. Widespread use of parabens can lead to steady-state levels in the environment, with wastewater treatment plants (WWTPs) and sludge disposal representing two important sources. Despite their biodegradability, parabens remain detectable at ng/L levels in treated plant effluent, and at ng/g dry weight levels in digested sewage sludge. Whereas parabens dissolved in WWTP process streams have been studied extensively, few studies have explored their occurrence and concentration in sewage sludge. Information on parabens in sludge is needed for risk assessments, since sewage sludge application on land represents a common disposal practice, potentially leading to contamination of soil, groundwater and surface waters. In this study, we reviewed literature data on parabens in sewage sludge, and estimated the estrogenicity contributed by parabens in sludge using as an indicator the Estrogenic Equivalent Quotient (EEQ). Parabens were found to be ubiquitous in sewage sludge, with methyl paraben and propyl paraben being the most frequently used and detected representatives of this chemical group. Overall, concentrations for parabens in sludge were moderate and varied between countries (n = 5) and sludge types. The overall theoretical estrogenicity burden contributed by parabens in sludge was less than 1 pg/g of 17β-estradiol equivalents or less than 0.1% of the burden posed by natural estrogens from food items present in sludge. This study indicates that the risk associated with synthetic parabens in sewage sludge is minor and essentially insignificant due to the comparatively low concentrations and estrogenicity. Future studies should include metabolites and derivatives of parabens, which also may act as potential endocrine disruptors and can occur in sewage sludge at concentrations higher than those of the parent compounds.

WP179 Oxidative stress-induced toxicity in Clarias gariepinus (Burchell, 1822) exposed to sub-lethal concentrations of pharmaceutical effluent

O.T. Aladesanmi, O.A. Eleyele, Obafemi Awolowo Univ / Inst of Ecology and Environmental studies

Contamination of aquatic environment with industrial effluent has become a matter of great concern because of its toxicity and persistence inducing alterations in the chemical composition of aquatic environment. This, in turn, alters the behaviour and biochemistry of the aquatic fauna among which is catfish, Clarias gariepinus. In this study, pharmaceutical effluent sourced from the discharge point of a pharmaceutical industry in Kwara State was analyzed to determine its physicochemical parameters, the sub-chronic toxicity and biochemistry of alterations in tissues and organs of post juvenile Clarias gariepinus. The impact of long term exposure to the effluent was evaluated through growth performance and selected anti-oxidant enzyme activities using 0, 2, 4, 6, 8 and 10 % concentrations of the effluent for 21 days, following a range finding test. Also, the physicochemical parameter of the culture water were determined. The results of the physicochemical analysis of the effluent showed that heavy metal concentrations were below the national (FEPA and NESREA) and international (USEPA) limits for aquaculture while other parameters like dissolved oxygen, alkalinity and total hardness deviated from the standard. C. gariepinus exposed to sub-lethal concentrations of effluent showed increased growth performance and nutrient utilization at the 10% effluent concentration. Biochemical studies carried out on the gill, fin, liver and muscle showed that activities of anti-oxidative stress enzymes, Superoxide Dismutase (SOD), Catalase (CAT), and Glutathione-STransferase (GST), were higher in the liver of the effluent exposed C. gariepinus when compared to other tissues. In this study, the effluent had pronounced effect on the growth and enzymatic activities of studied tissues and organs of C. gariepinus. Conclusively, this study revealed that the pharmaceutical effluent, although treated is still a potent contaminant to post juvenile C. gariepinus.

WP180 CECs in the Wastewater and Biosolids of Calgary, Alberta: Fate, Trends and Environmental Impacts

V. Cooper, The City of Calgary / Water Quality Services; N. Harckham, The City of Calgary

Municipalities are faced with an increasing number of questions from the public as to the presence and potential impacts of contaminants of concern (CECs) in wastewater effluent and biosolids. In order to develop an understanding of the occurrence, fate and potential impacts of CECs in Calgary's wastewater and biosolids, The City initiated monitoring programs in 2007 and 2011, respectively. The CECs investigated included: pharmaceuticals and personal care products, surfactants, hormones, plasticizers, perfluorinated compounds, synthetic musk fragrances, and flame retardants. Initial efforts were focussed on characterizing the final effluent and treated biosolids destined for land application, but the program was later expanded to include several other points in the treatment process. Calgary has 3 wastewater treatment plants (WWTPs), one with a distinctly different treatment process than the other two. Comparison of the influent and effluent concentrations between WWTPs suggests that the plants with biological nutrient removal were more effective at reducing certain CECs than the one with chemical nutrient removal. Separating the liquid and solid fractions of the sludge prior to analysis allowed for assessment of partitioning behaviour and for calculation of partition coefficients. Analyses of whole samples of digested sludges and lagoon-settled biosolids indicated that there is an overall increase in concentration for some CECs subsequent to lagoon-settling, particularly for the more hydrophobic contaminants. Although there are currently no regulations for CECs in wastewater or biosolids in Canada, guidelines are beginning to emerge at the federal and provincial levels for surface water for the protection of aquatic life. Concentrations of CECs in Calgary's downstream receiving waters will be compared to current guidelines to assess potential ecological effects.

WP181 Sucralose: a wastewater tracer or a water quality indicator?

H. Briceno, Florida International Univ / Southeast Environmental Research Center SERC; A. Serna, Florida International Univ / Southeast Environmental Research Center; A. Huba, Florida International Univ / Chemistry Biochemistry; P.R. Gardinali, Florida International Univ / Chemistry Biochemistry and SERC

Traditionally, water quality investigations are geared to measure the occurrence of common chemical contaminants such as nutrients, priority pollutants and or bacterial indicators that are linked to well known detrimental effects on the receiving water bodies. Eutrophication, is easily recognized since the increased introduction of nitrogen and phosphorous to a body of water results in a cascade of visible signs such as algal blooms followed by hypoxia that may result in lethal effects for fish or other organisms. The effects are well known but the sources of the contamination are not always easily identifiable. Nutrients have a number of potential sources such as agricultural runoff, storm water runoff, domestic wastewater disposal or even septic tanks. There is no easy way to fingerprint the provenance of inorganic nutrient species. Many chemical tracers that are unique to human consumption have been proposed in the past. Among them, caffeine and now sucralose have been proposed a "tracers" to follow the intrusion of human derived wastewater into aquatic ecosystems. Nevertheless, for a tracer to become an indicator a relationship to traditional water quality parameters must be identified so a potential link to common impacts such as eutrophication can be elucidated. Such relationship between caffeine and elevated human-derived pathogens has been previously established but the concentration at which the relationship is evident (>400 ng/L) is too high to have environmental relevance. Sucralose, on the other hand has been explored as a tracer but not as an indicator. The purpose of this work was to add routine measurements of sucralose to a comprehensive water quality monitoring effort in a system of canals in the Florida Keys that have been subject to a conversion from traditional septic systems to municipal sewage collection. Statistical analysis of time series of traditional water quality parameters and sucralose showed an upward change in the trends of nutrients and dissolved oxygen for concentrations of sucralose above 57 ng/L. Cluster analysis indicated that samples whit sucralose levels below the threshold did not show evidence of water quality issues while concentrations above 53 ng/L and above 150 ng/L grouped the sites influenced and affected by eutrophication respectively. This study presents the first application of sucralose as an effective human-derived wastewater "indicator" rather than just a tracer.

WP182 Assessing Poultry Litter Composting Techniques and their Impact on Estrogen and Pharmaceutical Concentrations

E.J. Mullin, S.C. Travis, Univ at Buffalo / Chemistry; L.T. Yonkos, Univ of Maryland / Environmental Science and Technology; D.S. Aga, State Univ of New York-Buffalo / Dept of Chemistry

Confined animal feeding operations (CAFOs) of poultry generate significant amounts of litter which is often used to fertilize farmlands. The raw (untreated) poultry litter is known to contain naturally excreted estrogens as well as pharmaceuticals that were given to the chickens. These compounds can contaminate surface waters through runoff. Poultry litter can be applied in the composted, pelletized, or raw form. Composting poultry litter is advantageous because it decreases noxious odors and toxins and lowers the rate of nitrogen mineralization, which lowers the potential risk of contaminating the groundwater with high nitrate levels. This process is carried out using forced aeration and mechanical turning techniques to accelerate the degradation process by controlling moisture, temperature, and oxygen levels. In order to determine if different composting methods are effective at reducing estrogen and pharmaceutical levels in poultry litter a variety of pilot-scale (two ton capacity) composters were utilized. The poultry litter was obtained during a whole-house cleanout of a conventional broiler operation. The poultry litter was divided into four treatment categories: aerated, turned, turned and aerated, and piled (not composted). At the end of composting, samples were collected and lyophilized. Pre and post composting samples were extracted using solid-liquid extraction, followed by concentration and further cleanup using solid phase extraction, before analysis by liquid chromatography tandem mass spectrometry. Analytes of interest included macrolides, sulfonamides, tetracyclines, and both natural and conjugated estrogens; however, no sulfonamides or tetracyclines were detected in the samples. Tylosin, erythromycin and clarithromycin (which are all veterinary macrolide antibiotics) were detected in addition to the estrogens. Of the compounds detected, tylosin had the highest removal after all composting techniques while the removal of the other macrolides and estrogens favored certain composting treatments over others.

WP183 Factors controlling antibiotics levels in biosolids

L.A. Rodenburg, Rutgers Univ / Dept of Environmental Sciences; N. Fahrenfeld, Rutgers Univ / Civil and Environmental Engineering; B. Blackburne, Rutgers Univ / Dept of Environmental Sciences

Removal rates of pharmaceuticals and personal care products during wastewater treatment are of great interest. The Targeted National Sewage Sludge Survey administered by the USEPA collected samples of biosolids from wastewater treatment plants (WWTP) across the US using a variety of treatment trains. Factor analysis was applied to antibiotic concentrations. Then comparisons of WWTP influent levels of antibiotics from a broad literature review were made to the antibiotics observed in biosolids. Treatment processes, biosolids class, and other key treatment factors were examined as possible explainers for the differences observed between WWTP influent levels from the literature and levels of antibiotics in biosolids. This data mining effort provides insight into the fate of antibiotics during wastewater treatment.

WP184 Exposure to municipal wastewater effluent influences fecundity and and hormone-signaling pathways in fathead minnows (Pimphales promelas)

K. Steeves, Univ of Saskatchewan; S. Hanson, Univ of Saskatchewan / Toxicology Centre; T. Bagatim, Univ of Saskatchewan / School of Environment and Sustainability; S. Wiseman, Univ of Lethbridge / Biology; P.D. Jones, Univ of Saskatchewan / School of Environment and Sustainability; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre; A. Hontela, Univ of Lethbridge / Dept of Biological Sciences; N.S. Hogan, Univ of Saskatchewan / Toxicology Centre

Municipal wastewater effluents (MWWEs) contain anthropogenic substances that can exhibit endocrine disrupting activity. In the Prairie provinces of Canada, increasing urban populations and industrial activities has meant greater water demand and therefore greater MWWE released into the aquatic environment. The objectives of this study were to (1) determine the biological effects of MWWEs on fathead minnow (Pimephales promelas) using the USEPA short-term fish reproductive bioassay assay and (2) compare responses to effluents collected from both the Regina and Saskatoon wastewater treatment systems. Fish were exposed for 21 days to 0 %, 10% and 50% effluent. Impacts on reproductive success (fecundity, fertility) as well as morphological, histopathological, and molecular/biochemical indicators were assessed in male and female fish. Exposure to Regina MWWE resulted in a significant decrease in fecundity compared to non-exposed minnows. Fecundity was increased in fathead minnow exposed to 50% Saskatoon effluent treatment when compared to the control. Fertilization rate remained consistent regardless of treatment. Histological examination revealed an increase in proportion of spermatogonia and testicular degeneration in male fathead minnow testes in 50% effluent concentrations compared to control minnows in both Regina and Saskatoon exposures. There was no change in female histopathological criteria with effluent exposure and to effects of either effluent on circulating sex steroid hormones (estradiol, 11-ketotestosterone) in male or female minnows. Transcriptional analysis was conducted for various genes involved in hormone signaling and steroidogenesis. There was no induction of vitellogenin in male or female fathead minnows exposed to Regina or Saskatoon MWWE suggesting a lack of estrogenicity. Induction was observed in select target genes but did not demonstrate a clear mechanism of endocrine disruption by either effluent source. This study determined functional reproductive impacts of short-term exposure to MWWE discharged into Saskatchewan aquatic systems but mechanism of action and causative agents remain to be identified.

WP185 Larval Zebrafish (Danio rerio) behavioral screen identifies altered spontaneous behavior with neuroactive pharmaceutical exposure

I. Huang, Stony Brook Univ / School of Marine and Atmospheric Science; H. Sirotkin, Stony Brook Univ / Neurobiology and Behavior; P. Clyde, B.J. Brownawell, A.E. McElroy, Stony Brook Univ / School of Marine and Atmospheric Sciences

Neuroactive pharmaceuticals (NP) are a diverse group of drugs designed to target the brain (e.g. antidepressants, anticonvulsants, antipsychotics, etc.) and are increasingly detected in the aquatic environment as human use of NPs increases. NPs have been detected in surface water and fish tissue samples around the world at concentrations ranging from ng to ug/L levels, thus the potential impact NPs have on aquatic ecosystems needs to be evaluated. Conserved structure of both the nervous systems and genomes of fish and mammals suggest that NP exposure is very likely to have behavioral effects on fish as well. Due to the rapid development and use of NPs, a sensitive high throughput procedure is necessary to characterize toxicological impacts of NP exposure. We've developed a behavioral screen using larval zebrafish (Danio rerio) that tests a wide variety of fish behaviors, ranging from spontaneous behaviors to simple cognitive processes. Preliminary work with the model antidepressant fluoxetine indicates decreased spontaneous locomotor behavior and startle response. Evaluation of many other NPs, including haloperidol, citalopram, lamotrigine, amitriptyline, primidone, bupropion, risperidone, paroxetine, sertraline, venlafaxine, oxazepam, carbamazepine and their metabolites, as well as waste water treatment effluent are currently underway. This protocol allows us to screen and compare a large number of compounds, mixtures, or environmental samples quickly, allowing us to rank their potency as modulators of early life stage fish behavior and inform more detailed work on modes of action.

WP186 The removal of endocrine disrupters using TiO2 immobilized on porous titanium sheets

M. Arlos, Univ of Waterloo / Biology; R. Liang, Univ of Waterloo; M. Hatat-Fraile, CIRAIG École Polytechnique de Montréal; L. Bragg, Univ of Waterloo / Dept of Biology; N. Zhou, Univ of Waterloo / Dept of Mechanical and Mechatronics Engineering; S. Andrews, Univ of Toronto; M.R. Servos, Univ of Waterloo / Dept of Biology

The insufficient removal of endocrine disrupters from wastewater discharged into nearby watercourses can pose risk to aquatic and human health. Most conventional treatment systems were not designed to remove these compounds and additional treatment options must be explored. The use of TiO_2 photocatalysis, a potentially low-cost advanced oxidation process, has recently been the subject of several water treatment studies. In order to increase its feasibility in water treatment applications, TiO_2 has been modified as nanomaterials or immobilized on a variety of supports such as porous alumina and polymeric membranes. In this study, immobilization was completed by thermo-chemically oxidizing the porous titanium supports, producing a self-assembly of TiO_2 on the surface. The efficiency of the immobilized TiO_2 (UV-LED irradiated) to degrade a mixture of five estrogenic compounds (17α-ethinylestradiol, 17β-estradiol estrone, estriol, and bisphenol A) at different pH conditions was assessed. The compound disappearance was determined using LC-MS/MS and a yeast-estrogen screen assay was employed to assess the ability of the synthesized material to remove the biological activity associated with these compounds. Removals were observed for all compounds except 17β-estradiol and lower pH conditions showed better removal. Although 17β-estradiol was found to be poorly degraded by the immobilized TiO_2, the total estrogenic activity decreased over time for all pH conditions. Since the rest of the compounds (17α-ethinylestradiol, estrone, estriol, and bisphenol A) expressed 60% of the biological activity, their simultaneous removal substantially reduced the total estrogenic activity even with the inefficient degradation observed for 17β-estradiol. Overall, the results show that the combination of UV-LEDs and the newly synthesized TiO_2 material is capable of significantly removing selected target estrogens and their associated biological activity.

Contaminated Sediment Remediation and Restoration: Assessing and Measuring Effectiveness

WP187 Challenges of Reliably Assessing Contaminant Exposure in Migratory Waterfowl at Contaminated Sites

J. Collins, B.J. Reese, AECOM; R.G. Stahl, E.I. DuPont de Nemours and Company / Corp Remediation

Mercury concentrations in mallard duck (Anas platyrhynchos) tissue are being monitored as part of the Long-term Monitoring (LTM) program for a mercury impacted riverine system in the Shenandoah Valley, Virginia. The primary objective of the monitoring program is to evaluate potential changes in human exposure to site-related mercury contamination through the consumption of mallard ducks harvested within the system in response to remediation. The project study area spans a contamination gradient over 160 river miles and includes aquatic habitats influenced by a diverse spectrum of land uses including, urban, agricultural and national forests. Reliably assessing mercury exposure at a given site to migratory waterfowl can be problematic due to a number of confounding factors including the life history, habitat preferences and migratory habits of the selected waterfowl species. Additionally, regional climate conditions and anthropogenic influences can affect the timing of the annual migration and duration a species spends at a given site. The presentation will focus on study design, a review of baseline and historical data and discuss the challenges associated with the interpretation of this data in a risk-based remedial decision making framework.

WP188 Multiple Lines of Evidence to Assess Remediation and Restoration in a Mercury Contaminated River

J. Collins, B.J. Reese, AECOM; R.G. Stahl, E.I. DuPont de Nemours and Company / Corp Remediation

Historical mercury (Hg) releases occurred at a textile manufacturing facility on the South River, Virginia. These releases resulted in increased Hg concentrations in biotic and abiotic media, which have not declined over the past thirty years, as originally expected. Introduction of legacy Hg impacted soils to the South River, through bank erosion is the highest source of Hg loading to the system. Interim remedial measures targeted at reducing this source within the first few river miles are anticipated to begin in 2016. However, owing to its size, linear nature and spatial variability of the site, the remedial strategy requires that the river system be divided into manageable segments, and that remediation occurs in an upstream-to downstream fashion over a period of several years. A monitoring program comprised of multiple lines of evidence is being instituted that aims to document a reduction in Hg concentrations in a range of endpoints at differing spatial and temporal scales, in recognition of the phased remedial approach. The Short-term Monitoring (STM) program is intended to evaluate changes in Hg concentrations as well as ecological habitat quality at a specific bank segment following remediation over a relatively short time period (i.e. 2-10 years). The Long-term Monitoring (LTM) program is intended to document reductions in methylmercury exposure and improvements in habitat conditions throughout the South River and South Fork Shenandoah River at larger spatial (~160 river miles) and temporal (>10 years) scales. Monitoring data will be evaluated in an adaptive management framework that will inform remedial decision making and future monitoring efforts. This presentation will cover specific details of the monitoring plans and focus on the benefit of collecting synergistic lines of evidence that may help explain potentially confounding results in monitoring datasets.

WP189 Assessing remediation of contaminated sediments using biological endpoints: toxicity, food web tissue contamination, biotic condition and DNA damage

J.M. Lazorchak, USEPA / Office of Research and Development; K. Fritz, USEPA; J. Meier, Retired NCOAA/USEPA; H. Haring, The McConnell Group; M. Mills, USEPA / National Risk Management Research Laboratory; P. Wernsing, USEPA Office of Research and Development; D. Walters, USGS / Fort Collins Science Center; J.M. Kraus, USGS; B.M. Armstrong, Michigan State Univ / Fisheries and Wildlife

The Ottawa River is a component of the Maumee, Ohio Area of Concern (AOC) as defined by Great Lakes Water Quality Agreement between the U.S. and Canada. A Great Lakes Legacy Act sediment remediation project took place in the lower 14.2 km of the river where urban and industrial activities impacted the beneficial resources of the river. Sediment was removed based on a surface weighted average concentration model where PCB and PAH levels exceeded targeted levels. Each year from 2009-2013 and again in 2015, various biological indicators were collected to assess the remedy effectiveness: fish from different trophic levels (largemouth bass, brown bullhead, white sucker, pumpkinseed, gizzard shad, bluntnose minnow, emerald shiner), macroinvertebrates (collected with multi-plate samplers) and tetragnathid spider tissue concentrations were analyzed; DNA damage was measured in brown bullhead blood; sediments were tested for toxicity using amphipod and midge 10-day survival/growth methods and macroinvertebrate biotic condition was assessed using Ohio's multimetric Lacustrine Index of Community Integrity (LICI). Sediment concentrations of PCBs immediately showed a significant decrease from pre-dredge levels. Tissue concentrations for most biological indicators increase the year following dredging and remained at pre-dredge concentrations until at least 3-years post-remediation. Gizzard shad and emerald shiner showed lower tissue concentrations 3-yrs post-dredge compared to pre-dredge across the entire project area. Five years post-dredge macroinvertebrate and spider PCB tissue concentrations were below pre-dredge levels. DNA damage in brown bullhead increased during dredging then declined in subsequent years. Sediment toxicity was reduced within 1-yr post-dredge for Hyalella azteca and 2-yrs post-dredge for Chironomus dilutus as measured by survival. No difference in the LICI was found based on samples collected before and after dredging from dredged and undredged reaches. The 5-year post-dredge fish tissue results will also be presented. The long-term tissue level targets are being met at least as quickly as the predicted 10-yr timeframe (by 2020) based on modeling performed during the project's design phase.

WP190 Estimating the Rate of Recovery in Hudson River PCB Levels: An Assessment of MNA Rates prior to the Start of Remediation

E.A. Garvey, S. Gbondo-Tugbawa, J. Atmadja, K.A. Takagi, R.B. Fidler, Louis Berger, Inc.; J.R. Wolfe, LimnoTech, Inc.; M.S. Greenberg, USEPA / Environmental Response Team; G.J. Klawinski, USEPA

The 2002 Record of Decision (ROD) for the Hudson River PCBs Site called for environmental dredging of approximately 2.65 million cubic yards of PCB-contaminated sediment that began in 2009. Therefore, the long remedial design (RD) period (2002-2008) provided the opportunity to collect annual data on PCB levels in water and fish for a long time interval, thus representing monitored natural attenuation prior to the start of dredging. These data provided a basis whereby the estimated rates of recovery incorporated in the ROD could be examined in light of the new data. In addition, a synoptic study of PCB levels in sediment was also conducted during the RD period. The analysis of these data provided important verification of the predicted rates of decline for PCB levels in fish and water. For the sediments, however, the new data challenged the accuracy of the original studies completed for the ROD. PCB levels at 3 different water column monitoring locations in the Upper Hudson were shown to decline at approximately 10 %/yr, consistent with what was anticipated by the ROD. For fish tissue, the data set was quite extensive, covering up to 9 species across 2 freshwater Upper Hudson and 4 tidally-influenced Lower Hudson stations. For the Upper Hudson and furthest upstream Lower Hudson stations, lipid-normalized fish tissue burdens declined at a rate of approximately 9 %/yr (8-year half-life), consistent with ROD expectations. These rates of decline were observed across species representing multiple trophic levels and environments, including young-of-the-year and adult specimens. For the 3 remaining Lower Hudson stations, rates of decline decreased with distance from the Upper Hudson, with fish body burdens at the farthest downstream Lower Hudson station exhibiting little decline with time. In a parallel manner, concentrations in the Lower Hudson fish also decline with distance downstream from the Upper Hudson. The decreasing rates of decline in the Lower Hudson suggest diminishing influence of Upper Hudson conditions on the Lower Hudson. While rates of decline for PCBs in both fish and water column data are internally consistent, the estimated rates of decline obtained by comparison of 3 synoptic sediment surveys were not. This presentation will compare the sediment, fish and water results and highlight the difficulties in using generic sediment sampling as a basis to track recovery of impacted sites through time.

WP191 Integrating Unmanned Systems into Remediation and Restoration Practices

P. Martin, NewFields

The emergence of new technology is placing powerful data acquisition tools within reach of scientists and engineers engaged in remediation and restoration activities. Three diverse case studies are presented that highlight the utility of small Unamanned Aircraft Systems (sUAS) and Unmanned Surface Vessels (USV) in rapidly and effectively measuring key parameters which may be used to evaluate project sites on a scale previously not attainable with one or two staff technicians. These examples include: (1) Recurrent aerial imagery, topography, and video to evaluate the success of mainstem and side-channel salmon habitat restoration; (2) Combined sUAS topography and USV bathymetry to evaluate the feasibility of restoration alternatives for legacy mine sites; and (3) USV cross-section elevation profiles to inform a hydraulic model of in-stream chemical biodegradation. The common thread among this diverse range of projects is that all data were collected and processed in-house by staff scientists or engineers engaged in the projects. Furthermore, if not for the reduced cost, ease of mobilization, and low response time of the unmanned systems, the datasets would not have been collected, and the sites would not have benefited from critical information. Several themes will be highlighted through discussion of the case examples: The versatility of unmanned platforms creates new options for monitoring complex sites with challenging or unsafe access. Combining traditionally separate data types through a common workflow (e.g. multi-parameter aerial and aquatic surveys) leads to a synoptic understanding of processes occurring at a site by introducing multiple lines of evidence to support observations. Commercially available turn-key systems help to simplify mission planning and data acquisition, allowing researchers to focus on the problem rather than the details of operating the equipment. Unmanned tools are easily integrated into existing data-management systems by utilizing standard software to process and manipulate sensor-specific or geospatial data.

WP192 Engineered plant for phytoremediation of environmental contaminant-the current state of affairs

R. Anyasi, Univ of South Africa / Environmental Sciences; H.I. ATAGANA, Univ of South Africa / Inst for Science and Technology Education; C.E. Okereke, Univ of South Africa / Environmental Sciences

Phytoremediation has been described as an efficient medium through which chemical hazards that can be identified by various classes of pollution could be removed from the soil; hence it suffers various limitations that has prevented the field application of the technique. Plants lack the metabolic enzymes required for full pollutant remediation and this often results in slowing the pace at which phytoremediation activity occur. Such inherent limitation of plants for complete remediation of xenobiotic compounds calls for the idea to genetically modify plants using bacteria or mammalian genes that take part in the degradation of chemical compounds that are found to be toxic. Various plants have been implicated in this new line of biotechnology. Whilst most of them defile the inherent limitations, others are affected by the challenges and therefore are unable to achieve the primary goal which is environmental pollution remediation. This study provides an in-depth analysis of various endophytic-transgenic phytoremediation studies on organic contaminated environment. It also highlighted the kind of plants employed in such application, the strength and weakneses of the plants as regards the contaminant in question as well as the measure of remediation that were used. The study proffers better alternative plants for phytoremediation of organic chemical contaminants based on the type of contaminant and the intending remediation protocol to be followed.

WP193 A Comparison of Passive Sampling and Bioaccumulation Measurements in the Evaluation of Bioavailable Concentrations of Pesticides Impacted Sediments

M.M. Grover, Geosyntec Consultants; C.L. Thomas, The Univ of Texas at Austin / Civil Architectural and Environmental Engineering; J. Arblaster, J.M. Conder, Geosyntec Consultants; J. Word, Ramboll Environ; V.S. Magar, Ramboll Environ / Ecology Sediment Management; D.D. Reible, Texas Tech Univ / Civil and Environmental Engineering; G.H. Rosen, SPAWAR Systems Center / Energy and Environmental Sustainability; V.J. Kirtay, SPAWARSYSCEN SAN DIEGO / Energy and Environmental Sustainability; B. Chadwick, SPAWAR Systems Center San Diego / Energy and Environmental Sciences

Bioavailability of contaminants in sediment is an important consideration in the determination of potential risk of adverse effects from exposure to benthic invertebrate. Numerous tools are used to assess bioavailability, including measurement of contaminants in tissue via bioaccumulation testing and sediment porewater with passive sampling. These tools and different methods of application vary in cost effectiveness, efficiency, and ability to incorporate field conditions. In this presentation, the performance a thin-layer habitat enhancement sand cap (target depth 6 inches) to reduce bioavailable concentrations of organochlorine pesticides (e.g., 4,4'-dichlorodiphenyldichloroethane [4,4'-DDD] and 4,4'-dichlorodiphenyldichloroethylene [4,4'-DDE]) in sediment was evaluated at Site 99 Quantico Embayment in the Quantico Marine Corps Base, Quantico, Virginia, USA. The thin-layer cap placement is expected to reduce concentrations of total DDX in sediment more rapidly than natural recovery processes alone. Prior to and following installation of the cap, monitoring at the site included three tools to assess bioavailability. Concentrations of pesticides in tissue were obtained via two-week deployment of in situ bioaccumulation testing with Sediment Ecotoxicity Assessment (SEA) Rings using two species, Lumbriculus variegatus (oligocheaete worm) and Corbicula fluminea (Asian clam). Secondly, a two-week deployment of in situ solid phase microextraction (SPME) passive sampling was used to measure porewater from 0 to 24 inches below the sediment-water interface. Lastly, ex situ SPME was also used to measure porewater at multiple depth intervals within and below the cap. Strong correlation was also observed between the in situ and ex situ passive sampling in concentrations of total DDX in surface sediment porewater ($R^2 = 0.88$). Also, strong correlation between concentrations of total DDX in wormtissueandsurface sediment porewater as measured byboth in situ and ex situ passive sampling approaches was observed ($R^2 = 0.82$ and 0.95, respectively). However, concentrations of total DDX in clamtissueandsurface sediment porewater as measured byboth in situ and ex situ passive sampling approaches was found to be poor ($R^2 = 0.28$ and 0.16, respectively), likely due to the filter feeding clam being exposed to overlying water rather than sediment porewater. Further evaluation between these bioavailability assessment tools as well as advantages and disadvantages will be presented.

WP194 Assessing Sediment Remedial Status in Three Lake Ontario Areas of Concern

K. Stevack, Univ of Guelph-SES / School of Environmental Sciences; P.K. Sibley, Univ of Guelph / School of Environmental Sciences; D.G. Poirier, Ontario Ministry of the Environment / Laboratory Services Branch

Contaminated sediment has been identified as one of the major impediments to the remediation of many Areas of Concern (AOCs) in the Great Lakes. Three such AOCs within the Lake Ontario watershed were investigated in this project: Metro Toronto Harbour region, Hamilton Harbour, and Lyons Creek (Niagara River). Each AOC presents a unique set of beneficial use impairments in relation to sources and type of sediment contamination, and each has a unique Remedial Action Plan geared toward beneficial use improvement and eventual delisting. In this study, a sediment quality tetrad (SQTet) was applied in a weight-of-evidence assessment to evaluate current sediment contamination for these AOCs and to compare the current state to historical contamination levels and impacts to determine if improvements have occurred. The SQTet included assessment of bulk sediment chemistry, toxicity testing, benthic community analysis, and bioaccumulation. Results to date based on chemistry and toxicity show continued concern surrounding PAHs in Toronto and Hamilton Harbour sediments, with at least one site elevated above the severe effect level for Provincial Sediment Quality Guidelines in Toronto, and all three exceeding in Hamilton. Hamilton Harbour sediments resulted in growth and reproductive impairments in chronic laboratory exposures, as well as elevated PCB tissue concentrations. Sediments from Humber Bay in the Toronto AOC resulted in growth and reproductive impairments, as well as high tissue levels of PFCs in laboratory bioaccumulation exposures. Lyons Creek sediments resulted in acute toxicity and elevated tissue concentrations of PCBs and metals. These data indicate that there has been limited improvement for the sites investigated, and that present delisting targets may need to be revisited.

WP195 Using tree swallows to assess remedy effectiveness at Great Lakes Areas of Concern (AOCs), 2010-2015

C.M. Custer, T.W. Custer, P.M. Dummer, USGS / Upper Midwest Environmental Sciences Center; D. Goldberg, J. Franson, USGS / National Wildlife Health Center

Tree swallows (Tachycineta bicolor) are being sampled across the Great Lakes basin as part of the Great Lakes Restoration Initiative (GLRI) to provide a system-wide assessment of current exposure to organic contaminants. At selected sites dredging has been done, is ongoing, or is planned. Tree swallows, because their diet is mainly the aerial stage of benthic aquatic insects, offer a unique opportunity to assess the effectiveness of sediment removal on contaminant uptake in biota. Remedy effectiveness is monitored before and after sediment removal. When swallows migrate away from nesting areas, they depurate accumulated contaminants. Thus, when they return in the Spring, they start with virtually a 'clean slate,' and changes in bioavailability of contaminants at the Area of Concern (AOC) can then be assessed by analysis of eggs and nestlings. Three metrics, contaminant concentrations in eggs, contaminant concentrations in nestling carcasses, and the rate of accumulation in nestling carcasses can be measured. At Lincoln Park, Milwaukee Estuary AOC, tree swallows were monitored for 3 years pre-dredge and for 2 years post-dredge. Approximately 119,000 cubic yards of sediment were removed during Phase 1 of the cleanup effort. For PCB egg concentrations, while there was not a significant change in exposure pre- (1.53 mg/g wet wt.) vs. post-dredging (1.02 mg/g wet wt.) there was a declining trend. PCBs in nestlings (1.33 mg/g wet wt. pre-dredging vs. 0.74 mg/g wet wt. post-dredging) and accumulation rate (2.30 mg/day pre-dredging vs. 1.12 mg/day post-dredging), however, were significantly lower after dredging. Trends in egg exposure were more variable than nestling exposure, which may have contributed to the non-significant response observed in eggs. Data from other sites will be presented with different dredging scenarios.

WP196 Long-Term Monitoring of Remedy Effectiveness for Study Area 7 in Upper Newark Bay

P. Leitman, M. Sorensen, Ramboll Environ US Corporation, Atlanta, GA; T. Ahneman, J. Sananes, M. Nielsen, Ramboll Environ US Corporation, Princeton, NJ; W. Hague, Honeywell; V.S. Magar, Ramboll Environ US Corporation, Chicago, IL

This presentation discusses the long-term monitoring program of remedy effectiveness for approximately 37 acres of capped sediment located on the eastern shore of the Hackensack River in Upper Newark Bay adjacent to a site known as Study Area 7 (SA-7). Chromium ore processing residue (COPR) was placed as fill material to create what is now SA-7. Following several phases of investigation, the U.S. District Court approved a Consent Order requiring the remediation of sediments within the Hackensack River. The specified sediment remedy included dredging a 0.5-acre area adjacent to the SA-7 bulkhead, capping of approximately 37 acres (divided into 30 cap areas), and monitored natural recovery of approximately 33 acres, as well as requirements for a long-term monitoring program (LTMP). The dredging and capping of sediments for all but three of the cap areas were completed between July 2012 and October 2013. The long-term monitoring program was initiated immediately following remedy implementation, and is now in its third year. The LTMP will span 15 to 25 years, with monitoring activities taking place in Years 1, 2, and 5 and in 5-year intervals after Year 5. The monitoring activities of the LTMP are based on the following objectives defined in a Consent Order: ensuring that the integrity of the caps is maintained; confirming that areas of MNR are not scoured out; and collecting data regarding the nature of the benthic community in remediated sediments. The monitoring completed in Years 1 and 2 of the LTMP included hydraulic and hydrodynamic evaluations, bathymetric surveys, cap integrity monitoring, pore water sampling, sediment profile imaging (SPI), and biological sampling. To date, the monitoring program has demonstrated that the remedy remains stable and shows an improvement in the benthic community relative to as-built conditions. Bathymetric survey results generally show a net deposition of sediment across both the sediment cap areas and the MNR areas. Cap inspections confirm that the armoring of the caps remains in-place with no evidence of erosion of cap materials. SPI survey and biological sampling results indicate development of an established and diverse benthic community in both the cap areas and MNR areas. In addition, the planned methods of verification have been successfully implemented such that no changes in procedures are necessary.

WP197 Recommendations for the Use and Development of Biota-Sediment Bioaccumulation Models for cPAHs

S. Replinger, Windward Environmental, LLC / Environmental Scientist; S. Katka, J. Toll, B. Church, L. Saban, Windward Environmental LLC

Paired sediment and tissue data are used at contaminated sediment sites to develop biota-sediment accumulation factors (BSAFs) and biota-sediment accumulation regressions (BSARs), which are models of statistical relationships between concentrations in sediment and tissue. These models can be a key factor influencing sediment remedial decisions at sites where sediment remediation goals back-calculated from tissue concentrations drive unacceptable risks to humans and the environment. This paper evaluates the current practice of developing BSARs and BSAFs (BSAR/Fs) for carcinogenic polyaromatic hydrocarbons (cPAHs) and, based on an independent evaluation of co-located data, makes recommendations for developing cPAH BSAR/Fs in the future. The development of BSAR/Fs for cPAHs is more challenging than for other organic chemicals because PAH metabolism and site-specific factors affect the bioavailability and bioaccumulation of PAHs. Available cPAH BSAR/Fs found in the literature and at sites nationwide are highly variable; the range in values indicates that sites are potentially using inconsistent methods and assumptions to develop a sediment-tissue relationship, and illustrates the need for a consistent, defensible methodology. Uncertainties associated with BSAR/Fs have major remediation cost implications. Because of this, pragmatism is needed when evaluating, and if necessary, mitigating cPAH risks to people who eat fish and shellfish. First and foremost, if a suitable relationship cannot be developed using site-specific data, BSAR/Fs should not be used. If a site-specific BSAR/Fs can be developed, then the uncertainty associated with the BSAR/Fs and the reliability of risk estimates or remedial action levels (RALs) calculated using the BSAR/Fs must be seriously evaluated to understand the level of certainty that is inherent in this analysis. As the level of uncertainty increases and remediation costs escalate, alternative methods discussed in this report should be used to set risk management objectives and implement risk management actions.

WP198 Risk Assessment and its Role in the Remedial Design Process

M. Pattanayek, B.R. DeShields, Integral Consulting Inc.

Risk assessment is a standard tool employed during the remedial investigation (RI) phase for a contaminated site. Conservative and generic assumptions are often used in risk assessments, and this is done to insure that risks are not underestimated and health protectiveness is achieved at a site. However, such assumptions may not be wholly appropriate for a given site, or for separate portions of a site. This is especially true in the case of "screening-level" risk assessments. Risk results are then carried forward into the feasibility study (FS) and in most cases never refined or reviewed for their applicability, especially as the site is "carved out" into remedial decision units. Remedial goals, remedial action levels, and remedial footprints are then estimated using these initial risk assessment assumptions. Furthermore, the RI/FS process is often a prolonged process requiring multiple years to complete. If site conditions change (e.g., an interim measure is implemented involving removal of contaminated source material), the original risk assessment assumptions may no longer be valid, meaning that less remediation might presently be required. For large and complicated contaminated sediment sites such as ports and large rivers, the RI/FS phase is likely to take up to a decade or more, so changes in site conditions are common and can be significant in terms of their impact on the final design of the remedy. Changes may occur in sediment and biota concentrations; land use, the numbers and types of human and ecological receptors present; and even in what is known about the toxic effects of certain chemicals. To manage the potential for change, flexibility should be written into the FS, proposed plan, and record-of-decision to allow for necessary updates in the risk assessment which may cause the need for changes in the pre-design and design phases. Salient examples from risk assessment case studies describing instances will be presented where such flexibility was necessary given greater site-specificity or changes in site conditions related to chemicals of concern; exposure conditions; site-specific and applicable receptors; bioaccumulation and new information on chemical toxicity.

WP199 Use of multivariate analyses of macroinvertebrate community data to inform monitoring and remediation efforts: Niagara River tributaries case study

R. Yeardley, USEPA / Land Remediation and Pollution Control Division; J.M. Lazorchak, USEPA / Office of Research and Development; M. Mills, USEPA / National Risk Management Research Laboratory; B. Duffy, New York State Dept of Environmental Conserv; W. Thoeny, The McConnell Group co USEPA Cincinnati; E. Johnson, K.L. Kimbrough, NOAA National Ocean Service / National Centers for Coastal Ocean Science / Center for Coastal Monitoring and Assessment

Multivariate analyses specifically designed for ecological community data, such as nonmetric multidimensional scaling (NMDS), are useful to show the degree of similarity between communities and to determine if abiotic factors correlate with differences in community structure. A multi-agency (USEPA, NOAA, NY State DEC, USGS, USACE) study of 7 tributaries to the Niagara River Area of Concern (AOC) is measuring levels of polychlorinated biphenyls (PCBs) and polyaromatic hydrocarbons (PAHs) in the sediments and macroinvertebrates while collecting macroinvertebrates for community analyses. Also, the study is collecting PCB and PAH concentrations from mussels and passive samplers as part of a weight of evidence approach. To inform remediation efforts, ranking sites in terms of community metrics (e.g., HBI, taxa richness, tolerance values) and levels of contaminants of concern has provided useful information. We use NMDS and multi-response permutation procedures (MRPP) as additional tools to explore the complex community data. For example, part of this study compared two different Hester-Dendy (HD) sampler designs. An NMDS analysis was performed on the species abundance data for two HD sampler designs, which were co-located (attached to the same mooring), except that the Design 1 HDs were attached near the sediment, and Design 2 HDs were suspended in the water column. NMDS graphs showed that the communities retrieved by the 2 designs were similar in many cases (grouped together in 2D and 3D space), but for a few sites they were far apart. When the data for the co-located pairs of samplers that did not group together on the NMDS graphs was examined in more detail, it was found that for these few sites Design 2 HDs had greatly reduced taxa richness. Also, chironomids, which are fairly ubiquitous, were not retrieved at all. The coefficient of variation for taxa richness for Design 1 was lower (22%) than Design 2 (34%), likely due to these few site samplings. As there was no pattern with regard to variables like site location or water depth, the cause is likely some type of more random disturbance related to Design 2 HDs' position in the water column. We also use multivariate community analyses to enhance the process of ranking multiple tributary sites in terms of their disturbance, and to investigate correlations between PAH & PCB contamination and macroinvertebrate community assemblages.

WP200 Field sampling and laboratory evaluation of reactive capping/in situ treatment of mercury contaminated solids using DGT devices

T. Vrtlar, D.D. Reible, Texas Tech Univ / Civil and Environmental Engineering; P. Bireta, Texas Tech Univ; M. Bejar, Texas Tech Univ / Civil Construction and Environmental Engineering; G. Bland, Texas Tech Univ; E. Hung, Texas Tech Univ / Civil Construction and Environmental Engineering; R. Landis, DuPont Corporation, Wilmington, DE; N.R. Grosso, E.I. DuPont de Nemours and Company; B. Rao, Texas Tech Univ / Deparment of Civil Environmental and Construction Engineering

A major challenge in remediating contaminated mercury sites is the fact that the inventory of bulk mercury in sediments often does not relate directly to exposure and risk in organisms of concern. Much of that mercury may be largely immobile and unavailable for methylation. An alternative to traditional bulk mercury measurements is the use of Diffusive Gradient in Thin-film (DGT) profilers that measure the mobile and most available forms of mercury in porewater. Measurements are based on the rate of diffusion of mercury species through a diffusive layer of known thickness onto a resin that acts as an effectively infinite sink. DGT profilers are able to provide depth specific measurements of mobile and potentially available mercury and can be used to assess methylation potential through simultaneous measurement of reducing conditions via voltammetry. In this paper, DGTs are used to assess exposure and transport mechanisms as well as the effectiveness of potential remedial options for mobile and available mercury at a contaminated sediment site in South River, VA. DGT samplers were deployed in river bed and bank sediments for field assessment and in laboratory mesocosms to evaluate potential remedial approaches. The field sampling efforts suggested that leaching of non-particle associated mercury from bank sediments during bank drainage after flooding events was a potentially important mercury source. Simultaneous measurements of methyl mercury and reducing conditions suggested that the mercury was primarily inorganic mercury. Under normal (i.e. non-draining) conditions, there was greater evidence of reduction and methylation but less direct exchange between bank waters and the river. The mesocosm efforts were designed to evaluate potential remedial approaches that would address this mercury release mechanism including the addition of layers of sorbents to more strongly retain the mercury. Biochar, activated carbon, and layers of natural sediment were all considered for these sorbing layers. A granular activated carbon layer was shown to be the most effective in the removal of total mercury and methylmercury from the sediment under the reactive cap.

WP201 Evaluating the toxicity of Pine River Sediments Downstream from the Velsicol Superfund Megasite, St. Louis, MI

G.E. Sutherland, Alma College / Environmental Studies; A.D. Harwood, Alma College; B. Hamilton, Alma College / Environmental Studies; M. Borrello, Alma College

Downstream of the Velsicol Superfund site has had historic contamination of numerous chemicals including DDT, PBB, and HBB among others. Remediation and sediment dredging near the site began in spring of 1999, and was completed in 2006. In 2011, the Michigan Department of Environmental Quality completed a Baseline Assessment Report Long Term Monitoring Plan for the Pine River. This report revealed that downstream from the Velsicol Superfund site, there were several locations with levels of DDT that were still greater than 50 parts per million. However, there has been limited assessment of the benthic community since this evaluation. The objective of this research was to determine if Pine River sediment downstream from the superfund site was still toxic to aquatic macroinvertebrates after decades of degradation and removal of the source via dredging. Three sites were selected downstream and an upstream reference site was used. At each site, macroinvertebrates surveys were conducted and sediments were collected for laboratory toxicity tests for mortality and sublethal effects using Hyalella azteca, Chironomus dilutus, and Hexagenia spp. This study indicated that the most severe impacts may be limited to areas within a few miles downstream. However, more research is needed to evaluate potential effects on ecosystem function and other riparian species.

Fate and Effects of Chemicals from Diffuse Sources and Stormwater – Poster Only

WP202 Developing Low-Cost Stormwater Sampling Equipment Using Programmable Microcontrollers

R.E. Casey, Towson Univ / Chemistry

Stormwater issues are gaining regional, national and international prominence as regulatory agencies, water utility practitioners and academic researchers grapple with the quantity and quality of stormwater in developed landscapes. There is a need for better understanding of stormwater chemistry and the contributions of these dynamic events to pollutant transport, impacts on biota and regulatory compliance. At present, efforts to gather stormwater data involve a compromise between personnel costs, equipment costs and sample analysis costs. Typically, this compromise leans heavily toward personnel and equipment costs, limiting the amount of actual data collected. This project seeks to shift the balance toward data acquisition, enabling more comprehensive stormwater sampling campaigns that can address the chronic shortage of reliable stormwater data and promote a more data-rich context for stormwater decision-making. Low-cost programmable microcontrollers can be utilized to create stormwater sampling equipment that can automate sampling campaigns at a fraction of the cost of commercial equipment. These platforms can also allow for project-specific customization of sampling functions that is not possible with commercial equipment. This effort utilized the open-source Arduino programmable microcontroller to generate a composite stormwater sampler capable of flow-weighted composite sampling when coupled with an impeller-based flow gauge or with a tipping bucket flow gauge. The system incorporates a data logger to record flow and sampling events at customizable intervals for each data type. Comparable commercial equipment can cost US$900 – US$2000 per sampling location but this system was built for US$115 and could be reproduced for US$70 per sampling location, while meeting or exceeding the performance requirements for use in research. Low-cost automated stormwater sampling can decrease personnel costs, decrease risks to personnel during storm conditions (lightning, high water conditions) and increase sampling frequency and spatial resolution. Low-cost equipment can also open stormwater sampling to citizen-science groups including watershed organizations and schools. The utilization of open-source components and the ability to easily disseminate and edit the code mean that this prototype can be readily reproduced, optimized and adapted to the needs of specific sampling projects.

WP203 Combined effects of water hardness and stormwater contaminant toxicity to Daphnia magna

K. Hauser, D.R. Ownby, R.E. Casey, Towson Univ / Chemistry

Regulatory concerns have been expressed regarding diffuse and non-point sources of copper (Cu) released by Cu roofs. Copper roofing materials can contribute much higher mass loads of dissolved copper per unit area than other surfaces such as parking lots and roadways. Bioretention structures such as planter boxes, swales and rain gardens are being increasingly utilized in built landscapes as a strategy to attenuate both storm water flows and contaminant loads. In previous studies, storm samples were collected before and after treatment through bioretention structures and tested for toxicity with Daphnia magna. Daphnia magna live naturally in hard and moderately hard waters. Storm samples are typically of very low water hardness, so in order to remove the low ion stress during testing, Daphnia were acclimated in intermediate hardness water (62 mg/L $CaCO_3$). Acclimated Daphnia survived 48 h acute testing, whereas Daphnia raised in moderately hard water (83 mg/L $CaCO_3$) died when exposed to control stormwater. We have conducted further studies of intermediate water acclimated Daphnia related to stormwater testing conditions. Intermediate water cultured Daphnia as well as hard (165 mg/L $CaCO_3$) water cultured Daphnia were tested for reproductive success in a chronic 21-day experiment. Daphnia were exposed in a 2x2 design where < 48 h old F1 generation neonates (n=10) from parents raised in intermediate water were placed individually in 40 mL of intermediate or hard water, and < 48 h old F1 generation neonates from parents (P1 generation) raised in hard water were also evaluated for reproductive success. Feeding and water renewal occurred 3 times weekly, and reproduction data was collected daily for 21 days. Results showed the highest offspring production for the P1 Hard x F1 Hard combination, followed by P1 Intermediate x F1 hard, then P1 Hard x F1 Intermediate, and lastly P1 Intermediate x F1 intermediate combination. In addition to lower offspring production, Daphnia tested in intermediate water showed longer time to first brood. With this information, further testing will be conducted to evaluate the stress of low hardness waters on Daphnia reproduction and response to chemical stressors. Additional chemical stressors will be evaluated in acute and chronic tests to further understand the relative sensitivity of Daphnia raised in lower ionic conditions.

WP204 Sodium, Calcium and Chloride Removal Efficiencies of Self-Converted Dry Detention Ponds in Baltimore County, MD

R.A. Owen, C. Hill, M. Pieper, KCI Technologies, Inc.; R.E. Casey, D.R. Ownby, Towson Univ / Chemistry

Road de-icing materials, such as road salt (NaCl and $CaCl_2$) and brine, have become common practices for pre and post winter storm application in Maryland. High salinity runoff goes either directly into streams or into stormwater ponds. Stormwater ponds are a common best management practice (BMP) for the management of runoff from impervious surfaces in suburban and urban landscapes. These ponds range from constructed depressions designed to detain and slow stormwater runoff to allow some sedimentation to occur or can be deeper more engineered structures that hold water year round. Stormwater BMPs have shown to be beneficial for nutrient removal, but what about for de-icing materials in the winter. In this study, ponds designed to have short hydro-periods, and therefore be dry most of the time, were evaluated for their Na, Ca and Cl removal efficiencies. Over time, these ponds can convert from “dry” ponds to ponds that have wetland characteristics (soils, plants) and may also hold water for longer periods of time. This study collected data from six ponds (three control and three self-converted), between August 2014 and October 2015. Continuous water level sensors were installed for continuous flow records at each inlet and outlet and during selected rainfall events, grab samples were collected at inlet(s) and outfalls during the rise, at the peak, and during the falling limb of the hydrograph. Grab samples were analyzed for Na, Ca and Cl. Ion loading and removal efficiencies are based on flow-weighted event mean concentrations. With an increase in impervious surfaces in Maryland and the need to use more de-icing material during winter storms, freshwater streams and groundwater are increasing in salinity causing stress to organisms and everlasting effects on the ecosystem. This study showed that in all six ponds, there was an increase in loadings and concentrations leaving the pond. The analysis suggests that stormwater BMPs may be concentrating Na, Ca and Cl inside the ponds and releasing high concentrated water in pulses. Changes will need to be made with how urban and suburban stormwater is treated if we want to keep our freshwater systems fresh.

WP205 Preliminary Evaluation of Alternative Toxicity Testing Methods for Episodic Discharges Including Stormwater

G.H. Rosen, SPAWAR Systems Center / Energy and Environmental Sustainability; M. Colvin, SPAWAR Systems Center Pacific; C.N. Katz, Space & Naval Warfare Systems; C. Stransky, AMEC Foster Wheeler; N. Hayman, J. Munson-Decker, San Diego State Univ

Whole Effluent Toxicity (WET) tests for the monitoring of continuous point source discharges are highly standardized and typically include static exposure of an undiluted end-of-pipe sample over a period 4-7 days, depending on the toxicity endpoint. These standard WET test protocols overestimate the exposure conditions of non-continuous discharges such as episodic storm water runoff events, periodic short-term applications of pesticides, short term spills, or other ephemeral or time-varying pulses of contaminants. This suggests that these tests potentially overestimate the toxic effect of these types of discharges. We investigated an approach to modifying WET testing procedures to account for the time-varying aspect of the exposure condition. We believe that these procedures have the potential to improve the ecological relevance of the testing outcomes, particularly as they are applied to compliance monitoring. We conducted side-by side acute and chronic toxicity tests using both a standard 96-hr static test exposure protocol and a modified pulsed exposure condition. Chronic toxicity tests were conducted by exposing purple sea urchin (Strongylocentrotus purpuratus) embryos and mysid shrimp (Americamysis bahia) to laboratory seawater spiked with copper and/or zinc at varying concentrations. The pulsed tests used exposures of 3, 6, or 12-hrs followed by transfer to clean seawater for the remainder of the 96-hr test. The laboratory testing procedures were designed to simulate common contaminants and discharge durations found in San Diego storm water runoff. Additionally, these testing protocols were evaluated on multiple samples of storm water runoff collected during a single rain event in San Diego. Initial results indicate that pulsed exposures resulted in EC50 or LC50 values up to two orders of magnitude greater (i.e. less sensitive) than the standard 96-hr exposure conditions in both laboratory spiked samples and storm water runoff samples. The results suggest that short term pulses of copper and zinc have a lower toxic effect than is represented by standard continuous exposure testing. The presentation will summarize results to date, future research plans, and implications to compliance monitoring under National Pollution Discharge Elimination System (NPDES) permits.

The Other Oil Spills

WP206 Extreme temperature and oil contamination shape the relative abundance of copepod species in the Arctic

K. Dinh, DTU (Technical Univ of Denmark) / Section for Marine Ecology and Oceanography, DTU Aqua; T. Nielsen, DTU Aqua / Technical Univ of Denmark

The retreat of sea ice in the Arctic under global warming is predicted to intensify oil exploitation and shipping activities in this region, posing the risk of oil contamination. Knowledge on how Arctic secondary producers deal with the combined effects of global warming, particularly the extreme temperature and oil exposure is limited. To address this, we exposed females of two copepods species Calanus glacialis and C. finmarchicus to pyrene at three temperatures: 2, 6 and 10°C. Both species co-exist in the Disko Bay, Greenland, but only C. glacialis is a true Arctic species while C. finmarchicus is of north Atlantic origin. Pyrene is one of the most toxic components of crude oil to marine copepods. The temperatures of 2, 6 and 10°C represent the mean sea water temperature, the 4°C increase in mean temperature by 2100 as predicted by IPCC scenario RCP8.5 (2013) and the extreme sea water temperature, respectively, in Disko Bay. Four-degree increase in mean temperature did not have an effect on grazing rate and survival of both species. However, the extreme temperature (10°C) increased the grazing rate and mortality of C. glacialis, but not in C. finmarchicus. Exposure to high pyrene (250 nM) strongly reduced survival and grazing rate in both species and this pattern was independent of temperatures. Notably, exposure to high pyrene (250 nM) resulted in 72% of mortality in C. finmarchicus that was two times higher than the mortality observed for C. glacialis. These results suggest that extreme temperature under global warming and oil contamination may drastically change the relative abundance of pelagic copepod community by changing the species-specific vulnerability to the extreme temperature and oil exposure.

WP207 Evaluation of sublethal effects of the soluble fraction of Mexican light oil and gasoline on the oyster Crassostrea virginica

C. Bastidas Bonilla, G. Barrera Escorcia, P. Ramirez Romero, Universidad Autonoma Metropolitana Iztapalapa / Hydrobiology

Due to the energy reform, Mexico is increasing its efforts to obtain oil from deep water deposits, this increases the probability of having accidental oil and other fuels spills in the Gulf of Mexico, which represents a risk to important fisheries resources like oysters. The response of these organisms to oil and other fuels has not been studied in local populations of Crassostrea virginica, so the aim of this study was to investigate the effects of the soluble hydrocarbon fraction in oysters extracted in local lagoons, using biomarkers at different levels of organization. C. virginica has been used as a bioindicator organism in several studies due its ability to bioaccumulate contaminants and reflect their effects. The water-soluble fraction of Mexican gasoline Magna and light Mexican oil were obtained after shaking a 4:1 solution of fuel:water for 24 h. The bioassay included a seven days exposure period and a seven days recuperation period to assess toxicity and recuperation. A group of biomarkers were evaluated during the exposure and recovery phases: acetylcholinesterase (AChE) activity was evaluated using Ellman´s colorimetric method, while lysosomal membrane stability (LMS) was evaluated by the retention time of neutral red. In the exposure phase, significant differences were observed in LMS and AChE, associated to concentration and time. The exposure to gasoline indicated a partial recovery, however exposure to light oil showed damage without recovery. C. virginica is recommended for the monitoring of pollutants in the coast of the Gulf of Mexico due its ability to reflect the sublethal effects of these pollutants. AChE and LMS can be used as biomarkers of response in aquatic organisms in short-term exposures to hydrocarbons.

WP208 Identifying toxic components in Iranian Heavy crude oil on zebrafish (Danio rerio) embryos by sequential fractionation

J. Lee, Seoul National Univ; H. Shin, Seoul National Univ, Graduate School of Public Health / Dept of Environmental Health Sciences; I. Lee, Seoul National Univ / School of Public Health; D. Jung, Seoul National School / Inst of Health and Environment; S. Hong, J. Khim, Seoul National Univ / School of Earth and Environmental Sciences; U. Yim, Korea Inst of Ocean Science and Technology / Oil and POPs Research Group; K. Choi, Seoul National Univ / School of Public Health

Crude oil is a complex mixture composed mainly of aromatic and alkylated hydrocarbons. Identification of key components that exert biological effects in crude oil is important. We employed effect-driven analyses to identify the key components in crude oil that exert adverse effects such as malformation of fish. A series of fractionation techniques were used to separate Iranian Heavy crude oil; 33 fractions by true boiling point, further 3 subfractions by silica gel column, and (into further 3 subfractions), and even further 10 secondary subfractions by HPLC. Developmental outcomes (mortality, hatchability, and time to hatch) and malformation (yolk sac and heart edema) were observed in zebrafish (Danio rerio) embryos following 120 h exposure to each distilled fraction. Only four fractions, containing mostly high molecular weight compounds, showed toxicological effects. Following further fractionation by polarity using silica gel column, aromatic and polar/resin compounds, that include mostly alkylated dibenzothiophenes and phenanthrenes, induced significant malformation (heart edema). When these subfractions were further separated by HPLC according to their logKow values, malformation incidences generally decreased. This observation indicates that malformation in fish was caused not by small group of chemicals but by interactions of multiple constituents of oil. The subfractions that showed increased malformation in fish, as well as their secondary subfractions showed higher arylhydrocarbon receptor (AhR)-mediated potencies in H4IIE-luc AhR binding affinity assay. Overall, our results indicate that components of crude oil that include alkylated dibenzothiophenes and phenanthrenes may interact with one another to exhibit toxicity on teleost development, perhaps via AhR-independent pathway. This work was supported by Korean Ministry of Oceans and Fisheries Project PM56951.

WP209 Air Exposures Following Oil Spills – An Overview

A.B. Rosenstein, Environmental Risk Expertise; D.P. French-McCay, RPS ASA; J.J. Rowe, RPS/Applied Science Associates

Oil, when spilled in the oceans, emits volatile and semi-volatile compounds at the ocean surface which dissipate quickly. Organic aerosols are also emitted, and can transform into secondary organic aerosols in the air. These particles have the potential to be transported over longer distances. Air exposures for workers, for shoreline communities, and for wildlife may occur, depending on the size of the spill, the locations of off-shore workers at the time of the spill, the distance of the spill from shore, meteorological conditions, and oil type. Air concentration data were collected by a variety of groups following the Deepwater Horizon oil spill, but were neither easily accessible nor were collated in one database. In addition, the various groups collected air data using different sample collection methods, and different laboratories and analytical methods. Importantly, air concentrations at heights above the water and locations that would be relevant for health risk assessment, for example, for marine mammals and for workers, were not consistently measured. Clearly, the air concentrations to which humans and wildlife may be exposed following both larger and smaller oil spills is not well-quantified. We outline the modeling processes that would be necessary to accurately estimate air exposures for risk assessment. As examples, we present air fluxes from small, medium, and large oil spills, and discuss how these fluxes can be used to estimate exposures for workers, both off-shore and on-shore, and for coastal communities.

Experimental and Modeling Approaches to Account for Real-World Complexity in Environmental Toxicology

WP210 A Commercial Agricultural Product, Borregro HA-1, Decreases Bioavailable Copper to Daphnia ambigua and Ceriodaphnia dubia

S.M. Harmon, Univ of South Carolina Aiken / Biology and Geology; J.D. King, Univ of South Carolina Aiken; M.R. Millings, B.B. Looney, Savannah River national Laboratory

In an aquatic system, Dissolved Organic Matter (DOM) provides macromolecules which strongly attract cations such as copper, lead, zinc, and mercury. It is possible, therefore, to take advantage of DOM for natural remediation of metals pollution, as the DOM will bind with metal cations and reduce their bioavailability for uptake by aquatic organisms. Here, we describe the effectiveness of a commercially-available agricultural humate product, Borregro HA-1, for the reduction of copper toxicity in a simulated point-source discharge. These experiments were conducted to support the operation of an engineered delivery system that uses real-time flow rate and pH data to deliver the Borregro HA-1 directly into the wastestream. The system's control equation is based on the Biotic Ligand Model (BLM) for copper. Effectiveness of the Borregro HA-1 was tested through a series of acute and chronic bioassays using the indicator organisms Daphnia ambigua and Ceriodaphnia dubia. Borregro HA-1 was added to simulated outfall water with very low hardness (< 15 mg/L as $CaCO_3$) and a pH of 7.05. Borregro HA-1 was added to water the to achieve a final dissolved carbon concentration of 2.62 mg C/L, the in-stream carbon concentration calculated using engineered system's control equation when run at this pH. The 48-hour LC_{50} values for the copper plus Borregro HA-1 tests were 35.6 and 22.5 µg Cu/L for C. dubia and D. ambigua, respectively. In the tests with copper only (no Borregro HA-1 addition), the LC_{50} values were lower than the lowest test concentration (3.12 µg Cu/L) and could not be calculated. Acute results, therefore, indicated that the addition of the product to the simulated wastewater effectively diminished the toxicity of copper. Chronic toxicity tests included concentrations that would reflect the Final Acute Value (FAV; 82 µg Cu/L), the Chronic Maximum Concentration (CMC; 41 µg Cu/L), and the Criterion Continuous Concentration (CCC; 25 µg Cu/L) as determined by the BLM. Chronic toxicity test results indicated that, at a minimum, the simulated outfall water with Borregro HA-1 responds as expected to added toxicants such as copper. This could not be said for the simulated outfall water without the Borregro HA-1, where copper is much more toxic without the additional DOC in the test medium.

WP211 A Risk Assessment Strategy for a Former Shooting Range in a Dynamic Estuary

S. Thakali, B.J. Reese, AECOM; C. Mancini, AECOM / Environmental Services; R.G. Stahl, E.I. DuPont de Nemours and Company / Corp Remediation

At former shooting range sites, spent lead shot can occur as either intact or weathered particles, or as ionized salts. The challenge at these sites involves integrating ecological exposures to different forms of lead (shot and non-shot), particularly to birds relying on grit to aid in digestion. Intentional ingestion of lead shot as grit by birds can be a critical ecological exposure pathway at these sites. Incidental ingestion of lead by birds and wildlife via diet and direct contact of invertebrates to soil and sediment lead may also pose a potential risk of adverse effects. An ecological risk assessment will be performed to evaluate the characteristic ecological exposure pathways involving lead (shot and non-shot) at a former shooting range site in a dynamic coastal estuary. In order to mitigate waterfowl exposures to lead shot, the remedial action for the site involved removal of lead shot from the intertidal and subtidal area sediment through physical processing of sediments. Subsequent erosional impacts to the sediment and the winnowing effects due to differential densities of lead shot and sediment substrate have resulted in limited sporadic patches of concentrated lead shot in these remediated areas. Currently, hazing and small scale removal of lead shot are in place to limit the waterfowl exposure to lead shot in these patches. A Living Shoreline pilot study at the site has shown that installation of artificial reef balls not only reduces ongoing erosion, but also promotes sediment accretion, effectively mitigating the waterfowl exposures to lead shot. The ecological risk assessment provides a basis for monitoring the effectiveness of the Living Shoreline to reduce ecological exposures to lead at the site. The approach and findings of the ecological risk assessment, in the context of supporting the on-going and future remedial and/or risk decisions at the site will be presented.

WP212 An individual based model of larval yellow perch to link behavioral effects of methylmercury to adverse population outcomes

B.M. Armstrong, Michigan State Univ / Fisheries and Wildlife; S. McNaught, Central Michigan Univ; F.X. Mora, Woods Hole Oceanographic Institution / Biology; R. Klingler, UWM-SFS / School of Freshwater Sciences; M.J. Carvan, Univ of Wisconsin-Milwaukee / School of Freshwater Sciences; N. Basu, McGill Univ / Dept of Environmental Health Sciences; J. Head, McGill Univ / Natural Resource Sciences; C.A. Murphy, Michigan State Univ / Fisheries and Wildlife

Historically, yellow perch were highly abundant throughout the shallow areas of Lake Michigan; however their populations have experienced a decline since the early 1990's. The poor recruitment has been associated with changes in trophic structure and adverse environmental conditions; however the possible effects of contaminants have not been explored fully. Methylmercury (MeHg), a persistent contaminant found in the Great Lakes, has been shown to alter foraging and predator avoidance behaviors of larval yellow perch and these behaviors could affect overall growth and survival. We adapted an individual based model (IBM) to incorporate laboratory derived MeHg effects on a larval yellow perch cohort. The model was calibrated to simulate real-life situations in Lake Michigan and nearby Crystal Lake (Benzie County, MI), and varied community structures to accommodate multiple stressor scenarios. Our model simulations suggest that exposure to neurotoxic contaminants such as MeHg, when coupled with low food availability and suboptimal water temperatures, could significantly reduce cohort survival. These findings suggest that contaminants could be another factor impacting recruitment of larval yellow perch in Lake Michigan, and that this deserves further exploration.

WP213 Application of a Novel Groundwater-to-Surface Water Model to Support Ecological Risk Assessment at a Former Oil Refinery

P. Mugunthan, K. Russell, B. Gong, Anchor QEA; B.G. McDonald, Golder Associates Ltd; L.J. Eastcott, Imperial Oil

Long-term water levels and free extractable petroleum hydrocarbon (EPH) recovery volumes, along with dissolved concentrations of EPH's in upland groundwater and sediment porewater, have indicated possible exposure of aquatic biota to upland contaminant sources at a former oil refinery in Western Canada. A novel mechanistic groundwater-to-surface water contaminant fate and transport model (GSM) was developed to provide one line of evaluation in a multiple lines of evidence approach adopted for risk assessment at the site. The GSM represented dynamic linkages between the surface water and groundwater, taking into account variable density flow, and tidal exchange and dynamics. Two-dimensional cross-sectional models were developed for three representative cross-sections that intersected potential areas of concern identified from site investigations, which included the collection of high-frequency temperature data through a distributed temperature sensor (DTS) network to identify potential seepage zones, and collection of porewater chemistry data from prospective seepage areas in the inter-tidal zones to identify priority contaminants. The GSM was calibrated to site-specific hydrogeological data and was able to reproduce seasonal and tidal patterns in historical groundwater level measurements in the different hydrogeological units. The GSM was applied to evaluate contaminant migration over the long term to assess attenuation within the surficial sediments due to tidal exchange and degradation processes. Contaminants of concern simulated differed considerably in mobility and degradation potential. The GSM provided a means for estimating dissolved contaminant concentrations across different environmental compartments including groundwater, sediment porewater, and surface water. Model simulations indicated that biodegradation could be an important factor in reducing contaminant levels in the transition zone for certain contaminants. Moreover, the contaminant migration paths identified in the GSM were consistent with porewater contaminant data and GSM-predicted seepage patterns were consistent with those identified from the DTS study, thereby providing additional lines of evidence for refining the conceptual site model. In conjunction with the other site investigations, the mechanistic modeling results were used to identify contaminants that are likely to persist in the sediments and integrated into the ecological risk assessment for the site.

WP214 Assessing effects of harbor contaminants on snails in situ

M. Bighiu, Stockholm Univ / Environmental Science and Analytical Chemistry ACES; B.T. Watermann, LimnoMar; B. Carney Almroth, Univ of Gothenburg / Biology and Environmental Sciences; A. Eriksson-Wiklund, Stockholm Univ / Environmental Science and Analytical Chemistry ACES

Many contaminants are being released continuously into water bodies. Thus it is important to assess the long term, sublethal effects of contaminants on biota, as they can be early warning signals for effects at population level. Field experiments are particularly valuable, as they account for natural variability and environmentally relevant concentrations of pollutants. In this study we chose leisure boat harbors as typical sites of contaminant accumulation (e.g. metals from antifouling paints), due to their enclosed design and poor water mixing. The test organism was the nerite snail Theodoxus fluviatilis, a highly abundant and representative species of the area studied. The aim was to investigate both mortality and histopathological effects of harbor contaminants on snails, as well as the importance of contaminant pre-exposure on the sensitivity of snails. We exposed two different populations of snails (i.e. 'clean' and 'pre-exposed') in situ in 6 locations nearby Stockholm, Sweden (3 harbors and 3 references). We hypothesized that snails originating from a clean habitat will have higher mortality rates than those from the pre-exposed population (which is likely to be adapted to contaminants). After 2, 4 and 8 weeks of exposure, we assessed snail mortality and histopathological alterations in all organs (e.g. gonadal atrophy, gill inflammation, parasite infestation etc). As expected, the mortality was significantly higher amongst snails exposed in all harbors, compared to the reference sites. However, the snails originating from the pre-exposed population had higher mortality rates compared to the clean population and this contradicts our hypothesis on adaptation to contaminants. Interestingly, the rate of parasite infestations varied with snail sex differently for the two snail populations, i.e. females had the highest infestation rate for snails from the pre-exposed population, whereas in the clean population males were affected by parasites to a higher degree than females. Analysis of the mitochondrial genome (cytochrome c oxidase I gene) was assessed to determine differences in genetic diversity within and between populations, which might explain differences in tolerance to contaminants.

WP215 Assessing the risk to pelagic species of the cyclic volatile methyl siloxane, Octamethylcyclotetrasiloxane (D4)

A. Fairbrother, Exponent, Inc. / EcoSciences; K.B. Woodburn, Dow Corning Corporation / HES

Assessing ecological risks of the widely used cyclic volatile methyl siloxane octamethylcyclotetrasiloxane (D4) to aquatic systems is difficult due to its high volatility and low water solubility. The latter may create environmental labeling issues even when chronic and acute no-observed effect concentrations (NOECs) approximate functional water solubility due to low measured concentrations. This work explores the difficulties inherent in determining the toxicity of D4 to pelagic species and then applies the techniques of probabilistic risk assessment (PRA) and chemical activity to explain the apparent lack of toxicity of D4 to pelagic species under field conditions. Field water samples have been collected and measured for D4 from freshwater and marine sites in Tokyo Bay, many Scandinavian countries, and receiving water downstream of municipal and industrial wastewater treatment plants in Canada; the distribution of measured water concentrations may be compared to the chronic D4 pelagic NOEC values using PRA. In addition, field data on D4 in water and biota may be compared to the activity (fugacity) of the chemical in a variety of media. Chemical activities are simply the ratio of a concentration and its matrix solubility, adjusted for salinity, amount of particulate matter, and carbon content. Activities of concentrations in biota are the ratio of the lipid-based concentration and the apparent solubility of the chemical in lipid, which is approximated by the compound's octanol-water coefficient (K_{ow}) and its aqueous solubility value. This allows expression of all data in a range from 0 to 1, resulting in easy comparison of biota and environmental matrices. The chronic NOEC values for pelagic organisms exposed to D4 were calculated as the aqueous concentration divided by the functional solubility for each test resulting in activities of 0.02 to 1.0, with a median value of 0.53. Based on tissue concentrations in field biota, chemical activities for fish and invertebrates are approximately $1x10^{-7}$ to $1x10^{-6}$, respectively, far less than the NOEC values. Overall, these data show that chemical activities of D4 in biota are not able to reach values that are associated with nonpolar narcosis (i.e., toxicity) and that discharge levels for the past ~30 years have produced field measured concentrations that pose negligible risk to pelagic organisms.

WP216 Complex interactions among agrochemicals in aquatic systems: Can phosphate protect against fungicide toxicity?

V. Pereira, Towson Univ / Environmental Science and Studies; L. Lockett, Towson Univ / Environmental Science; C.J. Salice, Towson Univ / Biological Sciences / Environmental Science

There is a growing concern that Maryland waters can be polluted by surface-water runoff that contains both pesticides and fertilizers. While many pesticides can be toxic to aquatic organisms, less is known about the ecological impacts of phosphate, especially in conjunction with pesticides. Because phosphate is bio-active, such as in the production of ATP, it is possible that phosphate could protect against pesticide toxicity. Previous studies with Daphnia magna have indicated a protective effect of 5.0 mg/L phosphate with regards to survival. Individuals in high treatments of pyraclostrobin (16 µg /l) without phosphate had a survival rate of 20% while individuals with the same concentration of pyraclostrobin and phosphate exhibited a survival of 80%. Additionally there was a trend with regards to time to first reproduction in both the 16 µg/l without phosphate, and 16 µg/l with phosphate treatments, which showed a delayed time to first reproduction compared to the controls. Our next objective was to identify specific concentrations of phosphate that confer a protective effect. We exposed D. magna to a range of environmentally relevant phosphate (KH_2PO_4) and pyraclostrobin concentrations for 21 days. Survival, reproductive output, and size of D. magna were observed. Our working hypothesis is that concentrations of phosphate near 2.5 mg/L will show a protective effect. Importantly, traditional single taxa toxicity tests appear to provide data relevant to limited or unrealistic environmental scenarios and complex stressor designs may provide more ecologically relevant insight. Data like what is reported here may provide information to improve predictive capabilities of environmental managers in ecosystems impacted by complex stressor mixtures of high nutrient and pesticide loads.

WP217 Effects of 2,2′,4,4′-tetrabromodiphenyl ether (BDE-47) dietary exposure on two generations of the marine gastropod Crepidula onyx

B. Po, The Univ of Hong Kong / School of Biological Sciences; J.M. Chiu, Hong Kong Baptist Univ / Dept of Biology; R.S. Wu, The Education Univ of Hong Kong / Dept of Science and Environmental Studies

Polybrominated diphenyl ethers (PBDEs) are widely used brominated flame-retardants that have been accumulated in high concentrations in marine sediment and biota. While the biological effects including endocrine disruption and neurotoxicity of PBDEs on mammals and fish are well-documented, information on their effects on invertebrates is scarce. This study aimed at exploring the effects of long-term dietary exposure and parental exposure to environmental level of BDE-47 on marine invertebrate using Crepidula onyx (Gastropod, Calyptraidae). The bioaccumulation and physiological effects on the first (F_0) and second (F_1) generations of C. onyx fed by microalgae encapsulated with BDE-47 were investigated. Transcriptomic analysis by RNA sequencing was also performed to unravel the underlying mechanism. Bioaccumulation was evident in C. onyx from larval stage to adult. Reduction of juvenile survivorship and delay of time to emerge as male in both treatment groups showed physiological impairments of C. onyx upon BDE-47 exposure despite that shell growth and larval settlement percentage were unaffected. Further, reproductive impairment of F_0 adults was clearly evident by the reduction in number of oviposition per female and proportion of well-developed F_1 larvae. The maternally transferred BDE-47 in F_1 offspring had embryotoxic effect as demonstrated by the higher number of broods with non-viable F_1 embryos which failed to develop normally through early cleavage stages (blastula to gastrula). Lastly, the transcriptomic analysis provided potential mechanistic explanations on some of the phenotypic changes observed above, and suggested dysregulation of steroid hormones and alteration of proteins important for embryonic development. These findings have highlighted the need for long-term exposure study which involves multiple generations in toxicological evaluation.

WP218 Export Crops and MRLs: Implications for Ecological Health in Low-Regulation Environments

C.A. Ng, Univ of Pittsburgh / Civil and Environmental Engineering; A. Mendez, ETH Zurich / Safety and Environmental Technology Group

Many economically important fruit crops are grown in tropical environments in regions where there are relatively few or lax environmental regulations when compared to North America or Europe. However, these crops are required to meet maximum residue limits (MRLs) in order to be exported and sold in these regions. Because of this, MRLs often constitute de facto regulations in the growing environment that are set by the importing countries. Although this has led to the phase-out of a number of persistent and toxic pesticides in these tropical regions, it has also led to use of less persistent pesticides that nevertheless have very high aquatic toxicity. Therefore, even when fruits like bananas and pineapples consistently meet export requirements, the local growing environment may experience short-term peaks in aquatic concentrations of pesticides following runoff events that result in large fish kills. Here, we discuss dynamic modeling approaches to understanding the time- and application-dependent environmental pesticide levels that can result given the MRLs for current-use pesticides in fruit crops. We present the particular example of banana cultivation in Costa Rica and show how different application patterns, pesticide physicochemical properties and local environmental conditions interact to determine the ecological implications of MRLs defined solely to protect human health.

WP219 GSA-QHTS screening method, a robust and assumption free method to identify hidden drivers of combined stressor effects

I. Rodea-Palomares, Univ of Florida / IFAS / Agricultural & Biological Engineering; R. Muñoz-Carpena, Univ of Florida / Agricultural Biological Engineering; M. González-Pleiter, Universidad Autónoma de Madrid / Biology; S. Gonzalo, Universidad de Alcala; R. Rosal, Univ of Alcala; M. Casellas, ICRA; S. Sabater, Universitat de Girona; F. Fernandez-Piñas, Universidad Autónoma de Madrid / Biology

What is the expected combined effect of a set of stressors? When stressors are combined, what is their relative importance? Should we consider all possible stressors for environmental risk assessment? These are some pervasive questions relevant for the understanding and managing of the consequences of chemical pollution in the real world. Modelers recognize that it is difficult to model a highly dimentional system with all its complexity, its interrelations and feedbacks; and that models are most effective when experimental scientists can characterize the main processess and factors driving the system. Experimental scientists are often limited by the experimental costs and uncertainties of laboratory work. This is specially true when trying to understand the combined effect of multiple stressors. In fact, current experimental methods, being esentially reductioninst, are not very well suited to characterize together more than a few number of experimental factors/conditions. In this talk, a novel experimental and statistical integrated analysis framework (GSA-QHTS) is presented. This framework combines Global Sensitivity Analysis (GSA) with Quantitative High-Throughput Screening (QHTS) as a cost-effective integrated framework that allows to screen main drivers of an experimental system response when evaluated under a combined high-dimensional set of candidate explanatory drivers. This set of candidate drivers may include any chemical, physical or biotic factor/stressor that can be set up and control under laboratory experiments. Thanks to GSA parsimony, the experimental cost of GSA-QHTS increased only arithmetically with the number of factors, which is a key advantage when analyzing the relative importance of variables in high-dimensional systems. We will present a case study where GSA-QHTS allowed for the identification of the main pharmaceutical pollutants driving unexpected low-dose mixture effects at the microbial population level in sets of environmentally realistic complex mixtures of pharmaceutical pollutants. In addition, we show how these pollutants were consistently important at the microbial community level in mesocosm experiments. GSA-QHTS has a broader potential adoption across disciplines to identify main effect drivers in high-dimensional sets of candidate factors.

WP220 Incorporating effects of methylmercury on larval fish learning: Scaling up to population dynamics

L. Ivan, Michigan State Univ / Fisheries and Wildlife; S. Roach, College of Saint Benedict; C.A. Murphy, Michigan State Univ / Fisheries and Wildlife; M.J. Carvan, Univ of Wisconsin-Milwaukee / School of Freshwater Sciences; N. Vinas, Midsouth Regional Chapter / Inst for Genomics Biocomputing and Biotechnology; R. Klingler, J.K. Larson, Univ of Wisconsin-Milwaukee / School of Freshwater Sciences; M. Jones, Michigan State Univ

Methylmercury has been shown to negatively affect swimming speed and foraging success in larval fishes. These nonlethal effects on fishes can translate into reduced survival due to increased risk of predation and decreased growth rates in young fishes. In addition to impairments to swimming speed and foraging success, larval fishes exposed to methylmercury also exhibit learning deficiencies, including the inability to learn the best prey items to attack, handle and consume. We developed a new learning algorithm that we incorporated into an existing individual-based model (IBM) to determine how impacts of methylmercury on larval fish learning would impact larval growth rates and survival. The IBM followed a cohort of larval yellow perch from hatch through the first 100 days of life. Each day, individual larvae forage, grow, and experience predation and starvation mortality. Methylmercury-induced impairments on learning measured in laboratory behavioral assays were incorporated into the foraging subroutine via changes in handling time and capture success.

We hypothesized that effects on larval fish learning, through reductions in foraging success, would result in significantly slower growth rates and reduced survival than in scenarios in which learning was not affected. Further, these MeHg-induced effects would result in lower survival than effects of MeHg-induced reductions in swimming speed alone. Model results highlight the importance of considering nonlethal effects of toxicants on fish behavior and learning and how these can affect population dynamics. In the future, this model can be used to address questions related to other toxicants and/or species and can incorporate other behaviors affected by toxicants.

WP221 Interaction Effects Across Time and Concentration Gradients in Ceriodaphnia dubia Exposed to Pesticide-Predator Cue Mixtures

J. Carrick, G. Qin, Texas Tech Univ / TIEHH / Dept of Environmental Toxicology; T. Anderson, South Central Regional Chapter / Dept of Environmental Toxicology / The Inst of Environmental and Human Health; J.D. Maul, Syngenta Crop Protection / Dept of Environmental Toxicology / The Inst of Environmental and Human Health

There is a widely recognized need to include greater environmental realism in toxicity studies by considering chemical mixtures and the effects of modifying factors. Predator cues are one biotic factor present in the aquatic environment which, due to the energetically costly responses which they elicit in prey, could produce non-additive effects when combined with pesticides. Another deficiency in standard toxicity testing is the de-emphasis of time as a factor in toxicity. This study addresses the two aforementioned issues — mixtures and toxicity in time — by investigating the temporal dynamics of mixture toxicity. Just as mortality is a function of both concentration and time, interaction effects of mixtures may also be concentration- and time-dependent. In previous studies, Ceriodaphnia dubia were exposed to eight different pesticides separately, either with or without the addition of fish predator cues. In the original analysis, only survival at the 96-h time point was analyzed to test for interactions. The current study, however, utilized data collected at 9-13 time points throughout the exposures in order to characterize the occurrence of interactions across concentration and time gradients. Analysis consisted of fitting parametric distributions to right-censored survival data for cue and non-cue treatments at each concentration over successively longer intervals of time. For example, survival data over the 0-24 h period was first considered, followed by analysis of the 0-30 h, 0-48 h, 0-54 h, . . . , and 0-96 h datasets. Graphical summary of the results depicts a concentration-time “area” in which interactions were detected. In order to compare this area among the eight pesticides, standardized plots were constructed with concentration expressed as toxic units (TUs). Some observed patterns were that interactions generally occurred below ~3 TUs, and as early as 24 h or as late as 96 h. The results of the study provide insight into how single-chemical exposure studies may under or overestimate pesticide toxicity in aquatic habitats due to the presence of environmental factors such as predator cues. The results are also relevant to the design of mixture studies, since the detection of an interaction is highly dependent on the concentrations and duration selected for a study. In addition, the study may be useful in distinguishing mixture effects under exposures of varying duration.

WP222 Methods for Building a Quantitative Adverse Outcome Pathway for Acetylcholinesterase Inhibitors using Bayesian Networks

S. Graham, W.G. Landis, Western Washington Univ / Inst of Environmental Toxicology; J.D. Stark, Washington State Univ / Dept of Entomology; K. von Stackelberg, NEK Associates LTD / Dept of Environmental Health

Adverse outcome pathways (AOPs) are conceptual constructs that synthesize existing knowledge on the linkages between molecular initiating events and adverse outcomes at higher levels of biological organization. However, AOPs do not currently make quantitative predictions about population scale effects that would be relevant to decision-making. For this project, we are developing a case study that demonstrates how existing toxicological data for acetylcholinesterase inhibitors can be integrated into a quantitative framework that links environmental concentrations to molecular initiating events to population level endpoints using Bayesian network modeling and age structured population models. This poster will present details of the methods used to design the conceptual model, build quantitative relationships between variables, and determine site specific inputs to the model. The case study site is the Puget Sound in Washington, and the endpoint is ESA-listed salmonids including chinook and coho salmon. The model will be designed to predict effects of organophosphate pesticides both individually and in mixture.

WP223 The inclusion of toxic exposures in a population model of Chinook salmon (Oncorhynchus tshawytscha)

J. Lundin, NOAA Fisheries, Ecotoxicology Program

Salmon are a keystone species with a biological foundation that spans from coastal ecosystem health to human economies. Water pollution is becoming an increasingly important salmon conservation issue, particularly in watersheds affected by toxic runoff from urban development, industrial activities, and impervious surfaces such as roads. The physiological effects of many toxic substances are well studied, however the population-level effects are more challenging to evaluate due to differences in life history strategies. Toxic exposures are often not included in population abundance evaluations, particularly sub-lethal exposures or effects on prey abundance. The purpose of this study is to quantify the impacts of toxic insults, such as mortality, sub-lethal changes in growth, behavior, and reproduction, and effects of prey abundance, on Chinook salmon (Oncorhynchus tshawytscha) in the Willamette River basin resulting from exposures to contaminants in Portland Harbor. This study will build upon an existing population model of McKenzie River spring Chinook developed at the NWFSC, representing a sub-basin of the Willamette River. Known tissue residue concentrations from previous sampling efforts of juvenile Chinook at multiple sites throughout Portland Harbor will guide the assignment of chemical exposure. Toxicity will be determined by mechanism of action, and both mortality and sub-lethal effects dose-response relationships. Model scenarios will investigate the impact of toxic insults during smoltification and outmigration on overall population abundance and growth rate. Extrapolations of this model may be applied to Chinook salmon in other watersheds of the Willamette basin and used to guide recovery efforts. Lessons learned from this study will inform similar projects in the Puget Sound and elsewhere.

WP224 Toxicity evaluations of coastal sediments in Osaka Bay, Japan, using Japanese medaka embryos

S. Uno, Kagoshima Univ / Faculty of Fisheries; E. Kokushi, Kagoshima Univ / Education and Research Center for Marine Resources and Environment; M. Kawano, J. Koyama, Kagoshima Univ / Faculty of Fisheries

Many kinds of chemicals have been discharged into environments with human activities, carried ocean with rainfall, influx of river water, and directly setting from atmosphere. These are settled on sediments eventually. Despite being habitats of numerous species of aquatic organisms on and in sediments, we have only poor data for toxicities of environmental sediments, because it’s difficult to find the direct toxicities of sediments. We consider that sediments composed of soil and pore water. Therefore, new rearing systems of Japanese medaka (Oryzias latipes) embryos on the sediment without water, in order to evaluate toxicities of sediments. In present study, effects to embryos on coastal sediments, collected from Osaka Bay, Japan, were examined with our new toxicity tests, and compared among each sites. Sediments were collected from 15 sites at Osaka Bay closed to big cities as Osaka, Kobe, Nishinomiya, and Amagasaki cities, sifted with 1 mm mesh, and then dried for 72 hours. Dried sediments were washed with embryo raring mediums (ERMs, =pore water), removed extra ERMs with centrifugation, and set into glass petri dish. Three petri dishes per one site were prepared. Fifteen embryos were embedded in half of them in sediments, and incubated at 24°C for 7 days (=exposures to "sediments"). Both exposure periods to two species of medaka depended on the periods until their hatching. Control group with silica sand was also prepared similar with coastal sediment groups. After exposures in each sediments, all embryos were transferred to each one embryo/well into 48 well plates for the examination of effects such as mortality, hatching rate, growth rate and malformation rate. As a result, sediments collected around river mouth of Yodo River flowing in big city as Osaka city caused relatively high decreases of hatching rates with 60%. In addition, slight decreases of hatching rate (80%) were observed around river mouths of others. These results suggest that rivers flowing into Osaka Bay certain caused sediment toxicities to medaka embryos. Another site close to Osaka city was observed extreme hatching delay (16.2 ± 2.32 dpf) of hatch compared with control (10.4 ± 0.946 dpf). Similar tendencies for hatching delay were observed in sediments collected from coastal area around Osaka to Nishinomiya cities. However, we cannot found extreme effects on sediments collected around Kobe city.

WP225 When is it close enough? An evaluation of complexity trade-offs for modeling pesticide run-off risk with VFSMOD

R. Muñoz-Carpena, Univ of Florida / Agricultural Biological Engineering; A. Ritter, Waterborne Environmental, Inc.; G. Fox, Oklahoma State Univ / Biosystems and Agricultural Engineering; O. Perez-Ovilla, Bayer CropScience / Environmental Safety

A main issue when building models that represent the "real" behavior of a system is the complexity dilemma: how much complexity is required to get a close enough approximation of the system´s behavior? When is it close enough? While these questions may look rather philosophical, they cascade into major practical, economical and regulatory consequences. We will present a frameworks: Global Sensitivity and Uncertainty Analysis (GSA/UA) as pragmatic set of tools to deal with these questions. GSA/UA a global understanding of model sensitivity and uncertainty, and to rank model input factor´s relative importance when all factors varied together. One potential applications of GSA/UA is to guide the reduction of model complexity without losing model explanatory power. We will illustrate the usefulness of both frameworks with a series of case studies focused on the analysis of factor importance determining the efficacy of vegetative filter strips (VFSs) for reducing pesticide run-off risk to the aquatic compartment as represented by the process-based model VFSMOD (Vegetative Filter Strip Modeling System). Since the efficacy of VFSs depends on site-specific input factors, relationships of filter efficiency with filter length and other input factors may result in rather complex and non-linear relationships. We will illustrate how some model parameters assumed to be critical in endless discussions in different regulatory frameworks, may reveal themselves as non-relevant when measured in a common scale metric with all the other input factors present.

Demonstrated Remediation Technologies Addressing Contaminated Soil, Sediment and Water

WP226 Transformation of the Recalcitrant Pharmaceutical Compound Carbamazepine by the White Rot Fungus Pleurotus ostreatus

N. Golan, The Hebrew Univ of Jerusalem / Center of Excellence in Agriculture and Environmental health; B. Seiwert, Helmholtz Centre for Environmental Research UFZ / Dept of Analytical Chemistry; C. Riemenschneider, Helmholtz Centre For Environmental Research – UFZ / Analytical Chemistry; T. Reemtsma, Helmholtz Centre for Environmental Research UFZ / Dept of Analytical Chemistry; B. Chefetz, The Hebrew Univ of Jerusalem / Soil and Water Sciences; Y. Hadar, The Hebrew Univ of Jerusalem / Plant Pathology and Microbiology

Concern over the exposure to active pharmaceutical compounds (PCs) in the environment is increasing. Many PCs are not fully removed during municipal wastewater treatment; thus they are released to the environment with the treated effluents. Consequently, PCs and their potentially toxic degradation products may be found in surface and groundwater and being introduced into agricultural soils, where they can accumulate and be taken up by crops. Although PCs are found in the environment at very low concentrations, this is of health concern since the consequences of chronic exposure to a mixture of various PCs and their degradation products is largely elusive. Carbamazepine (CBZ) is a widely used anticonvulsant drug which serves as a model compound in the study of environmental exposure, implications and removal of PCs. This study aims to elucidate the metabolic pathway of CBZ by P. ostreatus grown in liquid media and on a natural lignocellulosic substrate. When P. ostreatus was grown in liquid medium 99% of the added CBZ were transformed to the 10,11- epoxy CBZ by cytochrome P-450 and Manganese Peroxidase. At the end of the incubation period a new product, 10,11-Dihydro-10,11-dihydroxy CBZ, was formed. Both products showed a limited removal also when they were applied as primary substrates. When P. ostreatus was grown on cotton stalks, 90% of the added CBZ were removed after 60 incubation days. In contrast to the findings in the liquid medium, the removal rate of eoxy-CBZ and dihydroxy-CBZ as primary substrates exceeded 90% and new 22 transformation products were discovered. epoxy-CBZ was further metabolized via acridine and dihydroxy-CBZ pathways. The latter was further metabolized via five sub-pathways. Some of the identified transformation products have been reported to be formed by oxidation of CBZ by abiotic agents, but never as a result of a biological processes. When ^{14}C-carbonyl-labeled CBZ was used as the substrate, ^{14}C-CO_2 release amounted to 17.4% of the initial radioactivity. This release can be attributed to at least two reactions where the carbonyl group was eliminated. However, due to the position of the radioactive labeling it is impossible to tell whether a mineralization has occurred. This work highlights the effect of growth conditions on the degradation pathway of PCs and formation of possibly toxic degradation products. This is of importance in the context of release of PCs to the environment, e.g. irrigation with treated wastewater.

WP227 Remediation efficiency of three treatments on water polluted with endocrine disruptors: Assessment by means of in vitro techniques

J. Silva, Sao Paulo State Univ – UNESP / Sorocaba Campus; A. Valdehita, INIA National Inst for Agricultural and Food Research and Technology / Dept of Environment; R. Fracácio, São Paulo State Univ – UNESP / Dept Environmental Engineering; J. Navas, INIA – National Inst for Agricultural and Food Research and Technology / Environment

Chemical substances with potential to disrupt endocrine systems have been detected in aquatic environments worldwide, making necessary the investigation about water treatments able to inhibit such potential. The present work aimed to assess the efficiency for removing endocrine disruptors (with estrogenic and androgenic activity) of three simple and inexpensive substrates that could be potentially used in sectors or regions with limited resources: powdered activated carbon (PAC), powdered natural zeolite (ZEO) (both at a concentration of 500 mg.L-1) and natural aquatic humic substances (AHS) (at 30 mg.L-1). MilliQ-water and mature water from fish facilities (aquarium water, AW), were artificially contaminated with 17β-estradiol (E2), 17α-ethinylestradiol (EE2) and dihydrotestosterone (DHT). Moreover, effluent samples from waste water treatment plants (WWTP) were also submitted to the remediation treatments. In order to assess estrogenic and androgenic activities two cell lines permanently transfected with luciferase as reporter gene under the control of hormone receptors were used: AR-EcoScreen containing the human androgen receptor (hAR) and HER-LUC transfected with the sea bass estrogen receptor (sbER). Results showed that only PAC was efficiently removing the estrogenic and androgenic compounds added to milliQ and AW. However, androgenic activity detected in WWTP effluents was only reduced after treatment with ZEO. It seems that hormonal activities detected in WWTP effluents are influenced by the plethora of substances present in them, that probably not only lead to antagonistic, agonistic or additive effect, but can also affect the adsorption of target molecules to the matrices used in this study. Such a possibility must also be explored.

WP228 Assessment of ozonation efficiency to disinfect municipal effluents

D. Simão, J. Malvestiti, E. Fagnani, R.F. Dantas, Univ of Campinas / Technology

The disinfection of wastewater is a technology recognized for its efficiency in many cities of the world, however if that disinfection is based on oxidation, the composition of the effluent can affect the treatment efficiency. The variation in reactivity and composition of the effluent can delay the inactivation of microorganisms due to the presence of competing reactive material to react with oxidants. For advanced oxidation processes, the radicals formed, mainly HO• may have its efficiency affected by varying the reactivity of organic matter (EFOM – effluent organic matter) and inorganic compounds such as carbonates and nitrates. Currently, the potential of oxidative processes to disinfect effluents is known as well as that the variation in composition and reactivity of the effluent can affect the treatment. However, it is still not clear how each component, components of EFOM, inorganic compounds and even chemical compounds of industrial origin may affect the process. The objective of this work was to verify the efficiency of ozonation to disinfect municipal effluents as well as to assess the toxicity variation along the treatment time. Initial results demonstrate that ozonation was able to remove E. Coli in the first minutes of ozonation, equivalent to a ozone dose less than 10 mg L^{-1}. Preliminary acute toxicity tests demonstrated that ozonation was able to reduce the acute toxicity with the ozone dose necessary to the complete disinfection.

WP229 Catalytic reduction of Cr(VI) and chloroacetic acids using Au@Pd/TiO2 and Pd/TiO2 catalysts

K. Wu, S. Zheng, Nanjing Univ / School of the Environment

Cr(VI) is a commonly identified heavy metal pollutant in the aquatic environment. It is listed as one of the priority pollutants by the USEPA due to its high acute toxicity to humans. Cr(VI) can be reduced to a less toxic form, Cr(III), which can be removed subsequently at neutral or alkaline environments through precipitation. Chloroacetic acids (CAAs), one of the disinfection byproducts (DBPs) formed in chlorination for drinking water treatment, attract significant concerns because of their strong carcinogenic, mutagenic and hepatotoxic effects. CAAs could be effectively dechlorinated into nontoxic acetic acid during reduction process. The catalytic reduction is a promising method to remove inorganic pollutant Cr(VI) and organic pollutant CAAs in water. We prepared Au@Pd catalysts supported on TiO_2 with delicate core-shell structures by a two-step photo-deposition method. The catalytic reduction performances of Au@Pd catalysts on Cr(VI) and CAAs are studied and compared to the performance of monometallic Pd catalysts supported on TiO_2. In this study, Au loading amount of bimetallic Au@Pd/TiO_2 catalysts was kept at 0.99 wt.% and Pd loading amounts varied from 0.05 to 0.15 wt.%. Pd loading amount of monometallic Pd/TiO_2 was 0.05 wt.%. The results showed that Pd atoms preferentially deposited on the exposed Au surface to form core-shell structured Au@Pd particles in the preparation of the bimetallic catalysts. The bimetallic catalyst Au@Pd/TiO_2 and the monometallic catalyst Pd/TiO_2 displayed completely different catalytic activities on the reduction of Cr(VI) and CAAs. For Cr(VI), Pd/TiO_2 showed negligible catalytic activity, while Au@Pd/TiO_2 exhibited a remarkable conversion percent of Cr(VI). The catalytic activity of Au@Pd/TiO_2 increased with the increase of Pd deposition amount from 0.05 to 0.10 wt.%, whereas remained the same when Pd deposition increased from 0.10 wt.% to 0.15 wt.%. For CAAs, Pd/TiO_2 exhibited higher activity than Au@Pd/TiO_2 and the reduction efficiency monotonically increased with the increase of Pd loading amount from 0.05 to 0.15 wt.%. In summary, the environmental pollutants Cr(VI) and (CAAs) in water can be converted to a less toxic form by catalytic reduction. The bimetallic catalyst Au@Pd/TiO_2 showed a higher activity in reducing Cr(VI) and the monometallic catalyst Pd/TiO_2 performed better in treating CAAs. The catalytic performance of both the catalysts can be optimized by controlling the loading amount of Pd.

Remediation/Restoration – Poster Only

WP230 4-Chlorophenol Degradation in Aqueous Media, Using Sono-electro-Fenton Method

R. Nazari, L. Rajić, A. Alshawabkeh, Northeastern Univ / Civil and Environmental Engineering

Electro Fenton (EF), ultrasound radiation and Sono-electro-Fenton's process (SEF) all are advanced oxidation process (AOP) that have drawn great interests for removal of chloro-organics from water. EF and ultrasound radiation are known to produce hydroxyl radicals that are strong oxidative agents. The main objective of this study was to combine these two processes to degrade 4-chlorophenol (4-CP) using SEF process in an aqueous solution and to investigate the effects of different parameters on contaminant removal efficiency. Initial pH, current, ferrous iron concentration and Pd/Al_2O_3 catalyst dosage were optimized in a two electrode (Ti/mixed metal oxide or Ti/MMO) batch system using electro-Fenton (EF) mechanism. The SEF was then tested with a pulsing 20 KHz ultrasound wave to optimize pulsing frequency and sonifiers amplitude. EF tests were conducted with a 200 mg L^{-1} 4-CP initial concentration and a 10 mM sodium sulfate (Na_2SO_4) as background electrolyte. More than 90% of 4-CP was removed within 300 minutes in the presence of 80 mg L^{-1} Fe(II), 200 mA of current, 1 g L^{-1} Pd/Al_2O_3 catalyst and initial pH of 3. In the SEF process where 70% amplitude was used along with a 5.9 and 59 seconds pulse on and pulse off, respectively, the removal rate of 4-CP degradation increased within the first 120 min compared to EF. However, degradation slowed down over time and complete 4-CP removal was observed after 300 minutes. Complete results along with the energy consumptions will be presented.

WP231 Analysis of amino acids of agricultural interest in composting

L.T. Cappelini, Univ Federal de São Paulo – UNIFESP; P.d. Eugênio, Instituto de Química de São Carlos – IQSC – USP; P.A. Leão, J.V. Alberice, A. Urbaczek, Instituto de Química de São Carlos – IQSC – USP / Instituto de Química de São Carlos IQSC USP; N.A. Assunção, Instituto de Ciências Ambientais, Químicas e Farmacêuticas, Univ Federal de Sao Paulo UNIFESP / Instituto de Ciências Ambientais Químicas e Farmacêuticas Univ Federal de Sao Paulo UNIFESP; L. Juliano Neto, Univ Federal de São Paulo – UNIFESP / Univ Federal de São Paulo UNIFESP; E. Carrilho, Instituto de Química de São Carlos – IQSC – USP / Instituto de Química de São Carlos IQSC USP

Composting is a sustainable approach to manage animal and vegetal waste generated in the Fundação Parque Zoológico de São Paulo (FPZSP). The resulting compost is often used in ZOO's premises as organic fertilizer for the production of vegetables, which is further used to feed the animals. The composting product provides many forms of mineral and also amino acids (AA) that are absorbed by plants as nutrients. Since most amino acids absorb only slightly or not at all in the UV wavelengths, we developed a method for the determination of AA of agricultural interest in the composting samples. Due to the complexity of samples, we used ion exchange chromatography for purification of AA prior analysis. The proposed CZE-C4D method allowed a separation of the AA in a short analysis time (less than 3.0 min), with great linearity (ranging from 0.993 to 0.998). Using a BGE of 10 mmol L^{-1} TEA, reduction of high-frequency noise and lower baseline fluctuations were obtained. The LOQ for the five AA were around 35 µmol L^{-1}, and were adequate for our purpose. In addition, the method showed good precision (RSD of peak area and migration time less than 1.55 and 1.16%, respectively).

WP232 Avoidance behavior of Eisenia andrei to Achromobacter spanius inoculated mancozeb and copper oxychloride pesticides spiked soils

C.M. Kim, O.G. Oladipo, C.C. Bezuidenhout, M.S. Maboeta, North-West Univ, Potchefstroom / Unit for Environmental Sciences and Management

The Earthworm avoidance behavior test is a rapid screening tool for the assessment of soil contamination and habitat function. Its short duration and cost effectiveness therefore makes it appropriate for quick risk assessment of pesticides in soils. Mancozeb and copper oxychloride are two commonly employed metal-based fungicides in vineyards and orchards. While mancozeb contains 16 % manganese (Mn) and 2 % zinc (Zn), copper oxychloride is composed of 60 % copper (Cu). In the present study, the avoidance test (ISO 17512-IFDIS, 2007) was conducted to assess the preference behavior of earthworms – Eisenia andrei in bacterial inoculum-pesticides soil substrates. A 24 hours broth culture of bacterial strain – Achromobacter spanius (KT819127) isolated from gold and gemstone mining site (and shown tolerance to 600, 300 and 200 ppm Mn, Zn and Cu respectively in a previous study) was introduced into mancozeb and copper oxychloride OECD spiked soils. The two-chamber design avoidance test was adopted. Five replicates of 10 earthworms (300 – 600 mg) were exposed in control and test substance of mancozeb (8, 44, 800 and 1250 mg/kg) and copper oxychloride (200, 450, 675 and 1000 mg/kg) and incubated at 23 ± 2 ^{0}C for 48 hours. The results revealed that at mancozeb 44 and 800 mg/kg, there was a net response of 8 and 92 % with the inoculum-pesticide test substrate while an avoidance response of 28 and 100 % was recorded in the non-inoculum-pesticide test substrate. Likewise for copper oxychloride 200 and 450 mg/kg, while a 100 % net response was recorded in the non-inoculum-pesticide substrate, an 87.5 and 96 % avoidance behavior was obtained with the Achromobacter spanius inoculum test. These results show some higher preference by Eisenia andrei for inoculum-pesticide substrates compared to the non-inoculum-pesticide substrates. However, a highly reduced habitat function was demonstrated by earthworms at mancozeb 800 and 1250 mg/kg and copper oxychloride 675 and 1000 mg/kg in both substrates with and without bacterial inoculum. The findings of this study therefore indicate that Eisenia andrei showed lower avoidance behavior towards inoculum-pesticide substrates compared to non-inoculum pesticide substrate at reduced mancozeb and copper oxychloride concentrations. Thus, a further study to determine acute and sublethal toxicity effects of mancozeb and copper oxychloride on Eisenia andrei in the presence of Achromobacter spanius will be conducted to confirm these findings.

WP233 Bioefficiency of Rhodanese Produced by Klebsiella edwardsii in the Clean-up of Cyanide Polluted Water

O.O. Adedeji, O.T. Aladesanmi, Obafemi Awolowo Univ / Inst of Ecology and Environmental studies

Water bodies used for cassava processing contains cyanide which is toxic to several forms of life. The use of enzyme for the remediation of polluted environment presents advantages over traditional technologies and also over microbial remediation. Extracellular rhodanese of strain of Klebsiella edwardsii isolated from cyanide polluted stream which is used for cassava processing was studied. Biochemical characteristics of the purified enzyme, including pH, temperature profiles, kinetic parameters, substrate specificity and effect of metallic salts were also determined. Production of rhodanese correlated with the rate of bacterial growth at the death phase and the optimum incubation time for maximum enzyme production was 48 h. The enzyme was purified by 85 % ammonium sulphate precipitation and DEAE-Cellulose ion-exchange chromatography. The purified enzyme was introduced to the cyanide-polluted water varying the conditions to assess the remediating ability. The pure enzyme had a specific activity of 0.0473 mg^{-1} with a purification fold of 4.56 and a percentage yield of 30.30 %. The Michaelis-Menten constants (Km) values of rhodanese from Klebsiella edwardsii for potassium cyanide and sodium thiosulphate were 50 mM and 200 mM respectively while their maximum reaction velocities (Vmax) were 0.56 RU/ml/min and 1 RU/ml/min respectively. The substrate specificity study showed the percentage utilization of the various substrates to be: 2-mercaptoethanol (33.7 %), ammonium persulphate (122.9 %), ammonium sulphate (178.3 %), sodium metabisulphite (67.5 %) and sodium sulphite (78.3 %). The enzyme demonstrated a broad pH range but the optimum pH was at 6.0 while the optimum temperature was 60 °C. The inhibition study on the enzyme by salts ($HgCl_2$, $MnCl_2$, $NiCl_2$ and $ZnCl_2$ and KCl) at concentrations 1 mM, 10 mM, 50 mM and 100 mM showed that the enzyme was inhibited by all the salts except for $HgCl_2$ at concentrations 50 mM and 100 mM. The results showed that the presence of rhodanese in the Klebsiella edwardsii suggests that the enzyme may possess functional cyanide detoxification mechanism necessary for the survival of the organism in the environment. Also, highest activity of rhodanese was achieved under optimum temperature and pH as well as using the polluted water as both cyanide and sulphate sources. The study therefore concludes that rhodanese can be used in a cheap and environmentally way to clean-up cyanide polluted water.

WP234 Can we improve extremely HM contaminated soil as habitat for E. fetida, using wood ash, biochar or humic substances?

M. Panova, M. Pukalchik, V. Terekhova, Lomonosov Moscow State Univ / Dept of Soil Science

Heavy metals are considered priority pollutants of environmental concern. But contrary to organic pollutants, HM cannot be degraded and thus constitute a persistent environmental hazard. We focus on chemical and ecotoxicology influence of Wood ash (WA), Biochar (BC, derived by pyrolysis of willows and poplars at 600C) and Humic substances – Lignohumate-K (LG) into fluviosoil. Native soil (NA) contained Zn 521±21 ppm, Cd 127.4±3.6 ppm, Cu 5.7±1.6 ppm, Pb 3035±26 ppm. A greenhouse pot experiment was carried out for 60 days. Soils were treated with different types and levels of amendments (2.8, 6 and 8.4% for WA; 0.05, 0.5 and 5% for BC; 0.05, 0.5 and 1% for LG) according to the final soil pH(CaCl2) value: 6.0, 6.5 and 7.0. Results revealed that Cd, Cu, Pb and Zn concentrations were significantly reduced in amended soils. WA showed the highest ability to immobilize HM. We observe the mobility decrease of 35% for Cd, 70% for Cu and 75% for Pb with no significant difference between amendment levels. For Zn 2.8%WA significantly reduced mobility to 47.49±4.18%, 6% WA to 55.13±3.00% and 8.4% WA to 69,12±7.44%. BC had no difference between levels immobilizing about 35% Cd, 65% Cu, 75% Pb, 50% Zn. LG showed the same results, but we point out that the lowest level of LG was the most efficient. NA soil showed the toxic effect on the E.fetida. Higher survival rate in amended with LG and WA soil indicated that remediation measures improved soil quality. BC treatments had a detrimental effect in soil toxicity, induced earthworms mortality, up to 100% after first 3 days. We also noted weight changing of earthworms body after 60 days. In NA and LG treated soil individuals had weightloss of 25-50% and 40-90%, while WA treatment leaded to 25% weight increase. Also, we estimated bioavailability of HM for E.fetida in contaminated soil with amendments of WA and LG. WA in 2.8% and 8.4% level reduced tissue concentration of Cu, Zn and Pb of about 40%. For 6% WA and all variants of LG no significant influence was observed. The results showed that mobility of HM can be reduced by all three amendments. But, BC and LG had negative ecotoxicological influence in the form of increased mortality and weight loss of E.fetida. We suggest that determination of the pollutants content is not enough to fully evaluate soil quality, because the ecotoxicological danger in the environment is not reflected by these factors. The research was supported by the RFBR project No.16-34-60011 mol_a_doc.

WP235 CO2 flux from oil contaminated intertidal sediments to evaluate in-situ biodegradation of oil: a mesocosm study

M. Kim, J. An, S. Ha, A. Loh, J. Jung, Korea Inst of Ocean Science and Technology / Oil and POPs Research Group; K. Kwon, Korea Inst of Ocean Science and Technology / Marine Life and Ecosystem Division; U. Yim, Korea Inst of Ocean Science and Technology / Oil and POPs Research Group

CO_2 fluxes were measured to monitor biodegradation of oil in mesocosms of oil contaminated sediments for 71 days. Mesocosms, placed in an intertidal zone exposed to semidiurnal tides, were constructed by mixing a given amount of crude oil with sediment from the site. Experimental groups include control (native microbes; NM), NM + fertilizer (F), NM + a commercial biological enzyme (ENZ), NM + a commercial nutrient based stimulant (STM), NM + activated carbon, F + effective microorganisms (EM), and F + a consortium of oil degrading microbes (ODM). Change of CO_2 concentrations in a closed chamber system was measured using an infrared gas analyzer to calculate CO_2 flux from the artificially contaminated sediments in each experimental group. On average, CO_2 evolution was highest in the F + ODM group (0.89 g CO_2 m^{-2} hr^{-1}), followed by NM + ENZ group (0.45 g CO_2 m^{-2} hr^{-1}) and F + EM group (0.38 g CO_2 m^{-2} hr^{-1}). Changes of CO_2 evolution were not obvious in the other groups. The highest flux was noticed at 4 days after the treatment in a NM + ENZ group (1.50 g CO_2 m^{-2} hr^{-1}) which was about six times higher than those from a control group (0.24 g CO_2 m^{-2} hr^{-1}). Thereafter, the CO_2 flux was decreased drastically and return to the level of control in 15 days after the treatment. In contrast, CO_2 evolution from the F + ODM group was maintained relatively high during the whole experimental period, with a maximum CO_2 evolution at day 23 (1.43 g CO_2 m^{-2} hr^{-1}). Maximum evolution in EM treatment was also observed at day 23. Initial effect was higher for the enzyme treatment but it diminishes quickly while the effects of microbe inoculations (ODM and EM) last relatively longer. The effects of the treatments were also confirmed by monitoring the changes of the concentration and composition of oil components in the sediments.

WP236 Competitive Adsorption of Reactive Black 5 Dye onto Sawdust of Parkia biglobosa

A. Giwa, Cape Peninsula Univ of Technology / Dept of Pure and Applied Chemistry; D.O. Aderibigbe, Ladoke Akintola Univ of Technology, Ogbomoso / Dept of Pure and Applied Chemistry; F. Wewers, Cape Peninsula Univ of Technology / Dept of Chemistry; I.A. Bello, M.A. Oladipo, Ladoke Akintola Univ of Technology, Ogbomoso / Dept of Pure and Applied Chemistry

The development and modification of existing processes for the abatement of pollutants in the environment is a continuous exercise. In this regard, the importance of wastewater treatment before its eventual discharge into the environment cannot be overemphasized. Adsorption process has been widely accepted as an efficient method, and research is ongoing on the possible application of agricultural residues as adsorbents in wastewater treatment. This study investigates the potential of Parkia biglobosa sawdust in removing Reactive Black 5 dye from aqueous solutions in single and binary dye systems. Several works have been conducted on the adsorption of reactive dyes but reports on their adsorption as a component of a mixture of dyes is scanty. The sawdust, collected from a local sawmill, was thoroughly washed, dried and characterized using Fourier Transform-Infrared (FT-IR) Spectrophotometer and Scanning Electron Microscope (SEM). Batch adsorption experiments were conducted to determine the effects of adsorbent dose, initial concentration and pH of the dye solution. Five isotherm models were employed in the interpretation of the equilibrium experiments. Kinetics and thermodynamics of the adsorption processes were also studied. The results indicate the presence of functional groups which could be potential adsorption sites for interaction with the dye on the sawdust. The kinetics of the adsorption in both single and binary systems could best be described by the Pseudo-second order model; and Langmuir gave the best fit for the equilibrium adsorption data ($R^2 > 0.94$). The maximum monolayer adsorption capacity of the adsorbent for the dye was low (2.21 mg/g) with no significant difference in the two systems. The adsorption processes in all the systems were spontaneous with DG becoming increasingly more negative (-0.15 to -2.81 kJ/mol) as temperature increases. The enthalpy change (ΔH) for the sorption in both systems was positive, indicating that the process was endothermic; the change in entropy (ΔS) was also positive an indication of increased disorderliness on the surface of the adsorbent.

WP237 Laser photo-stimulation of plants and microbes associated with plants, for better phytoremediation of heavy metal contaminated sites

B. Rimal, D.L. Carr, Texas Tech Univ / Biological Sciences; J.W. Dobrowolski, AGH Univ of Science and Technology / Environment Protection Engineering and Biotechnology

Empirically selected wavelengths and exposure times of low level lasers has resulted in immense possibilities of using plants for reclamation of degraded land masses and clean-up of contaminated water resources. Willow (Salix viminalis), which is one of the hyper-accumulator plants, used in the experiment, showed a remarkable increase in shooting and rooting, when the cuttings cultivated in hydroponic condition were photo-stimulated with low power lasers. Photo-stimulation with red beam Helium-Neon laser (power=20mW, wavelength= 660 nm) for 3 times at 10 seconds intervals after each 10 seconds irradiation followed by 3 times irradiation with blue beam Laser Diode (power=25mW, wavelength=514nm) for 3 seconds with 3 seconds pause after each irradiation was highly effective in increasing root and shoot growth. The increase in growth of plant parts, after laser irradiation, is attributed to an increase in the rate of adenosine triphosphate (ATP) production. The enhanced rate of energy production in plants and microbes associated with plants make them able to adapt and clean up the sites that are highly contaminated with heavy metals and environmental pollutants.

WP238 Metagenomic study of polystyrene degradation by meal worms

A. Navlekar, Texas Tech Univ; D.L. Carr, Texas Tech Univ / Biological Sciences

In the last 50 years, there has been a rapid increase in plastic usage in almost every sphere of life. Polystyrene (PS) or Styrofoam, as it's more commonly known, has been used in various products like cups and packing material and also as a raw material and solvent in the processing of polymers. Its uncontained production, constant daily usage and incorrect disposal have led to grave environmental problems including destruction of wildlife habitats, and bioaccumulation in food chains. Until very recently, it was assumed that polystyrene was non-biodegradable. A study conducted in 2015 showed the ability of meal worms to degrade polystyrene; the ability was attributed to their gut microbiome (Yang et al., 2015). The researchers concluded that the degradation must occur due to the secretion of enzymes by the gut micro-organisms. A metagenomic study focused on PS degradation and the gut microbiota has not been carried out to date. Mealworms, at different instars, were subjected to a diet of only Styrofoam for a period of 2 weeks and subsequently dissected to obtain intact guts. In order to determine the genomic content of the gut, rRNA was extracted, converted to cDNA and processed to acquire the 16S metagenome (for diversity and abundances). The bacterial v3 and v4 variable regions were used as primer targets during the sequencing. In this study we report on the metagenomic diversity and identification of the major as well as active species involved in the gut microbiota of mealworms with Styrofoam as their only food source compared to mealworms fed a normal diet. A change in diet reflects change in abundances of the microbial community (Ley et al., 2008) and the same was expected when the mealworm diet shifted from bran and oats to Styrofoam. Results from this study contribute to understanding of the functionality of this mixed community that enables it to degrade PS successfully. Applications for landfill management as well as plastic recycling, one of the most intractable problems of human society today are expected deliverables from this study.

WP239 Modeling reactive species transport within the electrochemical remediation process in a laboratory-scale flow-through reactor

S. Hojabri, Northeastern Univ; L. Rajic, Northeastern Univ / Civil and Environmental Engineering; A. Alshawabkeh, Northeastern Univ

Groundwater electroremediation involves applying direct current across electrodes immersed in groundwater to intercept and transform contaminants through direct and/or indirect oxidation and reduction reactions. The system undergoes significant changes in pH due to water electrolysis. Considering that pH is one of the most important parameters which controls reactions and influences the transformation mechanisms, a theoretical model can be a sufficient tool for understanding the change of pH during the process and adjusting the system for a full-scale implementation. However, developing new models is challenging due to multicomponent species transport. Here we present a theoretical model to describe pH changes during electrochemical processes with the use of inert (mixed metal oxide, MMO) anodes. Experimental data has shown that, pH within the system can alter within a wide range of 2 to 12. We developed the theoretical model which includes chemical reactions, water auto-ionization, and electrolysis to describe the dynamic changes in chemistry across the cell. The model accounts for direct electrolysis reactions of the species. The model study is considering different current reversal ratios and frequencies as well as different electrolyte concentration and composition. The model's output is compared with experimental studies where it showed a god correlation (R^2=0.7) between the theoretical results and observed data.

WP240 Morphological, physiological, biochemical and yield responses of lady finger grown on different MSW vermicompost amendment ratio

V. Srivastava, Banaras Hindu Univ / Environment Sustainable Development; R.P. Singh, Banaras Hindu Univ / Environment and Sustainable Development

Using municipal solid waste (MSW) vermicompost is one of the most promising and an alternative option for management of solid waste. A pot experiment was conducted to study the morphological, physiological, biochemical and yield responses of lady finger (Abelmoschus esculentus L.). MSW vermicompost (VC) was applied in four different amendment ratios (VC: Soil) viz. A (4:1), B (4:2), C (4:3) and D (4:4). Apart from that, plants were grown in soil as control and also in recommended dose of inorganic fertilizer (IF) for comparison. Total chlorophyll, carotenoid and protein content were reported to increase in all the amendments including 'IF' except 'A' as compared to control. Similarly, lipid peroxidation, peroxidase activity and proline content were also reported to increase significantly, particularly in A and B, however, thiol and phenol content decreased as compared to control in plants grown in different amendments. Photosynthetic rate (Ps) and stomatal conductance rate increased in different treatments except 'A' as compared to control. Likewise, total leaf area, specific leaf area, leaf area ratio, leaf weight ratio and total biomass increased in plants grown in different amendment ratios of MSW vermicompost except 'A' in comparison to control. In addition to this yield was also reported to increase in all the treatments except 'A' and 'B' with maximum increase in D (136.8%), which was followed by C (82.92%) and IF (38.59%). However, a decrease of 66.32% was noticed in 'A' which was followed by B (3.57%). The study concluded that MSW vermicompost may be good option for lady finger as plants has adequate tolerance mechanism showed by increased rate of photosynthesis and chlorophyll content, various antioxidant levels and yield (B, C & D). However, at higher dose of MSW vermicompost (A), plants growth decreased therefore, this dose is not recommendable for application of MSW vermicompo st in lady finger.

WP241 Performance of commercially available soil amendments for enhanced copper removal in bioretention media

M.T. Wilfong, Towson Univ; K. Hauser, D.R. Ownby, R.E. Casey, Towson Univ / Chemistry

Bioretention structures such as planter boxes, swales and rain gardens are being increasingly utilized in built landscapes as a strategy to attenuate both stormwater flows and contaminant loads. Copper roofing materials can contribute significantly higher mass loads of dissolved copper per unit area than other surfaces such as parking lots and roadways. While a recent study demonstrated that conventional bioretention media can remove over 90% of copper from copper roof runoff, the median discharged Cu concentrations from bioretention structures (66 μg L^{-1}) still did not achieve the lowest copper levels sought by some jurisdictions (< 14 μg L^{-1}). In this laboratory column study, three commercially available soil amendments, sold as fertilizers and soil conditioners, were evaluated for their ability to enhance the performance of bioretention media for copper removal. Biochar, greensand, and zeolite were tested; each of the amendments was prepared in both a layered and mixed treatment. Artificial stormwater containing 2000 μg L^{-1}Cu was added, to each column in 2.00 L increments using a peristaltic pump at 10 cm/hr flow rate to simulate natural rainfall. This pilot study demonstrated that the addition of these amendments generally promoted enhanced copper removal compared to the controls; however, greensand and zeolite tended to be more effective than biochar and layered treatments tended to be more effective than admixtures for greensand and biochar. The copper exports from the control ranged from 34-84 μg L^{-1} and amended columns typically exporting copper concentrations around 50% of the control. Extended duration column studies are ongoing for each of the soil amendments as both admixtures and treatments at varying ratios. Artificial stormwater containing 4000 μg L^{-1} Cu is being added in 2.00 L increments using a peristaltic pump at a 10 cm hr^{-1} flow rate to simulate maximum concentration and event volume conditions exhibited in a previous field study of runoff from copper roofing material. These studies utilizing biochar and greensand amendments have shown promising results. The biochar layered amendments consistently performed better than the control columns at both volume ratios and consistently achieved effluent concentrations below the 14 μg L^{-1} threshold. The greensand amendments were less consistent than biochar columns, with respect to performance compared to control; however, both greensand mixed amendments consistently achieved effluent concentration below the 14 μg L^{-1} threshold. The column study for zeolite is currently ongoing. In addition, cation exchange capacity is being determined for each treatment. Further studies will evaluate the most effective amendment, treatment, and volume configuration in a field study to determine effectiveness when subjected to runoff from copper roofing material.

WP242 Performance of Hybrid Pilot-scale Constructed Wetland Systems for Treating Oil Sands Process Affected Water from the Athabasca Oil Sands Area

A.D. McQueen, Clemson Univ / Dept of Forestry and Environmental Conservation; C.M. Kinley, Clemson Univ / School of Agricultural Forestry and Environmental Sciences; M. Hendrikse, Clemson Univ; D. Gaspari, Clemson Univ / Dept of Environmental Engineering and Earth Sciences; J. Rodgers, Clemson Univ / Forestry and Env Conservation; J. Castle, Clemson Univ / Environmental Engineering and Earth Sciences

Mining leases in the Athabasca oil sands area (AOSA; near Ft. McMurray, Canada) produce large volumes of oil sands process-affected water (OSPW) that contain potentially problematic constituents requiring treatment prior to surface water discharge into receiving aquatic systems. The aim of this research was to identify constituents of concern (COCs) in OSPW from an AOSA tailings pond and design hybrid pilot-scale constructed wetland treatment systems (CWTS) to mitigate risk to a sentinel aquatic species. COCs were identified based on comparisons to ambient water quality criteria for the protection of aquatic life (i.e. Canadian Environmental Quality Guidelines [CEQGs], Alberta Environment Water Quality Guidelines [WQGs], and United States Environmental Protection

Agency [USPEA] water quality criteria) and toxicity endpoints. Specific COCs identified in the OSPW include organics (naphthenic acids [NAs], oil and grease [O/G]), metals/ metalloids (Al, As, Cu, Ni, and Zn), and suspended solids. Characteristics of the OSPW are NA concentrations from 80 to 128 mg/L ("total" NAs quantified by HPLC), slightly alkaline, pH 7.91 to 8.45, and concentrations of metals/ metalloids exceeding numeric guidelines for protection of aquatic life. The hybrid pilot-scale CWTS were designed to promote treatment processes to alter (transfer and transform) the COCs using sequential reducing and oxidizing wetland reactors and a solar photocatalytic treatment reactor using fixed film titanium dioxide (TiO_2). Performance assessment of the hybrid pilot-scale CWTS used multiple lines of evidence, including rate and extent of COC removal and measured toxicity using the aquatic invertebrate Ceriodaphnia dubia. The CWTS decreased concentrations of NAs, O/G, and metals below performance criteria and decreased toxicity to C. dubia. Results from this study provide proof-of-concept data to inform hybrid passive or semi-passive treatment approaches (i.e. constructed wetlands) that could be used to mitigate COCs contained in OSPWs.

WP243 Performing Ecological Evaluations for Sites Under a Privatized State Remediation Program

K.B. Leigh, Ramboll Environ; J.G. Entin, C.M. Buzgo, Ramboll Environ US Corporation; M.T. Sorensen, Ramboll Environ / Senior Science Advisor

The privatization of contaminated site cleanup is a relatively new paradigm to streamline the investigation and remediation of an often overwhelming number of contaminated sites. Since Massachusetts initiated the first Licensed Site Professional (LSP) program in 1993, several other states have implemented similar programs, including New Jersey, with the Licensed Site Remediation Professional (LSRP) program, and Connecticut, with the Licensed Environmental Professional (LEP) program. Although the various programs privatize different aspects of environmental cleanup and some place significant restrictions on the types of sites eligible for management within each program, the overall goal of privatization is to reduce the contaminated site backlog within states and provide a cost effective approach to site closure. Site remediation programs typically require remedial approaches and remedies that are protective of both human health and the environment, which includes ecological resources and sensitive receptors. Under these programs, licensed professionals are obligated to reach conclusions regarding the protectiveness of remedies relative to both human health and ecological impact, and often without direct State involvement in decision-making. However, regulatory programs governing human health protection are typically well structured and mature, while the protocols for investigating potential impacts to ecological receptors are often less so. For example, while ecological screening criteria are generally available for surface water, sediment, and surface soil, few formal state-specific protocols exist to identify ecologically sensitive receptors, determine complete ecological exposure pathways, develop and use conceptual site models, and evaluate the availability of chemicals of interest to ecological receptors. Without these protocols, licensed professionals must rely on other agency or technical guidance, such as USEPA or NOAA, to develop testing, evaluation, and risk assessment approaches for ecological resources. These decisions require judgements that can result in inconsistently applied remedies. This presentation explores how ecological investigations are implemented under privatized remediation programs and highlights their strengths and weaknesses.

WP244 Polymer/biomass-derived biochar for use as a sorbent and electron transfer mediator in environmental remediation

S. Oh, Y. Seo, Univ of Ulsan / Dept of Civil and Environmental Engineering

Co-pyrolysis of polymer and biomass wastes was investigated as a novel method for waste treatment and synthesis of enhanced biochar. Co-pyrolysis of rice straw (RS) with polypropylene (PP), polyethylene (PE) or polystyrene (PS) increased the carbon content, cation exchange capacity (CEC), surface area and pH of the biochar. As a result, the sorption of 2,4-dinitrotoluene (DNT) and Pb to polymer/RS-derived biochar was markedly enhanced. The increased aromaticity and hydrophobicity may be responsible for enhancing the DNT sorption to the polymer/RS-derived biochar. In contrast, increasing CEC, higher pH, and the newly developed surface area may account for the enhancement in Pb sorption. The addition of polymer to RS did not significantly change the catalytic role of biochar during the reduction of DNT by dithiothreitol. Our results suggest that co-pyrolysis of RS and polymer can improve the biochar properties to enhance the sorption of DNT and Pb.

WP245 Redox transformation of explosives in contaminated soils using Fe-bearing materials: Kinetics and toxicity of treated soils

S. Oh, Y. Seo, Univ of Ulsan / Dept of Civil and Environmental Engineering

The oxidative and reductive transformation of nitro explosives in contaminated soils was examined via batch experiments conducted with Fe-bearing materials. Zero-valent cast iron (Fe(0)), steel dust from a steel manufacturing plant, and FeS can rapidly reduce 2,4,6-trinitrotoluene (TNT) and hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) in soil under anaerobic conditions as long as a sufficient amount of water is present. Fe-bearing materials can also effectively activate persulfate ($S_2O_8^{2-}$) so as to enhance the oxidative transformation of TNT and RDX in soil-water systems. Kinetically, reductive and oxidative transformations led to the removal of more than 90% of the explosives from a soil-water system within 5 h under the given conditions. Pseudo-first-order rates in the range of 0.7 – 23.4 h^{-1} were observed. By increasing the concentration of persulfate or Fe-bearing materials, the oxidative transformation could be promoted. Treated soils via redox reactions using Fe-bearing materials did not show significant toxicity, except for the case of TNT-contaminated soils oxidized by FeS-activated persulfate. Considering the kinetics of explosive degradation and the toxicity of treated solutions and soils, Fe(0) or steel dust-activated persulfate oxidation may be a favorable option as an ex-situ remediation process for the treatment of explosive-contaminated soils.

WP246 Stabilization of Heavy Metals in Mine Tailings Using Basic Oxygen Furnace (BOF) Slag

S. Jeong, Korea Basic Science Inst; S. Kim, Seoul National Univ / Civil and Environmental Engineering; K. Nam, Seoul National Univ / Dept of Civil and Environmental Engineering

Mine tailings contain several toxic contaminants, including heavy metals, and the potential is high for deterioration of ecosystems. Inorganic stabilization/solidification processes have been studied to reduce the solubility of heavy metal in mine tailings using binders such as cement, lime, and fly ash. This study considered the possibility of applying stabilization technique to the treatment of mine tailings, using basic oxygen furnace (BOF) slag. The efficiency for stabilization of heavy metals in mine tailings using BOF slag was also evaluated to find the optimum condition. Two mine tailings were used in this study: neutral mine tailing and alkaline mine tailing. The neutral mine tailing (pH 7.0) were highly contaminated with Cu, Zn, Pb, and As, and relatively large amounts of heavy metals leached. Most of heavy metals in the alkaline mine tailing (pH 9.2) were already being stable form, thus did not need to be stabilized. The mineralogical constituents of BOF slag were about 38% of CaO and 29% of Fe_2O_3. Batch slurry test was with 0.5, 3, 5, 10 wt% of BOF slags mixed with 5 g of mine tailings under different moisture contents (i.e., 0.05, 0.1, 0.2, 0.35, 0.5, 0.75, 1 L-water/kg-mine tailing). After agitating for 24 hours under room temperature, and dried in the 65°C oven, then leached by TCLP method to determine the stabilization efficiency. For neutral mine tailings, 10% of BOF slag showed the highest efficiency for cation heavy metals such as Cu, Zn, and Pb (57, 32, 98% of stabilization efficiency, respectively), while 5% of BOF slag did for anion heavy metal including As (81% of stabilization efficiency). Cation heavy metals were highly stabilized with the water holding capacity of mine tailing (0.2 L/kg) under 5 and 10% BOF slag added condition. In the case of As, there was a tendency to be higher stabilization efficiency with decreasing water contents. These differences in optimum condition between cation and anion heavy metals may be due to different stabilization mechanisms. To identify the stabilization mechanism, SEM-EDS and XPS analysis are carried out, and the stabilization efficiency using blast furnace (BF) slag which has a different mineralogical constituents with BOF slag (i.e., about 45% of CaO and 0.8% of Fe_2O_3) was also compared to investigate further mechanism for heavy metal stabilization.

WP247 The re-use of foundry sand by composting – laboratory-scale experiments

O. Penttinen, Univ of Helsinki / Faculty of Biological and Environmental Sciences; J. Pollari, Univ of Helsinki / Dept of Environmental Sciences

In Europe, around 18 M tons of foundry waste sand is left over from industrial activities every year, and in many cases big landfills do not have the capacity to deal with it. In addition, transport costs to landfills are increasing and alternative ways of treating foundry waste in an environmental friendly way have to be found. To address this, a LIFE Foundrysand project (LIFE13 ENV/FI/2855) piloted a study on how foundry sand waste can be cleaned and hazardous organic substances degraded through novel biological methods. Here we focus on short-term laboratory scale experiments that were run parallel to field scale composting experiments using four different foundry sand types (green, furan, phenolic and their mixture) and composting materials. A 220 L compost system was constructed that consisted of 20-30 % of a foundry sand type and organic materials like wood chips from deciduous trees, horse manure and waste water sludge. The composting process was followed thrice over a period of 8 week by taking samples for chemical and biological analyses, including metals, PAH compounds, fluoride, chloride, sulphates, phenol index, BTEX, DOC, total and soluble N and P, and pathogens (E.coli and Salmonella). Foundry sand specimens showed major differences in their chemical characteristics. Furan sand had the lowest pH and the highest DOC concentration. Phenolic sand had the highest phenol index. Green sand had the highest metal and fluoride concentrations, and a relatively high BTEX level. Our results demonstrated a decrease of the total concentration of PAHs during the experiments. The concentrations of naphthalene, phenanthrene and anthracene were the highest among the 16 PAH compounds analyzed. Fluoride and phenol concentrations were clearly reduced during composting. There were no time-related changes in concentrations of metals, nutrients or BTEX. Salmonella was not detected but E. coli was present i (>1000 cpu/g) in all foundry sand treatments at the end of the experiments. From cleanup and re-use perspectives, our laboratory-scale experiments were only partly successful. Waste water sludge used in the composting was challenging agent because it is characterized by high concentrations of DOC, sulphates and phenols. At the end of the composting tests, these concentrations were above the guideline values, demonstrating an unsuccessful composting process. The final concentration of fluoride and the presence of the pathogens were additional negative indicators.

WP248 Understanding and Evaluating Ecosystem Services at Superfund Cleanups

J. Lipps, USEPA / Office of Superfund Remediation and Technology Innovation; M.J. Kravitz, USEPA / Office of Research & Development/ NCEA; C. Pachon, USEPA / Office of Superfund Remediation and Technology Innovation; K. Lynch, USEPA / Office of Research and Development Office of Science and Policy

Ecosystem services (ES), briefly defined as the contributions of ecosystems to human well-being, are affected by contaminant stressors in the environment and by site remediation activities. Quantifying changes in ES which result from remedial action can inform site management decisions and can show how cleanup supports future ES provisions. This research project utilizes publicly available ES evaluation tools to identify and measure ES endpoints at two pilot Superfund sites representing different ecosystems and scales (a rural watershed-scale setting in the Rocky Mountain west, and a smaller urban setting in the northeastern U.S.). It also highlights how the ES evaluation may be integrated into the ecological risk assessment process. Input for the ES evaluation was derived from land cover maps, reuse planning documents, stakeholder discussions, site visits, and other existing data. The evaluation can help site teams examine relationships between remedial actions and ES, and select best management practices to minimize damage to or improve ES during remedy construction. Evaluation results provide a baseline for any ecological restoration efforts when the pilot sites go into the reuse phase. Outcomes from the pilot sites' evaluations will be codified into a replicable protocol or methodology for ES evaluation at other Superfund sites. Moreover, the ES evaluation protocol will be integrated into Superfund's green remediation strategy. The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the U.S. Environmental Protection Agency.

WP249 Visual Field Characterization of NAPL in Sediment Cores: Developing Standardized Tools Relevant to Assessment and Remediation

M.C. Ciarlo, EA Engineering, Science, and Technology; J. Beaver, F. Barranco, R. Short, J. Klassen, M. Gelinas, EA, Engineering, Science, and Technology, Inc. PBC

Non-Aqueous Phase Liquids (NAPL) are a frequent target of investigation and remediation for sediment sites contaminated with coal tar, creosote, fuel oils, and other hydrocarbons. In some cases cleanup is required for any sediments containing visually observed NAPL. Such an approach places great importance on the methods used to record observations of NAPL in the field. This approach also differs from that taken for remediation of NAPL in soils, which often differentiates between mobile and residual NAPL. The two-fold purpose of this study is to 1) define the challenges associated with documenting visual presence of NAPL in sediment cores and 2) identify tools that can be used to standardize terminology, field screening methods, and documentation techniques such that they are more relevant to remediation. This study draws from numerous case studies. The study begins by describing typical settings in which NAPL is encountered in sediment and how these settings challenge visual characterization. Based on these settings, simple models of contaminant contribution are developed for several types of NAPL; these models relate NAPL volume and distribution to concentration-based metrics of toxicity and mobility. The study then sets forth tools that can be used to standardize field characterization of NAPL in a way relevant to management of toxicity and mobility. These tools include a framework of terminology that consistently captures NAPL volume and distribution patterns; core collection, processing and photographic methods that minimize impacts of disturbance and maximize visibility of NAPL indicators; screening techniques that help distinguish NAPL from surrounding sediments; and documentation procedures that capture information key to remedial planning. The study identifies recommendations for field characterization methods and potential follow-on work.

Terrestrial or Wildlife Toxicology and Ecology – Poster Only

WP250 Accumulation features of organohalogen compounds and their hydroxylated metabolites in pet cats and dogs: effects on thyroid hormones homeostasis

K. Nomiyama, Y. Yamamoto, Ehime Univ / Center for Marine Environmental Studies; H. Mizukawa, Hokkaido Univ / Graduate School of Veterinary Medicine; A. Eguchi, Chiba Univ / Clinical Cell Biology and Medicine; S.M. Nakayama, Y. Ikenaka, M. Ishizuka, Hokkaido Univ / Graduate School of Veterinary Medicine; T. Kunisue, S. Tanabe, Ehime Univ / Center for Marine Environmental Studies

The present study determined the levels and accumulation patterns of PCBs, PBDEs, and their metabolites (OH-PCBs, OH-PBDEs, and MeO-PBDEs) in the blood of pet cats and dogs collected from a veterinary hospital in Japan. Furthermore, in order to assess the effects of contaminants in pet cats and dogs, we also examined relationships between the levels of organohalogen compounds and serum thyroid hormones levels analyzed using LC-MS/MS. Median concentrations of PCBs (wet weight) in the cat serum (290 pg g^{-1}) were higher than in dog serum (54 pg g^{-1})

in Japan. OH-PCBs were detected in all serum samples of both dogs and cats (median: 120 pg g^{-1} for dogs and 93 pg g^{-1} for cats). The congener profiles of the OH-PCBs were different for dogs and cats, 3-5Cl OH-PCB congeners (particularly 4′OH-CB18, 4OH-CB25/31/4′OH-CB26) in the cat blood accounted for approximately 90% of the OH-PCBs. In contrast, 5-8Cl OH-PCBs (in particular, 4OH-CB199 and 4OH-CB202) in the dog blood accounted for >90% of the OH-PCBs. Median concentrations of PBDE (wet weight) in the cat serum (630 pg g^{-1}) were higher than in dog serum (150 pg g^{-1}) in Japan. Especially, deca-BDE was the predominant homologue, accouting for 60% of total PBDEs concentrations. Concentrations of OH-/MeO-PBDEs in the serum of dog serum were below the LOQ. On the one hand, OH-/MeO-PBDEs were detected in all the cat serum samples. The major congeners of OH-/MeO-PBDEs identified in both pet food products and blood were natural products (6OH-/MeO-BDE47 and 2′OH-/MeO-BDE68) from marine organisms. In particular, higher concentrations of 6OH-BDE47 than 2′OH-BDE68 and two MeO-PBDE congeners were observed in the cat blood, although MeO-BDEs were dominant in cat foods, suggesting the efficient biotransformation of 6OH-BDE47 from 6MeO-BDE47 in cats. T4, T3 and reverse T3 (rT3) levels showed significant negative correlations with PBDEs and OH-PBDEs concentrations in regression analyses ($p< 0.01$). Especially, DecaBDE was the most affecting isomer for T4, T3, rT3 and free T3 levels, suggested disruption of TH homeostasis. These relationships suggest that the decrease in the levels of T3 and rT3 in the serum of pet cats accompanied with suppression of the T4 in thyroid gland was induced by decaBDE, because T3 and rT3 are produced by the deiodination of T4.

WP251 Assessing Toxicogenomic Effects of 17β-Trenbolone on the Japanese Quail Hypothalamic-Pituitary-Gonadal-Liver Axis

K. Mittal, McGill Univ / Dept of Natural Resource Sciences; B.M. Armstrong, Michigan State Univ / Fisheries and Wildlife; P. Henry, Chesapeake Potomac Regional Chapter; C.A. Murphy, Michigan State Univ / Fisheries and Wildlife; N. Basu, McGill Univ / Dept of Environmental Health Sciences; N.K. Karouna-Renier, USGS Patuxent Wildlife Research Center / Beltsville Lab

Trenbolone-acetate is a synthetic anabolic steroid used as a livestock growth promoter. The breakdown product, 17β-trenbolone (17βT), is a known endocrine disruptor; elevated concentrations of 17βT have been reported in solid dung collected from livestock farms. To date, only a limited number of studies have looked at effects of 17βT in birds. Those studies examined sub-lethal effects on the reproductive organs of Japanese quail (JQ) along the hypothalamic-pituitary-gonadal-liver (HPGL) axis and reported reduced numbers of maturing yolk follicles, lowered egg production, decreased plasma testosterone concentrations and changes in mRNA expression of relevant genes such as vitellogenin (VTG). However, these past studies with adult JQ examined only one time point and late in development: 13 weeks post exposure. This missed the initial or earlier exposure period, which might be critical for determining whether the animal compensates for the exogenous endocrine stress, or whether the biochemical/genomic response is inadequate, thereby resulting in adverse effects on reproduction. Furthermore, these previous studies did not look at which changes along the HPGL axis could be specifically linked to changes in egg production. The objective of our research was to build upon previous studies, add 17βT to the adult JQ's diet, and collect samples from the birds on days 3, 7, 14 and 21 allowing us to focus on earlier exposure windows. We analyzed plasma steroid hormone and VTG concentrations, and mRNA expression of HPGL genes such as VTG, 17β-hydroxysteroid dehydrogenase, luteinizing hormone receptor, and CYP19A1, to further characterize the toxicogenomic effects of 17βT on the adult JQ endocrine system. Finally, we determined which changes in these biomarkers can be linked to egg production in JQ and which endpoints are good indicators of egg number and quality. Data collected from this study will also be used to parameterize a computational model that simulates the avian female HPGL axis and vitellogenin production, and relates these biomarkers to the reproductive cycle as well as ecologically relevant endpoints, important for natural resource management and risk assessment.

WP252 Assessment of phytotoxicity (Raphanus sativus and Oryza sativa) of sulfuric acid and nitric acid introduced into agricultural soil by chemical spill

M. Park, S. Hyun, Korea Univ / Dept of Environmental Science and Ecological Engineering

In Korea, about 44,000 chemicals are used in various chemical industries and transported countrywide. In 2015, 111 chemical accidents occurred and most of the incidents were related to leaks and spills of chemicals from the chemical industry complex or transporters, which can impact nearby soil and terrestrial ecosystem including crops. We assessed phytoxicity of sulfuric aicd (H_2SO_4) and nitric acid (HNO_3), designated as the accident preparedness substances by Korea ministry of environment, contaminated soil using radish (Raphanus sativus) and rice (Oryza sativa), major crops cultivated in Korea. We followed OECD guidelines 208 and 227 for assessing phytoxicity of the chemicals for radish and rice, respectively. Concentrations of the chemicals in aqueous solutions are designated 5 levels including blank. Radish seed were planted in the test soil mixed with the chemical solutions homogeneously and we estimated germination rate and shoot biomass after the test period. We transplanted rice seedlings non-contaminated test soil in pot and the chemical solutions were sprayed into the soil surface. After the test period, we estimated mortality and shoot biomass of the rice. We calculated the toxicity value on the basis of the endpoint observation and measurement during the test period.

WP253 Characteristic for biotransformation of polychrolinated biphenyls in cats

H. Mizukawa, Hokkaido Univ / Environmental Veterinary Sciences; M. Maehara, N. Yokoyama, O. Ichii, M. Takiguchi, Hokkaido Univ / Graduate School of Veterinary Medicine; K. Nomiyama, Ehime Univ / Center for Marine Environmental Studies; H. Nishikawa, Ehime Univ / Center for Marine Environmental Studies CMES; Y. Ikenaka, S.M. Nakayama, Hokkaido Univ / Graduate School of Veterinary Medicine; K. Takaguchi, S. Tanabe, Ehime Univ / Center for Marine Environmental Studies; M. Ishizuka, Hokkaido Univ / Graduate School of Veterinary Medicine

Hydroxylated polychlorinated biphenyls (OH-PCBs) are formed by the oxidative metabolism of PCBs and PBDEs by cytochrome P450 (CYP) monooxygenase enzyme systems. Our previous study showed congener profiles of OH-PCBs in the blood of cats were totally different from other terrestrial mammals. It is suspected that the thyroid hormone homeostasis is disturbed by these hydroxylated metabolites because of structural similarity with thyroid hormone. However, there are only a few studies on metabolic capacity in cats, and there are many unclear points about the toxic effects and risks of chemical exposures. In this study, we exposed PCBs as model compounds to cats, and analyzed hepatic enzyme activity and gene expressions to collect the foundational information about the metabolic mechanism in cats. Finally, we expect the toxicological effects for thyroid hormone. Difference of residual pattern between high and low chlorinated biphenyls was found. Comparing the results with a similar in vivo experiment conducted in dogs in previously, interspecies differences were found. We also analyzed the change of hepatic enzyme activity and gene expressions of the exposed cats. No change of the activities of the glucuronosyltransferase and sulfotransferase enzymes was detect, although AROD activity (EROD, MROD and PROD activities) was increased, which indicates that the PCBs exposure does not affect the conjugation ability in cats. Also, the expression levels of the CYP1A1 and 1A2 genes were increased, suggesting they were inducted. The expression of the CYP2B genes was unanalyzed because of lack of data base of cats. This study is suggesting PCBs absorption, metabolism and excretion ability of cats differ from dogs, and cats have a higher risk of toxic effects from low-chlorinated OH-PCBs. Especially, it is concern that affects to thyroid hormone homeostasis such as the depressed thyroid hormone levels of cats by PCB exposure, and thus disruptions of thyroid function.

WP254 Characterization of the Effects of Selenium on the Lipid Profiling Induced by Phenyl Mercuric Acetate Exposure in Caenorhabditis elegans

S. Jamadar, Texas Southern Univ / Dept of Environmental Science and Technology / Environmental Toxicology; F. Abdel-Rahman, Texas Southern Univ / Dept of Biology; M. Saleh, Texas Southern Univ / Chemistry Dept

Mercury (Hg) compounds exposure from environmental and food sources is a significant threat to public health. Studies showed that alkyl compounds of mercury, such as Phenylmercury acetate (PMA) can cause serious damage to the nervous system with sensory and motor deficits syndromes. Recent Caenorhabditis elegans (C. elegans) studies showed that chronic exposure to mercury compounds induces neuron degeneration likely due to the increase in reactive oxygen species (ROS). Selenium (Se) is an essential trace element required for activation of many antioxidant enzymes that have pivotal roles in the brain and endocrine tissues. Accordingly, Se is capable of both decreasing deposition of Hg during co-exposure possibly due to the high affinity between Hg and Se, and reducing the ROS level by activating antioxidant enzymes. In this study, C. elegans utilized as an efficient model system that helps to identify the effect of PMA on the lipid profiling as a proven model for lipid metabolism research. In addition, It can help to reveal the mechanism by which Se associated enzymes may inhibit the toxic effect of PMAby reducing the level of ROS, which reversing oxidative damage in the nervous system. The methodology involved acute and chronic exposure to concentrations of PMA on growth media to investigate the effect of PMA on the lipid profile of C. elegans. Lipid profiling is analyzed by using high-resolution gas chromatography/accurate mass quadrupole time of flight mass spectrometry (GCMS-QTOF). Additionally, the methodology included assessing the oxidative damage of PMA on C. elegans, which involved the probe; 2, 7 – Dichlorodihydrofluorescein diacetate (DCFH-DA). Fluorescence was measured using Spectrofluorometer at excitation 430nm and detection 530nm. Our results suggest that fatty acids profiling, the building block for lipids, may serve as a biomarker for both exposure and effects of environmental toxicant and stress. By utilizing chemical ionization GCMS with accurate mass of the molecular ions we identified the fatty acids profiling of the C. elegans particularly the polyunsaturated fatty acids of the omega 3 type (n-3 PUFAs) such as the C20:5 n-3 and C20:4n-3 which comprising 13.4 % and 2.8% of the total fatty acids in C. elegans respectively. Moreover, results showed a positive relationship between increased concentrations of PMA and the level of ROS in the exposed C. elegans,which eventually affected the fatty acids profiling of C. elegans.

WP255 Comparative in vitro Sensitivity of Amphibian and Mammalian Acetylcholinesterase to Inhibition by Organophosphorus Inhibitors

T. Anderson, Oklahoma State Univ / Integrative Biology; C. Pope, J. Liu, Oklahoma State Univ / Physiological Sciences; S.T. McMurry, Oklahoma State Univ / Integrative Biology

Organophosphosphorus compounds (OPs) are used extensively as pesticides worldwide. The acute toxicity for OPs is initiated by inhibition of the enzyme acetylcholinesterase (AChE), leading to accumulation of acetylcholine and disruption of cholinergic signaling throughout the nervous system. A number of studies have reported that amphibians are less sensitive to acute OP toxicity compared to mammals, but the basis for these differences is unclear. Understanding differences in sensitivity to OPs could potentially provide insight into phylogenetic differences in AChE and cholinergic signaling as well as aid in risk assessment. This study compares the in vitro sensitivity of amphibian (Anaxyrus cognatus) and mammalian (Mus musculus) brain and liver AChE to inhibition by paraoxon and chlorpyrifos oxon, the active metabolites of the pesticides parathion and chlorpyrifos. Enzyme sensitivity was evaluated by pre-incubating brain or liver homogenate with one of a range of paraoxon or chlorpyrifos-oxon concentrations (0.001 – 100 µM, 20 min, 37°C), prior to adding substrate (acetythiocholine, 1 mM final) and measuring residual activity. In all cases, AChE in amphibian tissues was markedly less sensitive to inhibition in vitro. The IC_{50s} (concentration that inhibits 50% of enzyme activity) for paraoxon were 275-fold higher (5.3 vs. 0.019 µM) in amphibian brain and 175-fold greater in amphibian liver (8.3 vs. 0.047 µM) compared to that in mammalian tissues. Similar but less extensive differences were noted with chlorpyrifos oxon, i.e., the IC_{50s} for amphibian brain and liver AChE were 31- (136.5 vs. 6.4 nM) and 3-fold higher (128.8 vs. 44.8 nM) than those in the respective mammalian tissues. Substrate kinetics of AChE from the brain and liver in both species were also evaluated. V_{max} was similar between species and tissues, and K_m for liver AChE was also similar between the species. The K_m for mammalian brain AChE, however, was 4-fold lower than that in amphibian brain (0.052 vs. 0.23 µM). These data suggest that phylogenetic differences in AChE and relative sensitivity to OP inhibitors may contribute to observed species differences in acute OP toxicity.

WP256 Compared effect of isolated and combined pesticides on the survival rate in workers of Africanized Apis mellifera (Hymenoptera: Apidae)

C.E. Domingues, Univ Federal de São Carlos UFSCar Sorocaba; R.A. Barbosa, UNESP Rio Claro / Departamento De Biologia; E. Silva-Zacarin, Univ Federal de São Carlos – UFSCar – Sorocaba / Biology

Bees are important pollinating insects and contribute to the maintenance of most natural and agro-ecosystems. However, bees are being affected by different environmental stressors such as habitat fragmentation associated with the increase in intensive agriculture and, consequently, exposure to pesticides on field might be causing the decline of their populations. This study aimed to analyze the effect of thiamethoxam insecticide and picoxystrobin fungicide, isolated and in combination, on the survival rate of Africanized honeybee. Toxicological bioassays by continuous oral exposures were performed with newly-emerged workers (20 individuals in triplicate per group) that were divided in control, solvent-control and the exposed groups: thiamethoxam 1ppb (TXT); picoxystrobin 18ppb (PXT); and TXT+PXT (0,5ppb and 9ppb, respectively), which simulated the dilution of these pesticides in intra-colonial conditions. During oral exposures, two conditions were tested: (I) food with pesticides was offered ad libitum during five days with subsequent substitution by a pesticide-free food until the end of the bioassay; (II) food with pesticides was offered ad libitum during the whole time of bioassay, i.e. twenty-five days. Mortality was recorded daily and survival rates were performed at the end of experiments by means of Kaplan-Meier Survival Analysis: Log-Rank. At the condition I, the results of survival rates showed decreased longevity of bees only for the groups exposed to PXT and TXT+PXT compared to the control group. In the PXT group, bee longevity was reduced to 42.6%, whereas in TXT+PXT group the longevity decreased 23.4%. After twenty-five days of exposure (condition II), the results showed decreased longevity of bees in the groups exposed to TXT, PXT and TXT+PXT compared to the control group. In the TXT group, longevity was reduced to 46.8%, with PXT it decreased 51.7%, whereas TXT+PXT group the longevity decreased 47.8%. Comparing the two tested conditions, oral continuous exposure to sublethal concentrations of pesticides for the period of twenty-five days induced the greatest negative impact on the survival rate of honeybees. Concluding, the results showed the risk of the continuous exposure at sublethal concentrations of these pesticides, indicating that the intra-colonial exposure through food can affect the performance of individuals and, consequently, the homeostasis of the colony.

WP257 Copper toxicity in tropical soil

T. Corrêa, Univ de Sao Paulo / Soil Science; E.J. Cardoso, F. De Lara, Univ of São Paulo USP / Dept of Soil Science

Copper is a heavy metal, widely used in the electrical industries and construction, so its presence in the air, water and soil has increased considerably. Copper is considered an essential micronutrient, once it plays an important role in photosynthesis, respiration, perspiration, detoxification, lignification and nitrogen fixation. However, excess of this metal may harm the environment, resulting in reduction of metabolic processes as photosynthesis and growth, reducing the diversity of molds and decreasing the reproductive capacity of animals. The aim of this study was to evaluate the acute and chronic toxicity of copper to the earthworm Eisenia andrei, in two kinds of tropical soils, clayey and sandy, and in an artificial tropical soil (TAS). The TAS was prepared with sand, kaolin and cocoanut fiber, in a proportion of 7:2:1 (w:w:w), respectively. The tropical soils were sampled in areas free of agrochemicals. Copper was incorporated into the soil in the form of a copper nitrate solution prepared with distilled water using eight concentrations, which were 0; 50; 100; 200; 400; 800; 1600 and 3200 mg kg^{-1}, in a volume of water needed to reach 60% of the soil water holding capacity. All the survival and reproduction tests were done with four replicates, using circular plastic containers with approximately 700 g of contaminated soil, 5 g of defaunated horse manure and 10 clitellate worms with an individual body weight of 250-600 mg. Weekly, the humidity was measured and food was provided. The acute toxicity test lasted 28 days with evaluation on the 14th day. The chronic test lasted 56 days with evaluation on the 28th day. Soil parameters as pH, texture, organic matter, copper and cation exchange capacity also were determined in the soils. The sandy soil contained 895 g kg^{-1} of total sand, and presented a pH of 3.9 and 1.5 mg dm^{-3} of copper. The clayey soil presented 295 g kg^{-1} of total sand, pH 4.1 and 1.5 mg dm^{-3} of copper, while the TAS was composed of 810 g kg^{-1} of total sand, with a pH of 5.5 and 2.9 mg dm^{-3} of copper. The LC_{50} and EC_{50} values obtained were 348 and 61 mg kg^{-1} for the sandy soil, 800 and 70 mg kg^{-1} for the clayey soil and 802 and 64 mg kg^{-1} for the TAS. Thus, the acute and chronic toxicity were higher in sandy soil. The lower toxicity observed in clayey soil and TAS probably are due to a higher CTC of the soil, since the smaller particles help to retain copper in the soil, thereby decreasing the bio-available amount.

WP258 Cross omics analysis for PCBs toxicity in the dog brain -Effect on mitochondrial functions-

K. Takaguchi, K. Nomiyama, Ehime Univ / Center for Marine Environmental Studies; C.M. Lauan, Ehime Univ / Center for Marine Environmental Studies CMES; J. Yoo, Ehime Univercity / Center for Marine Environmental Studies CMES; H. Mizukawa, Hokkaido Univ / Environmental Veterinary Sciences; H. Iwata, CMES, Ehime Univ / Center for Marine Environmental Studies; T. Kunisue, S. Tanabe, Ehime Univ / Center for Marine Environmental Studies

Recent studies reported that polychlorinated biphenyls (PCBs) and their hydroxylated metabolites (OH-PCBs) affect the brain nervous system. Dogs are known to have high metabolic capacity toward PCBs and thus may accumulate higher amounts of OH-PCBs in their brain and are potentially at high risk from these compounds. However, there are few studies on the adverse effects of PCBs and OH-PCBs in the brain. The present study performed proteomic and metabolomic analysis of dog (Canis lupus familiaris) brain following PCB exposure. Adult (5-7 months old) male beagle dogs were divided into 3 groups (n=3 each): G1 treated with vehicle control, G2 with PCBs mixture (IUPAC No. 18, 28, 70, 77, 99, 101, 118, 138, 153, 180, 187, and 202). The administration test was performed according to the guideline approved by The Institutional Animal Care and Use Committee. After 5 days of administration of PCBs, all dogs were euthanized and brain samples were collected. In two-dimensional gel electrophoresis, we found 19 significantly up-regulated and 21 down-regulated spots in the G2 and 33 proteins were identified by using MALDI-TOF-MS. In metabolomics, 198 metabolites were detected in the dog brain. Subsequently, partial least squares regression analysis was used to select factors affected by PCBs or OH-PCBs in the brain. 14 (1 positive and 13 negatives) and 21 metabolites (1 positive and 20 negatives) were correlated with the concentrations of PCBs and OH-PCBs, respectively. These metabolites were those involved in mitochondria functions such as urea cycle and glycolytic system/gluconeogenesis. In addition, ATP and ADP were significantly down-regulated by PCB exposure. Proteomic analysis showed a decrease of NADH dehydrogenase [ubiquinone] 1 alpha subcomplex subunit 8 (NDUFA8); which is one of the protein constituents of complex I in the inner mitochondrial membrane. Complex I transfers electrons from NADH to the respiratory chain and simultaneously creates a proton gradient across the inner membrane that powers complex V to generate ATP. Therefore, proton gradient might be disrupted. PCB exposure also down-regulated the expression of proteins related to mitochondria functions including ACSBG1, HADHA and SLC25A12. These results suggest that PCBs and/or OH-PCBs might inhibit mitochondria functions in the brain.

WP259 Declining surf scoter populations in Puget Sound: Capturing the signal from multiple sublethal endpoints

M.L. Brooks, Biogeochemistry and Conservation Biology / Zoology; J.H. Behnke, Kauai Seabird Habitat Conservation Program; E.M. Anderson, British Columbia Inst of Technology; J.R. Lovvorn, Southern Illinois Univ Carbondale

North American populations of surf scoters (Melanitta perspicillatta) and white-winged scoters (Melanitta fusca) have declined approximately 60% over the last 40 years. Food resources, selection, and availability explain some but not all of the population decline. It is intuitively clear that coping with contaminants redirects resources from growth and reproduction, affecting fitness and ultimately, population dynamics. Thus, we hypothesized that accumulation of cadmium, mercury, and selenium in kidney and liver predict body condition. Adult males were collected in December 2005 and March 2006 from three Puget Sound locations. Response variables included four aspects of body composition (mass, lipid, protein, ash) and three plasma metabolites (triglycerides, butyrate, and uric acid). Both predictor and response variables had non-normal distributions with unequal variances. Using the software PRIMER-E, we present the novel approach of several using multivariate, permutational methods. More importantly, we were able to integrate the seven response variables into "signature" centroids that were unique for each individual. Overall, scoters in this study contained low contaminant levels below those that cause pronounced damage in mallards. All sea ducks trended to lower mass and generally poorer body condition in spring. Distance-based Linear Models (DistLM) showed that among Surf Scoters, Se and Cd in liver and kidney explained 21% of the variance in their body condition. DistLM further showed that despite seemingly high correlations with Cd and Se in an ordination analysis, these contaminants did not significantly explain body condition in White-Winged Scoters. Surf Scoters are approximately 60% smaller than White-Winged Scoters. Smaller species have increased basal metabolism, higher costs of thermoregulation and locomotion, and store less energy. Distinct interspecific response to contaminants is consistent with greater diversion of resources from body condition. Subtle sublethal responses among surf scoters indicate the need for innovative statistics that capture what is ultimately a substantial amount of variation in their body condition, which is analogous to reproductive fitness. Such improvements in signal recognition provide critical insights into the contribution of sublethal stressors to population declines.

WP260 Dermal Uptake of Organic Contaminants by Amphibians Based on Location of Exposure and Hydrophobicity of Contaminant

W.H. Mimbs, Oklahoma State Univ / Zoology; P.W. Cusaac, S.T. McMurry, J.B. Belden, Oklahoma State Univ / Integrative Biology

Dermal exposure, which is likely the dominant uptake route for amphibians for most contaminants, is likely dependent on location of exposure and hydrophobicity of the contaminant. The objective of this study was to characterize both ventral and dorsal dermal uptake of contaminants across a range of hydrophobicities in Blanchard's cricket frogs. Amphibians were dosed with contaminants (atrazine, lindane, fluoranthene, benzo(b)fluoranthene, and bifenthrin) suspended within the Sniper® insecticide formulation (AI: bifenthrin) applied using a dermal patch system on either the ventral or dorsal side. Individuals were collected at specific time points, sacrificed, and prepared for analysis. Excised exposed skin samples and remaining carcass were processed separately using the QuEChERs method and analyzed using GC/MS. Comparable data between ventral and dorsal contaminant movement allows risk assessors to note differences in availability depending on the site of exposure and how ventral and dorsal skin locations differ in their taking up of hydrophobic contaminants from a hydrophobic vehicle.

WP261 Development of a Behavioral Assay to Test Pesticide Toxicity in Amphibians

K.r. Scarlett, Graduate Society of Interdisciplinary Toxicology / Dept of Integrative Biology; J.P. Cusaac, K.A. Dudley, Oklahoma State Univ / Dept of Integrative Biology; S.T. McMurry, Oklahoma State Univ / Integrative Biology

Prey capture in toads consists of a stereotypical series of behaviors beginning with orientation toward the prey item, followed by pursuit and striking. Prey-orientation behaviors have been used to explore neurological function in toads; however, orientations toward the stimulus decrease over time, indicating toads habituate to the stimulus when behaviors are not reinforced. The goals of this study were to characterize prey-orientation behaviors and develop an assay for use as an indicator of toxicity from pesticide exposure, and then verify the effectiveness of the behavioral model by examining the effects of chemicals on prey-orientations. Because prey capture is dependent on neurological function, exposure to compounds that inhibit or stimulate neurotransmitters may influence the prey capture sequence, including prey orientation, strike accuracy, and endurance. Thus, we first examined whether reinforcement of prey-orientation behaviors influences habituation in sub-adult Great Plains toads (Anaxyrus cognatus). Results indicate that habituation occurred when the toads were not 'rewarded' after testing. Therefore, without motivation to capture a prey stimulus, prey-orientations decreased over time. Furthermore, we were also able to use different time intervals and 'rewards' to establish a system where orientations were consistent and maintained long term. Our results will be discussed relative to the usefulness of prey-orientation behaviors as indicators of toxicity following environmentally realistic, worst-case exposures to chemicals.

WP262 Diethylhexyl phthalate increases deposition of 14C-bisphenol A in reproductive tissues of mice (Mus musculus)

E.D. Borman, N. Vecchi, T. Pollock, D. deCatanzaro, McMaster Univ / Psychology, Neuroscience and Behaviour

Xenoestrogens, estrogen mimicking chemicals, are widely used in many personal care products and containers. This widespread use exposes a large percentage of the population in developed countries to these chemicals through inhalation, ingestion, and skin absorption. Two popular xenoestrogens, bisphenol A (BPA) and diethylhexyl phthalate (DEHP), have been shown to disrupt blastocyst implantation. Recent research has indicated that concurrent administration of BPA and DEHP can reproduce these effects at a lower dosage. This may caused by DEHP increasing available BPA in reproductive tissues, thus requiring less of the chemical to exert an effect. Consequently, we sought to test BPA deposition in various peripheral tissues by injecting 0, 3, 9, or 18 mg DEHP into female and male CF-1 mice followed by 50 µg/kg ^{14}C-BPA through oral consumption. Animals were dissected 1 h following ^{14}C-BPA administration and various tissue samples were acquired. Samples were solubilized and results were obtained through a liquid scintillation counter. Results indicated that the 18 mg and 9 mg DEHP doses magnified BPA deposition in the uterus and ovaries relative to controls, in both cycling and peri-implantion females. The 18 mg dose also increased BPA deposition in the epididymides in males, with similar trends increasing with DEHP dose in other reproductive tissues. These results demonstrate that DEHP can synergize with BPA in estrogen-binding reproductive tissues.

WP263 Effect of Exposure to Pesticide Mixtures on Body Burden and Metabolomic Profiles in Amphibians

R. Van Meter, Washington College; D. Glinski, Oak Ridge Inst for Science & Education at USEPA; M. Henderson, USEPA / NERL; T. Purucker, USEPA / Ecosystems Research Division

The agricultural use of pesticides to control undesirable species has gained momentum in recent years, despite a growing body of research highlighting the potential adverse ecological effects of these chemicals. Multiple pesticides are often applied to fields in combination through tank mixtures, in an effort to minimize multiple pests' impacts, cost and time spent on control measures. Many non-target organisms, such as amphibians, also come into direct contact during application or indirect contact with pesticide contaminated soil and plants in agricultural areas. While individual pesticides are known to have adverse effects on amphibians, research on multiple pesticide co-exposures in terrestrial phase amphibians is lacking. The purpose of this study was to compare amphibian body burdens and hepatic metabolomic profiles after exposure to a single pesticide or pesticide mixtures to better understand the possible synergistic, antagonistic or additive effects these exposures induce. In total, five common-use pesticide active ingredients were used in this study, three herbicides (atrazine, metolachlor and 2,4-D), one insecticide (malathion) and one fungicide (propiconazole). Juvenile southern leopard frogs (Lithobates sphenocephala) were reared from egg masses to 30-60 days post-metamorphosis. Individual frogs were then exposed to a single pesticide, a combination of herbicides (atrazine, metolachlor and/or 2,4-D) or a combination of different classes of pesticides (atrazine, malathion and/or propiconazole) at the labeled application rate on low organic matter soil. Following 8 hr exposures, liver samples were excised for metabolomic profiling and body burdens determined from whole tissue homogenates. Body burden results indicate that amphibian accumulation of multiple pesticides occurs synergistically between certain compounds. Metabolomic profiling of livers support this and pesticide mixtures appear to also synergistically influence biochemical perturbations in these non-target species. Co-exposure to multiple pesticides in amphibians may enhance uptake and decrease normal metabolic function, thereby limiting the overall health and stability of amphibian populations in agricultural areas.

WP264 Effects of a glyphosate end-use product on the flowering of black-eyed Susan (Rudbeckia hirta) and red clover (Trifolium pratense)

S.I. Rodney, Intrinsik Environmental Sciences / Biology; C. Boutin, Environment and Climate Change Canada; F.R. Pick, Univ of Ottawa / Dept of Biology

It has long been recognized that standard terrestrial plant toxicity tests are on their own insufficient for assessing the risk of pesticide use to non-target terrestrial plants. Current standard tests only consider a small fraction of a plant's life cycle (seedling emergence and vegetative vigor), and they only involve early life stage exposures. Understanding the overall effects of realistic plant exposures to pesticides is critical for an accurate ecological risk assessment. Initial test results with black-eyed Susan (Rudbeckia hirta) and red clover (Trifolium pratense) have indicated early bud-stage plant exposure to glyphosate may cause flower deformation at relatively low exposure levels (1% of application rate). We will present our findings of current follow-up experiments with the same species over a wider range of exposure levels, in an effort to resolve rate-response relationships for effects on flower phenology and morphology in these species.

WP265 Embryonic Origins of Altered Ovarian Gonadotropin Responsiveness in an Environmental Model of Endocrine Disruption, the American Alligator

M.D. Hale, Univ of Georgia – Savannah River Ecology Laboratory; J. Cloy-McCoy, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences; N. O'Connell, Medical Univ of South Carolina / Public Health Sciences; T. Galligan, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences; B. Doheny, Medical Univ of South Carolina and Hollings Marine Laboratory / Marine Biomedicine and Environmental Sciences; F. Nilsen, National Inst of Standards and Technology / Environmental Chemical Sciences Division; J.T. Bangma, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences; B. Parrott, Univ of Georgia – Savannah River Ecology Laboratory / Odum School of Ecology

Exposures to endocrine disrupting contaminants are thought to broadly impact reproductive health in humans and wildlife. As an environmental model of endocrine disruption, the American alligator has provided significant utility to our understanding of population-level effects of exposure to endocrine-active chemicals on vertebrate reproduction.

Reports from a contaminated lake (Lake Apopka, FL) have indicated a causal role for these contaminants in the rapid decline of alligators living there in the 1980s-90s. Juvenile alligators from this site are characterized by genital abnormalities, aberrant sex-steroid hormone production, and abated ovarian responsiveness to gonadotropin signals. Consistent with a "developmental origins of adult disease" model, studies from our lab have provided evidence that this collective reproductive disorder has embryonic origins. We seek to further understand the mechanism(s) underlying these observations by testing the hypothesis that precocious exposure to hormone signals during critical windows of embryonic development is responsible for suppressed gonadotropin response later in life. We have exposed alligator embryos to 17β-estradiol or dihydrotestosterone at a stage just prior to sex-determination and raised resulting hatchlings for five months prior to administering exogenous ovine follicle-stimulating hormone (FSH). We aim to investigate gonadotropin responsiveness by: quantifying induction of transcriptional targets critical to ovarian function, increases in gonadosomatic index (GSI), and by examining cellular dynamics of FSH action at the histological level. Utilizing multiple regression modeling, we have established induction of ovarian increases to GSI and gene expression of eleven targets in response to FSH-stimulation in control and treated animals from a contaminated site, Lake Apopka, and a reference site, Lake Woodruff. We have further detected significant impacts of site and developmental exposure on expression of four nuclear receptors, estrogen receptors α and β (ESR1, ESR2), and arylhydrocarbon receptor isoforms AHR1A and AHR2. Incidental or experimental exposure during development to endocrine-active compounds significantly modulates the response of these genes to FSH in a manner not observed in control animals. Given the broadly conserved role of these genes in vertebrate reproduction, these findings implicate developmental endocrine disruption in altered gonadotropin responsiveness later in life.

WP266 Evaluating the terrestrial toxicity of hydrophobic contaminants using a standardized soil mixing and aging procedure

J.D. Butler, ExxonMobil Biomedical Sciences, Inc / Environmental Toxicology and Chemistry Laboratory; B. Kelley, B. Hedgpeth, D. Letinski, M. CONNELLY, Exxon Mobil Biomedical Sciences Inc; A.D. Redman, Exxon Mobil Biomedical Sciences / Toxicology and Environment Science Division

Environmental risk assessments require quality toxicity data to provide defensible environmental quality benchmarks. Hydrophobic organic compounds (HOCs) are often difficult to test due to multiple compound loss processes (sorption, volatilization, biodegradation, etc.) and slow kinetics. Poorly performed exposures with little to no equilibration between the test material and soil media often confound test result interpretation. Proper soil mixing and aging prior to the in-life phase of a terrestrial toxicity experiment is critical to minimizing artifacts of physical effects of neat test material that had not fully equilibrated with the test media. The study objectives were to 1. Develop an aging procedure which could be used to accurately and consistently characterize the hazard of HOCs in soil, 2. Apply the aging procedure to chronic toxicity tests with terrestrial plants (Chronic plant toxicity test with Brassica rapa and Avena sativa) and soil invertebrates (28-d survival and reproduction test with Folsomia candida) and assess effects, 3. Validate the Target Lipid and Equilibrium Partitioning Model TLM-EQP for deriving Predicted No Effect Concentrations (PNECs) in soil for HOCs. Compounds tested ranged in log K_{OW} values of 5-9. Terrestrial plant endpoints observed consisted of shoot weight (wet and dry), number and weight of inflorescences. Soil invertebrate endpoints observed consisted of adult mortality and number of young produced. The datasets generated here demonstrate that the TLM-EQP models are protective of these endpoints and support efficient use of data for general purpose risk assessments.

WP267 Factors Affecting Arbuscular Mycorrhizal Fungal Colonization in Soils Contaminated with Heavy Metals

S. Garvey, B. Casper, L. Dietterich, Univ of Pennsylvania / Dept of Biology

High concentrations of heavy metals in soils have been shown to adversely affect microbial and plant populations. Arbuscular mycorrhizal fungi (AMF) colonize the root cortex of certain plant species, engaging in nutrient exchange and facilitating a symbiotic relationship. This relationship becomes particularly important when considering plant growth on severely disturbed and contaminated sites. This study examined how the AMF status of pre-existing plant communities affects the microbial colonization of newly arriving plant species and how aboveground plant competition affects those AMF dynamics in soils contaminated with heavy metals. C4 grasses and sugar maple trees rely heavily on AMF, while grey birch trees are thought to more commonly form relationships with another type of mycorrhizal fungus, ectomycorrhizae. AMF colonization was tested against two independent factors: the type of vegetation characterizing the area (grey birch or C4 grass) and the status of that vegetation (intact or cleared). Clearing the plots helped to isolate the soil effect of interest from potential differences in aboveground competition between grasses and birches. Sugar maples, representing later-successional trees that one might expect to follow the birches naturally in succession, were planted in these experimental soil conditions. In this study of 44 root samples, AMF colonization was assessed by looking at several separate microbial structures. The percent colonization by AMF showed a statistically significant increase in areas of C4 grasses relative to grey birch soils. For those microbial structures where there was significant interaction between vegetation type and status, areas cleared of grasses showed the highest AMF colonization. This suggests that C4 grasses create a pre-existing mycorrhizal community in which the symbiotic relationship between AMF and sugar maples can flourish, even in heavy metal environments, in a way that grey birch does not. However, competition with intact grasses may reduce AMF colonization rates. These findings become important when considering phytoremediation practices and identifying the most effective plant and microbial treatments for a given environmental problem.

WP268 Factors Affecting the Toxicity of Headline® Fungicide to Terrestrial Toads

P.W. Cusaac, Oklahoma State Univ / Integrative Biology; W.H. Mimbs, Oklahoma State Univ / Zoology; J.B. Belden, L.M. Smith, S.T. McMurry, Oklahoma State Univ / Integrative Biology

Previous studies have demonstrated that pyraclostrobin-based fungicides (e.g., Headline® and Headline AMP® fungicides, BASF) are toxic to some amphibians at environmentally relevant concentrations. However, various factors influence exposure and effects in an environmentally realistic exposure scenario. These include age of the individual, exposure route, and physiological state of the individual. Further, there are no data available on the sublethal effects of pyraclostrobin-based fungicides in terrestrial amphibians. Thus, we investigated factors affecting toxicity of Headline formulations to amphibians, including body size, exposure route, and hydration state of the animal. Additionally, we examined sublethal effects of Headline AMP fungicide using prey-orientation behaviors as indicators of toxicity. Neither Headline nor Headline AMP fungicide caused mortality of adult Great Plains toads (Anaxyrus cognatus)and Woodhouse's toads (A. woodhousii) with overspray exposures up to 5x the maximum label rate for North American corn. Exposure to Headline AMP via previously treated soils caused dose-dependent mortality of juvenile A. cognatus when toads were placed immediately onto treated soils, but no toxicity was observed when toads were placed onto treated soils 60 and 120 min post-treatment. Hydration state did not influence the toxicity of Headline AMP to juvenile A. cognatus (LC_{50}= 2.4 and 2.3 µg pyraclostrobin/cm^2 in dehydrated and hydrated treatments, respectively). Finally, orientations toward a simulated prey item by juvenile A. cognatus decreased over time; however, Headline AMP did not influence the number of orientations toward a simulated prey or the rate at which orientations toward the stimulus changed over time. Therefore, risk from Headline fungicides to terrestrial amphibians in a routine crop setting appears generally low.

WP269 Factors Influencing Mallard Duck (Anas platyrhynchos) Fertility in the Avian Reproduction Test

M. Christ, SynTech Research Laboratory Services; J. Loveall, SynTech Research; S.P. McGee, Bayer CropScience LP / Environmental Health Sciences

In 2012, the Avian Reproduction Test guideline (OCSPP 850.2300) was revised stating that validity criteria for mallard duck fertility (i.e. number viable embryos of eggs set) in the control group must achieve 80%. Historical data suggests that achieving 80% fertility may present significant challenges as a result of the incompatibility in mating pairs. Courtship and pair formation are of great importance to waterfowl populations with many duck species forming pair bonds each breeding season (seasonal monogamy). These courtship factors suggest that female ducks will tend to select their mates prior to the breeding season which heavily influences successful copulation and egg fertility. In addition, research has shown that females have developed elaborate behavioral and anatomical sexual strategies to resist forced copulation of unwanted males. The research presented here reinforces these concepts of mallard hens either accepting or rejecting the males, or males being deficient in producing fertile eggs during the avian reproduction test. Laboratory trials were conducted with mallards in the reproductive phase in which unsuccessful males (those not producing any fertile eggs) were replaced with proven breeder males in cages with female hens. Conversely, the unsuccessful males were paired with fertile females to determine to what extent fertility would be negatively impacted. To eliminate the variable of infertility attributed to regressed testes or ovaries, necropsy was performed on all birds at test termination. Additional factors influencing mallard duck reproduction including age of birds, compatibility of mating pairs, and randomization of pairs will be discussed.

WP270 Female vinegar flies reared in leaded environments do not avoid leaded (Pb2+) egg-laying substrates

E. Peterson, Univ at Albany-SUNY / Biology; A. Stark, Univ at Albany-State Univ of New York / Biological Sciences; B. Possidente, Skidmore College / Biology; G. Lnenicka, Univ at Albany-State Univ of New York / Biological Sciences

Research has shown that female vinegar flies (Drosophila melanogaster) prefer to lay eggs on sugar-based agar medium and that preference is linked to efforts to decrease larval foraging costs.Therefore, females would likely selectively prefer egg-laying substrates devoid of potential harmful toxins, such as heavy metals, which could potentially decrease offspring fitness. The purpose of this research was to determine if females would avoid or prefer leaded medium as egg-laying substrates, based upon their development in control or leaded medium. Wild type D. melanogaster were reared on control or leaded (250, 500 or 1000 µM PbAc) medium from egg stage to adulthood. Females were mated, provided three substrates to lay eggs (control, acetic acid, and leaded medium) and the number of eggs laid on each substrate was counted. There was a dose-dependent response in the mean total number of eggs laid by females ($p = 0.05$), but not for female preference for control, acetic acid or leaded egg-laying substrates. However, control females preferred to lay eggs on control substrates ($p < 0.05$) and avoided leaded substrates ($p < 0.001$) whereas leaded females (in any dose) did not exhibit a preference for either substrate ($p > 0.05$). These results indicate that females reared in a leaded environment may be unable to determine the toxicity of egg-laying substrates. The ecological consequences of laying eggs in a lead-polluted environment include potential increased larval foraging costs for offspring, as well as bioaccumulation in the food chain and multi-generational accumulation within the population.

WP271 Heavy metal lead induced aberrant expression of microRNAs in cotton

B. Zhang, East Carolina Univ / Biology; Q. He, East Carolina Univ

MicroRNAs (miRNAs) play key roles in plant responses to various metal stresses. To investigate the miRNA-mediated plant response to heavy metals, cotton (Gossypium hirsutum L.), the most important fiber crop in the world, was exposed to different concentrations (0, 25, 50, 100, and 200 mg/L) of lead (Pb) and then the toxicological effects were investigated. The expression patterns of sixteen stress-responsive miRNAs and 10 target genes were monitored in cotton leaves and roots by qRT-PCR; of these selected genes, several miRNAs and their target genes are involved in root development. The results show a reciprocal regulation of cotton response to lead stress by miRNAs. The characterization of the miRNAs and the associated target genes in response to lead exposure would help defining the potential roles of miRNAs in plant adaptation to heavy metal stress and further understanding of miRNA regulation in response to abiotic stress.

WP272 Hepatotoxicity of gasoline fume inhalation in albino rats

G.A. Dedeke, Federal Univ of Agriculture, Abeokuta / Pure and Applied Zoology; F.O. Owagboriaye, Olabisi Onabanjo Univ / Applied Zoology

Hepatotoxic and Genotoxic effects associated with gasoline fumes were assessed in forty Albino rats following inhalation exposure. The rats were randomly assigned to five experimental treatments (T) with eight rats per treatment (T1, T2, T3, T4 and T5). The control treatment, T1 was housed in a section of experimental animal house free from gasoline fumes while T2, T3, T4 and T5 were exposed to gasoline fumes in exposure chambers for one, three, five and nine hours daily respectively for a period of twelve weeks. Serum alanine aminotransferase (ALT), Aspartate aminotransferase (AST), Alkaline phosphatase (ALP) and histopathological examination of the liver tissues of each treatment were used as diagnostic markers to assess liver dysfunction. Genotoxicity test on the lung tissues of each treatment was conducted based Randomly amplified polymorphic DNA fingerprinting polymerase chain reaction (RAPD PCR) technique. Significant increase ($p< 0.05$) in the level of ALT, AST and ALP for T2, T3, T4 and T5 as compared to T1 were recorded. Photomicrograph examination of the liver sections of T1 showed hepatic tissue with normal liver cell architecture while that of T2, T3, T4 and T5 revealed degenerative changes in the ultrastructural integrity of the hepatic cells. Genotoxicity test revealed DNA bands at a reducing intensity from T1 to T5. The suspected DNA damage as compared to T1 followed the trend: T3>T5>T4>T2. Similarity between the DNA bands of the experimental rats was followed by rats exposed to T2, T4 and T5 and T3 respectively. In conclusion, frequent exposure to gasoline fumes may induce hepatoxicity and genotoxicity, hence impairing the normal liver function and gene structure.

WP273 High throughput screening for pesticide-induced mitochondrial dysfunction

J. Boyda, U Florida; J. Schmidt, C.J. Martyniuk, Univ of Florida / Physiological Sciences

Pesticides include the broad classes of herbicides, insecticides, and fungicides. While pesticides can elicit adverse effects in non-target organisms through different mechanisms (i.e. endocrine disruption, neurotoxicity, tissue necrosis), mitochondria can also be a prominent target for toxicity. Mitochondria serve multiple roles in the cell, including ATP production, calcium regulation, and apoptosis. Pesticides can act to impair mitochondrial bioenergetics, which results in energy deficits and disruptions in downstream cellular processes. In this study, we tested pesticides from different classes to establish whether these chemicals act in a common way to disrupt mitochondrial bioenergetics. The overarching goal is develop a high throughput screening assay for pesticide-induced mitochondrial dysfunction and to determine the underlying mechanisms of mitochondrial toxicity. We tested (1) Fipronil, a broad-use insecticide that belongs to the phenylpyrazole family, (2) Fluazinam, a broad-spectrum fungicide classified as an arylaminopyridine, (3) Itraconoazole, a triazole antifungal used as a medication to treat fungal infections, and (4) Paraquat, a redox-active heterocycle herbicide that is structurally similar to compounds that induce Parkinson's disease. Rat N27 dopaminergic cells were treated for 24 hours with a dose range of 0.25, 2.5, 25, or 250 µM. Using the Seahorse XFe24 extracellular flux analyzer, cells treated with 25 µM of all 4 pesticides inhibited basal respiration of mitochondria. N27 cells treated with 25 µM pesticide also showed lower maximum respiration following treatment with the uncoupling agent carbonyl cyanide p-trifluoromethoxyphenylhydrazone (FCCP), the most dramatic response being that of fipronil (~25% decrease compared to ~50% for the other compounds). Noteworthy was that PQ2+ reduced "spare respiratory capacity" of the mitochondria, which is the difference between ATP produced by oxidative phosphorylation at basal and maximal activity. Pesticides resulted in different cell energy phenotype profiles, suggesting different mechanisms of action on mitochondria. Each of the four pesticides were demonstrated to impact mitochondrial bioenergetics, but some pesticides were stronger mitochondrial toxicants (i.e. fipronil) than others. Future objectives include identifying the mechanisms of mitochondrial dysfunction in cell lines and whole animals, to determine the relationship between pesticide exposures and increased risks of neurodegenerative diseases.

WP274 Lead-induced physiological and biochemical changes in cotton

Q. He, East Carolina Univ; B. Zhang, East Carolina Univ / Biology

Heavy metal lead (Pd) is one major environmental contaminant, which exists anywhere around us and is causing significant environmental and human health problem. Although there are much study on animal health, few studies has been performed on the impact of plants. In this study, we systemically investigated the effect of lead in the aspect of plant physiological and biochemical change. Lead exposure significantly inhibited cotton plant growth and development in the aspect of both fresh and dry biomass yield of both roots and aboveground parts with a dosage-dependent manner ($p< 0.001$). Lead treatment inhibited root development potentially by damaging root apical meristem and root cell elongation. Low concentration lead promote seedling water contain; but this only affected aboveground parts not the roots. Lead exposure significantly inhibited the biosynthesis of chlorophyll a, chlorophyll b and total chlorophylls ($p< 0.001$) and further affected the photosynthesis of cotton seedlings. Lead exposure caused oxidative damage in cotton seedlings evidenced by cell membrane damage and the expression profile changes in oxidative stress-related enzymes. The contents of the indicator of membrane damage, malondialdehyde (MDA), were significantly increased under Pb stress exposure. All tested anti-oxidative enzymes, SOD, POD and CAT, was induced at low lead concentrations and then inhibited at high concentrations with a peak at 50 µM. This suggests that cotton has an oxidative stress protection system to prevent heavy metal-caused oxidative damage.

WP275 Mercury contaminated food decreases the growth of collembolans: A bioaccumulation and growth study

D. Nunes Cardoso, CESAM, Univ of Aveiro / Dept of Biology and CESAM Centre for Environmental and Marine Studies; N.G. Ferreira, CESAM & Univ de Aveiro / Departamento de Biologia and CESAM; P.d. Tourinho, Univ of Aveiro / Dept of Biology CESAM; C.S. Santos, Ghent Univ / Terrestrial Ecology Unit TEREC Dept of Biology; A.M. Soares, Univ de Aveiro / Dept of Biology and CESAM; S. Loureiro, Univ de Aveiro / Biology

In the terrestrial environment, mercury (Hg) is subject to redistribution and transformation into different inorganic and metal – organic species that are uptake by vegetation and soil organisms. In the present study, we assessed the effects of food contaminated with relevant concentrations of Hg in the form of $HgCl_2$. Food was provided ad libitum to a soil dwelling representative invertebrate, Folsomia candida. Changes in growth rate and Hg bioaccumulation levels were assessed at different concentrations of Hg in food providing data that could complement the effects of Hg on reproduction and survival using standardized organisms and protocols. In this study, collembolan growth was dependent of the Hg food concentration. At all the studied concentrations the growth of collembolans was affected by the Hg in yeast with differences in growth rate of organisms. Also, the length of animals were statistically different for all treatments at the end of the test, comparing with the control. Collembolan growth was recorded every two days, and a Von Bertalanffy's growth curve was derived along with growth rate. The toxicokinetics patterns at the exposure concentrations of Hg in food were not significantly different from each other. It is advised that growth tests could be seen as an important step to fill the gaps not only of the bioaccumulation tests, but as well of the advised chronic reproductive assays that could explain some effects. Even at low and environmental relevant concentrations of Hg, collembolans suffered differences in their growth rate, which could pose a risk to ecosystems, knowing the important role of these kind of organisms. Also, this study highlights the importance of these complementary tests for a better and complete approach in risk assessment studies.

WP276 Metal Accumulation in Terrestrial Animals

S. Hough, W.J. Loughry, J.M. Lockhart, Valdosta State Univ / Biology; G.K. Bielmyer-Fraser, Jacksonville Univ / Chemistry

Metals are commonly used in many facets of modern society and are thus frequently released into the environment. Metal accumulation in wildlife may occur as a result of excess metals in the environment, which in turn can lead to toxicity when concentrations exceed certain threshold levels. Unfortunately, tissue metal concentrations in many terrestrial mammals are to a large extent unknown. Here, we present the first analyses of liver metal concentrations in 6 species of mammals collected over four years from four sites in Georgia and Florida that experienced relatively similar levels of human disturbance. Liver tissues were obtained from hundreds of armadillos, bobcats, coyotes, opossums and raccoons, and were screened for multiple metals. Differences in metal concentrations due to age (juvenile versus adult), sex, site and time (yearly variation) were examined. This study provides the first extensive reference data for metal concentrations in various key wildlife species found in terrestrial habitats. Results of this study will also increase understanding of metal accumulation and transfer in terrestrial food webs.

WP277 Mitochondrial bioenergetics are impaired by the legacy pesticide dieldrin

A. Rushin, J. Boyda, U Florida; J. Schmidt, C.J. Martyniuk, Univ of Florida / Physiological Sciences

Mitochondria are direct targets of chemicals in our environment. Toxicants can modify mitochondrial function via a number of mechanisms including DNA damage, electron transport chain inhibition/uncoupling, and generation of reactive oxygen species, among others. Dieldrin (DLD) is a legacy organochlorine pesticide (OCP) that bioaccumulates in tissues and is epidemiologically associated to an increased risk for Parkinson's disease (PD). This study aimed to determine whether DLD impacts mitochondrial bioenergetics in dopaminergic neuronal cells, testing the hypothesis that DLD decreases oxygen consumption rate and overall performance of the mitochondria. Due to the association with Parkinson's disease, immortalized dopaminergic N27 cells were treated for 24 hours with one dose of either a solvent control or one dose of 2.5, 25, or 250 µM DLD. Cells treated with 250 µM showed higher apoptosis (caspase 3 activity) relative to control cells. Cell viability decreased with 25 and 250 µM DLD, but there was no cytotoxicity with DLD at the doses and time point examined. Following treatments, viable cells were subjected to a mitochondrial stress test using the Seahorse XFe24 extracellular flux analyzer. N27 cells treated with 25 µM DLD showed lower maximum respiration compared to the solvent control following treatment with the uncoupling agent carbonyl cyanide p-trifluoromethoxyphenylhydrazone. There was also evidence of lower spare respiratory capacity in mitochondria with treatments >25 µM. Studies are ongoing to measure the expression profiles for transcripts related to oxidative phosphorylation (e.g. cytochrome C), oxidative stress (e.g. superoxide dismutase), and mitochondrial membrane polarization and permeability (e.g. Bcl2, TSPO, and voltage dependent anion channel), to determine the mechanism associated with impaired bioenergetics. In order to increase the relevance of the study to PD, tyrosine hydroxylase (TH) protein abundance was measured. TH did not differ among groups, suggesting that impaired mitochondrial respiration may not directly impact DA synthesis. This study suggests that impaired mitochondrial bioenergetics may, in part, underlie the relationship between pesticide exposures and neurodegenerative diseases.

WP278 Movement of Hydrophobic Organic Contaminants from Soil into Amphibians Based Upon Soil Characteristics

W.H. Mimbs, Oklahoma State Univ / Zoology; P.W. Cusaac, S.T. McMurry, J.B. Belden, Oklahoma State Univ / Integrative Biology

Limitations in our understanding of dermal uptake of pesticides adds to the difficulty of incorporating amphibians into the ecological risk assessment process. This study seeks to characterize the degree to which soil-contaminant aging and soil organic carbon content affect the uptake of five moderate to highly hydrophobic contaminants into amphibians. Amphibians were exposed to Sniper® formulation (AI: bifenthrin) spiked with atrazine, lindane, fluoranthene, and benzo(B)fluoranthene. Low and high organic carbon soil was sprayed with this spiked formulation and amphibians were introduced at either 10 minutes after spray or 4 hours. Individuals were collected at specific time points, sacrificed, and prepared for analysis. Whole body amphibians samples were homogenized and processed via the QuEChERs method and analyzed using GC/MS. Information on the uptake of soil contaminants into an amphibian will not only be valuable in assessing the magnitude of uptake in general, but will also allow us to visualize the time course of contaminant uptake and allow us to characterize the effects of soil OC on soil-contaminant aging and amphibian uptake.

WP279 Polycyclic Aromatic Hydrocarbons metabolites in bile and serum from resident sea birds (F. magnificiens, S. leucogaster, L. dominicanus) from Brazil

P. Baldassin, Univ of São Paulo / Laboratório de química orgânica marinha; S. Taniguchi, Univ of São Paulo / Physical Oceanography Dept; A. Mastrangelli, A. Trazzi, CTA Meio Ambiente; M.C. Bícego, IOUSP

Resident seabirds can be used for biodiversity monitoring programs because these animals are vulnerable to pollution, such as Polycyclic Aromatic Hydrocarbons (PAHs) from oil and derivatives. Seabirds assimilate PAHs by the dermis contact with contaminated water, and sediment, and contaminated particles ingestion, , ending up in the blood stream and being mostly metabolized in the liver and secreted by the gall bladder through a hepatobiliary duct. There is evidence that vertebrates have a system of xenobiotics metabolizing enzymes highly developed, located by the cytochrome P-450, able to metabolize PAHs, secreting or absorbing them from the intestinal tract. The aim of the present study was to compare the PAHs metabolites in serum and bile from resident sea birds (Fregata magnificiens, Sula leucogaster, Larus dominicanus) from the state of Rio de Janeiro, Brazil, in specific oil exploration and urban occupation areas, as the Campos Basin region. The samples of serum (n=19) and bile (n=24) were collect from animals that were either found dead during beach monitoring procedures or died at rehabilitation center, located in Araruama city, between 2015 and 2016. The metabolites were analyzed with a high performance liquid chromatograph with fluorescence detector (HPLC/F) and quantified as Naphthalene (NAP) Phenanthrene (PHE) and Benzo(a)pyrene (BaP) equivalents. In only three individuals (two S. leucogaster and F. magnificiens) it was possible to collect serum as soon as the animal arrive and bile after their death. The results of all samples demonstrated that the concentration of the serum were almost one order of magnitude lower than the bile. The concentration of the metabolites was NAP >PHE>BaP for both serum and bile. The majority of the bile samples have presented higher levels than those found in preliminaries studies with migrate seabirds, such as Magellanic penguins stranded in the Brazilian coast.

WP280 Relationship between body condition and contaminants in Overwintering Canvasbacks (Aythya valisineria) in the Lake St. Clair/St. Clair River Area

S. de Solla, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; K.D. Hughes, Environment and Climate Change Canada; P.A. Martin, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; M.L. Schummer, State Univ of New YorkOswego; S.A. Petrie, Delta Waterfowl

Overwintering canvasbacks were collected in the Lake St. Clair/St. Clair River area in the winter of 2008/09 and 2010, and livers were analyzed for PCBs, organochlorine pesticides, brominated flame retardants, mercury (Hg) and selenium (Se). Hepatic concentrations of organochlorines, brominated flame retardants, and Hg in all birds were low and Hg concentrations were below levels associated with adverse effects on survival.Hepatic concentrations of Se were largely low but were more variable among birds with 25% of canvasbacks showing concentrations considered elevated and 5% (i.e., one bird) with a concentration exceeding the threshold associated with toxicity. Significant increases in hepatic concentrations of Hg and Se, sum PCBs, p,p'-DDE and other organochlorines were evident over the four month period of collection in which mean concentrations in January and/or February were significantly higher than mean concentrations in November when overwintering birds arrived in the study area. The largest increases were most often between December and January which also coincided with the period when birds from Lake St. Clair moved, following freeze-up of the lake, to the St. Clair River to forage. Simultaneous with the increase in body burdens, body condition of the birds declined from December onward. Although it is unclear to what extent possible changes in diet, level of contamination and/or declines in lipid reserves following movement to the St. Clair River contributed to observed temporal trends in body burdens of overwintering canvasbacks, our evidence suggest that a reduction of body condition, through loss of fat reserves, may have contributed to the higher body burdens in winter in canvasbacks.

WP281 Risk assessment of lead exposure from recreational fishing tackle to nestling bald eagles in a heavily utilized recreational fishery

T. Pittman, FL Fish and Wildlife Commission / Fish and Wildlife Research Inst; T.G. Grubb, United States Forest Service / Rocky Mountain Research Station; S. Windels, L. Grim, US Park Service / Voyageurs National Park; W.W. Bowerman, Univ of Maryland / Dept of Environmental Science and Technology; P. Datema, Clemson Univ / Wildlife and Fisheries; J. Warmbold, US Park Service

Risks associated with lead exposure in wildlife are well documented and have been found to cause physiological dysfunction, development deformities, and mortality. Opportunistic feeding avian species, such as bald eagles (Haliaeetus leucocephalus), have most often been associated with lead exposure from spent ammunition left behind in the offal of big game and formerly lead shot from wounded or lost waterfowl. The U. S. Fish and Wildlife Service banded lead shot for waterfowl hunting in the 1980's and many state agencies are beginning to phase out the use of lead for big game hunting for non-toxic alternatives. However, other sources of lead exposure such as that from lost or improperly discarded recreational fishing tackle still exist. We initiated a field study and retrospective analysis to assess the risk of recreational fishing tackle to nestling bald eagles in a heavily utilized recreational fisheries. Voyageurs National Park (VNP) in Northern Minnesota receives up to 750,000 angler hours per year. Our study had two objectives, 1) determine the blood lead concentration of nestling bald eagles in VNP, and 2) assess the exposure risk of nestling bald eagles to recreational fishing tackle, especially fishing tackle that could result in lead exposure. In 2013, we samples 25 nestling bald eagles for blood lead concentration and found 24 were below the 3.3 ug/dl detection limit. The only nestling greater than the detection limit had a blood lead concertation of 6.0 ug/dl. We also scanned all nestlings sampled with a BlueMax 950 Metal Detector to determine if nestlings had recently ingested lead and found no detectable lead fragments within nestlings. To assess the exposure risk of nestling to recreational fishing tackle we conducted a retrospective analysis of banding records from 1989 to 2013 for the documentation of fishing tackle and any harmful effects of tackle. We found no observable incidences of acute lead toxicosis that might be associated with ingestion of lead fishing tackle. However we did find that 10.3% of all nests visited had fishing tackle present in or around the nest and 18.5% of all nestling injuries and 28.6% of all documented nestling mortalities were directly related to fishing tackle exposure. In conclusion, our study suggests that the risk of lead exposure from recreational fishing tackle is low even in a highly utilized recreational fishery, but risk does exist from fishing tackle does through entanglement and injury.

WP282 Screening for Genotoxic Agents with the DT40 Immortalized Avian Cell Line

J. O'Brien, Environment and Climate Change Canada; S.P. Jones, Environment and Climate Change Canada / Books Acquisition; D.E. Crump, Environment and Climate Change Canada

We regularly use toxicogenomics in primary avian cell cultures to screen and prioritize environmental pollutants of potential concern to wild bird species. However, primary cells are limited in their ability to identify agents that can cause genomic damage. This is largely because primary cells undergo very little DNA replication and cell division, which are two cellular functions generally required for most genotoxic modes of action. In contrast, the chicken B-lymphocyte DT40 cell line is an immortalized avian cell line that has been used increasingly in genotoxicity testing due, in part, to its very rapid growth rate. Here we incorporated the DT40 cell line into our in vitro toxicogenomics screening pipeline. DT40 cells were exposed to a variety of chemicals, including some known genotoxic agents. Gene expression profiles were determined using chicken ToxChip polymerase chain reaction (PCR) arrays which contain probes for genes in a variety of toxicologically relevant pathways, including cell cycle regulation and DNA repair. Chemicals with toxicogenomic profiles that suggested genotoxic activity were further assessed for genotoxicity using an in vitro flow cytometry micronucleus assay. Successful incorporation of the DT40 cell line into our in vitro toxicogenomics screening pipeline will provide the additional ability to detect genotoxic modes of action and significantly reduce the number of animals required for our chemical screening program. Future work will require the addition of metabolic enzymes into our screening assay, which are often required to activate the genotoxic activity of some chemicals. The sensitivity of this assay for genotoxicity may also be improved by using variants of the DT40 line with impaired DNA-repair capacity.

WP283 The effect of ingested aluminum on forage quality assessment and patch fidelity in honey bees (Apis mellifera)

A. Chicas-Mosier, Oklahoma State Univ / Integrative Biology; C.I. Abramson, Oklahoma State Univ / Psychology

Aluminum concentrations are naturally variable in soil and may be increasingly bioavailable to organisms through mining activity and acid rain. Bioavailable aluminum can be absorbed into plant tissue and dispersed to other organisms through pollen or nectar collection and herbivory. Elevated bioavailable aluminum has been linked to inhibited growth in plants and malfunction of the cholinergic system in animals. Honey bees (Apis mellifera) can be used as a model organism to understand how aluminum affects the cholinergic system. Consumption of aluminum from floral nectar and pollen food resources may inhibit acetylcholinesterase activity resulting in disorientation, delayed learning and spasms. Preliminary data shows naturally occurring concentrations of aluminum may minimally shorten lifespan, however, how aluminum affects behavior and forage assessment and fidelity is not yet known. We will present behavior data of Apis mellifera caucasia foraging on an artificial flower patch with color-dependent sugar concentrations to determine color fidelity before and after aluminum treatment and when fed sucrose alone. This allows us to understand how forage quality assessment is affected by potentially neurotoxic aluminum. If aluminum is affecting foraging decisions is may be reducing hive survival and may similarly contribute to cholinergic malfunctioning in vertebrates such as is seen in neurodegenerative disorders.

WP284 The Unforeseen Challenges of Pollinator Toxicity Test Matrices

S.K. Long, Exponent / Center for Chemical Regulation and Food Safety; J.P. Staveley, Exponent; B.M. Polakoff, R. Coler, Exponent Inc; J.R. Hoberg, Smithers Viscient / Ecotoxicology; M. Patnaude, Smithers Viscient, LLC / Ecotoxicology; K. Rathjen, Smithers Viscient LLC

The USEPA has indicated an intention to codify requirements for toxicity data from laboratory tests with honey bees (Apis mellifera) as part of Tier 1 requirements for the registration of pesticides under the Federal Insecticide, Rodenticide, and Fungicide Act (FIFRA). The five required honey bee Tier 1 toxicity tests are adult acute oral, adult acute contact, larval acute oral, adult chronic oral, and larval chronic oral. The adult oral and contact studies have been conducted under finalized guidelines for a number of years. A recently finalized guideline exists for the larval acute oral test, but only draft guidelines are available for the newer chronic adult oral and chronic larval studies. Experience with the conduct of these draft guideline studies is still limited. One of the more challenging aspects of the testing has been the analytical confirmation of the dosed diets to be consumed by the adult or larval bees... The dosing matrices (50% sucrose solution for adult bees and royal jelly diet for larval bees) are quite different than most matrices used in ecotoxicological testing and, as such, prove to be quite challenging for chemists and ecotoxicologists alike. In addition to the uniqueness of these diet matrices, there are complications with the unusually high dose levels often needed for test materials with limited toxicity to bees. Working with these liquid colloidal diets has led to unforeseen analytical challenges sometimes producing unreliable analytical results. We will discuss a procedure we have developed to assess the homogeneity and reproducibility of dosed diets used in honey bee toxicity tests. This procedure is intended to demonstrate dose confirmation of adult or larval honey bees during testing.

WP285 Toxaphene causes deformities and mitochondrial dysfunction in developing zebrafish embryos

N. Wu, Huaiyin Normal Univ / School of Life Science Jiangsu Collaborative Innovation Center of Reginal Modern Agriculture and Environmental Protection; V. Perez, A. De-La-Cova, U Florida; V. Dang, J. Schmidt, N.D. Denslow, C.J. Martyniuk, Univ of Florida / Physiological Sciences

Toxaphene is a restricted use pesticide that is a mixture of over 670 different chemicals produced by reacting chlorine gas with camphene. This pesticide was used heavily in the Lake Apopka region in Florida for agriculture, and today it remains elevated in the soil despite being banned for more than 50 years. Toxaphene has been reported to elicit adverse effects in both mammals and fish, and increased cancer risk has been demonstrated in laboratory rodents. The objective of this study was to determine the effects of toxaphene exposure on zebrafish early life stages, a model fish species widely used for developmental toxicity research. Zebrafish were exposed to 0.011-11.1 µg/L from 6 hours post fertilization (hpf) to 96 hpf. Significant mortality was observed in embryos exposed to >1.11 µg toxaphene/L. Deformities were noted at >0.11 µg/L doses, and included edema as well as spinal and cranial deformities. As energy production is important for development and may be related to the observed deformities, mitochondrial bioenergetics of 24 hour embryos were assessed following exposure. ZF embryos were exposed to 0, 11.1, or 111 µg toxaphene/mL (0.5% v/v DMSO) for 24 hours starting at the blastula stage (~3 hpf). Oligomycin, the uncoupler FCCP, and antimycin A were used to challenge the mitochondria in a stress test. Twenty-four hour old embryos treated with 11.1 and 111.1 µg/L showed lower basal respiration and lower ATP-dependent respiration compared to vehicle and water controls, suggesting that the capacity of the mitochondria to produce ATP was compromised following exposure to toxaphene. Future efforts are focused on the mechanisms of altered bioenergetics following toxaphene exposure, specifically on transcripts that are associated with mitochondrial dysfunction. Altered bioenergetics in early development can result in delayed hatch and compromised survival of wild species and studies are underway that are investigating wild, indigenous species in Florida.

WP286 Toxicity of polychlorinated biphenyls and N-phenyl-1-naphthylamine in juvenile turtle Chelydra serpentina

T. Colson, Queens Univ; S. de Solla, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; V.S. Langlois, Royal Military College of Canada / Dept of Chemistry and Chemical Engineering

Polychlorinated biphenyls (PCBs) as well as substituted phenylamines (SPAs) antioxidant are two chemical groups that have been used in multiple Canadian industrial processes. Despite the ban of PCB production in North America in 1977, they are still ubiquitously found in the environment. Previous studies with mammals, birds, amphibians and fish have shown PCBs to be neurotoxic, genotoxic, teratogenic, and they have been classified as endocrine disruptors. In contrast, SPAs, specifically N-phenyl-1-naphthylamine (PANA), have received very little attention despite their current use in Canada and their expected aquatic and environmental releases. There is a research gap regarding the effects of PCBs in reptiles and PANA in wildlife; therefore, snapping turtle (Chelydra serpentina) was studied due to its importance as an environmental indicator. The first experiment was conducted using food pellets spiked at an environmentally relevant concentration of the PCB mixture Aroclor 1254 (A1254) to model bioaccumulation and depuration of PCBs in the turtle's liver. Turtles were fed food contaminated with 500 ng/g A1254 for 31 days followed by clean food for 50 days. No differences were observed between the control and treated animals. This suggests that juvenile turtles exposed to 500 ng/g PCBs eliminated PCBs at a fast enough rate as to avoid bioaccumulation. Two additional dose-response experiments were performed using A1254 and PANA spiked food to determine hepatic toxicity and bioaccumulation in juvenile C. serpentina (0-12,500 ng/g and 0-10,000 ng/g, respectively). An increase in cyp1a was observed when exposed to the highest dose of A1254. PCBs are known endocrine disruptors, but although non-significant increasing trends were observed for both thyroid receptors α and β, no changes were found for aromatase or estrogen and androgen receptors, indicating that C. serpentina is less sensitive to PCB endocrine disruption than other species. Similarly to PCBs, a significant increase in cyp1a mRNA expression was also observed when exposed to the highest dose of PANA. Additionally, a suite of oxidative or cellular stress genes was studied for both PCB and PANA exposed animals, but none of the genes were altered by any treatments. Overall, this study has demonstrated the toxicity of a persistent and an emergent contaminant, which will help monitor and predict health risks associated with environmental contamination for C. serpentina populations.

WP287 Toxicological effects of Triclosan (TCS) and Triclocarban (TCC) to a model organism the nematode Caenorhabditis elegans

K.A. Lenz, UWM-ZSPH / Environmental Health Sciences; C. Pattison, H. Ma, Univ of Wisconsin Milwaukee / Zilber School of Public Health

Triclosan (TCS) and triclocarban (TCC) are antimicrobials that are widely used in soaps, plastics, clothing, and other household products, and have been detected in surface waters including the Great Lakes. Yet the potential environmental health implications of these compounds have not been well understood. Recent studies suggest that they may have adverse effect to aquatic life due to their potential endocrine-disrupting properties. Here we assessed the potential toxicological effects of TCS and TCC using a model organism the nematode Caenorhabditis elegans (C. elegans) using endpoints from organismal to molecular levels, including lethality, reproduction, lifespan, hatching rate, germline toxicity, and oxidative stress. Larval or young adult worms were exposed to environmentally relevant concentrations of TCS and TCC and examined using above-mentioned endpoints. Both TCS and TCC showed significant acute toxicity to C. elegans, with 24-h LC50s of 4.1 mg/L and 0.35 mg/L, respectively. In terms of sublethal effects, exposure to 1 mg/L of TCS and 0.01 mg/L of TCC, caused a 32% and 34% reduction in the number of offspring, respectively. Hatching time was extended by 6 hours, from 9 hours to 15 hours, or by 67% for both TCS (2 mg/L) and TCC (0.1 mg/L) at 20°C. Lifespan was decreased on average by 3.7 days and 3.2 days for TCS (2 mg/L) and TCC (0.1 mg/L), respectively. To understand the potential mechanism of observed toxicity on reproduction, a transgenic strain of the worm containing the fluorescent reporter Pxol-1::GFP was used to detect germline disruption by these compounds. Exposure to concentrations as low as 1 mg/L of TCS and 0.01 mg/L of TCC resulted in disruption in an average of 3.2 and 4.1 eggs per worm, respectively. Using the daf-16::GFP reporter system, significant oxidative stress was found in worms exposed to both compounds at concentrations as low as 1 mg/L of TCS and 0.01 mg/L of TCC. Collectively, these findings suggest that TCS and TCC may pose significant health risks to aquatic organisms. Our future work will focus on understanding the underlying mechanisms of these observed toxic effects as well as examining how environmental factors may affect such toxicity.

WP288 Trophic transfer of mercury in a terrestrial food chain from a contaminated floodplain

J. Morris, Restoration Services, Inc. / Field Services; J.G. Smith, Oak Ridge National Laboratory / Environmental Sciences Division; N. Jones, Xcel Engineering / Environmental Sciences Division; C. Standish, Univ of Tennessee; M.J. Peterson, T.J. Mathews, Oak Ridge National Laboratory / Environmental Sciences Division

Mercury (Hg), especially when transformed by environmental microbes into methylmercury (MeHg), is one of the only metals known to biomagnify in food chains, leading to elevated concentrations in higher trophic level animals. Because human exposure to Hg is through the consumption of contaminated fish, Hg biomagnification in aquatic food chains has been well characterized. However, recent studies have highlighted that Hg bioaccumulation in terrestrial food chains can be significant. Ecological risks from Hg are related to environmental concentrations, but perhaps more than any other contaminant, the magnitude of Hg bioaccumulation and risk is defined by a variety of site-specific environmental factors. East Fork Poplar Creek (EFPC), a Hg-contaminated stream in Oak Ridge, TN, provides a useful case study for evaluating the role of Hg-contaminated floodplain soil in a terrestrial food chain. The Carolina wren and the short-tailed shrew were targeted as endpoint receptors for evaluating the potential risk to wildlife from food chain exposure to Hg in the EFPC floodplain. Consequently, our goal was to characterize the bioavailability of Hg and MeHg in prey items of these two ecological receptor species. We collected soil, leaf litter, and invertebrates from different feeding guilds: herbivores (leaf hoppers), detritivores (earthworms and wood lice), and predators (wolf spiders). Samples were taken from randomly selected plots of varying distance from the stream and corresponding to a gradient of soil Hg concentrations. We analyzed samples for Hg and MeHg to calculate site specific bioaccumulation factors (BAFs) and stable isotopes ($\delta^{13}C$ and $\delta^{15}N$) to infer trophic structure of the invertebrate groups. Differences in total Hg, MeHg, % MeHg and BAFs among the invertebrate prey groups were greater than those among sampling sites. Total Hg concentrations were significantly different among all invertebrate prey groups with Hg and BAFs in worms > woodlice > spiders > leaf hoppers, while MeHg concentrations in spiders = woodlice > worms > leaf hoppers. Methylmercury concentrations in invertebrates were strongly correlated with trophic position but were not related to Hg concentrations in soil. Our results are relevant to the broader understanding of Hg bioaccumulation in terrestrial food chains, and to remediation decisions at this and other contaminated sites.

WP289 Urbanization effects at different biological organization levels of estuarine polychaete Laeonereis acuta

c. soares, Univ Federal de Santa Catarina / Biochemistry Dept; W. weis, P. Pagliosa, Univ Federal de Santa Catarina

Estuaries are ecologically important environments for many species, represent the boundary between fresh and sea water, the ideal environment where successfully perform their entire life cycle. Among polychaetes species the Nereididae Laeonereis acuta is widely spread in the South America Atlantic estuaries and sheltered areas, from 2°S to 42°S. The aim of this study was to assess the effects of diffuse pollution caused by urbanization in estuaries at different biological organization levels of the polychaete L. acuta. The study was conducted from August to September in 2014 at ten estuaries located between coordinates 25º5'S – 48º3'W and 27º5'S – 48º4'W. The effects of urbanization on different levels of biological organization of the polychaete were assessed using: i) the frequency of micronuclei, at subcellular level; ii) the body size and biomass, at individual level; and iii) the production-to-biomass ratio (P/B), at populational level. The biomass values of sampled individuals from each site were used to calculate empirically the production-to-biomass ratio of the population, uzing the formula adapted from model of Brey (2012). The determination of total nitrogen, total phosphorus and total phenols was performed by spectrophotometry according to Standard Methods (APHA, 1999).The aluminum, cadmium, chromium, copper and lead contents in sediments were obtained by inductively coupled plasma mass spectrometry. The spatial distribution of L. acuta samples was distinct between the urbanized and non-urbanized estuaries. Samples from urbanized estuaries were characterized by higher concentrations of metals (lead, cadmium, and chrome) and dissolved nutrients (phosphorus and nitrogen). Otherwise, biological samples of non-urbanized estuaries were more related with sandy sediments and well sorted grains (low variance). The analysis of variances of environmental variables showed significant higher values for aluminum, cadmium, lead and sorting in sediment as well as nitrogen in water from urbanized estuaries than from non-urbanized ones. The lower levels of biological organization (frequency of micronuclei at subcellular level; body size and biomass at individual level) showed higher values in urbanized than in non-urbanized estuaries. Contrarily, the higher level of biological organization assessed, P/B ratio of population, was significantly higher in non-urbanized estuaries than in urbanized ones.

WP290 Use of an In Vitro Protein Binding Assay to Characterize Interactions of OP Triesters and Metabolites with Thyroxine and Human Transthyretin

K.L. Hill, Intrinsik / Dept of Biology; T. Hamers, Vrije Universiteit Amsterdam / Inst for Environmental Studies; J. Kamstra, NMBU / BaSam; W.G. Willmore, Carleton Univ / Dept of Biology; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division

Organophosphate triester flame retardants (OPFRs) have been applied to plastics, foams and textiles for decades, and production of these additive flame retardants has increased substantially since the phase-out of polybrominated diphenyl ethers (PBDEs). Due to leaching, various OPFRs have been found in both indoor and outdoor environments leading to human and wildlife exposure. Recent studies have shown that the OPFR triphenyl phosphate (TPHP) is largely metabolized to hydroxylated metabolites, but also dealkylated to organophosphate diesters e.g. in vitro using human and herring gull liver microsomal assays as well as in vitro in chicken embryonic hepatocyte assay. Toxicological properties of OPFRs are not well understood to-date, though increasing evidence suggests possible effects on the thyroid system. Perturbation of thyroid hormone transport is considered to be one mechanism of action that may affect thyroid function, and this is a toxicological concern with PBDEs and especially hydroxy-BDE metabolite compounds. As such, the objectives of this study were to a) optimize an in vitro competitive protein binding assay that uses thyroxine (T4) as the natural ligand to thyroid hormone binding protein transthyretin (TTR, from human plasma), and b) apply this assay to investigate the abilities of select OPFRs identified in environmental biota, and diester and/or hydroxylated metabolites for each, to competitively displace T4 from TTR. The present method employs size exclusion chromatography, using pre-packed polyacrylamide gel filters, to separate free and protein-bound radiolabeled T4 across a series of concentrations of each organophosphate competitor. The characteristics of these interactions will be presented herein.

WP291 Wildlife Mortality Caused by Bromethalin: Implications for Incident Investigation and Risk Assessment

N. Mastrota, United States Environmental Protection Agency / Office of Pesticide Programs; C.M. Rossmeisl, USEPA

Recent regulatory restrictions of second generation anticoagulant rodenticides have led to an increased use of bromethalin in rodenticide bait products, and a potential for increased exposure to non-target wildlife. Bromethalin poisoning is quite distinct from anticoagulant poisoning, with abnormal behavioral and coordination impairment caused by neurologic dysfunction being the prominent signs of toxicity, rather than the uncontrolled hemorrhage caused by anticoagulant rodenticides. Recent reported incidents of wildlife mortality attributed to primary bromethalin poisoning have involved omnivorous mammalian species common to urban and suburban areas, including gray squirrels, raccoons, and striped skunks. Two gray fox poisonings have been reported; however, it is unknown if the foxes died from primary or secondary exposure. Notably, no mortality incidents involving raptors have been reported. Observation of granular green or turquoise material in the colon or in fecal matter, indicating possible ingestion of bromethalin bait, has been useful as a diagnostic indicator of bromethalin poisoning. Initial suspicion of bromethalin poisoning were confirmed by detection of the primary metabolite, desmethylbromethalin, in adipose and/or brain tissue, or the detection of bromethalin in the contents of the gastrointestinal tract. The co-occurrence of anticoagulant rodenticides in liver tissue has often complicated the diagnosis. Frequencies and patterns of wildlife incidents suggest that bromethalin poses a risk to non-target mammals from primary exposure, whereas risk from secondary exposure appears to be less than for anticoagulant rodenticides. Possible reasons for the reduced secondary risk are discussed.

WP292 Carolina Wren Revisited: The Challenges of Field Study

B. Henry, J. Murauskas, Anchor QEA

Field studies of contaminant impacts on avian nest success present numerous challenges for quantitative assessment. We analyzed the study design and data used to model a predictive relationship between blood mercury (Hg) concentrations and reduction in nest success of Carolina wren (Thryothorus ludovicianus) (Jackson et al. 2011), which has been considered for use in assessments of risk and natural resource damages. Our analysis indicated that study design and data interpretation were insufficient for predicting reduction in nest success at specific blood Hg concentrations. The reference site selection process was not documented, the number of samples was small (i.e., only two and four abandoned nests at reference and contaminated sites, respectively, in the 2010 dataset of 40 nests used in the predictive model), and the mixed use of artificial (box and tube) and natural nests (with artificial nests disproportionately used in contaminated sites in 2010) confounded interpretation. We calculated 30-day nest success and used the mathematical model MARK, similar to Jackson et al.'s use of MCestimate, to evaluate various statistical models to explain observations. For the pooled 2007 to 2009 dataset where all but one cavity was artificial (and therefore cavity type was controlled), 30-day nest success based on abandoned nests was the same at reference and contaminated sites. In 2010, 30-day nest success based on abandoned nests in the reference sites was higher than in the contaminated sites and higher than both in 2007-2009, however the reference sites had twice as many natural cavities as the contaminated sites. Our MARK results based on abandoned nests indicated that cavity type was an important covariate, along with location. While nest success data and mathematical models have potential for assessing contaminant impacts, robust studies require extensive data collection and accounting for multiple factors other than contaminants that impact nest success and, perhaps more importantly, fecundity. In addition, variable results among years indicate the need for multi-year studies. Mathematical models are powerful; however, conclusions are ultimately limited by the quality and quantity of observations. The Jackson et al. predictive relationship between blood Hg and reduction in nest success is compromised by its study design and small dataset, and therefore should not be used for quantitative estimation of risk, injury, or service loss to songbirds.

WP293 The Effect of Scaling Factors on Terrestrial Organism Pesticide Risk Assessments

C. Habig, Compliance Services International

EPA relies on the T-REX model for conducting pesticide risk assessments on birds and mammals, and often extrapolates the results for birds to reptiles and terrestrial-phase amphibians. This model focuses on potential risks to birds and mammals through ingestion of feed items containing pesticide residues. T-REX contains a set of default feed item categories, which include grasses, broadleaf plants, arthropods, fruits, and seeds. The model estimates potential acute and chronic risks to three size classes of birds (20 g, 100 g, 1000 g) and mammals (15 g, 35 g, 1000 g). T-REX also includes default scaling factors that adjust the toxicity endpoints for birds and mammals based on the weight of the tested animals compared to the three weight classes of birds and mammals evaluated by the model. For avian assessments the scaling factor adjusts the toxicity endpoints so that endpoints for smaller birds are lower than those for larger birds. In contrast, for mammals the scaling factor adjusts the toxicity endpoints so that endpoints for larger mammals are lower than those for smaller mammals. The overall result of using these scaling factors is to significantly change the toxicity endpoints from those determined in standard toxicity testing, which impacts conclusions concerning potential risks to different size birds and mammals, including endangered species. In contrast to these estimated toxicity endpoints, actual testing of animals of similar sizes to the sizes evaluated by T-REX often results in very different actual toxicity values. Examples comparing T-REX estimated toxicity values to actual toxicity values for several pesticides will be provided, along with discussion of the impact of these discrepancies on risk assessment conclusions. Impacts on risk conclusions concerning endangered species are much more likely because the bar for concluding possible effects on endangered species is much lower than for non-endangered species.

Aquatic Toxicology and Ecology – Poster Only – Part 3

WP294 Exploring mechanisms of organophosphate resistance in natural populations of the crustacean Hyalella azteca

A. Manny, Florida Dept of Agriculture and Consumer Services / Dept of Microbiology and Cell Science; K. Major, Univ Of Massachusetts Boston / School for the Environment; D.P. Weston, Univ of California / Dept of Integrative Biology; H.C. Poynton, Univ of Massachusetts, Boston / School for the Environment

Hyalella azteca are freshwater, epibenthic amphipods widely used in environmental toxicology to study the impacts of human activities including the consequences of pest management. In recent years, resistance to pesticides has been documented not only in insect pests but also non-target organisms including H. azteca. One such group of pesticides facing resistance is the organophosphate (OP) class, which targets and inhibits the neurotransmission enzyme acetylcholinesterase. While most wild populations of H. azteca, including the strain commonly used for toxicity testing, are susceptible to organophosphates, select wild populations of H. azteca are 5-1000 fold more tolerant to OPs compared to background sensitivity. The emergence of resistance in a non-target organism reveals environmental implications of pesticide application beyond their immediate insect target; therefore, there is a critical need to better understand the mechanisms and possible ecological consequences of organophosphate resistance. Our study investigated the genetic basis of OP resistance in H. azteca by examining the acetylcholinesterase (Ace) gene, the target site of OP insecticides, in both susceptible and resistant populations. In particular, a single amino acid substitution, G119S in Ace has been highly correlated with OP resistance in target pests. We found that although lab populations did not harbor this mutation, the G119S mutation was present with up to a 40% frequency in select resistant populations. In addition, through protein modeling we showed that this substitution alters the active site providing further support for its role in OP resistance. However, the presence of the mutation is not sufficient to explain differences in the sensitivity across resistant populations. As an alternative, and likely complementary mechanism of resistance, we also dove into the newly assembled H. azteca genome to identify and annotate genes involved in OP metabolism. Increases in gene expression of metabolic enzymes such as glutathione-S-transferases (GSTs) may provide further protection against OP insecticide toxicity. We annotated a total of 28 GSTs, which is similar to the expected number in crustaceans, providing confidence that we identified a nearly complete set of GSTs in H. azteca. Through the further investigation of Ace mutations along with expression levels of GSTs, we expect to fully characterize the mechanisms of OP resistance in natural populations of H. azteca.

WP295 Assessing the Developmental Neurotoxicity of 27 Organophosphorus Pesticides Using a Zebrafish Behavioral Assay

M. Waalkes, ORISE USEPA / ORD NHEERL ISTD; D.L. Hunter, USEPA NHEERL ISTD; K. Jarema, USEPA ORD NHEERL; W. Mundy, USEPA NHEERL ISTD; S. Padilla, USEPA / ISTD

The U.S. Environmental Protection Agency is evaluating methods to screen and prioritize organophosphorus pesticides for developmental neurotoxicity. As such, we are exploring a behavioral testing paradigm that can assess the effects of sublethal and subteratogenic concentrations of developmental neurotoxicants on zebrafish (Danio rerio). This in vivo assay quantifies the locomotor response to light stimuli under tandem light and dark conditions in a 96-well plate using a video tracking system on 6 day post fertilization zebrafish larvae. Each of twenty-seven organophosphorus pesticides was tested for their developmental neurotoxic potential by exposing zebrafish embryos/larvae to the pesticide at several concentrations (≤ 100 μM nominal concentration) during the first five days of development, followed by 24 hours of depuration and then behavioral testing. Approximately 22% of the chemicals (Acephate, Dichlorvos, Diazoxon, Bensulide,Tribufos, Tebupirimfos) did not produce any behavioral changes after developmental exposure, while many (Malaoxon Fosthiazate, Dimethoate, Dicrotophos, Ethoprop, Malathion, Naled, Diazinon, Methamidophos, Terbufos, Trichlorfon, Phorate, Pirimiphos-methyl, Profenofos, Z-Tetrachlorvinphos, Chlorpyrifos, Coumaphos, Phosmet, Omethoate) produced changes in swimming activity. Some of the latter group (Diazinon, Omethoate, Pirimiphos-methyl, Profenofos, Terbuphos) were particularly potent for developmental neurotoxicity, showing behavioral alterations at doses 2 to 3 orders of magnitude below the developmental concentrations that produced death or dysmorphology. These results indicate that some of these organophosphorus pesticides may elicit neurodevelopmental toxic effects in zebrafish at concentrations below those that produce lethality or dysmorphology. This abstract may not necessarily reflect official Agency policy.

WP296 An assay for quantitative detection of reactive toxicity in whole zebrafish embryos – case of two pesticides

T. Seiler, C. Lackmann, RWTH Aachen Univ / Ecosystem Analysis; H. Hollert, RWTH Aachen Univ / Dept of Ecosystem Analysis; S. Rainieri, Azti-Tecnalia / Food Research; M.M. Santos, Azti-Tecnalia / Food Quality Safety and Identity; P. Spirhanzlova, Watchfrog SA; M. Velki, RWTH Aachen Univ / Ecosystem Analysis

Reactive toxicity is a first line response of cells upon exposure to toxic substances and part of the process that leads to cytotoxicity of contaminants. Detection of reactive toxicity in complex organisms can help to identify cell stress way before effects become visible on an organ or organism level. This allows for an early and sensitive identification of adverse effects. A zebrafish embryo assay that uses a fluorescent dye for microscopic detection of glutathion was adapted to a 96-well plate format to allow for quantification of reactive toxicity through fluorescence measurement with a multiwell plate reader. The assay was initially developed using tert-butyl hydroperoxide (t-BHP) as a reference substance, and then benchmark tested against the two pesticides diazinon and diuron. Long and short-term exposure scenarios and different protocols for the fluorescent staining were used. Hatched larvae (96 hpf) were then anesthetized, transferred to 96-well plates with conical wells, and fluorescence measured using a tailored detection method for a multiwell plate reader. Embryos were also inspected under a fluorescence microscope to qualitatively record locations and intensities of reactive toxicity in the individual specimen. Prior to the assay, lethal and sublethal effects of the pesticides on zebrafish embryos had been determined in a common FET test. We found that the assay is capable of detecting reactive toxicity of diazinon and diuron at concentrations as low as 0.1 mg/L and 0.02 mg/L, respectively, using the long-term exposure scenario. For the short-term exposure LOECs were 2 mg/L for both pesticides. For the reader measurement we could not observe any difference in the data of repeated measurements after thorough shaking, while the position of the embryo in the well turned out to be crucial for microscopic inspection. The assay allows to detect effects on zebrafish embryos at an early stage and at a low level of exposure clearly before deleterious consequences on an organ or organism level become visible. Since the embryos are kept alive, subsequent investigations of, e.g., EROD or micronucleus induction or further enzymatic biomarkers are possible. We will use the assay to investigate the impact of reactive toxicity on mechanism-specific biomarkers in zebrafish embryos. This would allow to verify whether biomarker results are representing a specific mode of action, or are rather the consequence of decreasing cell fitness.

WP297 Assessment of the toxicity of dichlorvos on organisms of different trophic levels

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; A. Perez-Rojas, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia lab Geologia

Dichlorvos (DDVP) is an organophosphate insecticide considered by the EPA as highly toxic. This compound is effective in controlling lepidopteran, mites and homeópteros. It is used to control pests in domestic animals and to eliminate exogenous parasites in salmon aquaculture farms. Because there are few studies of the effects of DDVP in aquatic organisms The objective of this study was to evaluate the toxicity of dichlorvos in organisms of different trophic levels: Cladocerans: Daphnia magna, Daphnia exilis, Daphnia pulex and Simocephalus mixtus. The ostracod Cypris sp. and fishes: juvenile charal (Chrirostoma jordani) and juvenile zebrafish (Danio rerio). Furthermore their sublethal effects were evaluated by means of assessment of four biomarkers (growth rate, O:N index, lipoperoxidation and inhibition of acetylcholinesterase enzyme). Acute bioassays were performed, the organisms were exposed to 6 pesticide concentrations to determine the LC_{50}. Subsequently tests with duration of 15 days were made where the organisms were exposed to a sublethal concentration (LC_{10}), for assessment of 4 biomarkers. In the results it was evident that the cladoceran Daphnia exilis and juvenile Chirostoma jordani are more sensitive to DDVP compared to other species. The O:N index had values below 9 fact indicates that organisms were in a high degree of stress. Growth rates of intoxicated organisms were between 19 to 49% lower than those observed in the control group. The degree of lipid peroxidation was increased up to 200% in the exposed organism. A decrease in AChE activity was observed in cladóceros between 22 and 45% and fish from 22 to 35%. The results of this study indicate that the effects of the pesticide DDVP in organisms under study are likely irreversible.

WP298 Comparison of the transcriptional impact of chlorpyrifos and permethrin onolfaction in zebrafish larvae and adults

S. Volz, RWTH Aachen Univ / Inst for Environmental Research; S. Schiwy, Inst of Environmental Research-RWTH Aachen / Dept of Ecosystem Analysis ESA; H. Hollert, RWTH Aachen Univ / Dept of Ecosystem Analysis

A variety of essential activities and behaviors of fish, for instance food detection, kin recognition, homing, the predator response and mating habits, depend on olfaction. Consequently, an impairment of the olfactory system can affect both individual fish and whole populations. Despite the importance of the olfactory system for fish, only few studies investigating an impairment of the latter were published and little is known about underlying mechanism. The olfactory epithelium (OE) is locatedin two pits at the dorsal part of the snout. Through these pits the surrounding water is constantly flowing. The olfactory receptor neurons (ORNs), which are responsible for odorant detection, are situated within the OE and only separated from the environment by a thin layer of mucous. In such an exposed situation dissolved xenobiotics can interact with them as easily as natural odorants do. The olfactory system in zebrafish larvae is present albeit not fully developed yet. The number of neurons in the olfactory bulb (OB), for instance, counts 5 % of the amount of neurons in the OB of adult zebrafish. Previous studies have shown that several metals and pesticides are able to influence the olfactory system of fish in environmentally relevant concentrations. However, underlying mechanisms predominantly remain unidentified. The current study compared the effects of short term exposures (3 and 24 h) to sublethal concentrations of the commonly used pesticides chlorpyrifos and permethrin on the gene expression of marker proteins for the three different types of ORNs (olfactory marker protein B (ompb), transient receptor potential cation channel, subfamily C, member 2 (trpc2), s100 protein (s100z) and enzymes with protective function during oxidative stress (peroxiredoxin-1 (prdx1) and hemeoxygenase-1 (hmox1)) in both zebrafish larvae and adults. Thereby, information about the suitability of zebrafish larvae as an alternative test model for olfactory toxicity is gathered. Neither permethrin nor chlorpyrifos induced the gene expression of hmox1 and prdx. 24 h exposure to chlorpyrifos led to a concentration dependent slight decrease in the expression of ompb and trpc2. Following 24 h exposure to permethrin a minor decline of the gene expression of ompb and s100z was detected. The collection of the gene expression data of adult zebrafish is still in progress, but will be ready for presentation until the start of the conference.

WP299 The effect of chlorpyrifos on salinity acclimation of rainbow trout: Serum hormones and gene expression changes in liver, gill and olfactory rosettes

B.M. Amiri, Univ of Tehran / Dept of Fisheries Environmental Sciences; G. Xu, UC Riverside / Dept of Environmental Sciences; A. Kupsco, Univ of California Riverside; M. Giroux, Univ of Maine / School of Marine Sciences; J. Richards, J. Gan, D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences

As a part of their unique life cycle, most salmonids undergo transition from freshwater to saltwater, requiring various adjustments in metabolism, osmoregulation and ion regulation. The hypersaline acclimation of salmonids can be affected by pesticides during downstream migration of fish to the estuary. The present study aims to determine how toxicity of chlorpyrifos (CPF) impacts hypersaline acclimation of Steelhead/rainbow trout (Oncorhynchus mikiss). We exposed fish (52±5 g, 4 fish in each 4 replicate 20L glass tank) to 0, 20, 40, 80, 160 µg/L of CPF for 7 days, and then to hypersalinity (12ppt) for another 7 days. Blood or tissues (liver, gill and rosette) were collected after exposure. Mortality, levels of cortisol, T3 and T4 in serum, and expression of genes involved in detoxification, ion transportation and neural signal transduction were measured at the 7th day (CPF exposure) and 14th day (salinity) exposure. CPF exposure did not significantly alter cortisol levels, but fish exposed to hypersaline conditions showed higher cortisol levels than freshwater control groups. Serum thyroid hormones T3 and T4 were also increased after CPF exposure as well as during the salinity acclimation. Hepatic mRNA of Glutathione-S-Transferse pi (GST) was increased up to two fold following exposure to CPF and a similar trend was observed after hypersaline exposure. Expression of Na+/K+ATPase α1 mRNA in the gills was increased 4 fold during salinity exposure but was unchanged by CPF. These results indicate CPF may alter endocrine pathways that influence osmoregulation and growth in fish as they reach hypersaline water.

WP300 Exposure to a Common Pesticide, Butachlor, alters Tadpole Morphology

C. Richardson, M. Shuman-Goodier, C.R. Propper, Northern Arizona Univ / Dept of Biological Sciences; G.R. Singleton, Northern Arizona Univ

Butachlor is the most common herbicide used by rice farmers in the Philippines and throughout Southeast Asia. At concentrations much lower than the recommended application rate of 4.8 mg/l, Butachlor exposure has been linked to genotoxicity, neurotoxicity, carcinogenesis, and endocrine disruption in insects and amphibians. Rice fields provide substitute wetland habitat for several amphibian species that can be used as sentinels of farmer exposure risks. Amphibians represent valuable bio-indicators because they have the same general endocrine glands and hormones that control growth, development, reproduction, and other physiological responses in humans. Our experiment tested the effects of butachlor and interspecific competition as a second stressor on the growth and development of two species of frogs, Fejervarya vittigera (native) and Rhinella marina (invasive). Because of the success of the invasive species in our study population, we hypothesized that R. marina would be less affected by butachlor than F. vittigera. We conducted both geometric morphometric and traditional morphometric analysis using TSP DIG 264, MorphoJ, GeomoRph, and Image J. We measured total body, snout vent, tail, tail width, and hind limb length as well as general tadpole shape using landmark and semi-landmark coordinates after a 15-day exposure. Our results demonstrated that overall morphology and development in F. vittigera was slowed in butachlor and competition treatments whereas in R. marina development was much faster in butachlor and competition treatments. The results indicate that butachlor affects morphology and development in a species-specific fashion. Because amphibian development is under control of both thyroid hormone and stress hormones, we will investigate the underlining endocrine mechanisms that may influence development in these species when exposed to butachlor.

WP301 Oxidative Damage to DNA and Lipidic Peroxidation in Oreochromis niloticus exposed to the fipronil insecticide during periods of hypoxia

P. Dourado, UNESP/ IBILCE Sao Jose do Rio Preto; I.G. Batalhão, UNESP IBILCE Sao Jose do Rio Preto / Chemistry and Environmental Sciences; A. Arantes Felicio, UNESP/IBILCE/Sao Jose do Rio Preto / Dept of Chemistry and Environmental Sciences; E.R. Silva, UNESP IBILCE Sao Jose do Rio Preto / Chemistry and Environmental Sciences; E.A. Almeida, UNESP/IBILCE/ Sao Jose do Rio Preto

Fipronil is a pesticide used in sugarcane, persistent in soil and has been widely detected in aquatic environments. Its presence in water compartments can influence and promote changes in physiological processes of fish, causing oxidative stress, which can be demonstrated by increased lipid peroxidation in different organs, which is measured by the levels of malondialdehyde (MDA). Whereas, adverse effects on the environment such as the condition of hypoxia, can negatively influence in this process and cause changes in DNA integrity, we propose to evaluate the influence of exposure to a commercial formulation of fipronil (Regent®800WG) on parameters of lipid peroxidation in gills of Oreochromis niloticus under hypoxic and its effect on DNA. The fishes used in this study were exposed for 3 and 8 hours to fipronil in two concentrations (0,1 e 0,5 µg L^{-1}), in the presence and absence of hypoxia. The low oxygen concentrations in the water were maintained by bubbling with gaseous nitrogen. For each exposure time it was maintained a negative control. After each exposure times, the animals were collected and then evaluated the degree of lipid peroxidation in gills and oxidative damage to DNA by comet assay in fish erythrocytes. The results were submitted to the Kruskal-Wallis statistical test and post hoc Newman-Keuls and considered statistically significant difference with $p < 0.05$. The results indicated significant decrease in MDA levels in the gills of animals exposed to 0.5 ug L^{-1} concentrations compared to control, with the largest decrease in MDA levels observed in the groups exposed to hypoxia in combination with fipronil in the two concentrations tested. Some studies have shown that significant decreases in MDA levels upon exposure to different pollutants are related to the response to stimulation antioxidant. This effect could be observed in the groups exposed to hypoxia together with Fipronil, which showed a higher rate of oxidative damage to DNA, suggesting that, under hypoxia, the sites of electron transport chains are lower due to limited oxygen availability. So, there are more electrons to escape the fetters and add oxygen molecules, increasing the risk of tissue damage. These results indicate that Fipronil is capable of inducing cell damage in environmentally relevant concentrations, and their action can be compounded when coupled with environmental factors.

WP302 Evidence of DDT resuspension through dredging of a Midwest agricultural lake system

D.W. Simonsen, Buena Vista Univ / School of Science; M.A. Coogan, Buena Vista Univ / Science

Although the organochlorine dichlorodiphenyltrichloroethane, commonly referred to as DDT, was outlawed in select countries during the 1972 Stockholm Convention due to its long half-life and ability to sorb to substrate, DDT and daughter compounds can persist in the environment for approximately forty years. When sorbed to substrate, DDT does not pose a measurable threat, but once large quantities are disturbed by anthropogenic activities such as dredging, DDT could be released into the water column and recirculate through the ecosystem. Due to the lipophilic nature of DDT, resuspension and bioaccumulation in organisms readily consumed by humans may occur. This pilot study attempted to determine if DDT compounds were present at measurable levels in Storm Lake, a dredged 3,097 acre lake located in agricultural Iowa. Storm Lake averages a 20 foot depth with UTM coordinates being Zone 15T: (0318509E) (4723248N). The lake system was formed during the Wisconsin Glaciation period and is commonly used for recreation. Due to its relatively shallow depth, dredging began in Storm Lake in the early 2000's and continues to present time. This study worked with three substrate samples contributed by FYRA Engineering, Omaha, NE, which was contracted by the local Lake Improvement Commission to collect a series of 12 substrate samples for siltation analyses. The three samples used for this analysis were chosen based on when the site had been dredged. Site A had not been dredged, Site B was dredged in 2011, and Site C was dredged in 2015. To determine concentrations of DDT compounds in the samples, an external calibration curve was created through analysis of 0 ppm, 0.1 ppm, 0.2 ppm, 0.25 ppm, 0.5 ppm, and 1 ppm concentration solutions of DDT Mix Neat from Ultra Scientific in acetonitrile on an Agilent 7890A/5975 GC/MS. The GC was equipped with an HP5MS column, and Helium was used as the carrier gas at a flow rate of 1.0 mL/min. A range of m/z 50–500 was scanned to confirm the retention times of the analytes. The calibration curve related the DDT Mix concentrations in ppm to the abundance peak area at a retention time of 17.23 minutes for DDD and 18.61 minutes for DDT. Results indicated that DDT levels in selected Storm Lake sites were non-detectable, but this study plans to continue research investigating DDT bioaccumulation and metabolomics at all 12 sites using planarians as a biological model.

WP303 Effect of flow on bioaccumulation of DDT and other organochlorine pesticides in an apex aquatic predator from Kruger National Park, South Africa

R. Gerber, North West Univ Potchefstroom Campus; N. Smit, North West Univ / Environmental Sciences and Management; J.H. van Vuren, Univ of Johannesburg / Zoology; Y. Ikenaka, M. Ishizuka, Y.B. Yohannes, Hokkaido Univ / Graduate School of Veterinary Medicine; V. Wepener, North-West Univ / Unit for Environmental Sciences and Management

With the top gross domestic product in Africa, South Africa is known to have a high pesticide usage, which includes the highly persistent and banned group of organochlorine pesticides (OCPs). South Africa is also one of few countries to still actively spray DDT as malaria vector control. The aim of the study was therefor to determine the degree to which aquatic biota in selected rivers of the world renowned Kruger National Park (KNP) are exposed to OCPs used in the catchments outside the KNP. Tigerfish, Hydrocynus vittatus, an economically important apex predator, was selected as bioindicator for this study. Fish were sampled from the KNP sections of the Luvuvhu, Letaba and Olifants Rivers during the high and low flow periods from 2010 to 2012 and OCPs were determined in muscle tissue using GC-ECD techniques. Significant flow related and spatial (different rivers) OCP bioaccumulation was observed. Tigerfish from the Luvuvhu River displayed the highest OCP bioaccumulation. Concentrations of the majority of the OCPs including the DDTs were the highest levels ever recorded from South African freshwater systems and in many cases the concentrations were higher than most contaminated areas from around the world. The concentrations found in

H. vittatus muscle also exceeded maximum residue levels in edible fat as set by the European Union. This is of concern when managing the water resources of the conservation area since the contaminants enter the park from outside the borders and pose potential risks to the mandated conservation of aquatic biota within the KNP.

WP304 Effects of Bifenthrin on the Estrogenic and Dopaminergic Pathways in Embryos and Juveniles of Zebrafish (Danio Rerio)

L. Becker Bertotto, Univ of California Riverside; D.C. Volz, Univ of California, Riverside / Environmental Sciences; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences

Bifenthrin (BF) is a pyrethroid pesticide widely used in urban and agricultural applications. Previous studies in fish have shown that environmentally relevant concentrations of BF can affect the endocrine system by leading to the over production of 17b-estradiol (E2) and altering the expression of dopaminergic pathway components in the central nervous system in fish. Dopaminergic neurons regulate luteinizing hormone (LH) and follicle stimulating hormone (FSH), which control E2 biosynthesis, suggesting that BF may disrupt the hypothalamic-pituitary-gonad (HPG) axis. The hypothesis that BF impairs this pathway was tested in embryonic and one-month old juvenile zebrafish (Danio rerio). At 3 hours post fertilization (hpf), and one month of development, fish were exposed to 0.15 and 1.5 ppb BF for 96 hours. The relative levels of transcripts related to the dopaminergic and the HPG axis (tyrosine hydroxylase (TH), dopamine receptor 2A (DR2A), dopamine active transporter (DAT), sodium/potassium ATPase (NA/K ATPase), LHb, FSHb, and vitellogenin (VTG)) were investigated by qRT-PCR. Levels of E2 were measured by ELISA. Dopamine and its metabolites (3, 4-dihydroxyphenylacetic acid and homovanillic acid) concentrations were evaluated by LC-MS/MS. Preliminary results show significant decreases of TH, NA/K ATPase, and VTG transcripts in zebrafish embryos, and a significant increase in the expression of TH and DAT in zebrafish juveniles. Estradiol levels were significantly decreased in embryos. These results show a possible anti-estrogenic effect of BF in embryos, and estrogenicity in juveniles. Studies on dopamine concentrations are ongoing. Further analysis of differentially expressed genes coupled with endocrine responses can help assess potential toxic and sub lethal effects of BF using zebrafish as an animal model.

WP305 Effects of Bifenthrin on Sex Differentiation in Japanese Medaka (Oryzias latipes)

R. Bruce, Plymouth Univ / School of Biological Sciences; R. Sikder, Univ of California- Riverside; M. Giroux, Univ of Maine / School of Marine Sciences; L. Becker Bertotto, Univ of California Riverside; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences

Bifenthrin (BF) is a pyrethroid pesticide widely used in urban and agricultural applications. In vitro studies have indicated anti-estrogenic activity in this compound; however, in fish estrogenic activity has been observed. The Japanese Medaka (Oryzias latipes) is a unique model due to early life stage susceptibility to phenotypic sex reversal upon exposure to estrogenic compounds. Moreover, it is well known that this fish express the male-determining DMY gene,an easy way of verifying genotypic sex. The hypothesis that BF impairs sex determination was tested in larval and embryonic Japanese Medaka. Fish were exposed, in vivo, to environmentally relevant concentrations of BF (0.15ppb and 1.5ppb), a single concentration (0.5µM) of an E2 receptor antagonist (ICI 182780), and an agonist (E2). Separate exposures were implemented at 2 hours post fertilization (hpf) for 10 days and 7 days post hatch (dph) for one month to simulate environmentally relevant exposures at sensitive stages of embryonic and larval development, respectively. Phenotypic sex, secondary sexual characteristics (SSC) and genotypic sex were investigated at sexual maturity. Preliminary results show trends of increased feminine SSC scores in Japanese Medaka exposed to BF at the embryonic stage ($p = 0.083$), but not at the larval stage ($p = 0.924$). Mann-Whitney U tests indicated differences between 1.5ppb BF and ICI 182780 with increased feminization in BF ($p = 0.02$) following embryonic exposure. In addition, Mann-Whitney U tests also indicated significant differences between 0.15ppb and 1.5ppb BF ($p = 0.02$) with higher feminization in the 1.5ppb BF embryonic exposure. Although, a trend toward masculinisation in sex ratios was observed for ICI 182780, reductions in male fish percentages for 0.15ppb and 1.5ppb BF were observed. Ongoing studies will compare phenotypic values of SSC with DMY expression in the same individuals. These results show a possible estrogenic effect of BF in embryos, affecting sex determination.

WP306 Anti-predator responses of freshwater snails following chronic exposure to atrazine

A.M. Simpson, L.E. Beaty, B. Luttbeg, J.B. Belden, Oklahoma State Univ / Integrative Biology

This study examined the effect of chronic atrazine exposure on anti-predator behavior in freshwater snails (Physa spp.). Fifty adult Physa were collected from Teal Ridge Wetland in Stillwater, OK. Experimental snails (24-hours old) were obtained from the subsequent generation (F1). Fifteen snails were haphazardly assigned to each experimental unit—900mL pyrex bowls. For 21 days, each unit was subjected to one of six treatments: four nominal atrazine concentrations (50, 100, 200, 400 µg/L) or two controls (acetone or water). Following the chronic exposure period, five snails were randomly selected from each treatment replicate (n=4) and separated into individual deli cups for the behavioral assays. To establish baseline responses for each snail, avoidance behavior (above, below, or at the water line) and activity (movement) were scored at 15 minute intervals over a period of 90 minutes. Predator cues—water collected from tanks containing snail-fed crayfish —were then applied to each unit, and the same behavioral metrics were again scored every 15 minutes for an additional 90 minutes. In the presence of such cues, Physa can quickly detect predation risk and crawl out of the water—hence our avoidance metric. Preliminary results suggest that chronic atrazine exposure increases baseline activity, and alters anti-predator behavioral response. These data indicate that exposure to atrazine can alter prey behavior, which has implications for our understanding of the effects of multiple stressors in aquatic systems. Future studies will aim to investigate how atrazine exposure affects epigenetic inheritance of anti-predator phenotypes.

WP307 Photosynthetic capacity of Oedogonium sp. (Chlorophyta) exposed to technical-grade glyphosate and Roundup® treatments

R. de Campos Oliveira, L. Kortz Vilas Boas, C. Branco, Univ ESTADUAL PAULISTA – UNESP / Dept of Biological Sciences

The macroalgae constitute, usually, dominant autotrophic communities in streams, playing an important role in primary productivity. Although the macroalgae are susceptible to exposure to herbicides coming from agricultural fields near streams and rivers, there are few studies describing the effects of glyphosate on ecophysiological aspects of these producers. Considering this scenario, the present study measured the impact of technical-grade glyphosate and the commercial formulation Roundup® on the photosynthetic response of Oedogonium sp. (Chlorophyta), using data from chlorophyll a fluorescence, oxygen evolution and chlorophyll a content after one (T1) and seven days (T7) of exposure. Three herbicide concentrations were used: i) the maximum concentration for irrigation and animal consumption allowed under Brazilian law (0.28 $mg.L^{-1}$); ii) the recommended concentration to control plagues (3.5 $mg.L^{-1}$); and iii) the highest concentration found in a natural aquatic environment (6.0 $mg.L^{-1}$). Specimens of Oedogonium sp. had improved photosynthetic performance in technical-grade glyphosate treatment at the highest concentrations (3.5 and 6.0 $mg.L^{-1}$) in T1 and T7, and in Roundup® treatment at the lowest concentration (0.28 $mg.L^{-1}$) in T1. However, technical-grade glyphosate treatment showed, for highest concentrations, an increase on non-photochemical quenching in T1, and on quantum yield of non-regulated non-photochemical energy loss in T7, suggesting a damage in the photosynthetic apparatus in long-term. The quantum yield of non-regulated non-photochemical energy loss was also increased in Roundup® treatment for 6.0 $mg.L^{-1}$ in T1, besides the reduction of photosynthetic

efficiency. The results showed that Oedogonium sp. has a relative ability to resist the deleterious effects of technical-grade glyphosate and Roundup® and, depending on the concentration of active ingredient and surfactant, the presence of these herbicides could even enhance its photosynthetic yield. This indicates a probable change in the abundance of this macroalgae due to land use of adjacent areas in which the aquatic ecosystem is located. The comparison between both treatments showed that Roundup® was more harmful than technical-grade glyphosate, mainly in higher concentrations. This result is probably due to the presence of surfactant in Roundup® formulation, which has been repeatedly pointed out as evenly or more toxic than the active ingredient.

WP308 Glyphosate affects finfish cholinesterase activity in acute exposures

J.F. Gonzalez, Universidad Nacional de Colombia / Animal Health Toxicology; D.M. Ochoa, C. González, Universidad Nacional de Colombia / School of Veterinary Medicine; D. Figueredo, M. Ramírez, Universidad Nacional de Colombia; C. Moreno, P. Rojas, A. Jiménez, Universidad Distrital Francisco José de Caldas

Glyphosate is widely used in Colombia to control illegal crops such as poppy (Papaver somniferum) and coca (Erythroxylum coca) plants as well as weeds of edible crops. Acute (96-h), glyphosate exposures (as Roundup®) in different finfish species of importance in Colombia determined from mild to severe central nervous system (CNS) effects and changes in plasma (nmols/ml/min) and brain (nmols/min/mg protein) cholinesterases (AChE, BChE). Ghost fish specimens (Apteronotus albifrons), an electric fish found in the Orinoco and Amazon rivers basins, exposed to 0, 10 and 90 ppm Roundup® (v/v) (n=27) displayed a significantly higher plasma AChE activity (anova, $p< 0.05$) at 90 ppm Roundup® (112.8 ± 46) as compared to controls (65.0 ± 25.6) and 10 ppm (67.4 ± 26.4). These changes were accompanied by mild CNS signs. Juveniles of red tilapia (Oreochromis sp.) (n=36) exposed to 0, 1, 5, 15, 45 and 90 ppm Roundup® (v/v) showed significant increases in both plasma AChE and BChE at the two highest concentrations (anova, $p< 0.05$) along with severe CNS symptoms in comparison to controls or low-concentration exposures; whereas in Nile tilapia (Oreochromis niloticus) juveniles (n=12), exposed to 0 and 15 ppm Roundup®, there was a significantly lower AChE plasma activity in glyphosate-exposed fish (171.7 ±34.2) as compared to controls (334.5 ± 56.8) (T-test, $p< 0.05$) and no signs in CNS. Interestingly, after 10 days of ceasing the exposure, AChE activity returned to normal baseline levels in those Nile tilapias that had been exposed to Roundup®. Bocachico (Prochilodus magdalenae) (n=12) and yamú (Brycon amazonicus) (n=18), two indigenous fish species of Colombia, showed reduced brain AChE (nmols/min/mg protein) when exposed to 10 ppm (bocachico 1.8 ± 0.6, yamú 7.2 ± 1.8) as compared to controls (bocachico 47.0 ± 4.5, yamú 160.2 ± 13.7) whereas bocachico increased significantly AChE when exposed to 30 ppm Roundup® (113.0 ± 8.0) in comparison to controls and 10 ppm. All the species tested showed changes in cholinesterase activity when exposed to the herbicide. A mechanistic approach to explain interactions between the herbicide and the cholinesterases enzymes remained unknown in our investigations as well as likely ecological implications on fish behavior or interrelations amongst fishes in natural bodies of water due to the presence of glyphosate as a contaminant and the effects on cholinesterase activity.

WP309 Glyphosate (FAENAMR) exposure affects demographic parameters and the size of the progeny in the cladoceran Simocephalus mixtus

A.V. Rodriguez-Miguel, Instituto Politécnico Nacional ENCB; F. Martínez-Jerónimo, Instituto Politécnico Nacional ENCB / Lab de Hidrobiologia Experimental

Glyphosate, in different commercial formulations, is the herbicide more frequently used in agriculture to control weeds. As occurs with other pesticides, it can be easily spread by air dispersion or as runoffs, so they can reach aquatic environments and affect non-target species, producing undesirable, toxic effects in the aquatic biota. The objective of this study was to evaluate the effects of exposure to glyphosate (FAENA^{MR}), in the demographic parameters of the cladoceran Simocephalus mixtus, an additionally determine the possible effects in the body size of the progeny released by adults exposed to glyphosate. The EC_{50} was determined; after this, the chronic effect of sublethal concentrations on the demography was determined during 21 days through a Life Table approach; the size of the neonates in consecutive clutches was also determined. The obtained EC_{50} was 5.27 mg L^{-1}. The life expectancy at birth, survival and fecundity were significantly affected in the highest tested concentrations of glyphosate (2.71 and 2.19 mg L^{-1}) with respect to the control. The net reproductive rate and the intrinsic growth rate decreased as the concentration of the herbicide increases, also the clutch size was reduced approximately in 40% in the maximum concentration (4.06 mg L^{-1}). The obtained results show that S. mixtus has great sensibility to the commercial glyphosate formulation, compared with other cladocerans, and warn about the possible toxic effects in non-target species in the aquatic environment.

WP310 The aquatic fate of neonicotinoids under natural irradiation

M.M. McManus, Texas Tech Univ/TIEHH / Environmental Toxicology; J. Jordan, Texas Tech Univ / Environmental Toxicology; S. Subbiah, Texas Tech Univ / Environment Toxicology; J.E. Canas-Carrell, Texas Tech Univ / Environmental Toxicology

Exposure of non-target aquatic species to neonicotinoids has become an increasing concern given the high solubility of this pesticide class. Photodegradation is considered to be the major route of dissipation in aquatic ecosystems; however, little is known about the impact of water constituents on photodegradation in these systems. This study assesses the direct and indirect photolysis of three common neonicotinoid pesticides, clothianidin, imidacloprid, and thiamethoxam. The impacts of several aquatic constituents and pH are being assessed independently and in a factorial design with direct photolysis controls to determine how factor interaction affects photodegradation under natural sunlight. Radical producing and scavenging aquatic constituents found in agroecosystems were chosen including: dissolved organic matter (DOM), nitrate, and iron. A chemical actinometer, p-nitroanisole/pyridine (PNA/PYR), is used in the determination of light intensity and direct photolysis quantum yields. Kinetic models are used to determine the direct and indirect photolytic rate constants and half-lives of the neonicotinoid pesticides. This ongoing study will contribute to the understanding of the aquatic fate of neonicotinoids.

WP311 Evaluation of the toxic effects pesticides from surface agricultural runoff, to the neotropical Cladocera Macrothrix flabelligera

R. Moreira, Federal Univ of Sao Carlos / Dept of Ecology and Evolutionary Biolog; B.H. Vieira, A.M. Sanches, Univ of São Paulo USP / School of Engineering of São Carlos; M.R. Vanderlei, Univ de Sao Paulo / School of Engineering of São Carlos; A.S. Manzano, Federal Univ of Sao Carlos / Dept of Ecology and Evolutionary Biology; M.A. Daam, Dept of Biology CESAM Univ of Aveiro / DPPFCEER; E.G. Espindola, Univ of São Paulo USP / School of Engineering of São Carlos; O. Rocha, Federal Univ of Sao Carlos / Dept of Ecology and Evolutionary Biology

Brazil is one of the greatest users of pesticides in agriculture, resulting on severe environmental and human health risks. An example of this scenario is found in Bom Repouso/Minas Gerais State, where the insecticide Kraft®(abamectina) and the fungicide Score®(difenoconazol) are applied. Considering the environmental risks, the aim of this work was to evaluate the toxicity of the runoff water contaminated by the pesticides Kraft® e Score®, isolated and in mixture, to the Neotropical cladoceran Macrothrix flabelligera. Aiming to simulate natural conditions of aquatic ecosystems that receiving the input of allochtonous materials from agricultural runoff containing pesticides, the compounds were applied isolated or as a mixture, in different ploughed soil parcels without vegetation by simulating a rain intensity of 19 mm intensity, normally occurring in the rainy period. Doses applied were those recommended by the pesticide industry to strawberry cultures (Kraft®:30 mL/100L of water or 0.1 L/m^2 of solution;

Score®: 0.40 mL/100L, or 0.020L/m^2 of solution). The runoff with all carried materials from uncontaminated control soil and contaminated soil parcels from the various treatments, runoff without the pesticides(R_C), Kraft runoff(R_K), Score runoff(R_S), Kraft+Score runoff(R_{K+S}) was collected and tested in acute toxicity tests (48h) carried out in laboratory for the following dilutions:100%, 75%, 50%, 25%, 12.5%, 6.25%, 3.12%, plus the control using only reconstituted water. Test procedures followed the ABNT NBR13373 protocol for Ceriodaphnia spp. Test organisms. After the exposure period imobile organisms were counted. Results were analyzed by ANOVA followed by Dunnet test. Differences were considered significant when p≤0,05. Values obtained for physical and chemical variables did not differ among treatments, except for turbidity whose minimum and maximum values corresponded to 183 and 380 NTU, respectively. In relation to pesticides toxicity, no significant difference was found between soil runoff without the pesticides(R_C) and soil runoff from Score contaminated parcel(R_S). It was possible to obtainthe IC40 value for Kraft+Score(R_{K+S}) and to establish the IC50 for the 100% Kraft runoff solution. It was demonstrated that agricultural activities promoted the transport of soil particles to the aquatic ecosystems (physical alteration) and that when associated to the use of pesticides (chemical alteration) it can cause deleterious effect to the aquatic biota.

WP312 Ecosystems models (mesocosm) to evaluate the toxicity of the pesticides Kraft and Score in Ceriodaphnia silvestrii (Cladocera)

L.P. Figueiredo, Univ of São Paulo USP; B.H. Vieira, A.M. Sanches, Univ of São Paulo USP / School of Engineering of São Carlos; M.R. Vanderlei, Univ de Sao Paulo / School of Engineering of São Carlos; A. Vasconcelos, Univ of São Paulo USP / School of Engineering of São Carlos; M.A. Daam, Dept of Biology CESAM Univ of Aveiro / DPPFCEER; E.G. Espindola, Univ of São Paulo USP / School of Engineering of São Carlos

Bom Repouso (MG) is a municipality with agricultural characteristics and the production of potatoes and strawberry is relevant to the local economy. Nevertheless, in these crops farmers are using the acaricide/insecticide Kraft® (abamectin) and the herbicide Score® (difenoconazole), isolate or in mixture, and the ecological effects are not being evaluated yet. Considering that, the objective of thsi research was to assess the effects of these pesticides on the Crustacea Ceriodaphnia silvestrii, using studies in aquatic ecosystem models. The experiments were conducted in mesocosms (400 L) containing water, sediment and biological community, simulating the environmental conditions. The pesticides (Kraft and Score) were applied in soil without vegetation, according to the dose recommended by the manufacturer for strawberry crops which was simulated a rain of 19mm. The runoff of water containing all material transported (control and contaminated areas) was collected and placed in mesocosms, simulating a natural condition of contamination, and then water samples were collected for the acute toxicity tests (48h; n=5), under laboratory conditions, according to the NBR 13373 standards for the species C. silvestrii. The results were analyzed by analysis of variance (ANOVA) followed by Dunnett's test at 5% significance level. %. The values of physical and chemical variables were similar in all treatments. However, significant differences were observed for turbidity, in this case the minimum and maximum values were 183 and 380 NTU, respectively, indicating that there is a physical effect, which reduces to 53% and 87% after 24 and 72 hours of application runoff. Regarding toxicity, no significant difference were observed between runoff control, contamination isolated and mixture. This effect can be explained by the short half-life (up to 24 hours in water) of this pesticide, as well as by the adsorption thereof to the particulate material, which promotes its non-availability, reducing the toxic effects on the biological community as mentioned by Novelli et al. (2012).

WP313 Effects of temperature on the toxicity of herbicide sulfentrazone (Boral®SC) in two species of tadpoles in Brazil

J.S. Freitas, UNESP/IBILCE/Sao Jose do Rio Preto / Dept of Environmental Chemistry; E.A. Almeida, UNESP/IBILCE/ Sao Jose do Rio Preto

Global climate changes have caused extensive impacts on many species and ecosystems. Changes in environmental temperature can alter the chemical toxicokinects and one current challenge is to predict the risks established by the interactions between non-chemical and chemical stressors at the biological level. Tadpoles can experience large temperature fluctuations in their habitats and many species are distributed in areas impacted by agriculture. Sulfentrazone (Boral®SC) is a widely used herbicide in sugar cane and soy crops in southeastern Brazil. We evaluated the influence of temperature on the toxicity of sulfentrazone in two endemic species of tadpoles, Eupemphix nattereri and Rhinella schenideri, by analysis of oxidative stress biomarkers. Tadpoles were exposed to 0.01, 0.05 and 0.1mg/L at temperatures of 28ºC, 32ºC, and 36ºC during 3 and 8 days. Exposure of tadpoles to sulfentrazone caused changes in antioxidant enzyme activity with temperature-associated responses. At 28ºC, effects of sulfentrazone were only evident in tadpoles of E. nattereri, with an increase in catalase (CAT) and glutathione-S transferase (GST) activity after 3 days of exposure. Glucose-6-phosphate dehydrogenase (G6PDH) was also raised after 8 days in tadpoles of E. nattereri exposed to 0.05mg/L at 28ºC. For both species, the effects of sulfentrazone were more pronounced at higher temperatures. After 3 days of exposure, CAT activity was decreased and G6PDH increased in tadpoles of R. schneideri treated at 32ºC and 36ºC. E. nattereri tadpoles had GST and G6PDH increased when exposed to sulfentrazone at 32ºC and 36ºC. After 8 days, an increase in CAT and G6PDH enzymes was observed in tadpoles of R. schneideri treated at 36ºC. Levels of G6PDH and GST were raised by all concentrations of sulfentrazone tested in E. nattereri tadpoles at 32ºC and 36ºC. Levels of malondialdehyde (MDA) were also induced by the treatments, indicating that the exposure to herbicide sulfentrazone may trigger lipid peroxidation in tadpoles depending on the thermal gradient. Our results showed that temperature is an important variable influencing the toxicity of sulfentrazone in tadpoles and the changes in oxidative stress biomarkers are likely a result of physiological adaptation to stress conditions established by an interaction between chemicals and temperature changes. It suggests that environmental temperature should be considered in risk assessments of environmental contaminants for amphibian species.

WP314 Effects of Diuron and its main biodegradation products on antioxidant and biotransformation enzymes of Nile tilapia

A. Arantes Felicio, UNESP/IBILCE/Sao Jose do Rio Preto / Dept of Chemistry and Environmental Sciences; E.A. Almeida, UNESP/IBILCE/ Sao Jose do Rio Preto

Diuron is one of the most commonly used herbicide in agriculture, like sugarcane, in São Paulo State. The risk of diuron and its metabolites can represent for aquatic organisms that inhabit rivers and lagoons are not well understood, even though it have been found in many rivers and subterranean water. Diuron, in its original form, have low persistence in the environment, being mainly biodegraded in three other products, dichloroaniline (DCA), dichlorophenyl-urea (DCPU) and dichlorophenyl-methyl-urea (DCPMU), that could also represent a risk for the exposed biota. Considering the extensive use of Diuron in sugarcane crops in São Paulo State and the potential risk of these compounds and its biodegradation products to fish, in this work we measured some biochemical parameters in liver and gills of Nile tilapias, to evaluate the effects that these compound might exert in fish, at environmentally relevant concentrations. The experiment was done by exposing Nile tilapia to 40 and 200 ng/L of Diuron, DCPMU, DCPU and DCA, alone or mixed, for seven days. The activities of catalase (CAT), superoxido dismutase (SOD), glutathione peroxidase (GPx), glutathione reductase (GR), glutathione S-transferase (GST), ethoxyresorufin-O-deethylase (EROD) , and multixenobiotic resistance (MXR) were measured. Our results showed that

diuron and its metabolites, as well as the mixture of all compounds, are prone to alter antioxidant defense system, biotransformation enzymes and first line response protein MXR. We observed an increase in the efflux of the compound out of the cell in groups exposed to Diuron 200 ng/L, DCA 40 and 200 ng/L and the mixture of compounds at 40 ng/L. Furthermore, we observed significant alterations in all enzyme activities assessed, in both tissues. In gill we observed decrease in enzimatic activit and these differences agree with MXR data, except SOD, these correlation is more expressive in GST. According to other authors, the compound efflux can be correlated with decreases in GST activity, as observed in our work. Taken together, our data clearly demonstrated that diuron or its metabolites can impair the Nile tilapia metabolism.

WP315 Influence of temperature on the thyroidogenic effects of Diuron and 3,4-DCA in tadpoles of the American bullfrog Lithobates catesbeianus

J.S. Freitas, UNESP/IBILCE/Sao Jose do Rio Preto / Dept of Environmental Chemistry; A. Kupsco, Univ of California-Riverside / Dept of Environmental Sciences; G. Diamante, Univ of California, Riverside / Environmental Toxicology; A. Arantes Felicio, UNESP/IBILCE/Sao Jose do Rio Preto / Dept of Chemistry and Environmental Sciences; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences; E.A. Almeida, UNESP/IBILCE/ Sao Jose do Rio Preto

Temperature is a key variable affecting the timing of amphibian metamorphosis from tadpoles to tetrapods, through the production and subsequent function of thyroid hormones. Thyroid function can be impaired by environmental contaminants as well as temperature. Tadpoles can experience large temperature fluctuations in their habitats and many species are distributed in areas impacted by agriculture practice. Diuron is a widely used herbicide frequently detected in freshwater ecosystems throughout the world, and may impact endocrine function in aquatic organisms. We evaluated the influence of temperature on the action of diuron and its metabolite 3,4- dichloroaniline (DCA) on thyroid function and metamorphosis in tadpoles of Lithobates catesbeianus. Tadpoles were exposed to 40ng/L and 200ng/L of diuron or 3,4-DCA at temperatures of 28ºC and 34ºC for 7 days. Both compounds accelerated the metamorphosis of tadpoles maintained at higher temperature. Plasma T_3 concentration was also increased (3-fold) in tadpoles exposed to 200ng/L of diuron at 34°C. Transcripts of thyroid hormone induced bZip protein (thibz) were altered by exposure to both compounds at 28°C. Animals exposed to 200ng/L of diuron and 3,4-DCA at 34°C had higher levels of thibz, deiodinase (dio2 and dio3) and thyroid hormone receptors (trα and trβ) mRNA than animals only treated with contaminants, suggesting an important effect of temperature stress on the expression of these genes. A positive correlation between trβ and klf9 mRNA was observed for both compounds at 34°C. Our results showed that temperature can influence the toxic effects of diuron and 3,4-DCA on metamorphosis pathways of tadpoles by potentially changing concentrations of T_3 and expression of TH-target genes. Whereas changes in global abiotic variables such as frequency of heat waves are estimated to increase in coming years, it is suggested that environmental temperature should be considered in risk assessments of environmental contaminants for amphibian species.

WP316 DNA damage produced by Vinclozolin on two freshwater invertebrates

M. Aquilino, UNED; P. Sanchez-Arguello, INIA – National Inst for Agricultural and Food Research and Technology / Environment; J. Martinez-Guitarte, Universidad Nacional de Educación a Distancia / Fisica Matematica y de Fluidos

The dicarboxiamide Vinclozolin (Vz) is a widely used fungicide for agricultural purposes. Because of this, it is found as a residue in the environment, detected in underground water, lakes, rivers, and seawater. Most of the toxicity studies have been focused on vertebrates showing clastogenic activity, however, few studies have investigated their effects on invertebrates, which are key organisms in aquatic ecosystem maintaining. In this work we have analyzed the effects caused by Vz on two freshwater invertebrates. Fourth instar larvae of Chironomus riparius, a dipteran used frequently as reference species in ecotoxicology, and adults of Physa acuta, a gastropod widely extended, were exposed to this compound for 24 hours to different concentrations of Vz (20 and 200 µg/L). The level of DNA damage was evaluated by measuring different parameters following the comet assay. The results show a significant increase in the different parameters analyzed (%DNA in tail, tail length, tail moment and Olive tail moment) indicating that the presence of Vz affects the integrity of the DNA in these organisms. These results confirm the genotoxicity of this compound on invertebrates and support previous results obtained with micronuclei analysis in P. acuta. Furthermore, this is the first report of the DNA damage on insects by this compound, supporting comet assay as a potential biomarker for genotoxicity in aquatic invertebrates. This work was supported by the Plan Nacional de Investigación Científica, Desarrollo e Innovación Tecnológica (Spain), grant CTM-2015-64913-R from the Ciencias y Tecnologías Medioambientales program. M.A. is the receiver of a predoctoral contract Ministry of Economy and Finance (BES-2013-064041).

WP317 Effects of the fungicide imazalil on the fathead minnow (Pimephales promelas) reproductive axis – a case study in 21st century toxicity testing

E. Randolph, EPA / National Health and Environmental Effects Research Laboratory; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; B.R. Blackwell, ORISE / National Health and Environmental Effects Research Laboratory; J.E. Cavallin, USEPA / USEPA Mid-Continent Ecology Division; W. Cheng, ORISE; D. Feifarek, USEPA / National Health and Environmental Effects Research Laboratory; K.M. Jensen, M. Kahl, USEPA / National Health and Environmental Effects Research Laboratory; R. Milsk, ORISE; S. Poole, USEPA / National Health and Environmental Effects Research Laboratory; T. Saari, USEPA / ORD, NHEERL; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory

Since its introduction in 1983 imazalil has been used primarily as a fungicide on crops post-harvest, such as tubers and citrus fruits. Its effectiveness lies in the ability to inhibit the fungal enzyme, lanosterol 14 α-demethylase. However, like other azole fungicides, imazalil can inhibit a range of cytochrome p450 enzymes, including one or more involved in steroid biosynthesis. Previous in vitro and high throughput screening assays showed that imazalil can cause aromatase inhibition and reduce 17β-estradiol (E2) production by H295R cells. In the present study, we tested imazalil in a number of in vitro and in vivo bioassays with fathead minnows (Pimephales promelas) to evaluate whether it would elicit effects consistent with an adverse outcome pathway (AOP) linking inhibition of aromatase to reduced fecundity. Ex vivo ovarian E2 and testosterone (T) production by ovary tissue from reproductively mature female P. promelas exposed to imazalil for 24 h at concentrations of 100, 500 and 1580 µg/L were significantly lower ($p< 0.05$) than controls. Plasma E2 concentrations of females exposed for 24 h were significantly lower at imazalil concentrations of 80 and 250 µg/L, but not 2.5, 8, and 25 µg/L. In a separate 60 h exposure, plasma E2 concentrations were significantly lower than controls in mature P. promelas exposed to 200 µg imazalil/L, but not at 0.2, 2, or 20 ug/L. Real-time quantitative PCR analyses measuring relative abundance of mRNA transcripts for various CYPs in ovary indicated an upregulation of cyp19a1a, cyp17, and cyp11a in P. promelas exposed to 200 µg imazalil/L. This induction is potentially due to compensatory/feedback responses along the hypothalamic-pituitary-gonadal axis. Overall, data collected to date support the hypothesis that imazalil causes endocrine disruption in exposed female fathead minnows in a manner consistent with an established AOP and supports the broader utility of that AOP in hazard assessment. The contents of this abstract neither constitute nor necessarily reflect USEPA policy.

WP318 Toxicity of three anticoagulant rodenticides in non-target fish species

R. Riegerix, Univ of Missouri- Columbia / Biological Sciences; D.E. Tillitt, USGS / Columbia Environmental Research Center

Bird colonies at certain US Fish and Wildlife Service (USFWS) Pacific Island National Wildlife Refuges (PINWR) have suffered severe population losses due to rat infestations. Anticoagulant rodenticides (ARs) are a common tool used for rat eradication and control programs to protect native species at PINWR. In one such aerial broadcast of AR bait on Lehua Island, Hawaii, a 'fish kill' was reported on a neighboring island, Niihau Island. Reports were anecdotal, but investigations by the state conservation agency, Department of Land and Natural Resources (DLNR), and Division of Aquatic Resources determined a few species of fish were dead and potentially more were exposed. Due to lack of AR toxicity data in fish; it is difficult, if not impossible, to assess risk to fish. Therefore, our objective was to determine sensitivity of three AR chemicals: diphacinone, chlorophacinone, and brodifacoum in triggerfish, specifically, red-toothed triggerfish (Odonus niger) and black triggerfish (Melichthys niger). Due to low sample size, the Up and Down Procedure (UDP) was used to determine the median lethal dose. Preliminary red-toothed triggerfish LD50 results: brodifacoum (36-48 µg/g body weight, n=4) diphacinone (137-175 µg/g, n=4) and chlorophacinone (132-182 µg/g, n=3). Across-taxa Species Sensitivity Distribution (SSD) was used to model the variation of species' sensitivity to AR chemicals. The red-toothed triggerfish were among the least sensitive species to AR chemicals as compared to other taxa, and in particular, mammals and birds.

WP319 The effects of quercetin, a potential natural product pesticide, on zebrafish development

J. Zhang, U Florida; N.D. Denslow, C.J. Martyniuk, Univ of Florida / Physiological Sciences

Quercetin, a member of the flavonoid family, is a natural product that has also been shown to have synergistic effects when combined with insecticides such as organophosphates and pyrethroids. In addition to its potential use as an insecticide, quercetin has been used in food applications because of its potential anti-oxidant and other beneficial health properties. However, quercetin has also been shown to impair synaptic transmission and may have carcinogenic properties, thus data are controversial as to its benefits as a pesticide or a health supplement. To learn more about the toxicity of quercetin to non-target organisms, we exposed zebrafish embryos to three concentrations of quercetin (1, 10 ,100 µg/L) for 96 hours. Quercetin did not appear to induce significant mortality in zebrafish over 96 hours, but there was an increased prevalence of dorsal curvature in larvae in a concentration-dependent manner. No other gross deformities, such as pericardial edema nor yolk sac edema, were observed. As mitochondrial function is important for development, we aim to further explore the effects of Quercetin exposure on mitochondrial respiration using the Seahorse XFe24 Extracellular Flux Analyzer, to understand the interaction between ATP production and development which may be modulated by Quercetin. This study aims to determine whether there are significant developmental defects in fishes due to Quercetin, to provide a foundation for ecological risk assessment.

WP320 The evolution of tolerance to pesticides: insights from resurrection ecology

A.M. Simpson, P.D. Jeyasingh, J.B. Belden, Oklahoma State Univ / Integrative Biology

Previous research has demonstrated that resurrected genotypes from an ancestral population of Daphnia pulicaria have differential toxicity (median effect concentration – EC50) to the insecticide chlorpyrifos. Ancient genotypes (1301-1646 A.D.) were on average more sensitive to this chemical when compared to the contemporary genotypes (1967-1977, 2002-2008 A.D.). In order to determine the physiological mechanisms of tolerance, a series of biochemical assays was performed on the three most tolerant and three most sensitive genotypes from the population. In vitro acetylcholinesterase assays yielded no significant differences in constitutive activity or oxon-binding sensitivity. Acute toxicity tests were conducted using i) the toxic metabolite chlorpyrifos-oxon (CPY-O) and ii) CPY-O co-applied with piperonyl butoxide (PBO), a known Phase-I metabolic inhibitor. Both series of toxicity tests reduced the mean variation in sensitivity between tolerant and sensitive genotypes. Exposure to CPY-O reduced the disparity from a 4.7-fold to 1.6-fold difference in sensitivity. The addition of PBO further reduced the variation to a 1.2-fold difference in sensitivity. This suggests that pathways involving Phase-I detoxification and/or bioactivation of chlorpyrifos play a significant role in dictating tolerance in this population. Future work on this system will aim to illuminate the functional basis of metabolic tolerance via next generation RNA sequencing.

WP321 Effects of S-metolachlor and its typically paired safening agent (benoxacor) in C. riparius: 28-day chronic exposure study

K. Bolyard, S. Gresens, Towson Univ / Biology; J. Sivey, Towson Univ / Chemistry; C.J. Salice, Towson Univ / Biological Sciences/ Environmental Science

The environmental effects of safeners, chemicals that protect crops from herbicide toxicity, are largely unknown. Safeners are considered inert ingredients added to many major classes of herbicides. Under controlled anaerobic conditions in the laboratory, dichloroacetamide safeners can degrade into potentially toxic byproducts. This study's purpose was to determine the toxicity of the dichloroacetamide safener benoxacor, a degradation product of benoxacor (mono-chlorinated benoxacor), a typically paired active ingredient, S-metolachlor, and a simulated formulation (a mixture of S-metolachlor and benoxacor) to the aquatic, sediment-burrowing larvae of Chironomus riparius. Larval C. riparius were exposed to these four chemicals in chronic 28-day experiments within environmentally relevant microcosms. The results demonstrated that high concentrations of all four chemicals affected percent adult emergence (survival), and time-to-emergence (also known as time-to-event) curves. High concentrations of benoxacor and the mixture affected adult emergence rates, and high concentrations of S-metolachlor affected male adult dry body mass. The present study's results demonstrate that benoxacor and monochlorinated benoxacor are toxic to C. riparius at similar concentrations as the herbicide S-metolachlor, which is useful information for the better understanding of the ecotoxicological effects of dichloroacetamide safeners. The movement and equilibration concentrations of benoxacor were also demonstrated under replicated microcosm conditions in a separate experiment over 28 days.

WP322 Organic and inorganic contaminants in white shrimp from the St. Johns River, Florida

J. Higman, John Higman

Concentrations of organic and inorganic (metal) contaminants were measured in immature adult white shrimp collected by otter-trawls from four locations in the St. Johns River, Florida. Thirty to forty of the larger shrimp were selected from each location. Selected individual shrimp were decapitated and cephalothoraxes ("heads") were stored separately from abdomens ("tails") in pre-cleaned glass jars with Teflon lids. Penaeus shrimps are "quasi-catadromous" living much of their lives in estuaries. After hatching in the ocean, small postlarval Penaeus shrimp move into shallow estuarine nursery areas in bays, lagoons, rivers, tidal creeks, salt marshes. Postlarval shrimp continue to mature in the estuaries, molting and growing through juvenile stages in 2 to 6 months. As immature adults they begin migrating to the ocean where they mature. Therefore, immature adult shrimp caught before migration would have accumulated contaminant burdens in the estuaries where they were captured. Results for the 31 pesticides, 27 individual PAHs (polynuclear aromatic hydrocarbons), 23 individual PCB (polychlorinated biphenyl) congeners, 8 chlorinated industrial compounds and 11 metal contaminants were evaluated and discussed if concentrations were above analytical detection levels. The whole body contaminant concentrations calculated by summing cephalothorax and abdomen data from each site are also presented: (e.g. total mercury ranged from 11.9-13.8 µgHg/kg wet wt. (51.9-61.5 µgHg/kg dry wt.); (e.g. sum of 7 chlordanes ranged from 1.88-7.94 µgCdane/kg wet wt. (8.08-38.23µgCu/kg dry wt.) Shrimp samples at all four sites had low level measurable concentrations of PCBs, PAHs, derivatives of chlordane, DDT and traces of chlorinated benzenes in cephalothorax composites. Most of these compounds were also found in abdomen composites, but only in trace quantities. Chromium was the only metal not found in any of the abdomen or cephalothorax composite samples. In general, the majority of the shrimp contaminant burdens were associated with the cephalothorax, and typically less than 50% of the whole body value was detected in the abdomens.

WP323 Effects of species characteristics on bioaccumulation of polychlorinated biphenyls (PCB) in a boreal freshwater lake

K.M. Figueiredo, Univ of Eastern Finland / Dept of environmental and biological sciences; K. Mäenpää, Univ of Eastern Finland; M.T. Leppänen, Finnish Environment Inst SYKE; M. Lyytikäinen, Univ of Eastern Finland / Dept of Biology; J.K. Taskinen, Univ of Jyvaskyla

Equilibrium partitioning of hydrophobic organic chemicals (HOCs) drives chemicals towards equilibrium between the biota and their environment. However, several biological characteristics modify bioaccumulation resulting species specific body residues of HOCs. In addition, within species, age-, sex- or habitat-specific changes in body residue may take place e.g. due to changes in diet, capability for metabolation, or changes in concentrations of HOCs in the environment. This study explored the polychlorinated biphenyl (PCB) contaminated freshwater lake, and studied the species-specific and within-species differences in bioaccumulation in different taxa from invertebrates to top predators. The results generally indicated species-specific differences in correlation of PCB profile between the tissues and the source phases. The PCB profile of free-swimming macroinvertebrates correlated best with the profile of the water phase indicating bioconcentration as the main phenomena of the bioaccumulation. On the other hand, the PCB-profile of the higher predator fish species correlated best with the profile of their diet content, indicating the diet being the main source of bioaccumulation for HOCs. Closer examination of perch and roach revealed that metabolation capability changes during the life span, and that source of nutrition determined the biomagnification of HOCs being different between the species. As a conclusion, the biological characteristics of species modify strongly bioaccumulation of HOCs. Thus species composition in the given ecosystem, and hence available prey selection composes a unique bioaccumulation scenario for each food web.

WP324 Histopathology of Brown Bullhead, Smallmouth Bass, and Yellow Perch in Relation to Polychlorinated Biphenyl (PCB) Contamination in the Hudson River

F.E. Pinkney, US Fish & Wildlife Service / Chesapeake Bay Field Office; M.S. Myers, Myers Ecotoxicology Services LLC; J.C. Harshbarger, George Washington Univ Medical Center / Dept of Pathology

As part of the Hudson River Natural Resource Damage Assessment, the Trustees conducted a Fish Health Assessment study that evaluated the prevalence of toxicopathic lesions in adult brown bullhead (Ameiurus nebulosus), smallmouth bass (Micropterus dolomieu), and yellow perch (Perca flavescens). Fish were collected in September and October 2001 from each of four locations: two highly contaminated areas below the plants (Thompson Island Pool (TIP) and Stillwater Dam Pool (STW)), an upriver reference area (Feeder Dam Pool (FDP)), and a reference lake, Oneida Lake (ODA). The focus was on histopathologic lesions and observations associated with contaminant exposure: liver—neoplasms, foci of cellular alteration, bile duct hyperplasia; testes—ovotestis (testicular oocytes), germ cell degeneration, altered developmental stage; ovaries—atresia and altered developmental stage. Lesions associated with PCB exposure were defined as those with significantly greater prevalence and/or severity in TIP and STW collections compared with those from ODA and FDP. Results will be discussed.

WP325 Assessing potential endocrine disruption in largemouth bass from a PCB-contaminated reservoir in South Carolina

S.B. LaPlaca, Univ of South Carolina / Environmental Health Sciences; G.I. Scott, Univ of South Carolina / Env Health Sciences

Endocrine disruption is the abnormal modulation of normal hormonal physiology by exogenous compounds. In fishes, endocrine disruption of the reproductive system has been documented frequently throughout the Southeastern United States and worldwide. Many studies of endocrine disruption in fishes have looked at the effects of wastewater effluent or pulp and paper mill effluent as these are known sources of endocrine disrupting chemicals (EDCs). Another EDC that has not definitively been linked to endocrine disruption in fishes are polychlorinated biphenyls (PCBs). In this study, we examined if PCBs influence endocrine disruption, vitellogenin production, and intersex condition in wild largemouth bass, Micropterus salmonides (LMB). Portions of Lake Hartwell in South Carolina have been heavily contaminated with PCBs since the 1970's warranting additional research on biological responses to PCB contamination. LMB were collected from two sites on Lake Hartwell and a reference site upstream at Lake Keowee. Vitellogenin (Vtg), the egg-yolk precursor protein, and intersex condition in the form of testicular oocytes (TO) were measured and evaluated in LMB. In LMB fillet samples, average PCB concentrations at the impacted site on Lake Hartwell remain above 2 ppm. Elevated Vtg levels above the measurable detection limit (0.001 mg/ml) were found in male fishes collected from both Lake Hartwell and Lake Keowee. Intersex was also found in male fishes collected from both lakes. This is the first study to our knowledge that specifically looks at endocrine disruption in wild LMB from Lake Hartwell and Lake Keowee in South Carolina and will add to the understanding of the extent of endocrine disruption, possible EDC sources, and legacy effects of PCBs on fishes.

WP326 Evaluating the Role of UV Exposure and Recovery in PAH Photo-Induced Toxicity

J. Gnau, Univ of North Texas; A.P. Roberts, Univ of North Texas / Dept of Biology Inst of Applied Science; J. Oris, Univ of Miami; B. Venables, Univ of North Texas / Biology; J.M. Morris, Abt Associates

Photo-induced toxicity refers to the ability of a molecule to increase in toxicity in the presence of solar radiation. Polyaromatic hydrocarbons (PAHs) are one class of compounds known to be phototoxic. Several models for PAH phototoxicity have been developed that predict toxicity as a reciprocal product of PAH concentration, UV intensity, and exposure time. However, these models do not incorporate biological recovery time as a factor. Aquatic organisms are exposed to UV light in daily cycles where light exposure is inconsistent due to various environmental factors. Thus, inclusion of non-UV recovery time periods as factors in predictive models will increase their ecological relevance. The first objective of this research was to evaluate toxicity when UV is distributed in even intervals. Daphnia magna neonates were exposed to fluoranthene in four different concentrations and UV exposure intervals between assays included 24 hrs, 12 hrs, 6 hrs, 3 hrs, and 1.5 hrs. The second objective of this research was to evaluate toxicity when UV is distributed in uneven intervals. D. magna neonates were exposed to the same four fluoranthene concentration as in the first objective and UV exposure intervals varied between assays with inconsistent intervals of 12 and 6 hrs, 9 and 3 hrs, 9 and 1.5 hrs, 6 and 3 hrs, 3 and 1.5 hours. For both objectives, phototoxic dose remained consistent across all assays and mortality was assessed at 24 and 48 hrs. Here we show that LC50 values differ between even and uneven UV interval tests and that increasing recovery interval frequency significantly reduces mortality. In assays where recovery time intervals were in short frequent intervals LC50 values increased up to 3 times than assays where recovery were in long infrequent intervals. This research demonstrates how UV recovery time is an important consideration for photo induced toxicity model development.

WP327 The photo-induced toxicity of polycyclic aromatic hydrocarbons and a lubricating oil in two amphibian species, Xenopus laevis and Rana sylvatica

Z. Currie, N.S. Hogan, Univ of Saskatchewan / Toxicology Centre

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental contaminants derived primarily from the incomplete combustion of organic matter. PAHs are generally not acutely toxic to aquatic organisms; however, ecologically relevant intensities of UV light have been shown to increase the acute toxicity of certain PAHs. Early life-stages of amphibians may be particularly susceptible to PAH photo-induced toxicity as they are translucent, have permeable skin and undergo embryo and larval development in shallow ponds. Limited studies have investigated the potential photo-induced toxicity of PAHs in amphibian species making it difficult to predict the impact of individual PAHs and complex mixtures containing PAHs. The objective of the present study was to evaluate and compare the sensitivity of a model organism (Xenopus laevis) and an ecologically native species (wood frog, Lithobates sylvaticus) to the photo-enhanced toxicity of PAHs as well as a petroleum-based lubricating oil, UNIVIS J13, known to contain a mixture of PAHs. 96-h tests were performed in which tadpoles were exposed to individual PAHs (anthracene, naphthalene, acridine, benzo(a)pyrene) or UNIVIS J13 for 8 hours in the dark, transferred to clean water, and then exposed to UVA (315-400nm) / UVB (285-315nm) light for 12 hours. Results were compared using mortality, growth, body burden, and whole body transcriptomic responses. In the presence of UV light, 100 ug L^{-1} benzo(a) pyrene significantly increased tadpole mortality, and 200 ug L^{-1} anthracene significantly increased tadpole mortality and decreased tadpole length.Acridine and naphthalene were not found to significantly affect tadpole mortality or growth at any concentrations tested. The co-exposure of UV light and 1:1, 1:10 and 1:100 loadings of UNIVIS J13 water accommodated fractions (WAF) had no significant effect on tadpole mortality or growth. Based on mortality data, it appears that Xenopus is more sensitive to the photo-induced effects of PAHs compared to the wood frog. This may establish Xenopus as a protective model for native species of amphibians with regards to the photo-induced toxicity of PAHs. Overall, anthracene and benzo(a)pyrene exhibit photo-induced toxicity in larval amphibians while such toxicity is not demonstrated by UNIVIS J13, a petroleum-based mixture containing PAHs.

WP328 PAHs and Ultra Violet light DNA damage in Artemia franciscana

M. del Carmen Guzman Martinez, Universidad Autonoma Metropolitana / Hydrobiology; P. Ramirez Romero, U.A.M. Iztapalapa / Hidrobiologia; K. Davalos de la Cruz, M. Aguilar-Santamaria, Universidad Autonoma Metropolitana Iztapalapa / CIENCIAS DE LA SALUD

Polycyclic aromatic hydrocarbons are a group of substances with a wide environmental distribution; they can cause oxidative stress and DNA damage. The risk of these effects increases when exposure is combined with solar UV radiation. The objective of the present work was to evaluate DNA damage in Artemia franciscana exposed to fluoranthene and benzo(α)pyrene. Metanauplii of A. franciscana were used in a sublethal test where DNA damage was evaluated with the single gel electrophoresis method (comet assay). Two concentrations of fluoranthene (24 and 48 µg/L) and benzo(α)pyrene (4.8 and 9.6 µg/L) were tested, with 8 replicates of 100 organisms each. Two controls were included: one with sea water only, and another with acetone. A light control t was also run dfor each PAH Exposures lasted 24 h with a 12:12 photoperiod. Results indicated that the largest comets tails and the highest percent damage were obtained in organisms exposed to benzo(α)pyrene. in both concentrations. Fluoranthene, benzo (α)pyrene and anthracene are genotoxic for A. franciscana in the concentrations used for this work, the comet assay was a sensitive method and confirm that exposure to hydrocarbons and UVR damage the DNA chain and can be lethal for nauplii.

WP329 PAH-induced changes to gene expression in the gill and liver of the Atlantic stingray, Dasyatis sabina

E. Jones, R.J. Griffitt, Univ of Southern Mississippi / Coastal Sciences

Many elasmobranchs are keystone species that maintain balance within their environments, therefore conservation of these taxa is important to ecosystem health. Additionally, numerous elasmobranch species reside in the northern Gulf of Mexico, including 22 species listed as critically endangered, endangered, or vulnerable by the International Union for the Conservation of Nature. The distribution of these organisms is coincident with areas of heavy mineral exploration, however there is limited knowledge regarding the effects of PAH exposure on elasmobranchs. To investigate these effects we performed ex vivo incubations of liver and gill tissues from the Atlantic stingray, Dasyatis sabina. Three D. sabina were captured via trawl in the MS sound and acclimated to the lab for two weeks. Organisms were sacrificed using MS-222, liver and gill tissues harvested, and tissues incubated for 0.5, 6, or 12 hours in media of 0%, 5%, or 50% high energy water accommodated fraction (HEWAF) prepared with Elasmobranch Ringer's solution. To track changes in tissues over time, HEWAF-related alterations in gene expression of energy metabolism and osmoregulatory genes were measured using qPCR, and further gene expression changes were analyzed via RNA seq. These data represent the first report of changes in elasmobranch gene expression related to PAH exposure and further provide information useful for predicting oil spill impacts to elasmobranch populations.

WP330 Effects of dietary benzo[a]pyrene exposure on wood frog (Lithobates sylvaticus) tadpoles

M. Gallant, L. McPhee, L. Halyk, N.S. Hogan, Univ of Saskatchewan / Toxicology Centre

Recent large-scale amphibian population declines around the world have prompted investigation of the impacts of environmental contaminants on amphibian health and performance. Many toxicity studies focus on the model amphibian species, Xenopus laevis, and little toxicological data available for native North American species. Benzo[a]pyrene (B[a]P) is a polycyclic aromatic hydrocarbon that is widely found in the environment and is known to induce oxidative stress and detoxification pathways in mammals and fish; however, few studies examine the impacts on native North American amphibian species. B[a]P is also known to adsorb onto particles present in the water column, making dietary exposures ecologically relevant. In this study, pre-metamorphic tadpoles (Gosner stage 30-32) were provided food ad libitum that was spiked with 50 µg/g and 200 µg/g B[a]P for 14 days. Mortality was observed daily and following the 14-day exposure individuals were assessed for developmental stage, length, total weight, liver and gut weights, and sampled for histology (whole body and gut), antioxidant defense parameters (total glutathione, glutathione peroxidase, superoxide dismutase) and gene expression analysis of liver detoxification pathways (cytochrome P450 and glutathione s-transferase). There was no significant effect of a 14-day dietary exposure to B[a]P on body weight, organ weights or length of the tadpoles. Histopathology and gene expression analyses are ongoing but are expected to provide insight into the risks and health detriments of B[a]P exposure in a wood frogs through an ecologically relevant route of exposure.

WP331 Developmental sensitivity to benzo[a]pyrene exposure and changes in expression of immune-related genes in the amphibian Xenopus laevis

M. Gallant, N. Hogan, Univ of Saskatchewan Toxicology Centre

The need to understand contaminant-induced immunotoxicity in amphibians is evident given recent disease-driven population declines around the world. The amphibian immune system is dynamic over development; early embryo-larval life stages rely primarily on the innate immune system until the adaptive immune system begins to increase in function during prometamorphosis. Therefore, the impacts of environmental contaminants on the immune system may depend on the stage of development at the time of exposure. As a key component of the innate immune system, cytokines are among the first to respond to viral pathogens by mounting an inflammatory response and analysis of cytokine mRNA levels has been used to predict the immunomodulatory potential of chemicals. The current study assessed the response of pro-inflammatory cytokines (tumor necrosis factor α (TNF-α), interleukin -1β (IL-1β) and interferon-γ (IFN-γ)), cytochrome P450 1A1 (CYP1A1) and aryl hydrocarbon receptor (AhR) to benzo[a] pyrene (B[a]P) exposure at various stages of amphibian development. B[a]P is a model polycyclic aromatic hydrocarbon and a known immunotoxicant in mammals and fish; however, little immunotoxicity data is available for amphibians. Embryos were exposed for 96 hours to sub-lethal concentrations (10, 175 and 350 μg/L). Similar exposures for individuals at stage 51 (pre-metamorphosis) and 56 (pro-metamorphosis) were performed using the same concentrations for 7 days (sub-sampling at day 2). Individuals were examined for morphological abnormalities, lengthed, weighed and sampled for gene expression analysis. Impacts on morphological endpoints (abnormalities, length and weight) were more pronounced in earlier life-stages with a dose-dependent decrease in total length and tail length in embryos and no effects in pro-metamorphic tadpoles. Additionally, pre-metamorphic tadpoles exposed to B[a]P had lower TNF-α expression and no change in IL-1β while the opposite was true for pro-metamorphic tadpoles. This research will help us understand mechanisms underlying developmental stage-specific immunomodulatory effects of B[a]P exposure in amphibians. Reducing the efficiency of innate immune defense mechanisms during the tadpole life-stage could increase the susceptibility to infectious agents and contribute to disease-driven population declines.

WP332 Combined Effects of Polycyclic Aromatic Hydrocarbons and Other Environmental Stressors on Fundulus grandis

J. Serafin, Purdue Univ / Forestry and Natural Resources; M.S. Sepulveda, Purdue Univ / Dept of Forestry and Natural Resources and School of Health Sciences; R.J. Griffitt, Univ of Southern Mississippi / Coastal Sciences; S. De Guise, Univ of Connecticut / Dept of Pathobiology and Veterinary Science; T. Bosker, Univ of Leiden; C.R. Perkins, Univ of Connecticut / Center for Environemtnal Sciences and Engineering

In the spring of 2010, the Deepwater Horizon oil spill released > 3 million barrels of crude oil into the Gulf of Mexico. A major component of crude oil are polycyclic aromatic hydrocarbons (PAHs). Although the toxicity of PAHs to fish has been studied to a large extent, the combined effects of extreme abiotic factors and oil are poorly understood. Fundulus grandis larvae (< 24 hours post hatch) were exposed to varying environmental conditions (dissolved oxygen 6 ppm, 2ppm; temperature 20, 25, 30?C; and salinity 3, 10, 30 ppt) combined with varying concentrations of high energy water accommodated fractions (HEWAF) (total PAHs 0 – 140 ppb) for a total of 48 hr. High temperature and salinity resulted in the lowest survival. Surviving larvae were photographed and videos of the heart at high magnification taken. There were notable abnormalities of the heart supporting previous studies showing PAH effects on the cardiovascular system. Expression of the hepatic detoxifying gene cyp1a was highly induced in PAH-exposed larvae, but only in the high dissolved oxygen conditions. A subset of larvae will be processed for transcriptomics using next generation sequencing based on phenotypic cardiovascular changes and cyp1a expression levels. This data will be used to identify which combination(s) of environmental conditions and PAH levels are most likely to result in long-term physiological effects and therefore negatively affect population recruitment.

WP333 Dietary Exposed to Weathered Iranian Heavy Crude Oil : Effects on the detoxification and immune system in Rockfish (Sebastes schlegeli)

E. Lee, J. Jung, K. Choi, Korea Inst of Ocean Science and Technology / Oil and POPs research group; M. Kim, Korea Inst of Ocean Science and Technology / Oil POPs Research Group; U. Yim, Korea Inst of Ocean Science and Technology / Oil and POPs research group

This study examines whether acute toxic responses played by the immune system depend on which metabolic pathway was induced after exposure to weathered crude oil. We exposed juvenile rockfish to weathered crude oil (Iranian Heavy Crude Oil; WIHCO in gelatin capsules) from the "Hebei spirit" oil spill by feeding. The effects on fish hepatodetoxification enzymes (Cytochrome P4501A) and the expression level of the immune response genes, including interleukin-1beta (IL-1β), nuclear factor kappa-light-chain-enhancer of activated B cells (NF-kB), Interferon-stimulated gene 15 (ISG 15) and granulocyte colony-stimulating factor (GCSF), were measured in the liver and kidney. The WIHCO-fed fish had significantly higher concentrations of biliary fluorescent metabolites and CYP1A expression during the initial stage after exposure (6 h after exposure) than those of the control group. Similarly, expression levels of IL-1β, p53, NF-kB and ISG15 mRNA were detected highly in the kidney at the early stages of exposure (6 h after exposure). In this study, the apoptosis, phagocytosis activity and cell cycle arrest analysis of juvenile rockfish exposed to WIHCO were measured by flow cytometry, a novel approach. Our results demonstrated that WIHCO caused an increase of apoptosis and cell cycle arrest and inhibition of phagocytic activity in juvenile Rockfish. Several immune-related genes in oil-fed fish were induced at the initial stage of exposure to the WIHCO but decreased to less than that of the control group after the initial stage of response. Therefore, It can lead to a better understanding of impact on marine fish exposed to lingering oil may allow the pathogens, including the infectious diseases, to more easily affect fish.

WP334 A comparative study of RNA-seq analysis on two marine embryonic fish exposed to Iranian Heavy Crude Oil

J. Jung, Korea Inst of Ocean Science and Technology / Oil and POPs Research Group; J. Ko, Theragen Etex Bio Inst Inc.; E. Lee, K. Choi, M. Kim, U. Yim, Korea Inst of Ocean Science and Technology / Oil and POPs Research Group

This study clarifies the comparative developmental effects of Iranian heavy crude oil (IHCO) on the different toxic sensitivities of transcriptional responses between fish species and the weathering status of crude oil. We utilized high-throughput (Illumina RNA-seq) to characterize the developmental toxic effects from oil exposure. The assembled contigs contain 66,070 known unigenes in flounder and 76,498 known unigenes in spotted seabass. Comparison of different gene expression profiles reveals that the numbers DEGs are differentially higher up and down-regulated in embryonic seabass than those of embryonic flounder exposed to fresh IHCO (FIHCO) and weathered IHCO (WIHCO). Gene pathway analysis from the most differentially expressed gene set was classified from crude oil exposure: indicated the oxidative phosphorylation, disease pathway (Parkinson's, Alzheimer's, Huntington's disease) and cardiac muscle contraction. The expression patterns of 13 differentially expressed genes were validated by quantitative real-time RT-PCR (average correlation cutoff p< 0.005). Especially, the level of genes involving detoxification (CYP1A, CYP1B1 and CYP1C1) in embryonic seabass increased higher than those of flounder but the other genes involving cell processing, development and immune system changed higher in flounder exposure to FIHCO and WIHCO. In differentially orthologous gene clusters analysis, embryonic flounder seem likely to be affect similarly from FIHCO and WIHCO exposure but embryonic seabass is more likely to be affect from WIHCO exposure. These findings support that the severity of developmental defects was greater in flounder compared to that in sea bass. As found in our previous studies, we suggested that the species-specific differences should consider in risk assessment from resident fish species after oil spill incident. Additionally, our work extends the prior understanding of the role of nkx in embryonic heart morphogenesis in exposed to FIHCO and WIHCO in marine fish species. Over all, this information provide a useful new biomarker resource for future studies of effects on embryonic marine fish, which will facilitate future understanding of toxic molecular mechanisms on developing fish exposed to crude oil.

WP335 Effects of Three Crude Oil Aromatic Constituents on a Model Fish Species Anaplopoma fimbria

j. roberts, UNCW / Dept of Biology and Marine Biology; M. Boulais, B. Woodall, UNCW; M.M. McConville, Univ of North Carolina, Wilmington / Marine Biology; J. Guyomarch, S. LeFloch, CEDRE; L. Camus, Akvaplanniva AS; S.M. Brander, Univ of North Carolina, Wilmington / Dept of Biology Marine Biology; A. Volety, Univ of North Carolina, Wilmington / Marine and Ecological Sciences

When an oil spill occurs in the marine environment, the oil will either be mechanically collected, burned off, chemically broken down, or naturally be broken down by organisms in the water column. The actual composition of crude oil is a hydrophobic mixture of hydrocarbons consisting mostly of alkanes, cycloalkanes, and various mono and polycyclic aromatic hydrocarbons. Three aromatic hydrocarbon constituents found in many crude oils are phenanthrene, 2-methylnapthalene and toluene. These compounds are representative of tri, di and mono aromatic hydrocarbon classes that pose an aquatic toxicity concern. In this study, we have investigated the acute toxicity of these hydrocarbons to the juvenile deep-sea fish species (Anaplopoma fimbria). For each individual chemical, a range finding test was first conducted to determine the appropriate range of exposure concentrations that reduced survival of these test organisms. Then, testing was performed in closed systems over a 96-h period with four concentration levels, which depending on test compound, ranged from 0.05 mg/L to 15 mg/L. Analytical confirmation was performed to document exposure concentrations in each test. Mortality was recorded every 24 h and the LC50 of each chemical determined. Consistent with previous data, our results show that these aromatic hydrocarbons negatively impact fish survival as a function of the Log Kow of the test compound The 96-h fish LC50 was 0.28, 0.89, 6.84 mg/L for phenanthrene, 2-methyl naphthalene and toluene, respectively.

WP336 The comparative acute toxicity of crude oil, oil industry chemicals and refined petroleum products on Paleomonetes africanus

F. Ogundipe, Univ of Lagos, Nigeria / Zoology

A comparative assessment of the acute toxicity of Crude oil, Oil industry chemicals(corrosion inhibitors and drilling mud) as well as Refined Petroleum Products (Diesel and Petrol) acting singly against brackish water shrimp paleomentes afrianus obtained from the Lagos lagoon was investigated. The results of 96hrs acute toxicity indicated that diesel (LC_{50}=0.33mg/l) was the most toxic chemical substance followed by crude oil (LC_{50}=0.504mg/l), petrol (LC_{50}=0.646mg/l) and corrosion inhibitor (LC_{50}=3.978mg/l) while drilling mud (LC_{50}=1029000mg/l) was the least toxic. The computed toxicity factor(TF) indicated that diesel was 1.5,1.9, 11.9 and 30×10^4 times more toxic than crude oil diesel, corrosion inhibitor and drilling mud respectively. The findings from this study imply that crude oil, petroleum products and oil industry chemicals pose threat to sensitive aquatic species. Therefore crude oil exploratory, refining and transportation process should be executed in aquatic ecosystems in line with the best available practices to minimize negative effects on aquatic organisms.

WP337 Potential biomarkers of perfluorinated alkyl acid exposure in dolphin embryonic kidney cells

J. VanderJagt, Hawaii Pacific Univ / College of Natural and Computational Sciences; J. Lynch, National Inst of Standards and Technology / Chemical Sciences Division; Y. Chen, B.A. Jensen, Hawaii Pacific Univ

Perfluorinated alkyl acids (PFAAs) are anthropogenic contaminants that have been found in high concentrations in marine mammals worldwide. Perfluorooctane sulfonate (PFOS) is typically the dominant PFAA found in wildlife, while the majority of other PFAAs are long-chain perfluorinated carboxylic acids (PFCAs) with 8 carbons or more. However, the mere presence of these chemicals is not sufficient evidence to conclude the animal will experience negative health impacts. Investigating cellular changes in RNA and protein expression after exposure to a xenobiotic can help to deduce the potential mechanism of action and can also lead to the development of biomarkers of exposure and effect that can be used in health risk assessment. A majority of the cellular response to PFAAs has been shown to be mediated by peroxisome proliferator-activated receptors (PPARs), and specifically PPARa has been shown to regulate the transcription of cytochrome P450 4A (CYP4A) enzymes. Additionally, the constitutive androstane receptor (CAR) plays a vital role in the regulation of cytochrome P450 2B (CYP2B) enzymes. Both enzymes are necessary for the metabolism of endogenous lipophilic substances, as well as drugs and other xenobiotics, such as PFAAs. Previous observations in stranded cetaceans showed a significant positive correlation between certain long-chain PFAAs, PPARa mRNA and CYP4A protein expression in the kidney, while a relationship between PFAAs, CAR and CYP2B has yet to be evaluated. The purpose of this study was to evaluate the ability of PFAAs with a carbon chain length of 8 or greater to stimulate a cellular response in dolphin embryonic kidney cells (CDK), along with human embryonic kidney cells (HEK), and to ascertain the possibility of using that response as a measurable biomarker of PFAA exposure in vivo. The cytotoxic effects of 8-11 carbon PFAAs, including PFOS, PFOA, PFNA, PFDA, and PFUnA, were determined by incubating the cells with increasing concentrations of each compound for 4 to 72 hours and measuring cell viability with the Trypan blue dye exclusion assay. To determine the ability of each PFAA to activate PPARa, CYP4A, CAR and CYP2B, the dose-dependent response in mRNA was measured using real-time PCR and protein expression was measured using Western blot. Confirming a relationship between PFAA exposure and a specific cellular response in cetaceans will improve our understanding of the potential health impacts from these emerging contaminants.

WP338 Is PFHxA a good alternative to PFOA, based on a toxicity assessment of morphometric, behavioral, and gene expression endpoints in zebrafish?

K. Annunziato, Rutgers Univ / Joint Program in Toxicology; C.E. Greenfield, Rutgers Univ / Environmental Science; K.R. Cooper, Rutgers Univ / Dept of Biochemistry and Microbiology

Perfluoroctanoic acid (PFOA) and perfluorohexanoic acid (PFHxA) belong to the class of perfluoroalkylated substances (PFASs) which are extremely stable and resistant to biodegradation. These compounds have been detected in human, wildlife, and environmental samples worldwide. Both compounds consist of a fully fluorinated carbon backbone with a carboxylic acid end group. PFOA contains 8 carbon atoms in its backbone, whereas PFHxA contains a 6 carbon chain. PFOA was produced from 1950 to 2000, when a voluntary phase-out began. PFHxA was introduced as an alternative in manufacturing processes, in part, due to its shorter half-life in mammals in comparison with PFOA. Previous studies from the literature, as well as from our lab, have shown exposure to PFOA and PFHxA in zebrafish to result in both developmental defects and reduced survivorship. In the current study, zebrafish were exposed to PFOA or PFHxA (0, 0.1, 2.0 μM) for five days post fertilization (dpf). Morphometric, behavior, and gene expression end points were assessed at the sac-fry (5 dpf), larval (14 dpf), and adult (90 dpf) stages. At 5 dpf, both PFOA and PFHxA exposure resulted in significant increases in yolk sac size and interoccular distance, and significant decrease in total body length. However, at 14 dpf, PFOA-exposed zebrafish (14 dpf) remained significantly smaller in length, whereas there was no difference in total body length in the PFHxA-exposed larvae compared to the controls. In addition, the PFOA-exposed larvae showed an increase in total distance swam and swimming velocity in behavior assays. Gene expression analysis at all stages (5 dpf, 14 dpf, and 90 dpf) indicated a decrease in expression of organic anion transporting polypeptides (slco2b1, slco1d1, slco3a1, and slco4a1) in PFOA- and PFHxA- exposed fish. The short-term, embryonic exposure to PFOA resulted in negative outcomes in terms of growth, development, and behavior throughout critical life stages. At similar low doses these outcomes were observed in PFHxA-exposed zebrafish as well. The persistence of these effects following a brief 5 day exposure adds to the data raising question to the use of PFHxA as a safer environmental alternative to PFOA.

WP339 The cardiorespiratory and metabolic effects of acute naphthalene and pyrene exposure in adult zebrafish (Danio rerio)

C. Yeung, Univ of Saskatchewan / Toxicology Graduate Program; L.P. Weber, Univ of Saskatchewan / Veterinary Biomedical Sciences

Polycyclic aromatic hydrocarbons (PAHs) are aquatic contaminants often originating from anthropogenic sources. Naphthalene (NAP) and pyrene (PYR) are important petrogenic PAHs that are not as well studied as the prototypical PAH, benzo-a-pyrene (BaP). We hypothesized that acute exposure (48-hours) to NAP and PYR will cause sublethal cardiorespiratory and metabolic impairment similar to that observed in previous studies after acute BaP exposure in adult zebrafish (Danio rerio), but by different mechanisms. To investigate this hypothesis, adult zebrafish were aqueously exposed to PAHs (NAP, 0, 3.7, 370, and 3700 µg/L; PYR, 0.025, 2.5 and 25 µg/L) using static renewal (24h) and compared to dimethysulfoxide controls. No mortalities were observed in any treatment group. At 48h, fish (n=16 fish/group) were subjected to high frequency cardiac ultrasound. The ratio of the atrial contractile rate to ventricular rate (AV ratio) and stroke volume (SV) increased in both NAP- and PYR-exposed fish. This higher AV ratio is indicative of an atrioventricular conduction block similar to that observed with BaP in previous studies. However, while the atrial contraction rate for PYR was unchanged compared to control, NAP atrial rate was higher, likely representing an increased adrenergic tone on the heart. In addition, after NAP exposure, a large increase in end diastolic volume (EDV) was noted, but with a lower ejection fraction, indicating some impairment in ventricular contractility despite higher preload mediating great cardiac filling. The higher EDV observed with NAP, but not PYR, may be related to gill irritation and whole body edema observed with NAP. The acute effects of NAP and PYR on swimming endurance and metabolic rates will be examined and compared to tissue specific alterations in gene expression to help elucidate differences in adverse outcome pathways. In conclusion, acute aqueous PYR exposure resembles other AhR agonists, while NAP has additional cardiorespiratory toxic effects that make it a greater potential concern for acute sublethal toxicity in adult fish.

WP340 Phenanthrene may affect female reproduction via lipid homeostasis in fathead minnow liver

J.R. Loughery, Univ of New Brunswick / Biological Sciences; R. Wood, Univ of New Brunswick; A. Mercer, UNBSJ; K.A. Kidd, Univ of New Brunswick; C.J. Martyniuk, Univ of Florida / Physiological Sciences

Phenanthrene (PHE), a low molecular weight polycyclic aromatic hydrocarbon, is an environmental contaminant in waterways due to urban runoff, industrial effluents, and oil and gas extraction activities. Recently, PHE has been reported to affect reproductive processes in different fish species. The objective was to investigate the effects of PHE in both ovary and liver tissues to determine the potential impacts on the reproductive axis. Female fathead minnow (Pimephales promelas; FHM) were exposed to 0, 29.8, 389.4 and 942.5 µg/L average measured concentrations PHE over 24, 48 and 72 hrs. Ovarian tissues were processed for histology, ex vivo steroid production, and real-time PCR after 48hr exposure. There were no differences in steroid production or in the expression of transcripts involved in the steroidogenesis pathway. However, histological analyses showed increased proportions of cortical alveolar oocytes in 29.8 µg/L PHE fish and decreased proportions in 942.5 µg/L PHE fish suggesting that PHE may affect the distribution of oocyte stages in the ovary. As the liver is the main organ producing proteins for oocyte development, a transcriptomics experiment was performed to learn more about the pathways modulated in this tissue. Two microarray experiments were performed: a dose response at 48hrs exposure and a time course experiment over 72hrs at 29.8 µg/L. Sub-network enrichment analyses consistently identified pathways associated with lipids and fatty acids as affected by PHE. In the 48hr dose response experiment, pathways related to reproduction, lipids and fatty acids, and immune system function were affected. In the time course experiment, pathways affected included those related to reproduction, lipids and the immune system; there appeared to also be a shift towards lipid related processes at the later time point. In both experiments and across all treatments (dose and time), cholesterol metabolism was the one single pathway in common. We hypothesize that PHE may directly affect lipid processes in the liver, which leads to disrupted oocyte production downstream either through altered energy stores or lipid production.

WP341 Metabolic mechanisms of furan-based chemical alternatives (FBCAs): Assessment of toxicity at conserved aryl hydrocarbon receptors (AHR)?

M. Augustine, Univ of California – Berkeley / Nutritional Science and Toxicology

As trends toward urbanization and sustainable energy increase, biofuel consumption may become more widespread. There is a need to understand the resulting environmental consequences from the compounds found in greener fuel alternatives. Although legacy contaminants such as PCBs are decreasing, detection of biomarkers of aryl hydrocarbon receptor (AHR)-mediated toxicity (cytochrome P450 1A) is increasingly reported in fish from urbanized aquatic environments. Recent studies of chemical functional groups on aromatic hydrocarbons and their byproducts may differentially target AHR receptor pathways. We tested the hypothesis that furan-based biofuel analogs will differentially activate the zebrafish AHRs receptor and modify AHR targeted genes in early life stage zebrafish. Our screening approach consisted of developmental, cellular, and genomic endpoints. Zebrafish exposed at 24hpf were screened for 120hpf developmental endpoints. We selected the following furan-based compounds : a candidate biofuel, 2,5 dimethyl furan, and its combustion byproducts: 2,-3, hydrofuran, 2-ethylfuran, 2-methylfuran, 2-pentylfuran, 2,3-dimethylfuran, 2,5-dimethylfuran, furfural, indene, furan, as well as a potent AHR agonist, betanapthoflavone (BNF). Visualization of cyp1a-GFP was validated with qPCR of CYP1A1 gene expression. Characteristic AHR-dependent cardiotoxicity and pericardial edema measured for all compounds. Furfural, a dimethyl furan combustion product, produced characteristic cardiotoxicity. Using rt-qPCR, AHR battery genes nqo1, cyp1a1, nqo1, gst were measured for each chemical. The results in whole zebrafish were then compared to chemical-specific activation in invitro assays, and computational predictions of AHR activation with the furan library.

WP343 Bioaccumulation and toxicity of flame retardant TBPH or polychlorinated biphenyl PCB153 in dietary exposure in mummichog (Fundulus heteroclitus)

B. Clark, Atlantic Ecology Division, USEPA / Atlantic Ecology Division; A. Bertrand, Student services contractor, USEPA; I. Kirby, ORISE, USEPA / Atlantic Ecology Division; S. Jayaraman, USEPA; M.J. La Guardia, Virginia Inst of Marine Science / Aquatic Health Sciences; D. Champlin, D.E. Nacci, USEPA / Atlantic Ecology Division

The use of polybrominated diphenyl ethers as flame retardants in consumer products has been scrutinized increasingly due to their environmental persistence and potential toxicity; however, alternative replacement flame retardants may have similar drawbacks. The alternative brominated flame retardant bis(2-ethylhexyl)-2,3,4,5-tetrabromophthalate (TBPH) is a component of several commercial flame retardants, including Firemaster® 550, Firemaster® BZ-54 and DP-45. Here we investigate the bioaccumulation, bioenergetics and other adverse outcomes pathways (AOPs) predicted for dietary exposure to a carrier control, two levels of TBPH, or 2,2',4,4',5,5'-hexachlorobiphenyl (PCB153, a well-studied compound acting as a positive control for some aspects of the study). The TBPH concentrations chosen were at or well above the environmental concentrations documented in the literature, but similar to those causing toxicity in a previous study. Our experimental model is a small estuarine fish, the mummichog (Fundulus heteroclitus), exposed as individually tagged fish held in small groups (2 male, 2 female) in replicate tanks and fed contaminated food from day 0-28, followed by uncontaminated food from day 29-42. Throughout the experiment, individual growth was measured weekly, and at various time points, fish from replicate tanks were sacrificed, measured and dissected. To support putative AOPs, samples were obtained for analysis of hormone levels and transcriptomic responses to the exposures. After 28 days, the average sizes of fish in comparison to controls was larger in the PCB153 treatment group, and smaller in the treatment fed the high concentration of TBPH. These data will be used as input for a Dynamic Energy Budget model (currently under development for this species) to project effects throughout the life cycle. Rates of bioaccumulation and depuration determined during the study will be compared to predictions from standard bioaccumulation models, such as BASS. As expected, PCB153 was highly bioaccumulative and persistent; in contrast, a much smaller percentage of the provided TBPH was measured in fish. Coupling these growth and bioaccumulation data with ongoing transcriptomic analyses will improve our understanding of the bioaccumulation and adverse outcomes from dietary exposure to TBPH and PCB153. Ultimately, this work will support the application of ecological models to extrapolate effects of chemical exposures across species and chemical classes.

WP344 Tracking the fate of explosives, trinitrotoluene (TNT) and trinitrotriazine (RDX) in coastal marine ecosystems using stable isotopic tracer

T.S. Ariyarathna, Univ of Connecticut / Dept of Marine Sciences; P. Vlahos, Univ of Connecticut / Depts of Marine Sciences and Chemistry; M. Ballentine, Univ of Connecticut / Dept of Marine Sciences; R. Smith, Global Aquatic Research LLC, New York; C. Cooper, International Zinc Association / Dept of Marine Sciences; J.K. Böhlke, USGS, Virginia / National Research Program; S. Fallis, Naval Air Warefare Center Weapons Division / Chemistry Division; T. Groshens, Naval Air Warfare Center Weapons Division; C. Tobias, Univ of Connecticut / Dept of Marine Sciences

Although hundreds of coastal sites are contaminated with explosives, we know little about the fate of these explosives in coastal marine habitats. The goal of this study is to understand the fate of the explosives, trinitrotoluene (TNT) and trinitrotriazine (RDX) in coastal ecosystems using stable nitrogen isotopic tracer. Mesocosm experiments representing subtidal non-vegetated (coarse grained, organic-carbon-poor sediment and iron reducing conditions), subtidal vegetated and intertidal marsh (fine grained, organic-carbon-rich sediment and sulfate reducing conditions) ecosystems were conducted. Steady state concentrations of isotopically labelled ^{15}N-[TNT] and ^{15}N-[RDX] were maintained throughout a two-week period as two separate experiments. Sediment, biota, porewater and overlying water samples were analyzed for parent compounds, degradation products and ^{15}N inventories of inorganic nitrogen pools including ammonium, nitrate, nitrite, nitrous oxide and nitrogen gas. Quantification of sorption, degradation and mineralization using ^{15}N-isotopic tracer leads to mass balances of compounds in the systems. Fate of TNT and RDX in coastal marine ecosystems shows notable differences depending on characteristics of the compound. Persistence of TNT in mesocosms is fairly low compared to the RDX although the majority of system sequestrated TNT is unidentified. Higher sorption affinity of TNT and its derivatives makes sediment an effective sink with regard to remediation of contaminated aquatic environments. Instability of the aromatic ring of RDX facilitated ring breakdown and mineralization via several intermediates leaving nitrous oxide as the prominent product of RDX. Further, fate of TNT and RDX in coastal marine habitats depends on sediment characteristics and prevailing redox condition in the system. Subtidal vegetated and intertidal marsh ecosystems show notably higher mineralization rates for RDX in terms of production of dissolved inorganic nitrogen in the system. Sorption of TNT and derivatives onto sediment is highest in intertidal marsh system although no significant difference in mineralization among mesocosms. Sorption, biodegradation and mineralization of TNT and RDX were comprehensively related with geochemical variables of ecosystems using multivariate approach in order to acquire a better understanding of fate of compounds.

Neonicotinoid Insecticides: Current Research on Fate and Effects

RP001 Thiamethoxam concentrations in North American surface waters: A review of currently available data

J.D. Maul, Syngenta Crop Protection / Dept of Environmental Toxicology The Inst of Environmental and Human Health; R. Brain, Syngenta Crop Protection, Inc. / Dept of Environmental Risk Characterization; P.F. Hoekstra, Syngenta Canada / Regulatory and Biological Assessment; J. Overmyer, Syngenta Crop Protection, LLC. / Environmental Safety

There has been increased attention related to neonicotinoid aquatic exposure and potential effects on aquatic invertebrate communities. Efforts have been made in peer-reviewed journal articles and non-peer-reviewed documents to summarize the current state of knowledge of neonicotinoid concentrations (as a class) in surface waters of North America. However, physicochemical properties such as water solubility and adsorption/desorption (Koc) properties as well as degradation via photolysis, aerobic/anaerobic metabolism and hydrolysis can vary widely among compounds within the class and can potentially influence their fate in aquatic habitats. The present work focuses specifically on thiamethoxam with the goal of compiling aqueous concentrations in systems which serve as potential habitats for aquatic invertebrates. We surveyed the peer-reviewed published literature and state and federal data sources for thiamethoxam monitoring data in aquatic systems in the U.S. and Canada. We only included sources in which individual sample data were published or individual sample data that were obtained from the study authors when only summarized data were presented. Data were obtained from monitoring studies across a spectrum of aquatic habitats including streams/rivers, prairie potholes, and playas. Based on currently available data, the majority of detections are at levels below established toxicity endpoints. These results will also be discussed in context of previously reported thiamethoxam aqueous concentrations and established effect data.

RP002 Determining occurrence of neonicotinoid insecticides in agricultural and urban impacted US streams

M.L. Hladik, USGS / California Water Science Center

To better understand the fate and transport of neonicotinoid insecticides, water samples were collected from streams across the United States. In a nationwide study of 38 streams, at least one neonicotinoid was detected in 53% of the samples collected, with imidacloprid detected most frequently (37%), followed by clothianidin (24%), thiamethoxam (21%), dinotefuran (13%), and acetamiprid (3%). Clothianidin and thiamethoxam concentrations were positively correlated to the percentage of the land use in cultivated crop production and imidacloprid concentrations were positively related to the percentage of urban area within the basin. Additional sampling for neonicotinoid insecticides was also conducted in localized research areas to complement the national-scale results, including: (1) basins which have both agricultural and urban land uses (California, Georgia, Great Lakes Region), and (2) predominantly agricultural basins in two nationally important ecosystems (Chesapeake Bay and San Francisco Bay-Delta). These environmental data are important in determining the potential risk of neonicotinoids to non-target aquatic and terrestrial organisms.

RP003 Characterization of acephate and imidacloprid loss in containerized nursery runoff water

F.O. Hinz, Univ of Florida / IFAS / Soil and Water Sciences; P.C. Wilson, Univ of Florida / IFAS / Soil and Water Science

Pesticide formulation, application method, and irrigation intensity may significantly affect the losses of pesticides found in surface runoff water from containerized plant nurseries. For this study, four pesticides are being evaluated. Granular and sprayable formulations of acephate, bifenthrin, chlorpyrifos, and imidacloprid are being evaluated in small-scale plots irrigated at three different intensities. Plots were constructed in a shade house on the University of Florida campus in Gainesville, FL. Collection trays lined with plastic and landscape fabric were designed to collect drainage water into composite containers from individual containerized plants. Total mass (ug) of each pesticide discharged is calculated by multiplying the concentration (ug/L) by the volume discharged (L). Percentage of pesticide loss is determined by dividing the total mass discharged by total mass applied. In preliminary studies, containerized 1 gal dwarf Burford holly were treated with per pot applications of Precise 4% G (acephate; solubility: 7.9 x 10^5 mg/L at 20°C) and Marathon 1% G (imidacloprid; solubility: 6.1 x 10^2 mg/L at 20°C) at rates of approximately 15 g/pot and 5 g/pot , respectively. 14.5 L of water was applied daily for 10 days during 23 minute overhead irrigation cycles and all runoff water was collected in amber glass bottles. Total mass of acephate lost (n=3) was 1899 ± 1358 µg, with a percentage loss of 0.30 ± 0.22%. Acephate concentrations ranged from 3 µg/L to 1265 µg/L. The total mass of imidacloprid lost (n=3) was 6892 ± 262 µg with a percentage loss of 12.2 ± 0.73% during the same irrigation events. Pesticide losses relative to rainfall intensity and method of application (sprayed vs. per pot) will be discussed in this presentation.

RP004 Mass Balance Assessment for Neonicotinoids During Wastewater Treatment and Nationwide Occurrence in United States Wastewater

A. Sadaria, Arizona State Univ ; S.D. Supowit, Arizona State Univ / Biodesign Center for Environmental Security; R. Sutton, San Francisco Estuary Inst; K. Moran, TDC Environmental, LLC; R.U. Halden, Arizona State Univ / Center for Environmental Security

Over the last decade, an increased usage has been noted for neonicotinoids – a group of systemic insecticides with applications in agriculture, horticulture, and for urban nuisance pest control including pet flea treatment. Yet, knowledge is still limited as to the occurrence and fate of various neonicotinoid pesticides in urban wastewater process flows. Goals of the present study were to: (i) conduct a mass balance assessing the fate of six neonicotinoids during conventional wastewater treatment; (ii) assess the efficacy of wetland treatment; (iii) obtain the first national emission estimate by monitoring additional 12 treatment facility from across the United States; and (iv) to perform the first regional study in California via monitoring at eight local facilities. A mass balance based on analysis of flow-weighted 24-hour composites revealed insignificant removal of imidacloprid (p = 0.09, CI = 95%) and limited removal of the sum of acetamiprid and its primary degradate, acetamiprid-N-desmethyl (18 ± 4%, p = 0.01, CI = 95%). In the wetland, no removal of imidacloprid or acetamiprid were observed. Nationwide, imidacloprid, acetamiprid and clothianidin occurred at ng/L concentrations in WWTP influent (60.5 ± 40.0; 2.9 ± 1.9; 149.7 ± 289.5) and effluent (58.5 ± 29.1; 2.3 ± 1.4; 70.2 ± 121.8). Clothianidin was found only intermittently, whereas thiamethoxam, thiacloprid, and dinotefuran were never detected. Extrapolation of data from 13 WWTPs to the nation as a whole suggests annual discharges on the order of 1000-3400 kg/y of imidacloprid contained in treated effluent to surface waters nationwide. In eight Northern California WWTPs sampled under low-flow drought conditions, imidacloprid, which is used indoors primarily for pet flea treatment, was detected with 100% detection frequency (DF) in influent and effluent samples at 58-306 ng/L, concentrations that were generally higher than those observed nationwide. Sludge analysis yielded no detections (< 5 ng/g dw). Ubiquitous detection of neonicotinoids in wastewater demonstrates continuous entry of these compounds into the urban water cycle and their pronounced persistence during wastewater and wetland treatment, enabling entry into surface waters at significant loadings that potentially are harmful to sensitive aquatic invertebrates.

RP005 Transformation and fate of neonicotinoid insecticides during drinking water treatment

K.L. Klarich, E.M. Dewald, G.H. LeFevre, Univ of Iowa / Civil and Environmental Engineering; D.M. Cwiertny, Univ of Iowa / Dept of Civil and Environmental Engineering

Despite their widespread detection in surface waters, relatively little is known about the fate of neonicotinoid insecticides during engineered water and wastewater treatment. This work explores the transformation and removal of common neonicotinoids via the physical and chemical processes used in conventional drinking water treatment. The goals of this work are to establish the rates and extent of neonicotinoid transformation and/or removal during simulated treatment operations in the laboratory, while also identifying major transformation products generated during chemical treatment processes. In ongoing work, occurrence studies are seeking to identify transformation products from laboratory experiments and in finished drinking water. The results of this work will help to better identify potential risks posed to humans and other non-target organisms by neonicotinoids and their transformation products generated during treatment.

RP006 Investigating the Cumulative Toxicity of Neonicotinoid Insecticide Mixtures to Chironomus dilutus using MIXTOX Analysis

E. Maloney, Univ of Saskatchewan / Toxicology; C.A. Morrissey, Univ of Saskatchewan / Biology; J. Headley, Environment and Climate Change Canada / Watershed Hydrology and Ecology Resarch Division; K. Peru, Environment and Climate Change Canada / Aquatic Contaminants Research Division; K. Liber, Univ of Saskatchewan / Toxicology Centre

Neonicotinoids are a popular class of systemic insecticidal treatment, commonly applied as a seed treatment to protect young crops against biting-sucking insects. Extensive use of these seed treatments (e.g., imidacloprid, clothianidin, and thiamethoxam) in Canadian Prairie agricultural regions has resulted in the detection of neonicotinoid mixtures in ecologically important wetlands surrounding these arable areas. However, the impact of these mixtures on local insect communities is poorly understood. This research aims to address that knowledge gap by characterizing the cumulative toxicity of binary and tertiary mixtures of select neonicotinoids (imidacloprid (IMI), clothianidin (CLO), and thiamethoxam (TMX)) to the sensitive aquatic insect Chironomus dilutus under acute (96 h) exposure scenarios. Single-compound toxicity bioassays yielded toxicity threshold values (LC_{50}) of 4.63 (3.96 – 5.41), 5.93 (5.29 – 6.65), and 55.34 (43.98 – 69.64) for IMI, CLO, and TMX, respectively. These values were used to develop parametric models, which were statistically compared to the toxicity of binary and ternary mixtures from similar laboratory studies using the MIXTOX approach. CLO-TMX mixtures demonstrated concentration-additive synergistic toxicity. IMI-CLO mixtures demonstrated response-additive synergistic toxicity. IMI-TMX mixtures demonstrated response-additive dose-ratio dependent synergism, with toxicity shifting from antagonism to synergism as the relative concentration of TMX was increased. IMI-CLO-TMX mixtures demonstrated response-additive synergistic toxicity. Results obtained indicate that under acute exposure scenarios, the toxicity of these neonicotinoid mixtures to sensitive aquatic insects cannot be adequately predicted by direct addition of single compound concentrations. These results will be compared to those garnered in concurrent chronic (28 d) mixture studies, allowing for an assessment of whether these insecticide mixtures display similar deviations from concentration addition under more environmentally realistic exposure paradigms, and what risk this may pose to the aquatic environment.

RP007 Assessing the acute and chronic toxicity of neonicotinoid insecticides to non-target aquatic species

A.J. Bartlett, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A.M. Hedges, L.R. Brown, Environment and Climate Change Canada / Aquatic Contaminants Research Division; P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Struger, Environment and Climate Change Canada / Water Quality Monitoring and Surveillance Division; S. de Solla, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division

Neonicotinoids are the most widely used insecticides in the world. They are preferentially toxic to insects while displaying a low toxicity toward vertebrates; this selective toxicity has led to their rapid and ubiquitous use. However, neonicotinoids may negatively affect aquatic ecosystems because they are environmentally persistent and highly water-soluble, and thus are prone to leaching from the soil into surface waters via run-off events. Although non-target aquatic organisms may be adversely affected by these compounds, few data are available regarding the effects of neonicotinoids on aquatic invertebrates. The objective of this study was to assess the acute and chronic toxicity of six neonicotinoids (imidacloprid, thiamethoxam, acetamiprid, clothianidin, thiacloprid, and dinotefuran) to Hyalella azteca (amphipod) and Hexagenia spp. (mayfly). Neonicotinoid exposures were conducted in water-only systems, and test durations were 28 d (amphipod) and 96 h (mayfly). Endpoints assessed included survival and growth in amphipod tests, and survival and behaviour (number of animals inhabiting artificial burrows) in mayfly tests. Effects of neonicotinoids on amphipods varied depending on the compound: 28-d LC50s were 3, 4, 40, 50, 90, and 200 µg/L for clothianidin, acetamiprid, dinotefuran, thiacloprid, imidacloprid, and thiamethoxam, respectively. Amphipod growth was reduced at lower concentrations than survival for imidacloprid and thiacloprid, with 28-d EC50s of 4 and 3 µg/L, respectively. Effects of neonicotinoids on mayflies were variable among compounds: 96-h LC50s were 600, 700, 800, and 3000 µg/L for imidacloprid, clothianidin, acetamiprid, and thiacloprid, respectively, and were > 10,000 µg/L for thiamethoxam and dinotefuran. However, mayfly behaviour was inhibited at lower concentrations than survival for all neonicotinoids, with 96-h EC50s for number of animals inhabiting artificial burrows of 4, 4, 10, 20, 20, and 200 µg/L for acetamiprid, thiacloprid, imidacloprid, clothianidin, dinotefuran, and thiamethoxam, respectively. In addition, mayfly mobility was inhibited by imidacloprid, acetamiprid, and thiacloprid at concentrations ≥ 1 µg/L. The maximum environmental concentration of neonicotinoids measured in 2012-2014 surveys of 16 stream sites in southern Ontario was imidacloprid at 10 µg/L, indicating that environmental concentrations may adversely affect sensitive aquatic species.

RP008 Early chironomid emergence from chronic, low-level neonicotinoid exposure in a prairie pond: Is timing everything?

M.C. Cavallaro, Univ of Saskatchewan; K. Liber, Univ of Saskatchewan / Toxicology Centre; J. Headley, K. Peru, Environment and Climate Change Canada; C.A. Morrissey, Univ of Saskatchewan / Biology

Seasonal timing and phenological synchrony are critical components to an aquatic insect lifecycle and long-term population viability. Immature aquatic insects occupying surface water bodies adjacent to agricultural operations planted with seed-treated neonicotinoids are susceptible to chronic exposure from repeated run-off and long-term environmental persistence. These scenarios are often incredibly difficult to replicate with any level of control to determine environmental risk. To mimic these conditions, an in-situ, semi-controlled limnocorral experiment compared the neonicotinoids: imidacloprid (IMI), clothianidin (CLO), and thiamethoxam (THX) at two doses, 0.05 (low) and 0.5 (high) µg/L. Over a 15-week study, 21 limnocorrals were dosed weekly for 9 weeks to achieve a chronic, repeated exposure scenario simulating repeated run-off conditions, followed by a 6-week recovery period. Water concentrations and aquatic insect emergence were monitored continuously throughout the study. Thirty families and four chironomid tribes were identified over all treatments with two taxa exclusively emerging from the control treatments, (Hymenoptera: Trichogrammatidae) and (Diptera: Tipulidae). The Chironomidae was the most abundant family, representing 65% of all production. Total abundance of emerged chironomid adults among treatments were not significantly different (One-way ANOVA; F=0.752, df=6, n=21, p=0.618). However, on average the cumulative proportion emerged was 21-24 days, 7-18 days, and 3-16 days earlier than the control limnocorrals for imidacloprid, clothianidin, and thiamethoxam limnocorrals, respectively. Given the relatively short life span of adults among different taxa groups, difficulties of finding a mate in a fragmented landscape, and use of insect secondary production as a food source by higher trophic organisms, these expedited emergence events may have direct and indirect implications to aquatic insect communities and wetland dependent fauna, alike. Results from this study merits further investigation on the potential effect neonicotinoids may have on insect hormone regulation.

RP009 Effects of chronic exposure to thiamethoxam on summer generation mayfly populations in an outdoor mesocosm

M.C. Finnegan, Syngenta; D. Pickford, Syngenta / Inst for the Environment; U. Hommen, Fraunhofer IME; P. Ebke, MESOCOSM GmbH; W. Böhmer, Fraunhofer Inst IME; P. Stegger, Institut für Gewässerschutz Mesocosm GmbH; J. Maul, Syngenta; J. Overmyer, Syngenta Crop Protection, LLC. / Environmental Safety; P.F. Hoekstra, Syngenta Canada / Regulatory and Biological Assessment

The effect of neonicotinoids on mayfly nymphs has been investigated in recent literature, demonstrating they are amongst the most sensitive aquatic insect taxa to these insecticides. A publication by van den Brink et al (2015) reported the chronic effects of a continuous thiamethoxam exposure (28d) under laboratory conditions on over-wintering generation mayfly larvae (Cloeon dipterum); 28d EC_{10} = 0.43 ug a.s./L. A GLP outdoor mesocosm study was performed to investigate chronic effects of a continuous exposure to thiamethoxam on a summer generation mayfly (Cloeon dipterum) population. Twenty stainless steel enclosures within one large pond enclosure were used for the study; five untreated controls and five treatment levels with three replicates each. The treatment levels were, 0.1, 0.3, 1.0, 3.0, 10 µg a.s./L. Concentrations of thiamethoxam were maintained with twice-weekly applications to the water column via mixing. The time weighted average concentrations ranged from 93 to 108% of nominal, with a mean of 101% of nominal. Mayfly abundance was assessed with sweep-netting and substrate sampling (two baskets with aquatic macrophytes and stones). Adult emergence was also sampled. Mayfly sampling occurred weekly for the duration of the study. Statistical analysis (method: Minimum Detectable Difference (MDD);Brock et al, 2015) indicated that small effects could be detected throughout the study duration, with one exception. On day 34, only large effects could be detected, due to natural population decline. The no-observed-effect-concentration (NOEC) for larval abundance was determined to be 0.3 µg a.s./L and the lowest-observed-effect-concentration (LOEC) was determined to be 1.0 µg a.s./L.The results for adult emergence support the observed effects on the larval population. The results of the study indicate that under conditions of continuous exposure, there is no apparent difference in sensitivity to thiamethoxam between summer generation mayfly larvae tested under field conditions and over-wintering generation mayfly larvae that were tested under laboratory conditions. This study adds to the debate on the effects of neonicotinoids on sensitive aquatic insects by determining a no effect level for mayfly populations in outdoor mesocosms continuously exposed to thiamethoxam, representing worst-case conditions with respect to the EU FOCUS modelling drainage scenarios.

RP010 Residues of thiamethoxam at early reproductive stages of soybean and its potential impacts on non-target insects

C. Camargo, Univ of Florida / Entomology; B.D. Siegfried, Univ of Florida Gainesville / Entomology; T. Hunt, Univ of NebraskaLincoln / Entomology

Thiamethoxam is a widely used neonicotinoid compound applied as a seed treatment in soybean crops. During the last few years there has been a growing concern about the impact of thiamethoxam on beneficial insects in soybean. Negative impacts on beneficial arthropod communities are based on the hypothesis that neonicotinoid residues can be present in soybean vegetative tissue, host insects and flower tissues making them toxic to pollinators and natural enemies. The risk characterization of neonicotinoids to natural enemies in soybean requires baseline information of the concentration in soybean vegetative and floral tissue and the toxicity of this compound on beneficial insects associated to this crop through multiple routes of exposure to the insecticide. To identify exposure levels of non-targets insects in soybean fields we evaluated the translocation of thiamethoxam and mefenoxam applied as seed treatments in soybean crops. Furthermore, we evaluated the toxicity of thiamethoxam on key natural enemies of soybean aphid exposed to residues in vegetative tissue and in insect prey. To achieve this objective, the predators Orius insidiosus and Crysoperla rufilabris were exposed to different concentrations of thiamethoxam in soybean leaves and in soybean aphid using different laboratory methodologies. The results showed that the concentrations required to kill more than 50% of the evaluated insects were higher than the concentrations that the insects are likely to encounter in the field. There was found that the concentration-response evaluation of predators needs to be developed before 24 h if there is no availability of an alternative food source. Consumption of soybean aphid by O. insidiosus and C. rufilabris was not significantly affected at evaluated concentrations of thiamethoxam at 24 hours of evaluation. However significant mortality was observed in O. insidiosus at 24 hours after exposure to thiamethoxam treated aphids. The main challenges to determine the impact of neonicotinoids in soybean crops on non-target insects will be discussed.

RP011 Effect of Two Neonicotinoid Pesticide Products upon Utilization of Milkweed Plants by Monarch Butterflies

T. Bargar, USGS / The Wetland and Aquatic Research Center; T. Fanara, C. Wieser, USGS / The Wetland and Aquatic Research Center

Monarch butterfly larvae feed exclusively on milkweed plants (Asclepias spp). Comprised of over 100 different species in North America, milkweed plants grow in many locations including within and near agricultural lands in the Midwestern United States where they are considered pest plants, and are planted in residential flower beds due to their beauty and the tendency of their flowers to attract butterflies. In both situations, monarch larvae may be exposed to pesticides. Populations of monarch butterflies have declined over the past 10 – 15 years due to a variety of possible factors including habitat loss (i.e., loss of host milkweed) and pesticides. The study underway is evaluating monarch utilization of milkweed plants potentially contaminated by neonicotinoid pesticides from two different pesticide products (granular and corn seed treatment). For the seed treatment (active ingredient [a.i.] thiamethoxam), 200-gallon tubs with established milkweed plants were planted with treated (10 tubs) or untreated (10 tubs) corn seed in the spring and monitored weekly for utilization by monarch butterflies (number of eggs, larvae, and chrysalises). Corn and milkweed leaves, soil, and leachate were sampled 4-to-6 weeks after planting, and analyzed for thiamethoxam. For the granular product (a.i. clothianidin), 200-gallon tubs with newly planted milkweed were treated with the granular product at the label rate as well as at a medium (60 percent of label rate) and low rate (60 percent of medium) plus a control (3 tubs). Monarch utilization of the milkweed in the granular treatment tubs were monitored weekly for 6 months. Based on the label recommendations for the granular product, the tubs were retreated with every 8 weeks. Milkweed leaves, soil, and leachate were sampled following 5 months of treatments and analyzed for clothianidin. This study will provide information on the possible effect upon monarch reproduction of pesticide products with neonicotinoids. It will also provide data on the fate and transport of the respective neonicotinoids from the source (treated seed or granules) to soil, leachate, and lastly milkweed foliage that the monarch larvae consume.

RP012 Effects of imidacloprid and chlorpyrifos insecticides on migratory behaviour and physiology in a passerine, the white-crowned sparrow

M.L. Eng, Univ of Saskatchewan / Toxicology; B.J. Stutchbury, York Univ; C.A. Morrissey, Univ of Saskatchewan / Biology

Many migratory birds utilize agricultural landscapes for refuelling where they may be exposed to current-use insecticides through consumption of treated seeds, granules, or sprayed soils. Numerous insecticides are known neurotoxins, which could cause changes in critical phases of avian migration, such as mass gain, cognition and orientation behaviour. Changes in migratory behaviour could affect the ability of birds to successfully reach the breeding or wintering grounds, and ultimately have long-term effects on reproduction and survival. However, little is known about the direct impacts on migration. We compared behavioural and physiological effects and recovery following acute exposure to sublethal levels of two pesticides with different modes of action, Imidacloprid (IMI; a neonicotinoid) or Chlorpyrifos (CPF; an organophosphate), in a migratory seed-eating bird, the white-crowned sparrow. Sparrows were captured in the spring at migratory stopover sites in Saskatoon, Saskatchewan, and taken into captivity. Migratory behaviour was monitored with Emlen funnels, which can be used to assess migratory orientation and activity levels. After an acclimation period of ~2 weeks, birds were pre-tested in Emlen funnels to confirm they were in a state of zugunruhe (migratory restlessness). They were then dosed daily for 3 days with either the vehicle control (sunflower oil) (n = 10), 4.1 mg IMI/kg (n = 11), 10.3 mg IMI/kg (n = 11), 2.9 mg CPF/kg (n = 9) or 7.4 mg CPF/kg (n = 9), representing an estimated 10% and 25% of the LD50. Birds were re-tested in Emlen funnels at the end of dosing, after a 3-day recovery period, and again after a 14-day recovery period. Mass and fat was scored throughout the experiment. Once 14-day recovery trials were complete, birds were euthanized and livers and brains were collected for future analysis. Following IMI exposure, we observed acute effects in both exposed groups, including significant mass loss, reduced foraging, excess saliva in the crop, and respiratory distress. In birds exposed to CPF, we observed moderate weight loss in the high dose group, but no other overt effects. Effects on migratory activity, orientation behaviour, and recovery, are currently being assessed. This is the first study to evaluate the direct toxicity of neonicotinoids in comparison with older organophosphate chemistries. Uniquely, we were able to assess the sublethal effects on behaviour and physiology in wild songbirds during a migration event.

RP013 Impacts of passive contaminant exposures, including imidacloprid, on parental care behaviors and testosterone of golf course living eastern bluebirds

L. Gillespie, Univ of Southern Mississippi / Biology

Parental care behaviors, such as nest building, incubation, and nestling provisioning are essential for nest survival and fledging in monogamous birds. Such behaviors often correlate with ornamental plumages or physiology in many species. Expression of these traits may be influenced by genetics, environment, or hormones. Recently, behavioral studies demonstrate that anthropogenic disturbance can lead to altered parental care. Examination of behavior in relation to human disturbance and environmental contamination is increasing given relevant impacts behavior has on fitness in wildlife populations. Research presented here provides partial support for the hypothesis that level of human disturbance (including indirect, passive contaminant exposures) influence parental care behaviors in eastern bluebirds at a chronically disturbed golf course compared to those breeding at a rural military base. Sites differ significantly in habitat, human activity, and pesticide use, and golf course birds are more ornamented. Consistent with predictions, golf course pairs complete nests more slowly, produce smaller clutches, and fledge fewer young. Contrary to predictions, incubation length, and male feeding rate does not differ between sites. Female feeding rates, however, differ between sites but not in the direction predicted; golf course females provision at higher rates. Lastly, during nestling provisioning, golf course male display lower T while females display slightly lower T than birds at the rural site, and female T is positively correlated with higher average feeding trips (regardless of nestling number). There are no relationships between ornamentation and parental behaviors or reproductive indices, contrary to evidence from other bluebird populations. Lastly, males were observed performing female-typical nesting and incubation behaviors, and although not quantified, this observation appears unique for males of this species. While contaminants were not quantified in this research, data suggests that factors contributing to anthropogenic disturbance may cause females to delay breeding and reduce clutch investment but, later in the nesting cycle, does not appear to negatively influence provisioning behaviors. Delays in female breeding may also result in male compensation of previously unperformed parental behaviors to increase individual or pair fitness.

RP014 Northern leopard frog (Lithobates pipiens) developmental responses to neonicotinoid exposure: preliminary findings

S.A. Robinson, R.J. Chlebak, S.D. Richardson, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate; R.L. Dalton, Carleton Univ / Dept of Biology; J. Koprivnikar, Ryerson Univ / Dept of Chemistry and Biology; B.D. Pauli, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate; V. Trudeau, Univ of Ottawa / Biology; S. de Solla, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division

In recent years, neonicotinoid use has been linked to collapses of honey bee (Apis mellifera) colonies; however, relatively little is known about the impact of neonicotinoid insecticides on vertebrate wildlife. Amphibians are sensitive to environmental stressors and may be more vulnerable to neonicotinoid exposure due to their dual aquatic/terrestrial life cycle. Consequently, amphibians are excellent vertebrate bioindicators for a given environment. The objective of our study was to characterize the sub-lethal effect(s) of exposure to ecologically-relevant levels of neonicotinoid insecticides on northern leopard frogs (Lithobates pipiens, formerly Rana pipiens) during their aquatic life-cycle stage using mesocosm and laboratory exposures. Our previous work (summer, 2015), exposed northern leopard frog tadpoles to formulated neonicotinoid products containing thiamethoxam or clothianidin as the active ingredient in outdoor mesocosms. The exposure resulted in no effects on survival, growth or development. Here we followed up on our previous work via laboratory exposures with the technical product clothianidin to separate potential indirect and direct effects of neonicotinoids on tadpoles. In May of 2016, adult northern leopard frogs were bred in outdoor mesocosms and egg clutches were allowed to develop. Tadpoles from Gosner stage 25 to 42 were exposed for 8 weeks to environmentally-relevant concentrations (0 to 100 µg/L) following a static-renewal system. We assessed the effects of chronic exposure to clothianidin on conventional tadpole life-history traits, such as survival, growth and development that can affect amphibian fitness. Another objective was to assess whether neonicotinoid exposure affected tadpole susceptibility to parasitic helminths to add a disease-related component. The results of this study will help in establishing water quality guidelines and regulations for neonicotinoid use in Canada; however, more information is required on monitoring environmental concentrations of neonicotinoids and sub-lethal effects on chronically exposed non-target organisms to fully understand the risk of neonicotinoids on ecosystems.

RP015 Sub-lethal effects of the neonicotinoid clothianidin on developing sockeye salmon (Oncorhynchus nerka)

T.Y. Leung, Simon Fraser Univ / Biological Sciences; C.J. Kennedy, Simon Fraser Univ / Dept of Biological Sciences; V.L. Marlatt, Univ of the Fraser Valley / Biology

Current-use pesticides are a concern for the health of anadromous salmonids throughout the Fraser River Basin in British Columbia, Canada. Neonicotinoids are a class of widely used insecticides that have been detected in ng-µg/L concentrations in surface waters globally, including those in the Fraser River Basin, yet few studies have examined the potential sub-lethal effects of neonicotinoids on aquatic vertebrates. This study examined the effects of a neonicotinoid insecticide, clothianidin, following a chronic exposure, on critical early life stages of a wild salmon species, sockeye salmon (Oncorhynchus nerka). In this study, 4 concentrations of clothianidin (0.15, 1.5, 15 and 150 µg/L) plus a water control were tested in a chronic exposure experiment that was initiated immediately post-fertilization and experiment continued through to the swim up fry developmental stage. Three unique offspring sets (crosses) were tested within each experiment and all treatments were conducted in duplicate. Clothianidin did not affect survival or morphometrics in chronic exposure, although differences between crosses within clothianidin treatments were evident. Gene expression analyses to examine alterations in hepatic endocrine, nervous and immune system transcript abundance and hormone concentration analyses are ongoing to further investigate the sub-lethal effects of clothianidin in early life stage sockeye salmon. Supported by Fisheries and Oceans Canada National Contaminants Advisory Group.

RP016 Sublethal doses of imidacloprid reduce the efficacy of visual collision detection in Locusta migratoria

R. Parkinson, J.R. Gray, Univ of Saskatchewan / Biology

Imidacloprid is known to be directly toxic to insects and aquatic invertebrates at agriculturally-relevant doses. Indirect toxicity also occurs bees, birds, and other non-target organisms. Locusts (Locusta migratoria) are persistent and important agricultural pests, and once mature can survive high pesticide doses. We show that sublethal doses of imidacloprid disrupt the neuronal processing of salient visual cues, including those of objects approaching on a direct collision course. The Descending Contralateral Movement Detector (DCMD) is a motion sensitive neuron in the locust brain that is involved in collision avoidance and escape from predators. Analogous neurons exist in many species, including pigeons, crabs, and other insects such as flies. Typical responses of the locust DCMD to looming stimuli are well documented, providing a unique substrate for examining real-time effects of the neonicotinoid pesticide on a well-described visual detection system. Locusts were tested with sublethal doses of imidacloprid incrementing by an order of magnitude from 0 ng g^{-1} to 100 ng g^{-1}, with significant effects resulting from both 10 and 100 ng g^{-1} doses. Alterations of the firing properties of the DCMD were sustained even after acute effects of the dose subsided, suggesting the pesticide is capable of causing lasting changes to the neurons in this pathway. A dose response curve illustrated the relative effects within the range of doses tested. We show that sublethal doses may be indirectly lethal to mature locusts by disrupting a key motion detection pathway. This research is relevant to other insect species, including important pollinators, that may use analogous collision detection systems.

RP017 Sublethal concentrations of thiamethoxam affect synapsin levels in mushroom bodies of Apis mellifera after exposure in the larval period

D.A. Tavares, UNESP Univ Estadual Paulista Júlio de Mesquita Filho / Departamento de Biologia Centro de Estudo de Insetos Sociais Rio Claro São Paulo; T.C. Roat, UNESP Univ Estadual Paulista Júlio de Mesquita Filho / Biology; E. Silva-Zacarin, Univ Federal de São Carlos – UFSCar – Sorocaba / Biology; R.C. Nocelli, UFSCar / Departamento de Ciências da Natureza Matemática e Educação; O. Malaspina, UNESP Univ Estadual Paulista Júlio de Mesquita Filho / Departamento de Biologia Centro de estudos de insetos sociais

The exposure of bees to neonicotinoid insecticides such as thiamethoxam, has been appointed as one of the factors responsible for the worldwide decline of populations of Apis mellifera. Because having systemic action in the plant, this insecticide can contaminate the pollen, nectar and other floral resources used by bees as food. Thus, in addition to the exposure of worker bees during their forager activity on field, the bees that remain inside the hive can also be exposed to thiamethoxam through the consumption of contaminated pollen and nectar that have been stocked inside the colony, which are also provided to larvae by the nursing workers. The neonicotinoids are neurotoxic insecticides, which act as agonists at nicotinic acetylcholine receptors of the nervous system of insects, especially in the brain. Its molecules bind irreversibly changing the pattern of nerve transmission and causing excitation, paralysis and eventual death of the insect. This study aimed to analyze the immunostaining of synapsin in the brain, specifically in the pedunculated bodies, because this protein is involved in the process of releasing of acetylcholine vesicles during the neural synapses. In order to assess the neurotoxicity of thiamethoxam to pupae and newly emerged workers of Africanized Apis mellifera, the larvae were previously exposed to three sublethal concentrations of thiamethoxam, as follows 0.00001 ng/µL; 0.001 ng/µL e 1.44 ng/µL in the diet (acute oral exposure). Sections of bee brains were performed in a vibratome and the sinapsin immunostaining was detected by confocal laser scanning microscopy. The results showed a significant decrease in immunostaining of synapsin in the pupae brain from the group exposed to 0.001 and 1.44 ng/µL, as well as a decrease of this labelling in the brain of newly emerged workers from the group exposed to 1.44 ng/µL in comparison to the control group. The results demonstrate that exposure to sublethal concentrations of thiamethoxam during the larval stage may cause impairment of neural functions performed by the brain pedunculated bodies in pupae and newly emerged workers, which may negatively affect the performance or the survival of bees.

RP018 Imidacloprid promotes genetic damage and oxidative stress in different tissues of the Neotropical fish Prochilodus lineatus

C.D. Vieira, Univ Estadual de Londrina / Departamento de Ciências Fisiológicas; M. Perez, Instituto de Limnología – INALI / Laboratorio de Ictiología; C.B. Martinez, Univ Estadual de Londrina / Ciencias Fisiologicas

Imidacloprid (IMI) is a systemic neonicotinoid insecticide widely used around the world, and recent data highlight this compound among the ten active ingredients commercialized in Brazil. However, despite its increasing use only few toxicity studies have been performed about its effects on non-target organisms. The aim of the study was to identify the potential hazard of the commercial formulation Imidacloprid® (48% imidacloprid- Nortox S.A. Brazil) in juveniles of Prochilodus lineatus (14.1 ± 1.14 g, 10.77 ± 0.6 cm [mean ± SD, n=40]). Fish were exposed to IMI at nominal concentrations of 5 (IMI5), 50 (IMI50), 500 (IMI500) and 5000 (IMI5000) µg.L^{-1} or only to clean water (CTR) for 120 h, under static condition and daily water renewal. Biochemical parameters such as glutathione content (GSH), activity of the glutathione-S-transferase (GST) and acetylcholinesterase (AChE), lipoperoxidation (LPO), protein carbonylation (PC), genotoxic biomarkers (DNA damage), micronuclei (MN) and the erythrocytic nuclear abnormalities (ENAs) were evaluated in various organs. When compared to CTR fish, significant increases of LPO and PC were observed in the liver of fish exposed to IMI5000. In the gills we observed a significant increase of LPO in fish exposed to IMI50 and IMI500, and an increase of PC together with reduced GST activity in fish exposed to IMI5000. Fish exposed to IMI500 and IMI5000 showed significant increases of PC in the kidney. In addition, an increase of LPO and decrease of GST activity were observed in the kidney of fish from IMI5000 group. In the brain, a raise of GSH with concomitant increase of GST activity was observed at IMI500 and IMI5000. LPO also increased in the brain of fish exposed to IMI5 and IMI50, suggesting that the activation of antioxidant defenses (GSH and GST), observed at higher concentrations prevented oxidative stress in this organ. The comet assay showed increase DNA damage ($p = 0{,}018$) in the erythrocytes of fish exposed in all IMI concentrations tested. Also, there was a significant increase in ENAS frequency in fish exposed to IMI5000 ($p= 0{,}043$), relative to others groups. Taking together, these results suggest that IMI has the potential to promote oxidative stress and genotoxicity in P. lineatus, and kidney and gills proved to be the most affected organs, followed by the brain which showed oxidative damage in fish exposed to the lower IMI concentrations, which are the most environmentally relevant.

RP019 Weight-of-evidence evaluation of an adverse outcome pathway network linking activation of the nicotinic acetylcholine receptor in bees to colony loss

C. LaLone, USEPA / Mid Continent Ecology Division; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory; R. Milsk, ORISE; K.V. Garber, USEPA / Office of Pesticide Programs Environmental Fate and Effects Division; J. Housenger, USEPA / Office of Chemical Safety and Pollution Prevention; K.G. Sappington, USEPA / Office of Pesticide Programs Environmental Fate and Effects Division; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory

Ongoing honey bee colony losses are of significant international concern because of the essential role these insects play in pollinating staple food crops. Chemical and non-chemical stressors both have been implicated as possible contributors to colony failure, however, the potential role of commonly-used neonicotinoid insecticides has emerged as a focal point of potential chemical stressor impacts. Neonicotinoids act on the nicotinic acetylcholine receptor (nAChR) to eliminate target pest insects. However, mounting evidence indicates that these chemicals may adversely affect beneficial pollinators, such as the honey bee, through multiple mechanisms including impacts on learning and memory thereby affecting foraging success. However, the mechanisms linking activation of the nAChR to adverse effects on learning and memory are uncertain. Additionally, clear relationships between observed impacts on individual bees and colony level effects are lacking. Therefore, the objective of this work was to develop adverse outcome pathways (AOPs) as a means to evaluate the biological plausibility and empirical evidence supporting (or refuting) the linkage between the nAChR and colony level impacts. Development of these AOPs has led to the identification of research gaps which, for example, may be of high priority in understanding how perturbation of pathways involved in neurotransmission can adversely affect honey bee health, causing colony instability and failure. From this effort, an AOP network also was developed, laying the foundation for further insights as to the role of combined chemical and non-chemical stressors in impacting bee populations. Insights gained from AOP network assembly, which more realistically represent multi-stressor impacts on honey bee colonies, are promising aids for understanding common nodes in the biological pathway and identifying where mitigation strategies may be focused to reduce colony losses. The contents of this abstract neither constitute nor reflect official USEPA policy.

RP020 Quantitative Weight of Evidence Assessment of Higher Tier Studies on the Toxicity and Risks of Imidacloprid in Honeybees: I Methods & Procedures

K.R. Solomon, Univ of Guelph / School of Environmental Sciences; G.L. Stephenson, Aquaterra Environmental Consulting Inc. / Environmental Services

Higher tier studies have been conducted on the toxicity of neonicotinoids to honeybees, some in the open literature and some by the registrants of these insecticides. Individually, these studies were of varying quality; collectively, they comprise a body of evidence of the potential effects of these chemicals under more realistic conditions than those in laboratory studies. A framework for a quantitative weight of evidence methodology (QWoE) was developed and used to assess the effects of imidacloprid (IMD) on honeybees. Assessment endpoints were population size and sustainability of commercially managed bees via quantity and quality of hive products. A conceptual model for exposures was used to characterize important pathways of exposure of honeybees. Nectar and honey were potentially the most important sources of exposure for worker bees. Surface waters and guttation fluid from plants grown from treated seed was an incomplete pathway for all stages and casts. The queen is protected from direct exposures and larvae to a lesser but significant extent. The QWoE was based on a scoring system for evaluating the reports provided by the registrant and papers from the open literature. Criteria for assessing quality and relevance were developed before the assessment began and were based on best practices in ecotoxicology for measuring responses at the level of the hive and exposures via bee-relevant matrices such as nectar, pollen, honey, water, guttation fluid and dust. Some scoring criteria were critical (each had their own score) and others were general. General aspects of the experiment and the analysis of the data were grouped and weaknesses noted and used in the scoring. Scores for relevance were based, inter alia, on statistical significance and threshold no-observed-adverse-effect doses from toxicity tests at the level of the hive. Scores were assigned on a relative scale of 0-4 using a formal guide for scoring. The scores were averaged and then used to separate the higher from the lower quality studies and the relevant from the non-relevant results. The basis for each score was documented in a narrative and this was subjected to independent quality assurance. These scores were summarized graphically to illustrate the quality of the studies and their relevance and thus the overall strength of the evidence. Assessment endpoints were population size and sustainability of commercially managed bees via quantity and quality of hive products.

RP021 Quantitative Weight of Evidence Assessment of Higher Tier Studies on the Toxicity and Risks of Imidacloprid in Honeybees: II Results & Conclusions

G.L. Stephenson, Aquaterra Environmental Consulting Inc. / Environmental Services; K.R. Solomon, Univ of Guelph / School of Environmental Sciences

A quantitative weight-of-evidence (QWoE) analysis was applied to field and semi-field studies designed to assess the effects of the neonicotinoid, imidacloprid (IMD) on honeybees. The analysis considered the potential risks associated with exposure of honeybees to IMD via residues in bee-relevant matrices (nectar, pollen, guttation fluid, bee bread) and via different types of applications (seed dressing, foliar, soil drench, artificial feeding, and dust). The QWoE analysis data for exposures via IMD-dressed seed indicated that environmentally realistic concentrations (< 20 µg IMD/kg) result in no adverse effects to apical endpoints of honeybee colonies. The quality of the methods (QoM) or data (n=85 endpoints) was variable and relevance low (QoM = 1.21 ± SE of 0.06, relevance = 0). When applied to semi-field feeding studies, the QWoE analysis of dietary exposures (IMD-amended syrup or pollen patties) indicated that honeybees are at risk only when exposed to IMD at environmentally unrealistic concentrations >20 µg/L or kg. The quality of the studies and data (n=21 endpoints) was relatively strong and relevance low (QoM = 2.28 ± SE of 0.25, relevance = 0.2). The impact of dust residues on foraging honeybees and those flying in adjacent fields with flowering plants was negligible (QoM = 2.28 ± SE of 0.25) when the route of exposure considered was pollen and nectar originating from plants where TMX was taken up by plants. Non-seed applications of IMD (foliar, dust, and soil drench applications) were evaluated and the QWoE analysis indicated that the quality of the studies and data (n=28 endpoints) was variable and the relevance low (QoM = 1.64 ± 0.0, relevance = 0). One study indicated that a combination of concurrent foliar and soil applications could result in potentially hazardous nectar and pollen exposure concentrations; however, the QWoE for effects indicated no adverse effects. For higher-tier studies (ecoepidemiological), the weight of evidence did not support a causal relationship between exposure to IMD and adverse effects to honeybees. The data (n=32 endpoints) were from studies that varied in quality (QoM = 1.88 ± SE of 0.19; relevance 0.11 ± SE of 0.11); however, both the stronger studies and the weaker studies (with one exception) consistently showed no adverse effects. The overall weight of evidence suggests that there is minimal risk to honeybees at the colony level from exposure to IMD used as a seed treatment.

RP022 Quantifying sources of variability in neonicotinoid residue data for assessing risks to bees

K.G. Sappington, F.T. Farruggia, M. Wagman, K.V. Garber, USEPA / Office of Pesticide Programs Environmental Fate and Effects Division

The U.S. Environmental Protection Agency's 2014 guidance for assessing pesticide risks to bees relies on higher-tier studies of residues in pollen and nectar to refine pesticide exposure estimates obtained from lower tier information (e.g., default values and models). These higher tier residue studies tend to be resource intensive due to the need to address spatial and temporal factors which influence pesticide residues in pollen and nectar. Time and resource considerations restrict the number of crops and locations which can be studied. Given these resource constraints, questions remain on how to best optimize the design and number of residue studies for obtaining a robust dataset to refine exposure estimates of bees to pesticides. Factors to be optimized include the number of replicates in each sampling event, the number of sampling events over time, the number of sites per study, and the number of crops to be assessed within and across crop groups. Using available field residue data for neonicotinoids, we conducted an analysis of variability in residue data to address these and other study design elements. For imidacloprid, variation due to analytical measurement was relatively small (coefficient of variation [CV] < 20%). For foliar-applied imidacloprid to citrus and cherry, greater variability among replicate samples is seen with pollen (mean CV =33-64%) vs. nectar (mean CV =24-28%). For blueberry (soil applied), mean residues of imidacloprid in pollen and nectar varied by up to 5X between years for the same sampling period, indicating the importance of capturing inter-annual variability. Across three study sites, imidacloprid residues in blueberry ranged up to an order of magnitude which is likely related to differences in soil texture. For four species of cucurbits, residues in clothianidin varied up to 6X in nectar and 4X in pollen/anthers. The potential influence of the field was explored by comparing the average ratio of maximum to minimum measured concentrations in pollen from 4 crops (potato, tomato, cucumber and pumpkin) grown in common fields from California, Missouri, and North Carolina. Average ratios for potato, cucumber and pumpkin were nearly identical (range: 3X-7X) for each geographic region; however for tomato, the ratio differed by 63X. These results and additional analyses of neonicotinoid residue data will be presented in the context of optimizing field residue study designs for assessing pesticide risks to bees.

Environmental Impacts of Tobacco Products

RP023 A review of carbon monoxide in secondhand smoke of waterpipe

R. Edwards Jr, US FDA / Center for Tobacco Products

Waterpipes (WPs) have been used to smoke tobacco by indigenous peoples of Africa and Asia for at least four centuries.1 A typical WP includes a head where charcoal and tobacco are placed, a body through which vapors pass, a bowl that contains water through which vapors pass, and a hose that leads to the smokers' mouthpiece. WP's secondhand smoke (SHS) is comprised of side stream smoke (SSS) emitted from the WP and exhaled mainstream smoke (EMSS) from the user. Carbon monoxide is a component of the SHS. The burning of charcoal to heat the tobacco for the WP produces the majority of the SHS CO. The reviewed literature shows that CO levels can reach concentrations harmful to individuals exposed to WP SHS.

RP024 Assessing toxicity of tobacco product waste in leachate using chemical analysis and in vitro cell-based bioassays

H. Wei, San Diego State Univ; G. Xu, UC Riverside / Dept of Environmental Sciences; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences; E. Hoh, San Diego State Univ / Graduate School of Public Health

Discarded smoked cigarettes are the most prevalent types of litter found in ocean beaches and inland waterways. A discarded smoked cigarette is composed of a filter and unburned matter. It can contain many harmful compounds from the complex mixtures of chemicals in tobacco and tobacco smoke. We hypothesized that discarded smoked cigarettes would leach harmful chemicals into the aquatic environment. To test this, we analyzed the chemical constituents in freshwater and seawater leachate, and assessed the leachates for in vitro biological activity. Chemical identification was conducted by non-targeted analysis using comprehensive two-dimensional gas chromatography coupled to time-of-flight mass spectrometry (GC×GC/TOF-MS). In total, 687 unique compounds were found in both leachates. In the freshwater leachate, 53 were unique to that leachate, and in the saltwater leachate 173 were identified. The in vitro estrogenic receptor (ER), aryl hydrocarbon receptor (AhR) and p53 responses to leachates were further assessed by using the established LUMI-CELLTM ER (BG1Luc4E2), AhR (GeneBLAzer CYP1A1-bla LS-180) and p53 (p53RE-bla HCT-116) cell-based bioassays. Treatments of 10 cigarettes (cig)/L seawater and freshwater leachates showed no significant ER, AhR or p53 activities, while 100 cig/L seawater leachates had significantly higher AhR (2.7 ng/L aryl hydrocarbon toxicity equivalent (TEQ)) and p53 responses (41.9 µg/L mitomycin equivalent (MCQ)) than controls (< 0.17 pg/L TEQ, < 1.4 µg/L MCQ). Cytotoxicity measured by the MTT assay was also higher when cells were exposed to the seawater leachate (relative cell viability < 80% in general). Overall, these results indicate saltwater leachates of tobacco products were higher than freshwater leachates. Ongoing studies are underway to identify specific compounds responsible for the bioactivity.

RP025 Chemical Emissions from Cigarette Butts: A Literature Review

M. Gong, D. Poppendieck, S. Khurshid, L. Lawson, National Inst of Standards and Technology

Globally, 5.6 trillion cigarette butts are deposited into the environment per year, which are some of the most common forms of litter found on beaches and near streams, night clubs, bus stops, roads and streets. Cigarette butts are made of non-biodegradable cellulose acetate, which is used for reducing inhalation of harmful chemicals (e.g., tar and nicotine) during smoking. Many governments have made regulations to sanction penalties for littering of cigarette butts due to the substantial costs to clean them up. However, little is known about the emission characteristics of littered cigarette butts, even though some toxicological studies have shown the association between exposure to cigarette butts and adverse health effects (e.g., shorter life spans for mosquitoes, genotoxicity for house finches, mortality and behavioral modifications for snails). A literature review was conducted in order to identify data gaps related to chemical emissions of littered cigarette butts. We searched articles published prior to November of 2015 on ISI web of science database for the keywords – "cigarette butt" or "cigarette filter" or "cigarette tip" or "tobacco filter". The literature search identified 2382 articles. Only 200 of those articles were deemed relevant to emission characteristics of cigarette butts in general and reviewed in detail for this paper. The review focused on emission from cigarette butts into water and air, and composition of chemicals in cigarette butts. Generally, few studies have been conducted on chemical emissions from cigarette butts. Among those, present studies mainly focus on chemical emissions into water. Only 1 paper published in 1985 investigated airborne emission from cigarette butts. Chemicals detected from extraction studies and water emission experiments include nicotine, amines, pyrroles, PAHs, insecticides, radionuclides, heavy metals and terpenoids. Given the fact that many chemicals present in cigarette butts are harmful, even carcinogenic, more research on emission from cigarette butts is needed, especially airborne chemical emission from cigarette butts which may have different emission characteristics from the water leachate. Some recommendations are given for future work on airborne emission from cigarette butts.

RP026 Considerations of Environmental Effects of Tobacco Products

H.W. Chang, FDA / Center for Tobacco Products; G. Gagliano, US FDA / CTP Office of Science; M. Niazi, R. Edwards Jr, US FDA / Center for Tobacco Products; R. Alrefai-Kirkpatrick, US FDA; C. McCollum, US FDA / Center for Tobacco Products

On June 22, 2009, the President signed the Family Smoking Prevention and Tobacco Control Act (the Act) into law. The law grants the US Food and Drug Administration (FDA) new authority to regulate manufacture, marketing, and distribution of tobacco products to protect the public health and to reduce tobacco use by minors. On June 25, 2013, FDA announced the first decisions authorizing new tobacco products for introduction into interstate commerce for commercial distribution in the U.S. through the substantial equivalence pathway. FDA considered the environmental effects due to the actions, the authorizing of the products. FDA found no significant impact as a result of the actions. This poster presents the salient considerations in the environmental assessments prepared by FDA for these actions.

RP027 Data Gaps in the Environmental Risk Assessment Process for Tobacco Products

G. Gagliano, US FDA / CTP Office of Science; M. Niazi, US FDA / Center for Tobacco Products

Environmental risk assessment traditionally integrates exposure and effects data to predict potential adverse impacts. Although the high level considerations of environmental risk assessment are well-established, the environmental aspects of tobacco products reach beyond impacts to biodiversity (flora and fauna). The other environmental impacts, which include climate change, land use, water use, eutrophication and acidification, need to be considered as well. As with any emerging issue, all of the information necessary for a risk assessment is not readily available. The data gaps in the environmental risk assessment process for tobacco products are discussed here.

RP028 Sustainability Issues Regarding Smokeless Tobacco Product Manufacture using Findings from Semi-systematic Review on Sustainability of Consumer Goods

C. McCollum, FDA Center for Tobacco Products / Division of Nonclinical ScienceEnvironmental Science Branch; H.W. Chang, FDA / Center for Tobacco Products

Sustainability entails "maintaining or improving the integrity of the life supporting systems of the Earth"[1] under which humans and nature can co-exist in productive harmony, permitting social and economic provisions for present and future generations. Under Executive Order 13514, Federal agencies are required to develop, implement and annually update a plan that prioritizes actions based on a positive return on investment for the American taxpayer and to meet greenhouse gas (GHG) emissions, energy, water, and waste reduction targets[2]. CTP's mission is to reduce the death and disease from tobacco use. Smokeless tobacco products, such as snuff and chewing tobacco, adversely impact human health. The Agency does not anticipate the use of smokeless tobacco products to decline, based on an evaluation of the Alcohol and Tobacco Tax and Trade Bureau's historical reports. As a result, reduction in energy and water use, as well as GHG and waste generation, are not anticipated. CTP is responsible for protecting human health and safeguarding the human and natural environment. CTP does this by evaluating environmental sustainability related to tobacco product manufacture. Literature research into the sustainability issues related to smokeless tobacco products has identified insufficient information to fully understand sustainability in the products. Therefore, a rapid, systematized research review to explore environmental sustainability related to consumer goods can serve as a surrogate for the understanding of environmental sustainability issues related to smokeless tobacco products to encourage conservation of air, water, and land resources. This approach can also potentially serve as a model for the understanding of environmental sustainability in the context of manufacturing other tobacco products. Various indicators and metrics that help to identify potential problem areas will be explored. [1] Holden, J.P., Daily, G.C. and Ehrlich, P.R. 1995. The meaning of sustainability: biogeophysical aspects. In: Munasingha, M., Shearer, W. (Eds.), Defining and Measuring Sustainability, The World Bank, Washington, D.C. [2] Office of the Press Secretary, The White House. Executive Order 13514: Federal Leadership in Environmental, Energy and Economic Performance. Issued Oct. 5, 2009. RP029 Using GIS to Enrich Our Understanding of Tobacco Life Cycle

M. Niazi, US FDA / Center for Tobacco Products; R. Forche, Univ of Michigan

Geographic information system (GIS) is a widely used and valuable mapping tool that can depict geographic information in visually stimulating ways. We can use this tool to enhance our knowledge regarding tobacco life cycle – where it is grown, where it is manufactured, where it is consumed, and where it is disposed. We can continue to use this beneficial tool to further learn about the significant environmental impacts of all stages of the life cycle of tobacco, and in turn, we can answer key questions about tobacco and identify topics which may benefit from additional research.

Ecological Effect Models for Assessing the Risks of Pesticides: Ongoing Developments in the US and EU

RP030 Exposure specific species sensitivity – a toxicokinetic-toxicodynamic approach

E. Zimmer, IBACON GmbH; R. Ashauer, Univ of York / Environment; S. Augustine, Akvaplan-niva; A. Gergs, Research Inst gaiac; A. Nyman, European Chemical Agency ECHA; V. Poulsen, ANSES / French Agency for Food Environmental and Occupational Health and Safety; T. Preuss, Bayer CropScience / Environmental Modelling; P. van den Brink, Alterra and Wageningen Univ / Aquatic Ecology and Water Quality Management Group; K. Veltman, Univ of Michigan / Dept of Environmental Health Sciences

Currently in higher tier environmental risk assessment of chemicals, species sensitivity distributions (SSD) are used to describe and to quantify differences in sensitivity among species. When available for multiple species, no-observed-effect-concentrations (NOECs) or ECx, (representing x% of an affected population) usually derived from acute and chronic toxicity tests under constant exposure, are being used to calculate SSDs. In turn, these SSDs are used to extract 'safe' community effect thresholds in the form of an HC5, i.e. the concentration at which 5% of the species are affected. In current ERA practice, the ratio of effect measures and exposure, such as the maximum predicted exposure concentration (PECmax) or the time weighted average (TWA), are being employed to characterize risk ignoring that, depending on environmental conditions, the exposure concentrations are highly variable in space and time. Mechanistic models, such as the General Unified Treshold model of Survival (GUTS), take the process leading to an effect into account and can explicitly cope with time variable exposure. We present the outcome of a GUTS workshop held in March 2015 where species sensitivity distributions under time variable exposure have been studied. Our results point towards an unrecognized problem with the widely used SSDs and HC5 values: they could depend on the exposure pattern and differ a lot for exposures with the same time weighted average concentration but different temporal profiles. By using GUTS to analyze and compare species sensitivities, we can overcome the dependence of time and exposure patterns, and extrapolate toxicity to other exposure scenarios. Furthermore, we can develop a more thorough understanding of the underlying toxicity mechanisms by quantifying organism internal toxicity thresholds in conjunction with compensating processes.

RP031 Modelling survival: exposure pattern, species sensitivity and uncertainty

Veltman, Radboud Univ / Dept of Environmental Sciences; S. Vogel, Eawag Swiss Federal Inst of Aquatic Science and Technology

Stressor effects on survival over time are studied in a wide range of disciplines. A comprehensive survival data analysis entails specifying where the stressor is quantified, how to model compensatory processes and whether death is best viewed as a stochastic or a deterministic event. The General Unified Threshold model of Survival (GUTS) provides a framework for deriving consistent model equations for these different choices and assumptions. On this poster, we would like to present the results of a GUTS workshop held in March 2015. During the workshop and in the after math, we tested the ability of GUTS to predict survival of aquatic organisms across different chemical exposure patterns, time scales and species. We found that prediction uncertainty can be reduced by increasing the number of individuals in the calibration experiments. We here propose a method to optimize experimental designs using synthetic data. Our results further demonstrate that different temporal patterns of chemical exposure, even with the same time weighted average (TWA) concentrations, may result in different species sensitivity rankings as well as different estimates for safe concentrations. We conclude that the interplay of exposure pattern and species sensitivity deserves more attention and systematic investigation. The GUTS framework offers a straightforward and consistent platform for both scientific and regulatory questions on the dynamics of survival under stress conditions. This poster summarizes the results of the three working groups with different focus.

RP032 Intake and body burden: Complementary approaches in characterizing risk to wildlife associated with pesticide use

S.I. Rodney, Intrinsik Environmental Sciences / Biology

In assessing risk from pesticides to wildlife, exposure and effects metrics take a variety of forms. Exposure estimates may include dietary concentrations, total daily intake (TDI), body burden and application rates. Effects metrics are typically derived from standard tests, including acute oral gavage, and subacute and chronic dietary studies, in units of mg/kg bw, and mg/kg diet or mg/kg bw/d, respectively. For mortality risk, effects metrics are typically compared to: (1) body burden, or (2) TDI. The latter is far more common in regulatory risk assessment of pesticides, whereas the former has most recently been applied in the USEPA's pilot biological evaluations for threatened and endangered species. These two approaches can give strikingly different results for the same pesticide use and receptor. Differences are due in part to the inherent assumptions associated with the two methods. When body burden estimates are used to estimate mortality risk, it is implicitly assumed that effects will be equivalent to those estimated with oral gavage exposure for the same body burden. However, distribution over time within the organism will determine the amount of active ingredient at the site(s) of toxic action, and thus an equivalent body burden does not necessarily equate to equivalent toxic effects. Conversely, when TDI estimates are employed, mortality estimates are limited by the exposure duration of the test (for birds, typically five days). Depending on the pesticide, the receptor, available fate and toxicity data, and assessment tier, one approach may be more appropriate than another. Body burden estimates require knowledge of the rates at which the active ingredient is metabolized to non-toxic degradates and/or eliminated. When pesticides degrade rapidly in the environment and are quickly metabolized and/or eliminated, risk estimates based on peak exposure may be similar for the two approaches, or TDI may be more conservative. However, if the pesticide is somewhat persistent, the body burden approach may result in far more conservative risk estimates than the TDI approach. The TDI and body burden approaches can be used together to enable a comprehensive quantitative risk characterization that overcomes some of the uncertainties in both methods. Accordingly, a tandem approach may lead to more informed risk management. Case study examples will be provided.

RP033 Determining the probability of pesticide exposure for birds during migration

K.V. Garber, E.W. Odenkirchen, USEPA / Office of Pesticide Programs / Environmental Fate and Effects Division; M. Etterson, USEPA / ORD NHEERL Mid-Continent Ecology Division; A. Kanarek, EPA/OPP/EFED / Office of Pesticide Programs

Many species of birds that spend their summers in North America migrate to and from their wintering grounds in the southern United States and in central and South America. Migration occurs during late summer/early fall and during the spring. Most likely, species have evolved so that timing of migration coincides with availability of food sources. In the spring, emerging insects provide the calories and energy requirements necessary for birds to stop and fuel up between migration flights. If the migration period coincides with insecticide applications and birds stop in agricultural fields or adjacent areas (that receive spray drift), they may be exposed to pesticides through consumption of contaminated food items (e.g., insects), and/or contact with treated foliage or drinking water. The number or proportion of birds within a population that may be exposed to a pesticide is an important consideration for translating potential effects from individuals to understand population level consequences. In this approach, the probability associated with different magnitudes of exposed individual birds of a population is estimated. The following factors were considered: the migration range, percent of the range representing potential pesticide use sites, proportion of use sites that are treated, number of stops made during migration, and likely habitats used by the bird species when stopping during migration. An example is presented to demonstrate the likelihood of exposure of the migrating Kirtland's warbler (Setophaga kirtlandii) to the organophosphate insecticide, diazinon.

RP034 Population modelling and algae flow-through toxicity tests as higher-tier option in pesticide risk assessment – results for different compounds

D. Weber, Eurofins Regulatory AG / Bio V; G. Weyman, ADAMA Agricultural Solutions UK Ltd.; D. Schaefer, Bayer CropScience / Environmental Safety Environmental Fate; A. Wais, Eurofins Regulatory AG

Algae flow-through toxicity tests can be a useful higher-tier option to support the aquatic risk assessment of pesticides. A flow-through setup enables the evaluation of complex, time-variable exposure profiles. This allows for example the assessment of population-level effects after multiple pulsed pesticide exposure to algae. It is possible to observe the inhibition of algal growth directly as visible loss of population biomass on the one hand, and subsequent population recovery to an initial steady-state level on the other hand. A combination of the test system with an algae population model significantly enhances the interpretation of the experimental data. A priori, the test conditions and expected results of the flow-through test can be simulated. If the simulated outcome indicates that a flow-through test would be useful, the model can be used to design the test according to specific needs of a given risk assessment and to maximize the information that is gained from the experiment. The application of a generic exposure pattern in the flow-through test and simulation of the test results validates the model for further predictions of population-level effects of the specific test chemical and algae species. As a consequence the validated model can be used for extrapolations to any other exposure regime. This approach has been tested with different algistatic toxicants and two standard algae test species. Different types of pulsed exposure events, including a range of repeated peaks as well as more constant exposure periods were tested. The environmental conditions during a test, the physiological properties of the algae and toxicity data obtained from standard growth inhibition studies were the only necessary model inputs for simulation of flow-through tests. Experimental and modelling results for different compounds will be presented and an application of this approach within a regulatory context will be discussed.

RP035 Multi-phase distribution characteristics and risk assessments of pesticides in aquatic environments from an urban-industrial impacted coastal bay

Z. Wang, Key Laboratory of Urban Environment and Health; R. Li, Inst of Urban Environment, Chinese Academy of Sciences; C. Yan, Insitute of Urban Environment, Chinese Academy of Sciences

China is one of the largest producer and consumers of pesticides in the world today. Along with the widespread use of pesticides and the development of urbanization and industrialization, there is a growing concern for quality in aquatic ecosystems. To discover the distribution characteristics and complex risk in an urban-industrial impacted coastal bay, a multi-residue analysis method based on gas chromatography with electron capture detection (GC-ECD) was developed, and the residues of commonly used pesticides in China including organochlorine, organophosphorus, carbamates, pyrethroids, azoles, amides and anilines were analyzed in seawater, sediments and biota collected from various sites. Mean recoveries were satisfactory with 72-103%. A total number of 86 pesticides were detected and the occurrence and the risk to human and fish were then assessed. Most of pesticides with high frequency were medium or low toxicity except for DDTs. DDTs were the significant contaminant and the widely used dicofol was the new sources. The ratios between the parent DDT compound and its metabolites [(p,p'-DDE+p,p'-DDD)/p,p'-DDT] was determined as a useful indicator to provide information on the pollution source and indicate new inputs of the technical DDTs. The low ratio of (DDE+DDD)/DDT (< 1.0) is indicative for fresh DDTs application and a ratio much greater than 1.0 is indicative aged (microbial degraded) DDTs. In addition, the ratio of o,p'/-DDT/p,p'-DDT was also obtained to distinguish whether the DDT pollution caused by technical DDT or by dicofol. The spatial variation of pesticide distribution was linked with the fishing ships, where antifouling paint containing DDT was still utilized as an active component. Health risks from seawater and clams were assessed, respectively, where clam consumption was medium while pesticide in water posed great risk to fish. DDTs, dicofol, triazophos, fenvalerate, butachlor amd terbufos have become the significant pesticides in this investigation, indicating that these pesticides should be considered in aquatic ecosystem risk management and measures should be taken to decrease pesticide residues in order to improve the quality around urban-industrial regions. (The authors acknowledge financial support by the open fund from the State Key Laboratory of Environmental Criteria and Risk Assessment in Chinese Research Academy of Environmental Sciences (SKLECRA2013OFP13), and the Natural Science Foundation from Ningbo City (201301A6107013)).

RP036 Toxicity of various insecticides used for management of Asian citrus psyllid in Florida citrus against honeybees under laboratory conditions

X. Chen, Univ of Florida; L. Stelinski, Univ of Florida / Entomology and Nematology

The Asian citrus psyllid, Diaphorina citri Kuwayama is a major pest of citrus crops worldwide. A wide range of insecticide has been used to manage D. citri in Florida. However, in areas shared by citrus growers and beekeepers such as Florida, the use of insecticides can increase the risks of honeybee death and honey contamination. The objective of this investigation was to determine the toxicity and hazard of four different insecticide mode of action: neonicotinoid (imidacloprid), pyrethroid (fenpropathrin), organophosphate (dimethoate), and spinosyn (spinetoram) on honeybee workers (Apis mellifera L.). These insecticides are heavily used on Florida citrus. For this experiment, five to seven doses of each insecticide were tested, each one in triplicate. Each replicate was conducted on a group of 5 honeybees; all insecticide dilutions were made in acetone. For the control treatment, a similar procedure was performed, also in triplicate, but in which acetone alone. An adult mortality was assessed 48 h after exposure to treatments. Resulting LD_{50} values of test insecticides ranged from 0.85 to 0.13 mg/L. Hazard quotients ranged from 16.35 to 81.82. Also, chronic toxicity was investigated for imidacloprid, fenpropathrin, dimethoate and spinetoram at $LD_{0,}$ LD_{10}, LD_{25}, LD_{50}, LD_{75} and LD_{95} doses 24, 48, 72, 96, 120 and 144 hour after treatment. Results indicated that imidacloprid exhibited extreme chronic toxicity to adult A. mellifera. Fenpropathrin, dimethoate and spinetoram caused moderate and low mortality rates of A. mellifera with directly application at lethal and sublethal dosages of application for D. citri.

Epigenetics and Environmental Exposures: Mechanisms and Effects from Invertebrates to Fishes

RP037 Multi-stressor impacts on the development and maintenance of epigenetic regulation in larval and adult zebrafish (Danio rerio)

H. Ikert, Univ of Waterloo / Biology; P.M. Craig, Univ of Waterloo / Dept of Biology

As the human population increases, increased anthropogenic stress is placed on the environment. Venlafaxine is an antidepressant found downstream of wastewater treatment plants, at 1 µg/L. Also, increased water temperature and decreased oxygen content have been observed as a result of human activity. These effects are being studied in a multi-stressor approach to elucidate the combinatory effects of multiple chronic stressors. Specifically, the effects of venlafaxine, increased temperature and decreased oxygen on microRNA (miRNA) levels in larval and adult tissue were studied to determine sub-lethal, epigenetic effects on zebrafish. Adult zebrafish were chronically exposed to treatments for 21 days. Cardiac, liver, gonad, and muscle tissues were removed, RNA was extracted and RT-qPCR was performed on specific miRNA known to be related to genes involved in hypoxia, heat stress and response to contaminants to determine their relative abundances. Further, zebrafish embryos were exposed from 0 hpf to 96 hpf with an examination of the same miRNA and genes as in adults. Effects on juveniles and adults will be discussed. Understanding the epigenetic impact of multiple environmental stressors on different life stages and across generations will help us to understand the full impact on the aquatic ecosystem. Due to the conserved nature of miRNA, this will improve our understanding of the effects that environmental stressors have on epigenetic regulation.

RP038 Toxicity effects of PCB- 95 enantiomers on early neurodevelopment of zebra fish larvae

P. Ranasinghe, Clemson Univ / School of Public Health; S. Chapman, Clemson Univ / Biological Science; C.M. Lee, Clemson Univ / Dept of Environmental Engineering and Science

Early neurodevelopment is influenced by numerous genetic and epigenetic factors, with long-lasting effects on brain function and behavior, but the interface of these factors interactions are poorly understood. PCB-95 is a chiral molecule identified as one of the most potent neurotoxic PCB congener. Enantiomers of chiral PCBs have different neurotoxic effects as individual stereoisomers can interact differentially with other chiral molecules, such as enzymes and biological receptors. We are investigating the effects of PCB-95 enantiomers on neural development utilizing high-throughput analyses of behaviors in zebra fish larvae. Zebra fish (Danio rerio) larvae at 7 days post fertilization (7dpf) are exposed to racemic and individual enantiomers of PCB-95 concentrations (0.25, 0.5, 1, 5 ppm). Exposure time is 1 day with 3 day incubation period. Each treatment consists of four replicates with two controls (egg water and dimethyl sulfoxide). Morphological deformations such as pericardial and yolk sac edemas, curved body and stunted growth are assessed and those larvae are excluded from the behavioral assays. The performance of developing zebra fish in habituation assays is tested by exposing zebra fish larvae to a visual pattern presented beneath the well plate (a red 'bouncing' disk which runs in a straight line at the rate of 1.50 cm/s at the upper half of the well plate). Images are captured every 6 s for 150 minutes. Swimming behavior around the well is quantified based on either the animal's position or its turning behavior. PCB levels within exposed larvae are analyzed using GC/ECD. Data are analyzed using PROC GLM in SAS software. Preliminary data show morphological deformations with the embryonic racemic PCB-95 exposure. We expect to observe increased mortality rates and in survivors altered response to the visual startle stimulus such as mean percent avoidance, mean swim speed and mean percent still. Increased levels of morphological and behavioral deficits may be expected with increased exposure. Each PCB-95 enantiomer can have different potencies, and these may differ from that of the racemic mixture in neurodevelopment of zebra fish larvae. Outcomes from our study will reveal windows of susceptibility and underlying mechanisms of prenatal exposure of PCB- 95 with relevance to ecological consequences and human exposure.

RP039 Impacts on genome-wide DNA methylation pattern in early-life stages zebrafish (Danio rerio) after triclosan exposure

E. Falisse, Univ of Namur; A. Chatterjee, I. Morison, Univ of Otago; F. Silvestre, Université de Namur ASBL / Dept of Biology

DNA methylation is a dynamic epigenetic mark that contributes to gene regulation and genome maintenance. It appears mostly on cytosine residues within a CpG context. There are increasing evidences that toxicant exposure can alter methylation profiles, particularly during embryogenesis when DNA methylation patterns are established. In some extent these modifications can possibly last in adulthood and might be inherited through successive generations. In the present study, we analysed the effects of triclosan (TCS) at 50 and 100µg/L on DNA methylation during early zebrafish (Danio rerio) embryogenesis, during 7dpf. We used Reduced Representative Bisulfite Sequencing (RRBS) to profile genome-wide methylation pattern at single-nucleotide resolution. Using DMAP pipeline we have identified significantly differentially methylated fragments (DMFs) between conditions (cut-off q-value of < 0.01 after FDR adjustment and with percent methylation difference ≥15%). A total of 171 DMFs were identified, mostly between fish exposed to 50µg/L and 100µg/L (58% of DMFs). The main biological pathways involved were the metabolic, the cellular, the biological regulation and the developmental processes. Almost 50% of the DMFs resided within CpG island shore (defined as 2 Kb from either side of a CpG island core) while 48% of the DMFs were outside any CpG feature. These results highlighted the relevance of "non-CpG island" regions during genes regulation after stress exposure. Among all DMFs, we identified 51 fragments overlapping with intronic regions, 18 with exonic regions and only 4 fragments in a gene promoter region. 43 corresponding genes were selected for gene expression analysis using high throughput quantitative PCR (Fluidigm Biomark-HDTM system). These data will provide a deep understanding of the links between gene regulation and the modifications of the methylation landscape at specific CpG island and genomic features. Overall this study emphasizes the epigenetic effects of an exposure to TCS during early embryogenesis and the necessity to take into account the possible long term and transgenerational impacts of pollutant exposure during developmental stages. [1]Chatterjee A, Stockwell, PA, Horsfield, JA, Morison, IM, Nakagawa, S. Base-resolution DNA methylation landscape of zebrafish brain and liver. Genomics Data 2014 [2]Stockwell PA, Chatterjee A, Rodger EJ, Morison IM. DMAP: differential methylation analysis package for RRBS and WGBS data. Bioinformatics 2014

RP040 Does exposure to Bisphenol A or Ethinyl estradiol alter gonad structure and DNA methylation patterns in the aquatic turtle, Chrysemys picta?

D.K. Holliday, Westminster College / Biology and Environmental Science; R. Bhandari, Univ of North Carolina at Greensboro / Biology; L. Manshack, Univ of Missouri / Bond Life Sciences Center; C. Jandagian, Univ of Missouri / Veterinary College; F.S. vom Saal, Univ of Missouri Columbia / Biological Sciences; S. Deem, St. Louis Zoo / Inst for Conservation Medicine; D.E. Tillitt, USGS / Columbia Environmental Research Center

Environmental endocrine disrupting chemicals, such as Bisphenol A (BPA) and ethinyl estradiol (EE2), are widespread in aquatic habitats. Based on our previous work, we expected BPA and EE2 to disrupt sexual differentiation and override temperature dependent sex determination in painted turtles (Chrysemys picta). We incubated farm-raised turtle eggs at the male-producing temperature (26°C) and randomly assigned treatment groups: control, vehicle control, 0.02 µg EE2/egg and 0.05 or 5 µg BPA/egg. Doses were administered by spotting eggs during the temperature sensitive period. Subsequent hatchlings were reared for nine months, and tissues were harvested from euthanized hatchlings. One gonad from each turtle was sectioned and stained for histological evaluation of phenotype. Our previous results have indicated BPA exposure leads to demasculinized testes in hatchlings. The persistence of this condition within the gonad approaching the juvenile stage was evaluated. Finally, differences among treatments with respect to DNA methylation in the CpG promoter regions were evaluated. Collectively, epigenetic and anatomical changes in germ cells may have a significant impact on already struggling turtle populations.

RP041 Epigenetic Biomarkers in Herring Gulls From Contaminated And Reference Sites

E. Boulanger, McGill Univ / Natural Resource Sciences; D. Crump, Environment and Climate Change Canada; J. Head, McGill Univ / Natural Resource Sciences

Early life stages are extremely sensitive to exposure to environmental contaminants. This is also the period when epigenetic marks such as DNA methylation are established. Recent research suggests that disruptions to the epigenome early in life can cause persistent, lifelong consequences in individuals. The goal of this project was to evaluate global DNA methylation as a biomarker for embryonic exposure to environmental contaminants in herring gull (Larus argentatus), a colonial fish-eating bird that is a long-established bioindicator species in the Great Lakes. Research has shown that DNA methylation is affected by many classes of contaminants, (e.g. metals, organic contaminants, pesticides), in many animal models. We hypothesized that herring gulls living and feeding in highly contaminated sites would exhibit DNA hypomethylation compared with individuals from control sites. Fertile unincubated herring gull eggs were collectedfrom 3 different colonies Lake Ontario. Previous research indicates that eggs from these colonies exhibit a gradient of contaminant levels (Hamilton Harbour >Salmon Island >Cornwall). Eggs were artificially incubated until piping, and blood, brain and liver tissues were collected from the embryos. The remaining egg contents were preserved for chemical analysis. Global DNA methylation was assessed in each tissue type via LUminometric Methylation Analysis (LUMA). Levels of global DNA methylation were extremely stable across individuals (for example, average percent DNA methylation ranged from 65.67-70.46% in the blood samples), and there were no significant difference among the 3 herring gull colonies. Significant differences were detected in DNA methylation levels across tissue type (blood>brain>liver), and these were consistent among the herring gull colonies in Cornwall, Hamilton Harbour, and Salmon Island [$p < 0.0001$]. Future analyses will focus on the levels of contaminants in the eggs and methylation specific genes within the samples that were collected.

RP042 Network-inspired analysis of epigenetic responses to environmental stressors in bivalve molluscs

M. Suarez Ulloa, V. Aguiar Pulido, G. Narasimhan, Florida International Univ; J. Eirin-Lopez, Florida International Univ / Dept of Biological Sciences

Bivalve molluscs display a remarkable tolerance to the effects of marine pollution, particularly in the case of Harmful Algal Blooms (HABs) caused by proliferations of toxic dinoflagellates. In addition to the obvious impact for marine ecosystems and aquaculture industries, the accumulation of toxins on bivalve tissues during HABs is also responsible for acute intoxication syndromes in human consumers and genotoxic effects at sublethal concentrations observed in in vitro experiments. Consequently, there is great interest in developing innovative biomarkers for HABs monitoring. The present work builds on the transcriptomic response of the mussel Mytilus to a laboratory-controlled HAB exposure using low concentrations of the dinoflagellate Prorocentrum lima, which produces toxins that causes Diarrhetic Shellfish Poisoning. Our findings reveal sharp changes in gene expression patterns, which are consistent with the consensus responses of oysters to different environmental stressors. In order to identify gene expression patterns specifically linked to a single stressor and those that correspond to a general response to stress, publicly available data series were analyzed using co-expression networks, an approach selected based on its ability to integrate information. The identification of genes showing coordinated expression changes provides a potential source of highly specific biomarkers. More specifically, this approach has been applied to expression data of chromatin-associated genes (i.e., histone variants and histone modifying enzymes) providing relevant insights into the epigenetic response of bivalves to stress by abiotic factors. Future directions involve the validation of specific expression patterns in bivalves exposed to HABs in time-series studies. Overall, this work provides insights into the molecular mechanisms underlying the tolerance of bivalves to environmental stress, laying the foundations for the development of innovative tools for biomonitoring of HABs.

RP043 Crude oil-dispersant mixture induced spermatogenesis defects in Caenorhabditis elegans: implicating risk of tumorigenesis

X. Pan, B. Zhang, East Carolina Univ / Biology

The reproductive health impacts associated with crude oil-dispersant (Oil-dis) mixture exposure was investigated using the model organism Caenorhabditis elegans (C. elegans). Previously we reported that exposure to crude oil and dispersant resulted in reproductive defects such as decreased progeny numbers and increased germ cell apoptosis. In this study, we show that crude oil-dispersant mixture also affected reproduction by inducing abnormal sperm during the process of spermatogenesis. L4 larvae of wild type N2 hermaphrodites were exposed to different dilutionsofoil/dispersant mixture (20:1) for 24h, young adults were dissected and subjected to DAPI staining. Results showed that the abnormal immature sperm were significantly increased in the gonad arms of treated animals compared to controls. We further explored the oil-dispersant mixture toxicity effects on spermatogenesis by using a male C. elegans strain. After 48h exposure to oil- dispersant mixture, spermatids appeared with abnormal morphology including irregular shapes of the spermatid membrane and unexpected tails induced by dispersed oil. Significantly we utilized puf-8; lip-1 tumor sensitive strain to test the cell fate of immature sperm induced by Dis-Oil mixture treatment. Findings suggested increased tumor occurrence in exposure animals. Our study suggests that oil-dispersant mixture induce toxic effects on reproduction by not only affecting oogenesis but also affecting spermatogenesis and pose tumorigenesis risk. Global microRNA profiling and pathway analysis indicate the microRNA regulation of stress response and observed reproductive toxicity.

RP044 Effects of agro-pesticide cypermethrin on haematology of a freshwater catfish Mystus cavasius

M.H. Ali, Bangladesh Agricultural Univ / Fisheries Management; I.J. Tonny, Bangladesh Agricultural Univ / Environmental Science; K.A. Sumon, Bangladesh Agricultural Univ / Fisheries Management; M.A. Farukh, Bangladesh Agricultural Univ / Environmental Science; H. Rashid, Asian Univ for Women / Environmental Sciences

Cypermethrin is widely used as a pesticide in agriculture of Bangladesh. Since most of the agricultural lands of the country are in the floodplains, pesticides are readily leached into immediate aquatic habitat. Gangetic Mystus, Mystus cavasius, is a small freshwater catfish commonly available in the inland freshwater habitats close to agricultural lands. Therefore, a short term definitive exposure experiment was conducted to evaluate changes in hematological parameters of M. cavasius exposed to lower to higher concentrations of the synthetic pyrethroid pesticide cypermethrin. Adult female and male of M. cavasius were exposed to three triplicate concentrations of cypermethrin – 4 µg/L, 8µg/L and 16 µg/L and control (0 µg/L) for a period from Late June to Late August 2015; 40 fishes (20 female and 20 male) each per 200-L cement cistern were reared. Monthly sampling of blood glucose, haemoglobin (Hb), red blood cells (RBC) and white blood cells (WBC) were done. In both female and male, blood glucose levels increased significantly due to toxicity of cypermethrin. Blood glucose level (Mean ±SE) in control female were between 5±0.59 to 5.53±0.53 mmol L^{-1} and in treatment from 6±0.15 to 10.13±0.53 mmol L^{-1} and in male it ranged from 4.9±0.25 to 5.3±0.57 mmol L^{-1} in control and from 5.73±0.14 to 9.6±0.47 mmol L-1 in treatment. Blood Hb levels in both female and male dropped significantly due to exposure to cypermethrin. Hb (Mean ±SE) in control female ranged from 8.6±0.34 to 9.5±0.59 g dL^{-1} whereas it ranged from 4.6±0.31 to 7.86±0.29 g dL^{-1} in treatments. In male it ranged from 9.06±0.43 to 9.8±0.75 g dL^{-1} in control and 4.8±0.41 to 8.2±0.30 g dL^{-1} in treatments. RBC count also dropped significantly as an influence of cypermenthrine exposure. In female, monthly RBC levels (×106 mm-3; Mean ±SE) ranged from 0.59± 0.06 to 1.88± 0.95 in treatments compared to 2.03±0.36 to 3.27±0.03 in control. In male, the value ranged from 2.48±0.014 to 2.61±0.06 in control and between 0.38±0.03 to 1.88±0.36 in male. WBC counts elevated in most of the female and male fishes exposed to different concentrations of cypermethrin. These results indicate that hematological parameters may be useful as a diagnostic test for cypermethrin exposure in aquatic animals and calls for the limited and cautious use of cypermethrin.

Radionuclides in the Environment, Including Accumulation in Biota

RP045 Effect of Migratory Life History on North Pacific Albacore (Thunnus alalunga) Uptake of Radiocesium

D.R. Neville, Oregon State Univ / School of Nuclear Science and Engineering; A. Phillips, K.A. Higley, Oregon State Univ

The Fukushima Dai-ichi power station released radionuclides into the Pacific Ocean off eastern Japan in 2011. Previous radionuclide releases to the ocean were either of much lower magnitude, released over a much larger area or released in a continuous format. This pulsed-release provided an opportunity to examine how differences in migration routes and population structure of North Pacific albacore affected their uptake of radiocesium. Albacore samples collected (2011-2015) from two regions (North and South of 40° N) in the eastern Pacific were tested for ^{134}Cs and ^{137}Cs. Pre-disaster control samples (2008) were also tested. Measurements thus far have shown almost no ^{134}Cs in Southern region albacore and a mix of presence/absence of ^{134}Cs and elevated ^{137}Csin Northern region albacore. North albacore showed a positive correlation of ^{134}Cs and elevated ^{137}Cs with length, which indicated that the smaller individuals generally had not recently migrated from waters with ^{134}Cs such as eastern Japan or the North Pacific Transition Zone. The spatially variable concentrations of ^{134}Cs suggest latitudinal migratory differences and limited mixing of N/S albacore in the eastern Pacific. Albacore tissue contained radionuclide levels orders of magnitude less than both US FDA food standards and natural ^{40}K concentrations.

Recovery of Pelagic Fishery Populations Following Oil Exposures

RP046 Combined effects of oil exposure, temperature and UV-radiation on buoyancy and oxygen consumption of embryonic mahi-mahi, Coryphaena hippurus

C. Pasparakis, Rosenstiel School of Marine Sciences / Marine Biology and Fisheries; L.E. Sweet, Univ of North Texas / Dept of Biological Sciences; J. Stieglitz, Univ of Miami – RSMAS / Division of Marine Biology and Fisheries; D. Benetti, Univ of Miami RSMAS / Dept of Marine Ecosystems and Society; C.T. Casente, Univ of Miami / Biology; A.P. Roberts, Univ of North Texas / Dept of Biological Sciences Inst of Applied Science; M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology

The timing and location of the 2010 Deepwater Horizon (DWH) incident within the Gulf of Mexico resulted in crude oil exposure of many commercially and ecologically important fish species during the sensitive early life stages. Gulf of Mexico pelagic species, such as mahi-mahi (Coryphaena hippurus), typically produce small and rapidly developing buoyant embryos. These pelagic embryos and larvae that float in the upper layers of the water column are likely directly exposed to PAHs in surface oil slicks, along with multiple concurrent stressors, such as UV-radiation and high temperature. Mahi-mahi embryos typically become negatively buoyant a few hours before hatch, when raised in ambient, non-stressful conditions. Previous data from our lab has shown that negative buoyancy in mahi-mahi embryos correlates to a drastic increase in oxygen consumption. This study examined the effects of multiple simultaneous stressors on buoyancy change and oxygen consumption. When combined with oil-exposure, stressors such as temperature and UV-radiation induce negative buoyancy at earlier stages of development, correlating to significant increases in oxygen consumption for extended periods before hatch. Alterations to the timing of negative buoyancy onset and increased oxygen consumption likely have detrimental ecological implications for these developing embryos due to increased energy depletion and potential sinking to unfavorable hatching depths. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Data are publicly available through the Gulf of Mexico Research Initiative Information & Data Cooperative (GRIIDC) at https://data.gulfresearchinitiative.org.

RP047 Gene expression analysis of the impacts of crude oil toxicity on nitrogenous waste excretion in mahi-mahi (Coryphaena hippurus) early life stages

Y. Wang, RSMAS, Univ of Miami; E. Mager, Univ of North Texas / Dept of Biological Sciences; C. Pasparakis, J. Stieglitz, Univ of Miami / Rosenstiel School of Marine Sciences / Marine Biology and Fisheries; D. Benetti, Univ of Miami RSMAS; M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology

The timing and location of the 2010 Deepwater Horizon (DWH) incident within the Gulf of Mexico coincided with the spawning of many commercially and ecologically important fish species, such as mahi-mahi (Coryphaena hippurus). Recent studies by our lab have shown that oil exposure increases oxygen consumption of developing mahi-mahi larvae and that this increased metabolic demand is likely fueled by increased protein catabolism, as evidenced by increased nitrogenous waste excretion. Additionally, a recent RNA-seq study by our lab and others revealed a number of oil-responsive genes in early life stage mahi-mahi associated with nitrogenous waste excretion. Similar to other teleosts, mahi-mahi avoid the toxic build-up of ammonia by being ureotelic during the embryonic stage and gradually switch to being ammoniotelic around hatch. Thus, any disruption in the timing of these processes could indicate significant physiological impacts with implications for survival. In this study, we followed the mRNA expression changes for four genes involved in nitrogenous waste excretion over the initial 96 h of life: Rhag and Rhbg (ammonia transporters), SLC14a2 (urea transporter) and NHE3 a Na^+/H^+exchanger potentially involved in ammonia transport. Initial studies using control fish revealed the expected expression profiles for 3 of the 4 genes based on their putative roles. Rhag and Rhbg both showed progressive increases in expression over time, starting at the time of increased ammonia excretion and peaking during the larval stage at 96 h. SLC14a2 peaked before hatch at 30 hpf, at a time where urea excretion reached peak levels, and steadily decreased thereafter. However, NHE3 revealed no significant changes over time. Current efforts are focusing on examining oil-induced responses to these gene expression profiles and utilizing in situ hybridization to localize the tissue-specific expression of these genes. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Data are publicly available through the Gulf of Mexico Research Initiative Information & Data Cooperative (GRIIDC) at https://data.gulfresearchinitiative.org

RP048 Foraging behavior and olfactory capacity of Mahi Mahi (Coryphaena hippurus) exposed to crude oil from the Deep Water Horizon event

L. Schlenker, RSMAS, Univ of Miami / Marine Biology and Ecology; M.J. Welch, James Cook Univ; E. Mager, Univ of North Texas / Dept of Biological Sciences; J. Stieglitz, Univ of Miami – RSMAS / Division of Marine Biology and Fisheries; D.D. Benetti, Univ of Miami / Dept of Marine Ecosystems and Society; P.L. Munday, James Cook Univ; M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology

During the Deep Water Horizon event in 2010 approximately 4 million barrels of crude oil were spilled into the northern Gulf of Mexico overlapping with the spawning habitat of many ecologically and commercially important species of pelagic fishes, including Mahi Mahi (Coryphaena hippurus). Mahi Mahi are one of the top predators in the pelagic ecosystem and rely on olfaction and vision to find high quality prey patches in a pelagic food desert. In fishes, the olfactory epithelium is in direct contact with the aquatic environment making it particularly vulnerable to contaminants, such as crude oil, in the water. This study assesses the olfactory performance and behavioral response to prey cues in juvenile Mahi Mahi. Previous studies using a flume choice system have suggested that unexposed juvenile Mahi Mahi have the ability to detect and avoid crude oil, whereas, oil exposed (18 ug/L for 24-hours) conspecifics do not, and instead show attraction to crude oil at high concentration. Following these results, we measured the electrophysiological response of control and oil exposed juvenile Mahi Mahi to crude oil and prey cues using an electro-olfactogram (EOG) and measured the behavioral response to olfactory prey cues using video analysis with Loligo Systems Lolitrack software. We expect EOG data to show a reduction in olfactory performance with increasing concentration of crude oil. Altered physiological and behavioral patterns following oil exposure could result in inadequate foraging and reduced survival in this ecologically and commercially important species.

RP049 The effects of crude oil co-exposed with multiple stressors on the metabolomic profile of mahi mahi (Coryphaena hippurus) embryos

L.E. Sweet, Univ of North Texas / Biological Sciences; C. Pasparakis, Rosenstiel School of Marine Sciences / Marine Biology and Fisheries; T. Curran, Univ of North Texas / Biology; J. Stieglitz, Rosentiel School of Marine & Atmospheric Science / Deaprtment of Marine Biology and Ecology; D. Benetti, Rosentiel School of Marine & Atmospheric Science / Aquaculture; B. Venables, Univ of North Texas / Biology; M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology; A.P. Roberts, Univ of North Texas / Dept of Biological Sciences Inst of Applied Science

The timing of the Deepwater Horizon oil spill in 2010 overlapped with the spawning of several ecologically and economically important fish species, including the mahi mahi (Coryphaena hippurus). Several studies have shown that PAHs released into the marine environment from the DWH spill caused significant photo-enhanced toxicity to aquatic organisms. Mahi mahi eggs are transparent and positively buoyant until right before hatch (40 hpf). Their position within the water column during development makes them at risk for photo-enhanced toxicity with additional stressors such as temperature and salinity fluctuations. In this study, mahi mahi (6 hpf) were exposed to OFS crude oil for 24 h. During the 24 h oil exposure, mahi mahi were co-exposed to UV light. After the UV exposure, embryo respiration and the rate of buoyancy change was quantified. The embryos exposed to UV became negatively buoyant earlier in development than the non-UV exposed embryos, correlating with a significant increase in oxygen consumption in the UV exposed embryos. The effects on buoyancy change and oxygen consumption were further amplified when the same experiment was performed at increased temperature (30°C) or decreased salinity (30 ppt). A subset of embryos from each experiment was used for metabolomics analysis using GC/MS. The FIEHN metabolomics library was utilized to elucidate potential metabolic pathways involved with changes in buoyancy and oxygen consumption in mahi mahi exposed to multiple stressors. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Data are publicly available through the Gulf of Mexico Research Initiative Information & Data Cooperative (GRIIDC) at https://data.gulfresearchinitiative.org.

RP050 Effects of oil exposure on vision in a pelagic marine predator, mahi-mahi

J.T. Magnuson, Univ of North Texas / Biology; E.K. Barnes, Univ of North Texas; R. Garner, Univ of North Texas / Biology; L.E. Sweet, Univ of North Texas / Dept of Biological Sciences; B. Dubansky, Univ of North Texas; G. Xu, Univ of California Riverside; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences; J. Stieglitz, Univ of Miami – RSMAS / Division of Marine Biology and Fisheries; M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology; A.P. Roberts, Univ of North Texas / Dept of Biological Sciences Inst of Applied Science

During the Deepwater Horizon spill millions of barrels of oil were released into the Gulf of Mexico at peak spawning periods of commercially important fishes, including the mahi-mahi (Coryphaena hippurus). Developmental abnormalities have been shown to result from polycyclic aromatic hydrocarbons (PAHs) present in the oil, and could impact the vision of these fish. In this study, larval mahi-mahi, ranging from 1 day post hatch (dph) to 11dph, were assessed for visual function using the flicker fusion principle to monitor an optomotor response. Embryonic and juvenile mahi were exposed to high energy water accommodated fractions (HEWAFs) of weathered oil and optomotor response was determined. Visual acuity in juvenile mahi was significantly reduced following exposure to oil. Fish were taken from each dph stage and the expression of several genes associated with vision were measured using qPCR along with histological sections of the eye taken. The results of this study provide information on visual and behavioral impacts of oil on fish vision. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Data are publicly available through the Gulf of Mexico Research Initiative Information & Data Cooperative (GRIIDC) at https://data.gulfresearchinitiative.org.

RP051 Molecular and anatomical links between crude oil cardiotoxicity and osmoregulatory function in pelagic fish larvae

N. Scholz, NOAA Fisheries; E. Sorhus, Inst of Marine Research / Reproduction and developmental biology; R. Edvardsen, S. Meier, Inst of Marine Research; J. Incardona, NOAA Fisheries / Env Fisheries Division

Crude oil has been shown to affect a broad range of teleost species from a variety of habitats through impacts on cardiac function and morphogenesis. Polycyclic aromatic hydrocarbons (PAHs) from crude oil and other sources (e.g., urban runoff) are cardiotoxic to the developing fish heart, acting through multiple mechanisms, from disruption of ion channel function to activation of the aryl hydrocarbon receptor. In recent decades, the presence of edema in fish embryos and larvae has become a standard bioindicator of cardiotoxicity. However, the different ways that edema forms in fish from different habitats (i.e., freshwater vs. marine, pelagic vs. demersal) has not been rigorously examined. In particular, the accumulation of edema in marine fish embryos is paradoxical, given that they are hyposmotic to the surrounding environment. Our studies on several species of fish with pelagic yolk sac larvae provide novel insight into mechanisms of edema formation in marine fish. Pelagic marine larvae are characterized by large marginal finfolds encompassing a voluminous subdermal space. A relationship between this unique morphology was first related to osmoregulation and buoyancy control by Shelbourne over sixty years ago, but there has been little progress in the decades since, particularly at a molecular scale. Using evidence obtained from nine freshwater and marine fish species exposed to crude oils from different parts of the world, we show how patterns of cardiogenic edema are shaped by species-specific differences in developmental anatomy and ionoregulatory physiology. RNASeq studies in pelagic Atlantic haddock embryos and larvae provide insight into molecular pathways involved in edema formation, altered ion and fluid balance and lymphangiogensis. These data suggest there may be poorly understood adverse outcomes pathways related to osmotic gradients and water movement within embryos, the latter causing extreme shifts in tissue osmolality.

RP052 Developmental toxicity of 2- and 6-hydroxychrysene in zebrafish embryos

G. Diamante, Univ of California, Riverside / Environmental Toxicology; G. Muller, Federal Univ of Santa Catarina / Biochemistry; D.C. Volz, Univ of California, Riverside / Environmental Sciences; A. Bainy, Univ Federal de Santa Catarina / Bioquimica; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences

Oil spills are one of the primary sources of polycyclic aromatic hydrocarbons (PAHs) in marine environments and are subject to biotic and abiotic weathering, leading to alterations in physical and chemical characteristics of PAHs. PAHs can undergo photochemical oxidation, forming oxygenated photoproducts that have the potential cause adverse ecological effects. Among the PAHs found in crude oil, chrysene is one of the most persistent within the water column and is susceptible to photo-oxidation, resulting in production of oxygenated derivatives such as 2- and 6-hydroxychrysene. However, very little is known about the toxicity of hydroxylated PAHs. Previously, we showed that exposure to 2- and 6-hydroxychrysene can adversely affect the development of zebrafish embryos. Therefore, the goal of this study was to identify a sensitive window of embryonic development for 2- and 6-hydroxychrysene-induced toxicity. Embryos were statically exposed starting from 2, 5, 10 or 24 hours post-fertilization (hpf) to 0.5 and 5 μM of 2- or 6-hydroxychrysene for 74hrs. At 76 hpf, there was a significant decrease in survival after initiation of treatment with 5 μM 6-hydroxychrysene at 2 hpf, whereas no difference in percent survival (relative to vehicle controls) was observed following initiation of 2-hydroxychrysene treatment at any of the developmental stages tested. However, the prevalence of cardiac deformities was significantly higher after treatment with 2- and 6-hydroxychrysene compared to vehicle controls. These findings suggest that there is a critical time during early development when embryos show heightened sensitivity, leading to decreased survival after exposure to specific PAHs. Moreover, relative to vehicle controls, there was an increase in the intensity of yolk sac-localized fluorescence after treatment with either 2- or 6-hydroxychrysene. However, 2-hydroxychrysene resulted in the highest fluorescence intensity, suggesting differential uptake and/or metabolism between these two compounds. Overall, these studies highlight the regioselective impacts of hydroxylated PAHs on cardiac development and survival of fish embryos. Our findings raise the need to identify mechanisms involved in the toxicity of these compounds to assess the potential risks of oil spills on fish populations. This research was made possible in part by a grant from BP/The Gulf of Mexico Research Initiative to the RECOVER Consortium, and in part by CAPES/INCT-TA and CNPq.

RP053 Cross-generational toxicity of polycyclic aromatic hydrocarbons may prolong the ecological impact of oil spill events

J.S. Kozal, Duke Univ Nicholas School of the Environment / Integrated Toxicology and Environmental Health; N. Jayasundara, C.D. Lindberg, A. Massarsky, Duke Univ / Nicholas School of the Environment; A.N. Oliveri, Duke Univ / Dept of Pharmacology and Cancer Biology; J.N. Meyer, Duke Univ / Nicholas School of the Environment; E.D. Levin, Duke Univ / Dept of Psychiatry and Behavioral Sciences; R.T. Di Giulio, Duke Univ / Nicholas School of the Environment

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous aquatic contaminants that have become an important environmental health concern in part due to oil spill events. While the effects of adult and developmental exposures to PAHs are relatively well characterized, the potential for PAHs to have multigenerational effects remains to be explored. To this end, this study evaluated the cross-generational bioenergetic effects of the model PAH benzo(a)pyrene (BaP) following a chronic maternal exposure using the model teleost Danio rerio. Notably, maternally exposed (ME) F1 individuals exhibited mitochondrial dysfunction and oxidative stress during development at exposure levels that were asymptomatic in the exposed F0 females. The mitochondrial dysfunction persisted later in life in cardiac tissue with reduced mitochondrial reserve capacity, suggesting diminished capacity to respond to increased ATP demand. ME F1 individuals also exhibited significant cardiac hypertrophy, which may reflect

an attempt to compensate for reduced cardiac function. Notably, cardiac function and plasticity are thought to be key determinants of organismal fitness. Therefore, swimming performance and aerobic respiration are currently being evaluated in ME F1 adults. These data suggest that ME to BaP reduces an organism's mitochondrial function and metabolic plasticity that are critical for organismal ecological fitness. The ability to adjust metabolism will be crucial for organisms to effectively respond to a variety of natural and anthropogenic stressors with global change, creating potential for synergistic interactions with other abiotic stressors such as temperature and hypoxia. Further, ME F1 fish exhibited altered locomotor activity throughout life as well as reduced fear and anxiety behaviors as adults. Taken together, these data suggest that low-level exposure to PAHs such as BaP affect organismal physiology and behavior across generations, creating potential for downstream population and ecosystem level effects. These observations highlight the importance of considering multigenerational endpoints in risk assessments and environmental monitoring studies, including in the context of oil spill events. This work was supported by NIEHS T32-ES021432 and P42-ES010356.

RP054 Evidence for competitive inhibition in Cyprinodon variegatus in response to hypoxia and oil exposure as a function of age

D. Simning, The Univ of Southern Mississippi / Coastal Sciences; C.R. Perkins, Univ of Connecticut / Center for Environemtnal Sciences and Engineering; T. Bosker, Univ of Leiden; M.S. Sepulveda, Purdue Univ / Dept of Forestry and Natural Resources and School of Health Sciences; S. De Guise, Univ of Connecticut / Dept of Pathobiology and Veterinary Science; R.J. Griffitt, Univ of Southern Mississippi / Coastal Sciences

Hypoxia is a common environmental stressor of fishes in the northern Gulf of Mexico. Fish in these habitats were simultaneously exposed to hypoxia and polycyclic aromatic hydrocarbons (PAHs) during the 2010 Deepwater horizon oil spill. Previous research has shown that simultaneous exposures to hydrocarbons and hypoxia have resulted in competitive inhibition between the Hypoxia Inducible Factor and Aryl Hydrocarbon Receptor pathways due to competitive binding of the shared ligand protein Aryl Hydrocarbon Nuclear Transport Protein (ARNT). The objective of this research is to investigate the effect of cross-talk between these two pathways in response to different environmental conditions during early life development in the sheepshead minnow (Cyprinodon variegatus). Post-hatch (4 dpf) and post-larval (8 dpf) sheepshead minnows were exposed to different HEWAF concentrations under a combination of high/low salinity and hypoxic/normoxic conditions. After the initial 48h oil exposure the organisms were transferred to clean, normoxic water until 12 dpf. Cytochrome P450 1A1 (PAH detoxification) and erythropoietin (red blood cell production) gene expression analysis using qPCR was used to determine potential inhibition of defense pathways. The 48h tissue samples of the post-larval developmental stages indicated suppression of both defense pathways in the highest HEWAF concentrations (> 150 ng/mL), which was not observed in the post-hatch developmental stage or under normoxic or low salinity conditions. These results suggest the post-larval developmental stage of sheepshead minnow is the most sensitive stage to hypoxia and PAH exposure. Further investigation into transcriptional effects was performed using RNAseq, these results will also be discussed.

RP055 PAH biomarker levels in deepwater sharks impacted by the Deepwater Horizon Oil Spill from 2011-2016: Evidence of recovery?

J. Gelsleichter, Univ of North Florida / Biology; A. Leary, Univ of North Florida; D. Grubbs, Florida State Univ Marine and Coastal Lab; M. Heithaus, Florida International Univ

As the largest oil spill in history in U.S.-controlled waters, the Deepwater Horizon (DWH) Oil Spill resulted in extensive contamination of Gulf of Mexico waters. This posed significant health risks to numerous marine wildlife populations, particularly deepwater species residing in offshore waters within and/or adjacent to the primary contamination zone. Given the population-level impacts that have occurred in some wildlife species as a result of chronic exposure to oil constituents from prior oil spills (e.g., Exxon Valdez oil spill), it is critical to monitor the health of Gulf fish to assess the full impacts of the DWH Oil Spill on these animals. Therefore, to address this problem, we have examined biomarkers of exposure to polycyclic aromatic hydrocarbons (PAHs), the most toxic constituents of crude oil, in deepwater Gulf sharks for the past 5 years. Data on the activity of the PAH-metabolizing biotransformation enzymes, cytochrome P450 1a1 (Cyp1a1) and glutathione-S-transferase (GST), biliary concentrations of PAH metabolites, and levels of hepatic lipid peroxidation in 3 deepwater shark species (Squalus mitsukurii, Squalus cubensis, and Centrophorus granulosus) suggest that sharks residing in oil-exposed locations exhibited physiological responses to increased oil exposure up to 2-3 years after the spill occurred. However, more recent data provide evidence for reduced oil exposure as PAH biomarkers levels in sharks collected 4-5 years after the spill have been among the lowest observed in this study. We explore whether reductions in PAH biomarker levels in sharks from oiled sites represent a recovery trend.

RP056 Global transcriptional responses to Deepwater Horizon oil in red drum (Sciaenops ocellatus) embryos

G. Xu, UC Riverside / Dept of Environmental Sciences; A.J. Khursigara, Univ of Texas at Austin / Marine Science Inst; P. Perrichon, W. Burggren, Univ of North Texas; E.S. Hazards, G. Hardiman, Medical Univ of South Carolina; A. Esbaugh, Univ of Texas Marine Science Inst / Dept of Marine Science; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences

The Deepwater Horizon (DWH) incident resulted in extensive oiling of the pelagic zone and fouling of shoreline habitats of many commercially important fish species. Exposure to water accommodated fraction (WAF) of oil from the spill is known to result in developmental toxicity particularly cardiovascular defects in pelagic fish species, but little is known about the effects on local fast-developing estuarine fish species. Unraveling the potentially diverse molecular mechanism of oil toxicity is essential for understanding the hazard posed by complex DWH oil mixtures present in the environment. We analyzed the time-course (24, 48 and 72 hpf) transcriptional responses to two types of oil exposures as WAF from a weathered slick oil (2.5%; approximate 10.1 µg/L PAHs) and another from a non-weathered source oil (0.27%; approximate 0.7 µg/L PAHs) in red drum (Sciaenops ocellatus) embryos. Transcriptomic analysis was performed using high-throughput Illumina RNA sequencing (RNA-Seq) on an Illumina HiSeq2500. Short reads were mapped to reference transcriptomes using the Diamond Basic Local Alignment Search Tool (Diamond Blast) and subsequently counted using a custom perl script, and subsequent translation of the RNA ID's to gene ID's was performed using the NCBI database. RNAseq was analyzed using DEseq2, and significantly up-/down-regulated mRNAs were identified. Downstream gene ontology enrichment analysis was performed using the DAVID Bioinformatics Resource. Biological pathway, function, and network analysis was performed using Ingenuity Pathway Analysis software (Ingenuity Systems, Inc.). Hypothesized transcriptomic responses include Ca^{2+}-cycling and cardiac-, ocular-associated genes, AhR-mediated response, steroid biosynthesis, ribosome biogenesis and immune signaling. Comparisons of these pathways with phenotypic responses revealed cardiac function and morphology were impaired at 2.4 µg/L, and craniofacial malformation occurred at 2.2 µg/L by slick oil exposure. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Data are publicly available through the Gulf of Mexico Research Initiative Information & Data Cooperative (GRIIDC) at https://data.gulfresearchinitiative.org.

Complexity Kills the Minnow: Predicting the Ecological Consequences of Complex Pharmaceutical Mixtures

RP057 Global Probabilistic Hazard Assessment of Calcium Channel-Blockers in the Environment

G. Saari, Baylor Univ / Environmental Science; W.C. Scott, Baylor Univ / Dept of Environmental Science; B.W. Brooks, Baylor Univ / Dept of Environmental Science

The global population concentration is increasingly occurring in megacities where access to medicines is increasing more rapidly than waste management infrastructure is implemented. Calcium channel blockers are routinely observed in urbanizing watersheds receiving wastewater discharges of differential quality. We examined the literature to understand the global distribution of calcium channel blockers in influents, effluent discharges, surface waters, and biota. Diltiazem was the most frequently detected calcium channel blocker in urban systems throughout the world, especially the United States, while information was generally lacking from marine ecosystems and other geographic areas, particularly in developing countries. For example, though more than half of the studies reporting calcium channel blockers were from North America, very few observations were available from Latin America and none were identified from Africa. This information was employed to perform probabilistic ecological hazard assessments (PEHA). Based on data availability, we constructed an environmental exposure distribution (EED) of aqueous concentrations of diltaizem reported in literature, and compared this distribution to available ecotoxicity data, a predicted therapeutic hazard value (THV), and a 1 µg/L ecotoxicity threshold. Unfortunately, no studies were observed that examined mixture toxicity of multiple calcium channel blockers. THVs have been previously used to identify surface water and effluent concentrations predicted to result in fish plasma levels equaling the human therapeutic dose (C_{max}). These analyses revealed that diltiazem surface water concentrations in freshwater and marine ecosystems of developed countries fall below the THV (0.73 µg/L) and 1 µg/L. Within the reported wastewater treatment plant diltiazem observations, 11% and 8% of influent and 2% and 1% of effluent diltiazem concentrations are predicted to exceed the THV (0.73 µg/L) and 1 µg/L. However, diltiazem has been observed in fish plasma above human therapeutic doses. Thus, an additional PEHA revealed 17% of the reported fish plasma concentrations are predicted to exceed the human therapeutic dose (30 µg/L). These findings highlight the utility of global assessments of environmental contaminants to identify regions of additional environmental monitoring, assessment and management, particularly of complex pharmaceutical mixtures.

RP058 Effects of carbamazepine exposure on the whole transcriptome of the model plant Arabidopsis thaliana

E.L. Miller, Univ of Wisconsin – Madison / Molecular and Environmental Toxicology Center; S.L. Nason, Univ of Wisconsin – Madison / Environmental Chemistry and Technology Program; K. Karthikeyan, Univ of Wisconsin – Madison / Biological Systems Engineering; J.A. Pedersen, Univ of Wisconsin – Madison / Soil Science

Irrigation with treated wastewater and soil amendment with biosolids are increasingly common practices in agricultural systems, and result in exposure of crop plants to pharmaceuticals. Crop plants may accumulate these contaminants in edible tissues, but prediction of uptake relying solely on physico-chemical properties of the compounds can be confounded by metabolism in planta or the influence of one contaminant on the accumulation of another. In humans, some pharmaceuticals interfere with the efficacy of others. An example of this is the anti-seizure drug carbamazepine, which up-regulates several important drug-metabolizing enzymes. Carbamazepine is frequently detected in treated wastewater and is taken up by and accumulates in plants. Using whole transcriptome profiling, we assessed the effects of carbamazepine exposure on gene expression in the model plant Arabidopsis thaliana. We hypothesized that enzymes homologous to those up-regulated by carbamazepine in humans would also be up-regulated by carbamazepine in plants. We grew A. thaliana hydroponically and exposed roots to 1 µg/L or 100 µg/L carbamazepine for 24 hours. After exposure, we harvested leaf tissue and extracted RNA from exposed and unexposed control plants. We performed whole transcriptome profiling using the extracted RNA and Affymetrix gene expression microarrays, and compared mRNA expression levels between treatments for genes encoding drug-metabolizing enzymes and other proteins. We determined carbamazepine concentrations in leaf tissue by extracting additional plants from each treatment using accelerated solvent extraction followed by quantification using HPLC-MS/MS. Compared to the control, 8 genes were up-regulated and 42 genes were down-regulated in the 1 µg/L carbamazepine treatment, and 15 genes were up-regulated and 33 genes were down-regulated in the 100 µg/L treatment. The implication of these results on the accumulation of other pharmaceuticals will be discussed.

RP059 Altered Development: The effects of early venlafaxine (Effexor) exposure on zebrafish

W.A. Thompson, M.M. Vijayan, Univ of Calgary / Biology

The rise of antidepressant prescriptions worldwide has resulted in an increased release of these neuroactive compounds into aquatic ecosystems. Venlafaxine (Effexor) is one of the most highly prescribed antidepressants worldwide, resulting in levels of the drug in the µg/L range in our waterways. As antidepressants are often designed to function at low doses, there is growing concern over how these drugs will affect non-target species that often share evolutionary conserved pathways with humans. Venlafaxine acts as a serotonin and norepinephrine reuptake inhibitor in humans, suggesting that key systems such as the brain and heart may be impacted during development, adversely affecting the survival of developing organisms. This study assesses changes in the developmental profile of zebrafish (Danio rerio) exposed to venlafaxine immediately after fertilization. Zebrafish embryos were injected with venlafaxine at the 1-4 cell stage, and assessed for behaviour, neurogenesis, and cardiac performance. Embryo exposure to this drug caused precocious development, including increased hatch rate and larger larvae at 5 days post fertilization (DPF). Venlafaxine increased neurogenesis and affected behavior, including a dose-dependent reduction in the escape response of larval zebrafish at 5DPF. The drug also affected larval cardiac performance. Overall, embryo exposure to venlafaxine disrupts larval development and performances in zebrafish. This study was supported by the Natural Sciences and Engineering Research Council of Canada Discovery and Strategic Grants to MMV and an Eyes High Doctoral Scholarship to WAT.

Differing Biotransformation Capacity Across Species: Measurements, Modeling and Implications for Decision-Making

RP060 The Bioaccumulation Assessment Tool: An Organizational Framework for Bioaccumulation Assessment

J.A. Arnot, ARC Arnot Research & Consulting Inc.; K. Foster, Karen Foster Environmental Research / Dept of Chemistry; J.M. Armitage, Univ of Toronto – Scarborough / Physical and Environmental Sciences

Thousands of chemicals are under evaluation for potential hazard, exposure and risk to ecological receptors and humans. Screening methods include the application of Persistence, Bioaccumulation and Toxicity (PBT) criteria against available data. A variety of regulatory programs require Bioaccumulation assessment, e.g. Europe's REACH legislation, the Canadian Environmental Protection Act (CEPA), and Japan's Chemical Substances Control Law. The multitude of metrics for assessing bioaccumulation include: the octanol-water partition coefficient (K_{OW}); the bioconcentration factor (BCF) determined under controlled laboratory conditions (e.g., OECD 305); the biomagnification factor

(BMF) determined in the laboratory (e.g., OECD 305), or measured in the environment; the bioaccumulation factor (BAF) measured in the environment; the trophic magnification factor (TMF) measured in the environment; and the total elimination half-life (HL). Additionally, there are various quantitative criteria and quantitative and qualitative thresholds for the previously listed bioaccumulation metrics, e.g., REACH Annex XIII; however, there are no well-defined implementation strategies that include all of these lines of evidence. The objective of this research is to develop a user-friendly organizational framework and computational tool in the form of an Excel/VBA spreadsheet for integrating various lines of evidence in a consistent and transparent quantitative weight of evidence (QWOE) approach to guide bioaccumulation assessment decision-making. The Bioaccumulation Assessment Tool (BAT) brings together measured and modelled data, e.g., chemical properties, in vivo data (BCFs, BMFs, HL, absorption efficiency), in vitro data (intrinsic hepatic clearance rate) and in silico data (BCF-QSPRs, biotransformation rate constant QSPRs). These multiple lines of evidence are treated as "Input". Primary "Output" from the BAT includes a suite of bioaccumulation assessment endpoints presented against user-defined criteria/thresholds and data for benchmark chemicals, enabling the assignment of bioaccumulation classifications (e.g., "B" or "not B"). The BAT will enable transparent and consistent bioaccumulation assessment and guidance for integrated (tiered) testing strategies to address uncertainty. The development of the BAT will include multi-stakeholder participation and final versions of the BAT will be freely available.

RP061 Integration of Important Processes into a Novel Spatial Aquatic Food-Web Model for Accurate Assessment and Measurement of Chemical Bioaccumulation

J. Kim, Dow Corning Corporation / Health and Environmental Sciences; F. Gobas, Simon Fraser Univ / School of Resource and Environmental Management; J.A. Arnot, ARC Arnot Research & Consulting / Adjunct Professor Dept of Physical Environmental ScienceDept of Pharmacology and Toxicology; D.E. Powell, Dow Corning Corporation / Environmental Sciences; R.M. Seston, Dow Corning Corporation / Health and Environmental Sciences; K.B. Woodburn, Dow Corning Corporation / HES

A novel, complex food-web model has been developed to accurately assess and measure chemical bioaccumulation in real aquatic systems by incorporating important processes such as spatial heterogeneity, species migration, and field sampling design into the existing AQUAWEB model. The new Multibox-AQUAWEB (MBAW) model allows users to define properties of numerous sub-compartments by specifying vertical and/or horizontal concentration gradients in an aquatic system. The model also requires the users to define species composition, structure, and trophic dynamics of the aquatic food web. For species migration, the users can define the fraction of time that each species occupies a particular compartment. This input specifies the distribution of a species to a certain area and the degree to which a species may be present in multi-dimensional space. The model also provides the users with the option to specify the "sampling" location of each species by identifying the compartments from which the species will be collected. Using the inputs and mechanisms in the model, the MBAW model calculates the steady-state (whole body wet weight and lipid-equivalent) chemical concentrations in species in each compartment. Based on the predicted concentrations, trophic magnification factors (TMFs) as well other conventional bioaccumulation metrics such as BCF, BAF and BSAF are calculated. TMFs can be also calculated for various sampling scenarios to investigate the effect of sampling design on the determination of the TMF in areas with significant spatial concentration gradients. The MBAW model provides guidance on both the conduct and interpretation of field bioaccumulation studies and highlights the need for development of detailed protocols for field bioaccumulation studies in aquatic food-webs.

RP062 In vitro to in vivo extrapolation of hepatic metabolism in fish: an inter-laboratory comparison of in vitro methods

M.R. Embry, ILSI Health & Environmental Sciences Inst (HE; K.A. Fay, Univ of Minnesota – Duluth / Biology; M. Bernhard, The Procter & Gamble Company / Env Stewardship and Sustainability; I. Bischof, Fraunhofer IME – Inst for Molecular Biology and Applied Ecology; J.W. Davis, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; J. Domoradzki, Dow Corning Corporation / Health and Environmental Sciences; M. Halder, European Commission Joint Research Centre / DG Joint Research Centre IHCP EURL ECVAM; J. Hu, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; K.M. Johanning, KJ Scientific LLC / dba of Pura Vida Connections LLC; H. Weeks, Weeks Entox LLC / Environmental Safety

Chemical biotransformation represents the largest source of uncertainty in chemical bioaccumulation assessments. Model-based estimates of chemical bioconcentration in fish may be greatly improved by including biotransformation rates, as measured in vitro. Substrate depletion assays with trout hepatocytes or liver subcellular fractions (S9) have been successfully employed to this end. Building on previous work, a multi-laboratory ring trial was coordinated by the ILSI Health and Environmental Sciences Institute (HESI). The specific aims of the ring trial were to determine the reliability of these assays within and across laboratories, compare the performance of substrate depletion assays using the two biological systems, and support the development of two OECD test guidelines (OECD Project 3.13). Six laboratories conducted substrate depletion assays for 6 test chemicals (pyrene, 4-n-nonylphenol, fenthion, cyclohexyl salicylate, deltamethrin, methoxychlor) using both trout liver S9 fractions and trout hepatocytes to determine in vitro intrinsic clearance ($CL_{in\ vitro,int}$). Using either test system, participating laboratories measured similar rates of metabolism for each test chemical, and the rates for each chemical exhibited similar variability. The intra-laboratory agreement for each test chemical in $CL_{in\ vitro,int}$ averaged 15-23 %CV for the hepatocyte assays and 5-29 %CV for the S9 assays. The inter-laboratory agreement was somewhat less, ranging from 22-40 %CV for the hepatocyte assays and 10-29 %CV for the S9 assays. Variability in predicted hepatic clearance values, and by extension modeled BCF estimates, was lower than variability exhibited by the in vitro data sets due to blood flow limitations on clearance. For all test chemicals, hepatic clearance values determined by the two test systems were in good agreement (within 2-fold). Bioaccumulation predictions generated using the in vitro data had closer agreement with empirical BCF values than traditional modeled estimates, even for the more slowly metabolized compounds. Results of this ring trial firmly establish the reliability of these methods and provide strong support for use of this information in modeled BCF assessments for fish.

RP063 Metabolism of fragrance materials using trout in vitro metabolism assays

J.A. Weeks, Weeks Entox LLC / Environmental Safety; P.D. Guiney, Retired- S C Johnson & Son, Inc / Molecular and Environmental Toxicology Center; K.M. Johanning, KJ Scientific LLC / dba of Pura Vida Connections LLC

Bioconcentration data for many chemicals including fragrance materials still is scarce and much needed to determine bioaccumulation potential. There is an increasing global interest in the presence of fragrances in the environment due to fact that selected fragrance ingredients (e.g., synthetic musks) and their metabolites have been found at relatively low concentrations in a variety of aquatic environmental environments. There are several factors that pose significant challenges with the approach of assessing bioaccumulation using in silico models or extrapolation from measured log Kow (partition coefficient). Fragrance ingredients are comprised of many unique chemical classes (i.e., macrocyclic lactones and lactides, thiols, cyclic terpenes, hydroquinones, etc.) that are often not well represented in many of the common in silico databases upon which these environmental models (e.g. the USEPA's Estimation Program Interface Suite) are based and therefore, leading to over prediction of fragrance ingredient bioconcentration potential. Secondly, while it is well-established that BCFs can be reasonably predicted from log Kow values for neutral organics of intermediate lipophilicity (i.e., log Kow < 6), some fragrance ingredients may exceed this level and the determination of their experimental log Kow values (and subsequent BCF predictions) may be highly uncertain due to experimental errors. Finally, the determination of simple octanol-water partition coefficients do not take into account the potential for metabolism of the test chemical which has been shown to significantly decrease the amount of estimated passive bioaccumulation of highly lipophilic chemicals. The purpose of the present study was to determine metabolic stability in trout liver S9 fractions as well as in cryopreserved hepatocytes of various fragrances with Kow values >4. The results indicate that 19 out of the 21 fragrances tested were significantly metabolized by rainbow trout liver S9 fractions and hepatocytes. In vitro metabolism of chemicals such as those used in the present study support the conclusion that measured Kow values >4 are not always predictive of high BCF values. Liver S9 fractions and cryopreserved hepatocyte incubations are considered additional powerful tools to assess bioaccumulation potential of chemicals.

RP064 Concentration dependence on in vitro biotransformation rates: Hepatic biotransformation of organic sunscreen agents in rainbow trout

L.J. Saunders, Simon Fraser Univ; S. Fontanay, Polytech Clermont-Ferrand / Dept of Biological Engineering; F. Gobas, Simon Fraser Univ / School of Resource and Environmental Management

In vitro bioassays to estimate chemical biotransformation rate constants in fish are currently being investigated to improve bioaccumulation assessments of hydrophobic contaminants. The effect of concentration dependence on in vitro biotransformation rates (k_{dep}) has been recently illustrated. It's suggested that measuring k_{dep} initial substrate concentrations of 1 μM (a current convention) could underestimate the in vitro biotransformation potential and may cause bioconcentration factors (BCFs) to be overestimated if k_{dep} is used to assess BCFs in fish. Evaluating the concentration dependence on k_{dep} may also be important when no Michaelis Menten kinetic information exists for chemicals of interest. In this study multiple solvent delivery-based depletion experiments at a range of initial concentrations were conducted to investigate the concentration dependence on k_{dep} of organic ultraviolet filters (UVFs). UVFs are ingredients common in sunscreens and personal care products and may enter the aquatic environment directly from the skin during recreational activities in water or indirectly via wastewater effluents. Many UVFs are hydrophobic ($logK_{OW}$ > 4.0) and their bioaccumulation in higher trophic level organisms and in aquatic food webs in the field has been observed, suggesting that further investigations evaluating UVF bioaccumulation potential are warranted. The present study measured k_{dep} of selected UVFs: avobenzone, 4- methylbenzylidene camphor, ethylhexyl trimethoxycinnamate, and octocrylene ($logK_{OW}$s ranging from 4.5 to 6.9). The results illustrated that the relationship between k_{dep} and substrate concentration is well described by the Michaelis-Menten equation. Michaelis-Menten constants and maximum biotransformation rates are reported. Kinetic parameters were then incorporated into an in vitro-in vivo extrapolation (IVIVE) model to predict a BCF for UVFs. BCFs predicted by the model were then compared to: in vivo (empirical) BCFs; BCFs predicted from biotransformation rates estimated using a QSAR model; and BCFs predicted without biotransformation. We discuss the importance of considering the concentration dependence of biotransformation rates in the IVIVE of biotransformation data for bioaccumulation assessment.

RP065 Concentration dependence of in vivo biotransformation rates of organic sunscreen agents in rainbow trout following a dietary exposure

L.J. Saunders, Simon Fraser Univ; A.D. Hoffman, J.W. Nichols, USEPA / ORD NHEERL Mid-Continent Ecology Division; F. Gobas, Simon Fraser Univ / School of Resource and Environmental Management

Simple diffusion lipid-partitioning models have historically described the bioaccumulation of hydrophobic chemicals in fish. While these models are sufficient to describe the bioaccumulation of recalcitrant PCBs and other non-metabolized chemicals, they are inadequate for chemicals that are biotransformed. Consequently, efforts have been made to improve bioaccumulation models by incorporating estimated chemical biotransformation rates. While bioaccumulation models have become more sophisticated, they continue to assume that chemical uptake and elimination are independent of chemical (exposure) concentration, although this assumption has been scarcely investigated. The concentration dependence of in vitro hepatic biotransformation rates has been recently illustrated and is an important consideration for in vitro to in vivo extrapolation (IVIVE) of biotransformation data. Assays performed at substrate concentrations exceeding the Michaelis Menten affinity constant (Km) may underestimate a chemical's intrinsic clearance rate, potentially resulting in underestimates of in vivo hepatic clearance and overestimates of modeled bioaccumulation. These outcomes depend, however, on the relationship between tested in vitro concentrations and the in vivo concentration achieved the liver (C_{liv}). In this study, we investigated the relationship between dietary exposure concentration and observed accumulation and elimination of two organic ultraviolet filters (UVFs): ethylhexyl trimethoxycinnamate and octocrylene (log Kow of 5.8 and 6.9, respectively). Three dietary concentrations of UVFs covering 2 orders of magnitude were selected to result in a range of anticipated C_{liv} values. Rainbow trout were exposed over a 14d uptake period and 14d depuration period. Fish were collected during the 28d exposure and tissues (plasma, liver, gastrointestinal tract, carcass) were extracted and analyzed for chemical concentration. Fish were simultaneously exposed to non-biotransformed reference chemicals. The decline in chemical concentration over the depuration period was compared between the UVFs and reference chemicals to estimate k_{MET} for the UVFs. The influence of varying dietary concentrations on k_{MET} was then evaluated. Data generated from this test will be used to inform IVIVE approaches in bioaccumulation assessment.

RP066 Differences in detoxification pathways between sunfish and chub in relation to sensitivity to environmental pollutants

P. van den Hurk, Clemson Univ / Biological Sciences; D. Haney, Furman Univ

Observations in a previous study on biomarker responses in fish collected from urban creeks in Greenville, SC, indicated that there might be considerable differences in the expression of biotransformation enzymes in chub and sunfish species. To further investigate these species differences, a dosing experiment was performed in which bluehead and creek chub (Nocomis leptocephalus and Semotilus atromaculatus), and redbreast sunfish and bluegill (Lepomis auritus and L. macrochirus) were injected with benzo[a]pyrene (BaP) as a model compound for common pollutants in urban creeks. Fish were injected with BaP doses of 0, 25 and 50 mg/kg, and after 3 days BaP metabolites in bile, and enzymatic activities of cytochrome P450-1A (CYP1A), UDP-glucuronosyltransferase (UGT) and glutathione S-transferase (GST) were measured. CYP1A activity was significantly increased after BaP dosing in both species groups, but in chub were much lower than the levels that were observed in the dosed sunfish. The UGT activity in unexposed animals was comparable in both species groups, and was significantly increased in both groups as a result of BaP dosage. Finally, GST activity was not changed in either species group as a result of BaP exposure. However, the results confirmed that while unexposed chubs have much lower CYP1A activity than sunfish, they have a much higher GST activity than sunfish. The metabolized BaP was excreted in bile of both species groups, but at the time of sampling there were no clear differences in the amount of BaP metabolites in the bile of dosed animals, despite the differences in enzyme expression. The differences in baseline enzyme activity and induction capacity between both species groups may explain why chubs could be more sensitive to exposure to environmental pollutants than sunfish. This conclusion was corroborated by the observation of significant mortality in the chubs at the highest BaP dose of 50 mg/kg, which was obviously close to the apparent LC50 for chub, while no mortality was observed in the sunfish at this dose. These species differences in expression and regulation of biotransformation enzymes should be considered when implementing biological effect monitoring programs.

RP067 Correlation of Contaminant Levels in Whole Body and Fillet Tissue Samples: Application of a Simple Lipid-Based Model across Multiple Contaminants

E.A. Garvey, X. Wang, Louis Berger, Inc.; J.W. Kern, Kern Statistical Services, Inc.; J. Atmadja, Louis Berger, Inc.; N. Richardson, Battelle / Environmental Monitoring Assessment

A multi-year fish sampling program was conducted to support characterization of human health and ecological risks associated with contaminant exposure in the Lower Passaic River. Despite these efforts, not all fish tissue types needed for the risk assessments conducted for the lower 8.3-mile Focused Feasibility Study were obtained. Specifically, two additional tissue types were needed: whole body for white perch for ecological risk estimates and fillet for American eel for human risk estimates. Adjustment factors were developed to estimate these tissue concentrations for contaminants of concern using a larger set of co-located complimentary tissue types (fillet for white perch and whole body for American eel). The objective was to develop statistically supported factors to estimate whole body concentrations for white perch when only fillet samples were available, and to estimate fillet concentrations for American eel when only whole body samples were available. These factors were needed for a number of high K_{oc} compounds, whose concentrations in fish tissue are generally well correlated with tissue lipid content. To help reduce uncertainty in estimating concentrations for one tissue type from the other, the adjustment factors were developed based on lipid-normalized concentrations, which helped account for concentration differences between sample tissue types that are related to lipid content differences. The analysis considered 7 contaminants, including 2,3,7,8-TCDD, Total PCBs, DDT, dieldrin, chlordane, low and high molecular weight PAHs. For both adjustment factors, 95 percent uncertainty bounds based on bootstrap analysis of the uncertainty were + 22 percent of the value of the factor or less, indicating a strong predictable relationship between co-located samples of differing tissue types for the same species. For American eel, the adjustment factors of lipid-normalized concentrations (whole body to fillet) for these compounds yielded a mean value (1.1) with a range across the 7 compounds of 0.87 to 1.4. The adjustment factors of lipid-normalized concentrations (whole body to fillet) in white perch for these compounds yielded a mean value of 1.6, with a range of 1.2 to 2.0 across the compounds. The lipid-based adjustment factor approach using similarly exposed animals (co-located samples) for the 7 compounds provided a basis to develop estimates of the missing tissue concentrations for use in the risk assessments, with well characterized uncertainty.

RP068 Liver CYP1A expression induced by benzo(a)pyrene and its relation with biochemical and genotoxic biomarkers in a Neotropical fish

C. Santos, Univ Estadual de Londrina; S.H. Sofia, Univ Estadual de Londrina / Departamento de Biologia Geral; C.B. Martinez, Univ Estadual de Londrina / Ciencias Fisiologicas

The goal of this work was to study the expression of CYP1A gene in the Neotropical fish Prochilodus lineatus and its relation with phase I (EROD) and phase II (GST) biotransformation enzymes, the content of glutathione (GSH), and oxidative (LPO) and genotoxic damage after a single injection of benzo(a)pyrene (B(a)P). Juveniles of P. lineatus received one intraperitoneal injection of B(a)P (20 mg kg^{-1}) dissolved in canola oil (B(a)P group) or an equal volume (canola oil: 2 mL kg^{-1}) of the vehicle (OIL group). After injection, fish remained for 6, 24 and 96 h in clean water. At each experimental period blood samples were collected for the comet assay and fish were killed for the removal of the liver for RT-qPCR (using specie-specific primers), biochemical analyses (EROD, GST, GSH, LPO) and comet assay. B(a)P fish showed CYP1A gene expression in the liver significantly higher than OIL fish, at all experimental periods (6, 24 and 96 h). After 24 h, B(a)P fish showed the highest increase (18 x) in CYP1A gene expression. The hepatic activity of EROD increased significantly at the three experimental periods. Thus, enzyme activity (EROD) and the expression of the correspondent gene (CYP1A) increased after 6 h of B(a)P injection and remained elevated for 96 h. Despite the higher activity and expression of CYP1A, GST activity did not show any significant change suggesting the involvement of other biotransformation pathways. However, after 6 h of B(a)P injection, there was a significant decrease in GSH concentration , suggesting the consumption of GSH as antioxidant and the involvement of other antioxidant defenses, as no increase in oxidative damage (LPO) was observed at any period. Significant increases in DNA damage were observed in B(a)P fish, at 6 h period, both in the liver and red blood cells. As intermediate metabolites of B(a)P can be toxic and more reactive than the non-metabolized compound, these reactive intermediates would have caused this genotoxic effect in liver. DNA damage in blood cells supports this idea and suggests that B(a)P metabolites, produced in the liver, were transported through the bloodstream. The expression of CYP1A gene and its relation with the corresponding enzyme activity (EROD) are important tools to understand the response mechanisms of P. lineatus exposed to organic compounds. The results of GST, GSH and LPO indicate that other biotransformation pathways and antioxidant defenses are involved in B(a)P metabolism in P. lineatus.

RP069 In vitro and in silico assessment of cytochrome P450-dependent biotransformation capacity of PCBs in the Caniformia; the Baikal seal vs the beagle dog

H. Iwata, CMES, Ehime Univ / Center for Marine Environmental Studies; J. Yoo, Ehime Univ / Center for Marine Environmental Studies CMES; S. Tamura, Ehime Univ / Center for Marine Environmental Studies; M. Hirano, Ehime Univ / Center for Marine Environmental Studies CMES; K. Nomiyama, S. Tanabe, Ehime Univ / Center for Marine Environmental Studies; E. Kim, Kyung Hee Univ / Dept of Life and Nanopharmaceutical Science and Dept of Biology

Biotransformation of polychlorinated biphenyl (PCB) congeners is initiated by cytochrome P450s (CYPs) in a species- and CYP isozyme-specific manner. Our previous study revealed that the Baikal seal (Pusa sibirica) CYP1A1 has a low capacity for the biotransformation of PCBs, whereas CYP1A2 lacks the capacity due to the Pro substitution of highly conserved Thr in the I-helix. The beagle dog (Canis lupus familiaris) has been suggested to have a high CYP-dependent biotransformation capacity of PCBs. However, we still do not know which CYP isozymes are involved in the biotransformation of individual PCB congeners in the Caniformia including the seal and dog. We thus assessed the CYP-dependent biotransformation capacity of 62 PCB congeners by in vitro assays using the liver microsomes of the Baikal seal and the beagle dog and by in silico docking simulations of these PCBs with their CYP isozymes. In the liver microsome of wild Baikal seals, a decreased ratio of over 20% to loaded PCB congeners was observed for 10 of mono- to penta-chlorinated congeners, suggesting the preferential metabolism of low chlorinated PCBs by seal CYPs. As for the beagle dog, 35 PCB congeners with mono- to nona-chlorine substitutions were metabolized even in the liver microsome of non-PCB-treated dogs; constitutively expressed CYPs like CYP2A, 2C and 3A may be involved in PCB metabolism. In the liver microsome of dogs treated with 12 PCB congeners by which CYP1A1 and 1A2 levels were induced, only a few congeners like CB28 and CB123 were more metabolized than in non-PCB-treated dogs. This indicates that dog CYP1A1 and 1A2 participate in the biotransformation of only limited congeners. In the liver microsome of dogs treated with a mixtutre of phenobarbital and 12 PCB congeners by which CYP2B11 levels as well as CYP1A1 and 1A2 were induced, increased metabolism of 12 penta- to nona-chlorinated congeners was observed compared with the result of PCB-treated dogs, implying their metabolism by CYP2B11. We then constructed in silico homology models of seal CYP1A1, 1A2, 1B1, 2A, 2B, and 2C, and dog CYP1A1, 1A2, 1B1, 2A25, 2B11, 2C21, and 3A12, and simulated their docking with PCB congeners. The principal component analysis revealed a major contribution of CYP2A and 2B to PCB biotransformation in both seals and dogs. This study demonstrates that the combination of in vitro and in silico analyses is a useful tool to assess the biotransformation capacity of PCBs by each CYP isozyme.

Alternative Approaches to Complex Environmental Challenges

RP070 The Evaluation of Multiple Milkweed Species: Feasibility of Use in Standard Plant Toxicity Test Designs and Sensitivity to a Common Herbicide

N. Marchessault, Smithers Viscient / Plant Ecotoxicology; C.R. Picard, Smithers Viscient / Sediment and Plant Ecotoxicology; A. Kirkwood, Smithers Viscient / Ecotoxicology

On May 19, 2015 the Office of Science and Technology Policy released President Obama's interagency task force's Strategy to Promote the Health of Honey Bees and Other Pollinators. A part of that strategy is the U.S. Environmental Protection Agency's (EPA) commitment to the protection of the milkweed plants, the sole food source and significant habitat for the monarch butterfly (Danaus plexippus). Five commercially available milkweed species: Butterlfy Weed (Asclepias tuberosa), Common Milkweed (Asclepias syriaca), Swamp Milkweed (Asclepias incarnate), Whorled Milkweed (Asclepias verticillata) and Bloodflower (Asclepias curassavica) will be evaluated for their feasibility of use in the seedling emergence and vegetative vigor test formats outlined in the OCSPP 850.4100 and 850.4150 guidelines. The results pertaining to percent emergence, percent survival, shoot length, and shoot dry weight will be provided for each species. Previous work completed determined that Bloodflower (Asclepias curassavica) is suitable for testing as it meets the referenced guideline acceptability criteria. Based on the results of the feasibility trials, seedling emergence and vegetative vigor tests will be performed to evaluate the sensitivity of any suitable milkweed species to Glyphosate, the widely used broad spectrum herbicide. Endpoint sensitivity comparisons will be made across the milkweed species utilized and potentially compared to other standard crop species used in non-target plant testing.

RP071 Sensitivity of zebrafish larvae behaviour in the context of on-line contamination event detection in water distribution systems

L. Nuesser, RWTH Aachen Univ, Inst for Environmental Research / Dept of Ecosystem Analysis; E. Salomons, OptiWater; O. Skulovich, Technion Israel Inst of Technology / Civil and Environmental Engineering; N. Hartmann, DTU Technical Univ of Denmark / Dept of Chemistry and Biology; C. Ganal, C. Cofalla, H. Schuettrumpf, RWTH Aachen Univ / Inst of Hydraulic Engineering and Water Resources Management; A. Ostfeld, Technion Israel Inst of Technology / Civil and Environmental Engineering; H. Hollert, RWTH Aachen Univ / Dept of Ecosystem Analysis; T. Seiler, RWTH Aachen Univ / Ecosystem Analysis

An effective biological early warning system (BEWS) for the detection of water contamination should employ undemanding species that rapidly react to the presence of contaminants in their environment. BEWSs can provide more reliable predictions about substance toxicity than the chemical concentration alone, especially in case of mixtures of substances. This allows for the detection of potentially adverse biological effects in cases where traditional detection methods fail or are too costly. Here, we propose to use behavioural changes of zebrafish larvae for the detection of sudden contamination events in a water stream. In order to test for the sensitivity and rapidity of the response, zebrafish larvae at the age of 96 hours post fertilization (hpf) were exposed to cadmium chloride, permethrin, ethanol and sodium hypochlorite in low concentrations and immediately monitored for behavioural changes. For the analysis of zebrafish behaviour data we propose two approaches that have the potential to be used for the evaluation of on-line data streams. For the first approach data on the distance larvae moved was pooled within groups (control n=16; 4 treatment groups at different concentrations with n=20 each) and averaged for one minute per group. In this approach two upper thresholds for maximal activity of the larvae during darkness were defined (180 mm/min and 200 mm/min). For the second approach the x- and y-coordinates of the larvae's movement where transformed to polar coordinates in order to calculate the angle of their movement. Thresholds for the angle allow distinguishing between undirected movement of the larvae and directed circular swimming behaviour that was defined as avoidance behaviour. First results show that the approaches are promosing methods to detect alterations in zebrafish larvae behaviour in response to low concentrations of the investigated contaminants. The thresholds presented in this study are sensitive with a minimum in false positive alerts and have the potential to be used for the analysis of an on-line data stream. The second approach considers the directed behaviour of the larvae and therefore allows for the detection of a distinct parameter. Overall, the zebrafish larvae behaviour appears to be a sensitive and rapid endpoint that could be considered for the implementation in water monitoring.

RP072 Determining aggregation behavior and corresponding surface reactivity of copper oxide nanoparticles using a rapid colorimetric assay

L. Crandon, Oregon State Univ / CBEE; A. Engstrom, F. Wu, Oregon State Univ / Chemical Biological and Environmental Engineering; S.L. Harper, Oregon State Univ / EMT

The ability to predict interactions with abiotic or biotic surfaces in complex systems would enhance our understanding of the life cycle of nanoparticles (NPs) and assist in evaluation of risk. The aggregation behavior of NPs is a key process determining fate, transport, and bioavailability and is dictated by environmental interactions. In this study, we propose a method to evaluate NP homoaggregation and heteroaggregation, as measured by changes in surface reactivity. Methylene blue dye (MB) was used as a chemical probe to observe the reactivity of NPs used to catalyze the reduction of MB by sodium borohydride. The resulting color change was measured with ultraviolet-visible spectrophotometry. We hypothesized that the rate of reaction is directly related to the NP aggregation state. Copper oxide (CuO) NPs were selected as a model NP in this study due to their widespread industrial and commercial applications and their high reactivity. The relative reactivity of 1 mg/L CuO was evaluated after CuO NPs were allowed to either homoaggregate for 2 and 24 hours or heteroaggregate with green algae Chlorella vulgaris for 24 hours. The resulting change in surface area for homoaggregated CuO NPs was evaluated using nanoparticle tracking analysis (NTA). The reaction rate did not significantly decrease after 2 hours of homoaggregation. However, the rate significantly decreased by 80% after 24 hours homoaggregation compared to non-aggregated CuO NPs, and by 34% when CuO NPs were heteroaggregated with algae cells. The decrease in reaction rates corresponded to a decrease in overall surface area from nm^2/mL for non-aggregated particles to nm^2/mL and after 2 and 24 hours of homoaggregation, respectively. This method allows us to rapidly and efficiently assess both surface reactivity and aggregation and can be applied to environmentally relevant complex suspensions.

RP073 Pesticides and public health

L.N. Allison, Federal Univ of Technology Owerri / Biotechnology; A.C. Udebuani, Federal Univ of Technology / Dept of Biotechnology; A.N. Amadi, federal Univ of agriculture umudike Abia state / Dept of Animal Ecology I

Pesticides are designed to kill and because their mode of action is not specific to one species, they kill or harm organisms other than pests. The application of pesticides is often not precise, unintended exposure occur to other organisms in the areas where pesticides are applied. Children and indeed developing organisms are particularly vulnerable to the harmful effects of pesticides. Even very low levels of exposure during development may have adverse health effects. Pesticide exposure can cause a range of neurological health effects such as memory loss, loss of coordination, response to stimuli, reduced visual ability, uncontrollable mood and reduced motor skills. These symptoms are often very subtle and may not be recognized by the medical community as a clinical effect.Other possible health effects include asthma, allergies, hypersensitivity, cancer, hormone disruption, reproduction and fetal development. Pesticide formulations contain active and inert ingredients. Active ingredients are what kill the pests, inert ingredients help the active ingredients to work more effectively. These inert ingredients may not be tested as thoroughly as active ingredients, seldom disclosed on product labels. Solvents are inert ingredients in in many pesticide formulations may be toxic if inhaled or absorbed by the skin. Children are at greater risk from exposure to pesticides because of their small size: children eat, drink, breathe more than adults, they may be exposed to pesticides even while in the womb. In the light of the foregoing, it should be noted that pesticides are not the only way to keep pest away. There are many alternative repellents and pesticides as well as other natural methods such as biological control of pest. Pesticides present the only group of chemicals that are purposely applied to the environment with aim to suppress plants and animal pest and to protect agricultural and industrial products. However, the majority of pestsicides is not specifically targeting the pest only,they also affect non-target organisms. Overall, intensive pesticide application results in several negative effects in the environment that cannot be ignored.

RP074 ECETOC/RIFM WS: Developing a strategy to improve the environmental risk assessment of difficult to test multi-component substances Part 1: Background

D.T. Salvito, Research Inst for Fragrance Materials, Inc. / Dept of Environmental Science; M. Galay-Burgos, ECETOC

An international workshop was held on 2 – 4 November 2016 to address challenges in risk assessing complex mixtures of substances (e.g., multi-constituent substances (MCS), unknown variable composition and biological substances (UVCBs)). International regulatory schemes (specifically REACH, Environment Canada's DSL Categorization, and USEPA's PMN process) have highlighted the complexities of registering, characterizing fate and exposure, and risk assessing complex chemical mixtures whether from manufacturing environments or plant derived materials. Several industrial sectors (e.g., petrochemicals, personal care) have developed schemes for characterization and analysis of these complex substances. This Workshop was designed to identify best practices and key research needs to support environmental risk assessment. Reported here is the background leading up to this Workshop.

RP075 ECETOC/RIFM WS Developing a strategy to improve the ERA of difficult to test multi-component substances Part 2: Recommendations

D.T. Salvito, Research Inst for Fragrance Materials, Inc. / Dept of Environmental Science; M. Galay-Burgos, ECETOC

An international workshop was held on 2 – 4 November 2016 to address challenges in risk assessing complex mixtures of substances (e.g., multi-constituent substances (MCS), unknown variable composition and biological substances (UVCBs)). International regulatory schemes (specifically REACH, Environment Canada's DSL Categorization, and USEPA's PMN process) have highlighted the complexities of registering, characterizing fate and exposure, and risk assessing complex chemical mixtures whether from manufacturing environments or plant derived materials. Several industrial sectors (e.g., petrochemicals, personal care) have developed schemes for characterization and analysis of these complex substances. This Workshop was designed to identify best practices and key research needs to support environmental risk assessment. Reported here are the recommendations for best practices and areas for further research developed at the Workshop.

RP076 Screening Assessment for Unique Human Health Exposure Pathways

G.I. Greenberg, R. Mattuck, Gradient Corporation

USEPA and various states have developed health-based screening levels for various media (soil, water, air) which risk assessors commonly use to identify chemicals of interest (COI). Analytes with concentrations below corresponding health-based screening levels are not expected to pose significant risk and are subsequently not carried forward to the baseline risk assessment. In cases of uncommon exposure pathways, the absence of risk-based screening levels can result in the inclusion of all detected concentrations. The consumption of game meat potentially impacted by contaminated site media may pose a risk to human health. In the absence of game meat health-based screening levels, analytes detected in the various media may be considered a COI and carried forward in the baseline risk assessment. USEPA has acknowledged that screening based on risk contribution can greatly reduce the number of chemicals carried through a risk assessment. USEPA notes that "in many cases, only a few chemicals contribute significantly to the total risk for a particular medium." A modified screening evaluation was designed to reduce the number of COIs by eliminating chemicals that are not anticipated to contribute significantly to the baseline risks. The modified screening evaluation models the game meat exposure point concentration (EPC) and screens it against soil screening levels to determine relative risk contributions. Any compound with a relative risk contribution less than 1% of the total cancer or non-cancer ratio sum was eliminated as a COI. Of the 65 analytes detected in soil and/or surface water, 9 had maximum soil concentrations below background concentrations. Based on this modified screening approach using relative risk contributions, 47 analytes were eliminated. A total of 31 analytes contributed 0.4% of the total non-cancer hazard and 7 contributed 0.03% of the overall cancer risk. Of the remaining 18 analytes, 8 COIs contribute 0.1-80% of the non-cancer HI and 10 COIs 0.1-70% of the cancer risk. By applying a modified screening based on relative risk contribution, the list of COIs was reduced by over 70%, and the risk assessment avoided inclusion of analytes that are expected to pose insignificant risk.

RP077 Silicone wristbands detect occupation and lifestyle differences in chemical exposure in rural Peru

A.J. Bergmann, Oregon State Univ / Environmental Molecular Toxicology; L. Vasquez, Yantalo Peru Foundation; P. North, Medical College of Wisconsin / Pediatric Pathology; K.A. Anderson, Oregon State Univ / Environmental and Molecular Toxicology

It is a challenge to assess human exposure to complex mixtures of chemicals. Especially residents of developing regions can bear substantial chemical exposure due to poorly enforced regulations or education about safe practices. The Alto Mayo, in Peru, is a prototypical region with developing agriculture and potential health impacts on its residents are largely uncharacterized. The identification of the top chemicals in their environment and what groups may be most at risk is an important component of a comprehensive health assessment. Silicone wristbands are a novel passive sampling device for measuring lipophilic chemicals in the personal environment of people and are a promising technique for use in remote areas. In the current study, 69 volunteers from four communities of the Alto Mayo wore wristbands for 31-34 days. We screened the wristbands for 1418 compounds with gas chromatography and mass spectrometry coupled with deconvolution reporting software and we quantitatively measured 63 pesticides by gas chromatography-electron capture detection. We detected 106 unique compounds from eight chemical classes. Several chemical classes were associated with demographic variables, indicating an effect of occupation and lifestyle on chemical exposure. Some highlights include that personal care products were more frequent in wristbands worn by female participants than males ($p = 0.0004$) and different between communities ($p < 0.0001$). The frequency of PAHs and flame retardants were also different among demographics of the Alto Mayo. The presence of fungicides and insecticides were significantly associated with community and whether the participants were farm workers. Quantitative pesticide results showed that chlorpyrifos was one of the chemicals driving those differences. Chlorpyrifos was the most commonly detected pesticide and was measured from 17 to 9000 ng/g wristband. After accounting for other factors, chlorpyrifos concentrations were significantly different between communities and occupations. These results suggest a chemical signature associated with lifestyle, and could be used to identify groups of people that are most at risk for adverse health effects from specific chemicals. This is the first study to use wristbands to examine, across multiple chemical classes, differences in exposure between demographic groups, demonstrating a promising approach to investigating personal exposure to many chemicals, especially in developing regions.

RP078 Application of Bioavailability Corrections to Develop Site-Specific Toxicity Thresholds for Copper, Lead, and Zinc, at the Hanford Nuclear Site

B. de Jourdan, Oregon State Univ / Environmental and Molecular Toxicology; T. Baker, NOAA / Office of Response Restoration; S. James, US Fish and Wildlife Service

A group of eight State and Federal agencies and Tribes are participating in a Natural Resource Damage Assessment (NRDA) at the Hanford Nuclear Site in Eastern Washington. The Site has more than 40 contaminants of potential concern (COPCs) within a 1500 km^2 area, including portions of the Columbia River. For the purposes of injury determination, the Natural Resource Trustees rely upon thresholds, with exceedance of these values informing the development of a case for injury. We reviewed multiple available thresholds including promulgated regulatory standards, criteria, and literature values. The narrative intent of these thresholds varied depending on medium and jurisdiction, some of the reported values come from a single, sensitive organism or study (e.g., NOAEL, LOAEL, Benchmarks), or represent conservative screening values (e.g., Eco-SSLs), or were derived from species sensitivity distributions (e.g., Water Quality Criterion), and as such there was a wide range of values (e.g., 0.05 to 323,000 µg/L for lead in surface water). In addition to the wide range, these values may not adequately reflect injury to ecological receptors within the unique Hanford shrub-steppe ecosystem. In this poster we describe in detail the application of bioavailability corrections to develop site-specific injury thresholds for copper, lead, and zinc, in soil, surface water, and sediments, as part of the iterative process adopted by the Trustees to assess injury. We used multiple empirical approaches to inform our NRDA evaluation of these COPCs, notably a soil Predicted No-Effect Concentration (PNEC) calculator (ARCHE), the Biotic Ligand Model (WindWard), Consensus-Based Sediment Quality Guidelines, AVS/SEM, and Equilibrium Partitioning approaches. Many of these approaches have been successfully applied in environmental risk assessments, and are becoming more common in NRDAs. The benefits and challenges of these approaches will be discussed, and the results compared to promulgated thresholds, existing ecotoxicity literature, and Hanford specific ecotoxicity studies. Incorporating these multiple approaches has strengthened our ability to understand uncertainty, and aided in the decision making process.

RP079 Risk Assessment of Occupational Exposure to Polycyclic Aromatic Hydrocarbons (PAHs) and Metals in Firefighters

U. Akhtar, Univ of Ottawa / Biology; J. Keir, Univ of Ottawa; D. Matschke, Ottawa Fire Service; L. Chan, Univ of Ottawa / Biology; P. White, Health Canada; T.L. Kirkham, Univ of Toronto; J.M. Blais, Univ of Ottawa / Dept of Biology

Firefighters experience elevated risk of injury and developing chronic diseases such as cancer, respiratory diseases, etc. Limited studies have investigated occupational exposure assessments for firefighters; but most have been conducted during training exercises. The fires at the training environment are normally compartment fires and differ from real fire incidents in terms of compartment characteristics, fuel, ventilation profile, etc. The objective of this study is to determine firefighters' exposures to toxic compounds during real fire incidents. Twenty eight firefighters from four fire stations across Ottawa, Canada voluntarily participated and samples were collected from 29 fire incidents in this study (February-October, 2015). Ambient air was collected by the participants to determine the concentration of 16 PAHs (listed in the USEPA) and selected metals (cadmium, Cd; antimony, Sb; and lead, Pb) at real fire incidents. Wipe samples (skin, personal protective equipment (PPE), and personal clothing) were also collected from the firefighters pre and post-fire call to analyze for total PAHs and metal deposition. Concentrations during live fire events were: total PAHs: 5.2 to 28,600 µg/m^3, Cd: 0 to 6.8 µg/m^3, Sb: 0.02 to 170 µg/m^3, and Pb: 0 to 665 µg/m^3. Total PAHs and lead concentration exceeded occupational exposure limit for short duration in some incidents. Firefighters use a self-containing breathing apparatus (SCBA) during firefighting which is supposed to provide them a protection factor of 10,000. Thus, firefighters using SCBA should not be exposed to such high concentrations. However, failure to use SCBA, premature removal of SCBA, or poor-fit can lead to exposure to high concentrations of PAHs and metals. Deposition on skin, PPE, and personal clothing was significantly different between pre and post-fire for total PAHs, Sb, and Pb. Significant deposition on personal clothing suggested that chemicals can leak through the PPE resulting in whole body exposure to chemicals. Handling of equipment during fire and post-fire handling of PPE could also contribute to the deposition. These findings showed that firefighters are exposed to higher level of PAHs and metals during real fire incidents. These information will be used for assessing the hazardous risks associated with exposure to these chemicals during real fire incidents and developing procedures and policies that will effectively reduce exposures.

RP080 Determining the potential bioavailability of copper in apple snails to an avian predator using a simulated digestion method

A.D. Sowers, US Fish and Wildlife Service

As part of the Comprehensive Everglades Restoration Plan, former agricultural lands in South Florida are being acquired for conversion into stormwater treatment areas (STAs) designed to reduce nutrient flows into Everglades National Park. A large proportion of these lands are former citrus groves that were subject to copper-based fungicide applications for decades. As a former citrus grove is inundated with water during the conversion to an STA, colonization by the native Florida apple snail (Pomacea paludosa) and exotic apple snails is likely. Recent research has shown that Florida apple snails grown in systems with elevated sediment copper concentrations have the ability to accumulate large amounts of copper in their soft tissues. In order to accurately assess the risk that copper-laden apple snails pose to the federally endangered Everglade snail kite (Rostrhamus sociabilis), a species that forages exclusively on apple snails in South Florida, determining the fraction of copper in apple snail tissue that is potentially bioavailable to an avian predator is necessary. Florida apple snails grown in copper-impacted soils from citrus groves and field collected exotic apple snails from agricultural canals were processed using methods to simulate avian digestion. The fraction of soluble copper, which is assumed to be potentially bioavailable, and the fraction of insoluble copper in apple snail tissues were isolated and quantified. Preliminary results suggest that >70% of an apple snail's copper body burden is soluble in a digestive environment and potentially available to an avian predator.

RP081 Vulnerability and risks to floods and sewage spill in coastal cities

A. Visciglio, R. Bordon, V. Arias, J. Martinez Heres, M.E. Garcia, National Univ of Lanús / Environmental Laboratory / Urban Environmental Management / Dept of Productive Development and Technology; S.O. Demichelis, Urban Environmental Management Laboratory, DDPyT, UNLa / Productive Development and Technology

The socio-environmental vulnerability is defined as "the deterioration in a particular locality of the physical, economic and social conditions (particularly those related to the urban context) which can lead to the breakdown of the quality of life of its inhabitants." The threats they can arise from a combination of physical and social processes. Thus, human vulnerability integrates many environmental problems. Some are natural phenomena threats, including extreme events such as floods, droughts, fires, storms, tsunamis, landslides land, volcanic eruptions, etc. Coastal cities suffer the river floods cause are prone to flooding including overflowing of water bodies, often contaminated, representing a risk of exposure of inhabitants to contaminants. In this work the risks of exposure associated with flood events in coastal cities of the Río de la Plata river contamination is addressed. Quilmes, Berazategui, Ensenada-Berisso, Magdalena and Punta Indio coastal cities were selected. Urbanized areas with extremely vulnerable from NBI indicators (structural poverty) and exposure to the threat of flooding were identified in each city. Some of the variables surveyed were: level of settlements, population deficit or no access to drinking water, housing facilities, infrastructure in neighborhoods (eg presence or absence of paved roads, power lines.). Preliminary analysis of the sites seen with respect to the deficit or no access to drinking water the percentage of the population is, in the party of Quilmes 23%, in Berazategui 25%, in Magdalena 46% and in Ensenada 11%. As a result of information obtained risk maps were prepared identifying risk and vulnerable areas to flood events and pollutants in sewage overflows areas.

RP082 Increasing algal productivity using polycultures

S. Mandal, T.A. Mathews, Oak Ridge National Laboratory / Environmental Science Division; J.B. Shurin, Univ of California San Diego / Biological Science divsion

Algae holds much promise as a potential feedstock for biofuels, but large-scale algal production has not yet demonstrated the performance required for the economical production of biofuels. To date, the biofuel industry has focused on algal monocultures- single species of algae that have high growth rates and lipid accumulation potentials when cultured under controlled laboratory conditions. However, scaling up monocultural production has remained a significant challenge because monocultures are extremely susceptible to pests and disease. Further, nutrient and water supplies will become limiting as we scale up production unless new approaches are developed to mitigate these resource constraints. The use of wastewater resources that are rich in nitrogen and phosphorus to supplement a portion, or completely replace, traditional fertilizer and water requirements may help significantly reduce algal production costs and save the precious freshwater resources. We performed a laboratory experiment by growing 16 algal species communities (5- monoculture, 10- two species culture and 1 five species culture) in four separate nutrients media. Three of the media were made up separately with nitrate, ammonium and urea as a nitrogen source and another heterogeneous medium that simulates recycled (not fresh or potable) water was created by equal amount of nitrate, ammonium and urea, keeping nitrogen concentration constant. This study demonstrates increased productivity using multi-species algal assemblages, or polycultures grown in heterogeneous growth media. Nutrient uptake efficiency is highly correlated with biomass production. We suggest that cultivating and managing algal polycultures in wastewater may be a more sustainable and cost-effective solution for the biofuel industry than the current practice of monoculture production.

Soil and Water Contaminants: Evaluation, Biomonitoring and Abatement Bioindicators for Effective Management

RP083 Post-impact assessment of an oil spill site in Agaye, Lagos State, Nigeria, and role of metallothioneins in L. violaceous tolerance to oil spill

A. Ogunlaja, Redemeers Univ / Biological Sciences; O. Morenikeji, Univ of Ibadan Nigeria / Zoology

Agaye has experienced frequent spills of premium motor spirit due to pipeline vandalization. These contaminated the water sources and farmlands, and with the attendant inferno, destroyed the soil biota. This study determined the pH, Total Petroleum Hydrocarbon (TPH) and the heavy metals (Cd, Cu, Ni, Zn and Pb) levels of the soil and in the earthworm species. It also investigated the abundance of earthworms and presence of metallothioneins (MTs) in the most tolerant earthworm species. Soil samples were collected along transect of spill. Earthworms were handpicked from topsoil. Soil samples were analyzed using standard APHA methods. Heavy metal concentrations in tissue of the two most abundant earthworm species were determined using atomic absorption spectrophotometry. Presence of MTs gene code in the most abundant species was also carried out using standard molecular methods. Mean pH ranged from 5.3±0.04 to 6.5±0.02. Soil TPH, cadmium and copper reduced significantly during the last 11 months. Only soil TPH level was significantly higher than control soil. Lybiodrilus violaceous, Dichogaster modigliani Ephyriodrilus afroccidentalis and Heliodrilus lagosensis were encountered in both sites. The abundance of earthworm 500m away (204 earthworms/m^2) was significantly higher than within the epicenter (45 earthworms/m^2) in the first 12 months but not significantly different in the last 11 months. Significant levels of Pb, Cd, Cu, Zn and Mn in L. violaceous was recorded but Ni was not detected. Only zn and Cd were detected in D. modigliani. The increase in number and species of earthworm in the last 11 months indicated possible remediation of the environment. The high concentrations of heavy metals in the earthworms suggest possible roles in bioaccumulation. The presence of metallothiens genes could elucidate the mechanism of tolerance of L. violaceous.

RP084 Remediation of Ni Toxicity by Liming – Field Validation

A. Pellegrino, L. Vasiluk, Univ of Guelph / School of Environmental Sciences; E. Jones, Univ of Guelph; R.J. Thorn, A.E. Laird, B.A. Hale, Univ of Guelph / School of Environmental Sciences

Toxicity of metals is dependent on soil chemistry, especially pH. Liming of field soils contaminated with Ni in Port Colborne ON was studied as a remediation technique. Changes in pH not only affect bioavailability of metals but also soil nutrients and may cause adverse effects to plants. Treatments of 88t/ha of calcitic or dolomitic lime as well as positive control with no lime (mechanical equipment only) and a negative control with no treatment were applied to a field in Port Colborne early in 2015. The soil was sampled before and after lime application, and soybeans planted in July 2015. Soybean was harvested in October and yield was calculated. Soil pH, pseudo-total Ni, plant-available Ni (using $CaCl_2$) were measured on samples collected before and after liming. It was found that both types of lime increased soil pH, though calcitic lime resulted in a greater increase than dolomitic. A decrease in pseudo-total Ni was seen following liming, though this could be explained by the dilution effect of adding 88t/ha of lime to the top 5 cm of soil. Plant-available Ni was reduced by both types of lime; however calicitic had a greater effect than dolomitic. It was found that there is a very predictable relationship between soil pH and plant available Ni, which does not depend on the way the pH was increased. Soybean yield was significantly lower than that observed for Ontario due to late seed planting. The greatest yield was seen on the negative control; due to large error for that treatment the negative control yield was statistically greater than only the calcitic treatment and not the dolomitic. Higher yield was seen in the dolomitic treatment than calcitic, which may be due to calcitic pH being too high for optimal soybean production.

RP085 Altered calcium metabolism, blood lead levels and intelligence quotient scores in school children in Ibadan, Nigeria

N.L. Nwobi, Babcock Univ / Dept of Chemical Pathology; J.I. Anetor, Univ of Ibadan / Dept of Chemical Pathology; I. Nwazuoke, Univ of Ibadan; C.Z. Uche, Univ of Ibadan, Nigeria / Chemical PathologyToxicology Unit

Lead (Pb), a heavy ubiquitous metal, is one of the oldest and most studied environmental contaminant known. Exposure to this metal and its associated toxicity, remains a continuous problem especially in developing countries and children are mostly at risk. Childhood environmental lead (Pb) exposure has been linked to intelligence quotient (IQ). Lead neurotoxicity associated with cholinergic neurotransmission may be induced by altered calcium(Ca) homeostasis. The interplay between childhood environmental lead exposure and calcium metabolism as well as intelligent quotient has not been sufficiently explored in environment with prevailing nutritional deficits and related events. This study was therefore, conducted to address this gap in knowledge. Three hundred and nine healthy school children aged 6-12 years were recruited and divided into 2 groups; 169 with elevated blood lead level (EBLL) and 140 with BLL within acceptable limit as controls. Both groups were certified clinically free by a Paediatric Neurologist. Intelligence quotient was determined using Raven's Standard Progressive matrices. Red cell cholinesterase (ChE) activity and serum vitamin D level were determined using HPLC, blood lead was assessed with AAS while total Ca, phosphate and magnesium (Mg) were determined using standard spectrophotometric methods and ionized calcium levels were computed using standard formular. The ChE activity and vitamin D levels were significantly higher in children with EBLL compared with control ($P< 0.05$) while IQ, levels of total Ca and ionized Ca were significantly lower in children with EBLL compared with control ($P< 0.05$). The levels of phosphate and Mg were similar in both groups ($P>0.05$). Blood Pb demonstrated significant positive correlation with ChE activity and vitamin D. In contrast, non-significant negative associations were observed between blood Pb and IQ score, ionized Ca, total Ca, phosphate and Mg levels in children with EBLL. Environmental childhood Pb exposure was associated with alteration in Ca metabolism which manifested as a possible perturbation in Ca regulated events and may have implications for intelligence quotient. Dietary strategies based on calcium may be recommended for children at risk of Pb exposure to reverse neurochemical correlates. Our findings might have important implications for environmental policies, especially those designed to protect children's health and prevent factors that are operative early in life.

RP086 Elevation in estrogen level as a marker in chronic exposure of environmental PAHs

V.E. Okpashi, Univof Nigeria, Nsukka / Biochemistry; I.N. Onwurah, Univ of Nigeria / Biochemistry

This paper is a part of an on-going investigation of the long standing effect several crude oil spills in Eket, Akwa Ibom State, Nigeria, in which both a vast land area and Qua Ibo River were greatly polluted with petroleum hydrocarbons. The monitoring programme includes screening of PAHs in the environmental media, evaluation of bioaccumulation of PAHs in aquatic organisms exemplified with tilapia, and determination of in vitro endocrine disruptors in the women population of reproductive age. Based on a total of 88,635 women in Eket (Nigeria population census figures of 2006) and using a simplified sample size formula, a total of 186 reproductive age women were selected for blood sampling. The assay for endocrine disruptors involved determination of free E2 and SHBG concentrations in the selected women, after which the ratio of SHBG to E2 was determined. Blood serum samples were prepared from the blood collected and the assay carried out using AccudiagTM Estradiol and SHBG ELISA kits. The result shows that 47 individuals of the 186 women of reproductive age used for the analysis have elevated estrogen level beyond the recommended reference range of 15-60pg/ml, and this accounted for approximately 25% of 186 women. Also results showed variable concentrations of PAHs in water, sediment and in fish samples. Most apprehensive is the elevated concentrations of some PAHs beyond permissible limit in the fish and this calls for concern with respect to public health and safety. The sixteen priority PAHs listed by the United State Environmental Protection Agency as carcinogenic were detected. Comparing this results with our control reference community where there was relatively very low level of environmental PAHs, one can infer that the women community of Eket are more predisposed to breast cancer due to high level of PAHs in their environment, probably the result of incessant oil spill (pollution) incidents within their community. This investigation recommends that Eket women within reproductive age should receive anti-estrogen therapy intervention to reduce the risk of breast cancer. <br style="font-size: 12.0pt; font-family: 'Times New Roman','serif'; mso-fareast-font-family: Calibri; mso-ansi-language: EN-US; mso-fareast-language: EN-US; mso-bidi-language: AR-SA;" />

RP087 Pharmaceutical residues in surface water around Livestock Agricultural farms

O.S. Olatunji, O. Fatoki, Cape Peninsula Univ of Technology / Chemistry; B. Opeolu, Cape Peninsula Univ of Technology / Faculty of Applied Sciences; B.J. Ximba, Cape Peninsula Univ of Technology / Chemistry; R. Chitongo, Cape Peninsula Univ of Technology Cape Town South Africa / Chemistry

The health benefits, and the derivable economic advantages of the administration of pharmaceuticals and pharmaceutical products in livestock agricultural farms, have led to an increase in the dependence and use of these products. Substantial amount of pharmaceuticals pass into the environment either in the form in which they are administered, or as metabolites via animal excretion and wash/wastewater release from domestic, industry and farm sources into nearby surface water. In this study, a method which allows for the simultaneous determination of the residues of Tetracycline, 17β-estradiol, acetaminophen, and ivermectin in aqueous medium was developed using High Performance Liquid Chromatography coupled to a Diode Array Detector(HPLC-DAD). Water samples were collected from some water channels traversing the vicinity of some agricultural farms and wastewater streams in Cape Town environment. The samples were pre-concentrated by Solid Phase Extraction(SPE) using methanol pre-conditioned hydrophilic-lipophilic balance(HLB) cartridges. Residues of the pharmaceuticals were thereafter extracted into methanol. The extracts were thereafter analyzed for 17β-estradiol, tetracycline, acetaminophen and ivermectin using HPLC-DAD. Results showed that the concentrations of Tetracycline (< 0.08-26.74 µg/L), 17β-estradiol(< 0.36–5.92 µg/L), acetaminophen (< 2.80-9.67 µg/L), and ivermectin(< 0.1405-11.65 µg/L) generally varied and site dependent. There was no specific trend pattern to this. Seasonal weather variation, flow pattern, and physico-chemical quality of the water may account for the variations in observed concentrations. Analyte recovery achieved ranged between 76 and 88%, however the HLB solid phase extraction procedure may be manipulated to achieve better recovery. The selectivity and sensitivity of the method were also discussed.

RP088 Phenanthrene abatement from aqueous media using Vitis vinifera leaf litter

B. Opeolu, Cape Peninsula Univ of Technology / Faculty of Applied Sciences; A.A. Awe, CPUT / Chemistry; O. Fatoki, Cape Peninsula Univ of Technology / Chemistry; R.G. Snyman, Cape Peninsula Univ of Technology / Biodiversity and Conservation; V. Jackson, Cape Peninsula Univ of Technology / Consumer Science and Biotechnology

The deterioration in quality of freshwater bodies due to influx of toxic organic contaminants into the systems poses serious health risks to humans and aquaculture. These organic contaminants are capable of causing acute (diaphoresis and dermal irritation) and chronic (cancer and endocrine disruption) diseases. Anthropogenic activities have been reported to be major pathways of pollutants such as PAHs. PAHs have been reported to be ubiquitous and recalcitrant in the environment. This study therefore explored the potential of low cost adsorbents prepared from Vitis vinifera (grape) leaf litter for the remediation of phenanthrene from wastewaters. Adsorbents were prepared by activating raw biomass with H_3PO_4 and $ZnCl_2$ at various biomass/reagent ratios. Activated adsorbents were carbonized at 600 ^{o}C for 1 h under nitrogen stream. The percentage adsorbent yield was varied with activating reagents and values ranged between 41.63-58.40and 44.65-47.08 for H_3PO_4 and $ZnCl_2$ respectively. The moisture content, ash content, crude fibre content, carbon content and sulphur content of the precursor and activated adsorbent were evaluated and discussed. The adsorption of phenanthrene from aqueous media by raw and carbonized adsorbents was investigated as a function of adsorbent dosage, initial adsorbate concentration and contact time. Various adsorption isotherms and kinetic models were used to interprete the mechanisms of PAHs' removal by adsorbents.

RP089 Wastewater remediation: Batch adsorption of ciprofloxacin onto zeolites

D. Zide, Cape Peninsula Univ of Technology Cape Town South Africa / Chemistry; O. Fatoki, Cape Peninsula Univ of Technology / Chemistry; S. Nelana, Vaal Univ of Technology, South Africa; O. Oputu, Cape Peninsula Univ of Technology / Chemistry

Ciprofloxacin, a second generation of FQ's antibiotics is globally used for the treatment of several bacterial infections in humans and animals. It may reach the aquatic ecosystem from domestic discharge, or from the effluents of drug manufactures. Generally, 30 -90 % of the active ingredients are excreted un-metabolised after injection, due to incomplete metabolism in human and animals. The occurrence of ciprofloxacin in water even in low concentrations, can lead to the emergence of antibiotic resistant bacteria and other adverse consequences. Insufficient removal of antibiotics in conventional wastewater treatments imposes an examination of their removals by alternative methods. Low cost carbon-adsorption method has attracted researcher's interest because of its simplicity. Currently, the use of synthetic zeolites adsorbents are evaluated as appropriate adsorbents due to its low cost and high removal efficiency. In the present work, the adsorption of ciprofloxacin utilising coal fly ash based zeolites as driving force for the remediation of wastewater was investigated, with an intent to achieve the most effective, low cost and environmental friendly adsorbents. Studies on the surface morphology of the zeolites were carried out using SEM and TEM, while the identifications of mineral phases were carried out by using XRD. The physio-chemical properties such as the specific surface area, density, and particle size and lattice vibration were obtained with BET and FTIR respectively, with the adsorption monitored by HPLC-UV/Vis. The effective use of zeolites formulated from fly ash, in the decontamination of wastewaters contributes to the mitigation of coal fly ash (natural by-product) and reduce its environmental impact.

Ideas and Concepts for Dissemination and Communication of Research Findings in Times of Open Science and Science 2.0

RP090 Highlights: An interactive workshop designed to bring social and environmental scientists together to improve wildfire smoke health risk messages

C. Baghdikian, USEPA / National Health and Environmental Effects Research Laboratory; S. Stone, K. Rappazzo, K. Elstein, USEPA; K. Schulte, Student Services Contractor, USEPA; A. Rappold, B. Hubbell, USEPA

Scientists are asked to communicate their research for a variety of reasons, including general transparency of science, completing funding/grant applications, or making contributions to the greater body of research supporting public and environmental health. Conveying messages that are accessible, comprehendible and actionable requires an understanding of the audience. Particularly how the audience acquires and uses science-based information. Wildfires are increasing in intensity and frequency, meaning more smoke. Information about pollutants (e.g., PM2.5 and ozone) from wildfire smoke is important to enable protection of cardiovascular and pulmonary health of both healthy and sensitive populations. Low levels of smoke can be intangible and often invisible, resulting in perceived risk that is lower than actual risk. It is therefore critical to improve health risk messaging surrounding wildfire smoke, and provide tools that allow people to make decisions on how to reduce exposures and protect their health. In September 2016, the USEPA will host a workshop designed to investigate understanding, communicating, and managing health risks associated with wildfire smoke exposure. This unique workshop will bring together social and environmental scientists with community and institutional stakeholders to deconstruct this complex issue. Through collaborative engagement activities and interactive presentations workshop participants will develop a shared and multidimensional understanding of the nature of the public health problem associated with smoke exposures. This "understanding" should reflect scientific evidence and community attributes and experiences, as well as information and actions related to risk communication and management appropriate for further scientific evaluation. The expected workshop outcomes are: 1) an understanding of the network and players involved in wildfire smoke health risk communication; 2) an integrated "mind map" of the perspectives around the problem; 3) behavioral maps that illustrate step by step behaviors an individual would take to adopt health protective behavior, and the most influential step to deliver a message; 4) an understanding of what works with current messaging; and 5) integration of insights into a mobile app ("SmokeReady"), to be tested in 2017 using a crowd sourcing method, intended to improve access and delivery of health risk messages. This abstract does not necessarily reflect USEPA policy.

RP091 Oceanbites.org: Engaging Online Audiences with Stories of Oceanographic Research

C.A. McDonough, Univ of Rhode Island / Graduate School of Oceanography

In 1876, the HMS Challenger completed the world's first oceanic research expedition, bringing back news that the deep seas were teeming with life, and characterizing the ocean's complex currents and chemistry for the first time. Oceanography has captured the public imagination ever since, but finding out what's going on in current oceanography research can be very difficult for a non-expert. Journal articles are often extremely detailed and full of jargon that can be difficult even for other scientists to parse. Oceanbites.org is a blog written and run by graduate students that provides summaries of recent cutting-edge oceanography studies, written in a style that is engaging for anyone with a high school-level science background. The site was founded in September, 2013 with two goals in mind: to make new research more accessible to the non-expert public, and to provide graduate students with the opportunity to practice honing messages for broad audiences. Currently, more than 20 graduate students from universities around the world contribute regularly to the site, and it has grown to have dedicated followings on social media, with more than 10,000 Twitter followers, and more than 600 Facebook followers. Oceanbites publishes one article per weekday as well as occasional posts on science communication and popular media related to marine sciences. Other features to engage readers include biweekly Spanish translations and theme weeks focused on topics voted for by our readers. In this presentation, Oceanbites' journey so far will be described, as will our future aspirations to engage more undergraduates in producing content for the site by running blog-writing workshops, and our plans to involve our readers in ocean and environment-related citizen science projects.

RP092 Data exploration, Public Transparency and Enhanced Outreach through the use of Data Visualization Tools: PAHs in Ambient Air in Minnesota

K. Ellickson, Minnesota Pollution Control Agency / Environmental Analysis and Outcomes; M. Krause, Minnesota Dept of Health / Public Health Laboratory Organic Chemistry; C. McMahon, Minnesota Pollution Control Agency / Environmental Analysis and Outcomes Division; C. Herbrandson, Minnesota Dept of Health / Environmental Health retired; C. Schmitt, Minnesota Dept of Health / Public Health Laboratory Organic Chemistry; C. Lippert, Mille Lacs Band of Ojibwe Dept of Natural Resources and Environment / Air Quality; G. Pratt, Univ of Minnesota / School of Public Health Division of Environmental Health

This interagency project aimed to characterize air concentrations of vapor and particle-phase PAHs spatially and temporally in an inner city community and a rural site, to investigate sources, estimate Benzo[a]pyrene equivalent cancer potency, and compare measured and modeled concentrations. Three existing ambient air monitoring sites were chosen for active air samplers. Siting of 20 cylindrical passive air samplers (Wania et al 2003, Schrlau et al. 2011) was informed by modeled concentrations, community input, potential Environmental Justice areas, and proximity to known pollutant sources and sensitive receptors. Air sampling began in June 2013 and continued for 2 years. Active air samples were collected for 72 hours every 12 days. Passive samplers were deployed continuously for a sampling duration of 3 months. PAHs were extracted (size-fractionated XAD-4, Quartz Microfibre filters) using a Dionex ASE-350, separated using a Varian Select PAH, 30m x 0.25mm (0.15µm film thickness) analytical column, and analyzed by Agilent 5977 GC/MS. The PAH analyte list was selected to maximize the number of PAHs analyzed with cancer potency information, and the number of PAHs that inform source apportionment. As a governmental agency, it is important for our work to be transparent to our very interested and environmentally educated general public. We developed an interactive data tool in order to release our data in a format that allows interested users to interact directly with the data and potentially answer some of their own questions. The interactive data visualization tool utilizes Tableau Software © and is embedded in the project website. The tool allows users to chart data by sampler type (passive, gas phase, particle phase, total concentrations), and compare summarized results to inhalation health benchmarks. The results are also available in a mapped format, in which PAHs are selectable and concentrations that are summarized for the entire study and by season are displayed. These types of data visualization tools allow presenters to provide a planned tour of the data, and then open up the conversation to audience focused questions and interests. The data visualization tool will be presented in this format, with a planned talk through the project and data, and then opened up for audience based question and answers.

RP093 MOSAIC: A web interface with modelling and statistical tools for ecotoxicology

S. Charles, Univ Lyon 1 / Laboratory of Biometry and Evolutionnary Biology; P. VEBER, Univ of Lyon / Laboratory of Biometry and Evolutionnary Biology; M. Delignette-Muller, VetAgro Sup / Laboratory of Biometry and Evolutionnary Biology

MOSAIC stands for "MOdeling and StAtistical tools for ecotoxicology". In ecotoxicology, bioassays are standardly conducted in order to measure acute or chronic effects of potentially toxic substances on reproduction, growth and/or survival of living animals. MOSAIC has been designed as a user-friendly web-interface to disseminate the mathematical and statistical modelling of standard bioassay data. Its simple use makes MOSAIC a turnkey decision-making tool for the community of ecotoxicologists, both from academia and industry, and regulators. Without wasting time on extensive mathematical and statistical technicalities, the users are given the most advanced and innovative methods for a robust quantitative environmental risk assessment. MOSAIC is freely available at http://pbil.univ-lyon1.fr/software/mosaic/. Today, MOSAIC offers three operational tools : (i) MOSAIC_SSD, a tool dedicated to the species sensitivity distribution (SSD) approach aiming at defining safe levels for toxic compounds in an ecosystem through the calculation of the so-called hazardous concentration for p% of the species (HCp), even when the toxicity values are censored; (ii) MOSAIC_repro, which provides users with a complete statistical analysis of bioassay reproduction data simultaneously accounting for mortality all along the bioassay. Concentration-response models are fitted within a Bayesian framework to provide ECx estimates; (iii) MOSAIC_surv, which provides users with a complete statistical analysis of bioassay survival data. This presentation is an overview of the current MOSAIC features based on illustrative examples as provided within the web interface, as well as of the surrounding MOSAIC facilities, like the R code freely offered to the users to ensure transparency and reproducibility of analyses and a "pdf" button to easily export and save results. Future extensions of MOSAIC will be also presented in particular the possibility to comfortably fit TK-TD models.

Alternative Assessments Best Practices for Safer Chemistry

RP094 Update and Redesign of USEPA Office of Pollution Prevention and Toxics Predictive Tools EPISuite™ and ECOSAR

J.L. Tunkel, SRC, Inc. / Environmental Health Analysis; L. Cassidy, SRC Inc / Environmenal Health Analysis; K. Moran, USEPA / OCSPPOPPTRAD; W. Lee, EPA / OPPT; S. Savage, SRC, Inc.; K.E. Mayo-Bean, USEPA / OPPT

Under the Toxic Substances Control Act, the Office of Pollution Prevention and Toxics (OPPT) regulates both new and existing industrial chemicals. For new chemicals, OPPT makes a regulatory decision on each chemical, often with limited information on the specific chemical or chemical class. Given the large number of chemicals submitted each year and the fact that ~65 percent of them are submitted with limited data, OPPT relies on computational tools to predict over 150 attributes in order to make rapid decisions regarding hazards and risks of these materials. For over 25 years, the gold standard for the prediction of physical/chemical properties, environmental fate parameters, and ecotoxicity attributes for the assessment of new chemical substances has been the EPISuite™ and Ecological Structure Activity Relationship (ECOSAR) programs. A new Java-based, object-oriented, web version of EPISuite is under development. Improvements are focusing on an enhanced user experience as well as value-added data displays. Based on a web-services architecture, EPSuite™ estimates will also be accessible to remote servers. A new object-oriented version of ECOSAR is nearly completed and the latest update includes comments from an extensive beta test. The new features incorporated into these tools will be the focus of this presentation. In addition to the software improvements, updates to the QSAR models in these tools and models will be presented. For example, ECOSAR Version 2 contains new algorithms for surfactants, dyes, and polymers based on information and knowledge gained from the new chemicals program in OPPT. The QSARs are for acute and chronic toxicity endpoints for fish, aquatic invertebrates, and algae (surrogate species used in standard EPA new chemicals program aquatic toxicity profiles). Updates to EPISuite™ include new algorithms that enhance the predictive accuracy of highly fluorinated and silicon-containing compounds. The EPISuite™ update also include a new method for determining if estimates lie within the domain of applicability of any given model, which leverages the capabilities of OPPT's Analog Identification Methodology (AIM). The views expressed in this abstract are those of the authors and do not represent Agency policy or endorsement.

RP095 A QSAR to Predict Anaerobic Biodegradability of Hydrocarbon Mixtures

D. Lyon, Shell Oil Co. / Shell Health Risk Science Team; T. Austin, SHELL / Shell Health; B. Lee, Shell Global Solutions, Inc.

The biodegradability of chemicals speaks to their persistence, their risk, and subsequently their regulation. Most biodegradability testing and models focus on aerobic fate, but anaerobic conditions play a major role, particularly in wastewater treatment plants, contaminated sediments, and certain disposal practices. One relevant example is for the disposal of cuttings generated during drilling of oil & gas wells in the Gulf of Mexico. Part of the criteria for offshore disposal of the drill cuttings is that the drilling fluids used must pass an anaerobic biodegradability test, the Modified ISO 11734:1995 EPA Method 1647. In this method, the drilling fluid is mixed in a closed bottle with sediment from the Gulf of Mexico, and gas production indicative of methanogenic biodegradation is monitored over 275 days. Drilling fluids "pass" the anaerobic biodegradation test if they biodegrade at the same rate, or faster than a C1618 internal olefin standard. Producers of drilling fluids must test their drilling fluids on a yearly basis, which means that over the past 15 years, a large amount of anaerobic testing data has been generated. In 2014-2015, Shell Oil Company (USA) worked with a contractor to create an anaerobic biodegradation model based on 176 samples that underwent the ISO11734 test. This model addresses 2 unique variables: anaerobic biodegradation of hydrocarbons and working with defined mixtures. The model developed was able to account for the multi-component nature of the drilling fluids, and good results were obtained when predictions were made for mixtures that were within the applicability domain of the model, as defined by both the quantity and type of hydrocarbons present. The validation exercise (performed on data not used in model development) predicted 71% true positives, 92% true negatives, and had 79% concordance when pass–fail criteria were applied. While the model is not complete and suffers from limitations in the training data set, this data and approach can be adapted and developed for other types of hydrocarbons and other anaerobic conditions. The model can be used as a screening tool, to optimize anaerobic biodegradability of products, or to estimate performance of anaerobic biodegradation systems (e.g., anaerobic bioreactors, sediments, etc.). This presentation will discuss the data and design of this QSAR and the need for this type of model, especially from an industrial perspective.

RP096 Update and Reevaluation of the EPISuite™ MITI BIOWIN 5 and 6 Biodegradation Models

M. Kawa, SRC Inc. / Environmental Health Analysis; D. Lynch, EPA / OPPT RAD; W. Lee, EPA / OPPT; K. Nakayama, NITE; W. Meylan, SRC, Inc.; J.L. Tunkel, SRC, Inc. / Environmental Health Analysis

Under the Toxic Substances Control Act, the Office of Pollution Prevention and Toxics (OPPT) regulates both new and existing industrial chemicals. For new chemicals, OPPT makes a regulatory decision on each chemical, often with limited information on the specific chemical or chemical class. Given the large number of chemicals submitted each year and the fact that ~65 percent of them are submitted with limited data, OPPT relies on computational tools to predict over 150 attributes in order to make rapid decisions regarding hazards and risks of these materials. For over 25 years, the gold standard for the prediction of physical/chemical properties and environmental fate parameters has been the EPISuite™ program. The EPISuite™ models, BIOWIN 5 and 6, are predictive models for assessing a compound's potential for rapid biodegradation in the Ministry of International Trade and Industry (MITI-I) test originally derived on 884 chemicals, with 385 "readily degradable" chemicals and 499 "not readily biodegradable" chemicals. Re-evaluation of these models was performed using data from Japan's National Institute of Technology and Evaluation (NITE). The revised dataset contains 1,372 chemicals with well documented biodegradation data obtained according to MITI-I test guidelines. The current works adds over 700 chemicals to the training and validations sets. The BIOWIN 5 and 6 domain is for discrete organic chemicals. Mixtures, reaction products, polymers and chemicals that undergo rapid hydrolysis, or volatilization were not included in the re-evaluation; a process that was facilitated using the ChemACE clustering tool. Potential outliers and studies requiring a more detailed examination were also identified through cluster review. Evaluation of the results from different methods of analysis, including TOC, GC and HPLC, identified chemicals that may have degradation products with slower ultimate removal (low TOC and high GC or HPLC). Multiple linear and nonlinear regressions using new and existing BIOWIN fragments and descriptors were assessed so that the structural fragment library could be re-evaluated to improve BIOWIN 5 and 6 model performance.

RP097 The Quest for Safer Consumer Products through Alternatives Analysis

H. Muniz, California Dept of Toxic Substances Control / Safer Consumer Products

The Safer Consumer Products regulations, called for in California's Green Chemistry Initiative, created a practical, meaningful and legally defensible approach to identifying and moving toward safer consumer products. Using a science-based process during a product's design phase, the regulations require the identification of toxic ingredients and the analysis of alternatives to safer ingredients. Based on the results of the analysis a number of steps can be taken, including removal of the toxic ingredients, posting product information for consumers, further research and development and safety measures. Ms. Muniz, a principal drafter of the Safer Consumer Products Regulations, will provide an overview of the timelines and duty to comply; the chemical and priority product prioritization process; the petition process; the alternatives analysis process and the regulatory responses.

RP098 Advancing Alternatives Assessments: Ongoing Efforts of OECD's Ad Hoc Group on Substitution of Harmful Chemicals

E. Connor, Abt Associates / Environment Resources Division; K.M. Hart, USEPA

This presentation will highlight recent efforts of OECD's Ad Hoc Group on Substitution of Harmful Chemicals to advance the practice and understanding of alternatives assessments. The OECD's 49th Joint Meeting of the Chemicals Committee and the Working Party on Chemicals, Pesticides, and Biotechnology established the Ad Hoc Group with the goal of furthering tools and approaches to support decision making for substitution of chemicals of concern. This presentation will highlight two ongoing projects of the Ad Hoc Group -- updates and enhancements to the OECD Substitution and Alternatives Assessment Toolbox (SAAToolbox), and the capture and analysis of alternatives assessment case studies. The case study project aims to summarize real world cases of chemical substitution in a systematic way to facilitate the analysis of best practices, lessons learned, and benefits of chemical substitution. The resulting case study repository will be integrated into the SAAToolbox. For each project, the approach and results to date will be presented. As the demand for alternatives assessment approaches continues to grow (e.g., in response to the European Union's REACH regulation and California's Safer Consumer Products Regulations), the SAAToolbox and other project work of the Ad Hoc Group serve as important resources to assist practitioners in identifying and implementing appropriate methods and tools for conducting them.

RP099 IC2 Level 1 Alternative Assessment for Refrigerants in Domestic Refrigerators

D. Skall, T. Lewandowski, K. Reynolds Reid, J.M. Cohen, Gradient

Efforts to address global climate change have included phasing out the use of hydrofluorocarbons as refrigerants and propellants in many products. R-134a, the main refrigerant used in US household refrigerators, has a global warming potential (GWP) of 1,300, (i.e., 1,300 times that of carbon dioxide [CO_2]). Given that millions of refrigerators are purchased in the US each year, switching to a low-GWP refrigerant could substantially impact US greenhouse gas emissions. However, changing the main refrigerant in US refrigerators will likely require trade-offs, and Alternative Assessment (AA) can be used to evaluate the possible trade-offs of using various chemical substitutes for R-134a. To explore how an AA for residential refrigeration might work, we conducted a Level 1 AA according to the Interstate Chemicals Clearinghouse (IC2) Alternatives Assessment Guide. This first-phase analysis involves using readily available information in order to determine whether a more in-depth evaluation is worthwhile. We compared five possible alternatives to R-134a: propane, isobutane, ammonia, CO_2, and tetrafluoropropene (R-1234yf). We evaluated the hazards of these chemicals, which is a key part of an AA, using GreenScreen® for Safer Chemicals, an open source scoring system that is increasingly used in product stewardship programs. A simultaneous decision framework was used to evaluate the different IC2 modules (e.g., performance, hazard, exposure). CO_2 was screened out at the initial stage due to the lack of data concerning its use in domestic refrigeration. We found that when the standard GreenScreen benchmark, which does not include consideration of GWP, was used to evaluate chemical hazards, only propane was found to be preferable to R-134a. Including GWP as a variable in benchmarking resulted in all four alternatives being identified as preferable to R-134a. When GreenScreen hazard scores were evaluated in a more in-depth manner (i.e., comparing alternatives across individual health endpoints), propane, isobutane, and R-1234yf were all identified as preferable to R-134a; ammonia was rejected due to substantial human and ecological toxicity. Data gaps and questions that should be addressed in a more detailed Stage 2 AA will also be discussed.

RP100 Preparing for the new TSCA: how the TSCA Work Plan and EPA Safer Choice Standard can help

J. Nusz, E. Freeman, Exponent Inc; J.P. Staveley, Exponent

The TSCA Work Plan and the EPA's Safer Choice Standard both provide useful frameworks for evaluating the relative risk profiles of chemicals and products. Each of these frameworks evaluate chemical risks taking into account both the inherent hazard of the chemical and the potential for exposure resulting from a particular use. Companies can use these frameworks and criteria provided therein to effectively triage chemical/product inventories to identify chemical uses of highest and lowest relative risk. This type of assessment is useful for planning the allocation of financial resources and timing needed for management of inventory. For example, chemical uses that meet the Safer Choice Standard hazard criteria are likely to be of lower concern to EPA when prioritizing chemicals for review under TSCA. Further, they may be good candidates for submittal to EPA's Safer Choice Program. In contrast, chemical uses identified as having high relative risk through the TSCA Work Plan framework, or those with extensive data gaps, may require further investigation and allocation of resources. It is important to note, that while TSCA reform may result in changes such as EPA authorization for requesting generation of new data to fill data gaps, changes to the evaluation framework for prioritization of chemicals provided in the TSCA Work Plan Chemicals: Methods Document are not expected. We will compare and contrast the data required under both frameworks for the evaluation of ecological and human health hazards, potential for exposure, and risk.

RP101 Assessment of Soil Microbial Community Compositional and Functional Shift in Biodiesel vs. Petrodiesel Contaminated Soil

M. Dong, Texas Tech Univ / Biological Science; D.L. Carr, Texas Tech Univ / Biological Sciences

Soil microorganisms participate in many critical ecosystem processes, including nutrient mineralization, formation and enhancement of soil structure. Their activities and compositional changes due to contaminants could be indicators of soil health. Biodiesel is considered as a viable substitute for petroleum diesel primarily because it performs well, and it is assumed safe, readily biodegradable, and environmentally friendly. This study compared the effects of petrodiesel and three types of biodiesel on soil microbial community. Contaminated soil samples were tracked for 180 days to determine the degradation rate of the contaminants and their effects on the composition and function of soil microbial community. GC-FID was used to determine the degradation rate of contaminants while commercial Biolog EcoPlates™ were used to test the microbial community function based on carbon usage. Soil microbial composition were addressed by 16s rRNA gene sequencing. Results suggest that biodiesels are not statistically different from petroleum diesel in terms of their adverse impacts on soil microbial function. In addition, site restoration potential was evaluated by seed germination and plant growth in diesel and biodiesel contaminated soils for over 35 days. ANOVA results show all groups have similar plant germination rates. Petrodiesel treatments exhibit significant decrease in total plant length. One biodiesel, castor methyl ester, has a statistically similar yield of plant dry weight compared with plants grown in the untreated soil control. In conclusion, our results suggest that the chemical structure of biodiesels might determine whether they are environmentally benign, and that they should not be automatically considered as harmless substitutes for diesel.

RP102 Incorporation of Terrestrial Toxicity Hazard Endpoints into the GreenScreen® for Safer Chemicals Evaluations of Three Neonicotinic Pesticides

J. Rutkiewicz, ToxServices; M. Whittaker, ToxServices LLC; J. Sass, Natural Resources Defense Council

The GreenScreen® for Safer Chemicals is a comparative hazard assessment tool designed to evaluate chemicals across 18 human and environmental health hazards. The methodology is publically available and involves assigning hazard scores to each endpoint following a review of authoritative lists and toxicity data, as well as an overall Benchmark™ score, which is a high-level indicator of hazard based on the combination of hazard scores for the individual endpoints. GreenScreen has been used by industry and advocacy groups to evaluate and make decisions regarding chemical use in a variety of product types, is the hazard assessment platform for a number of standards and ecolabels, and is a preferred hazard assessment method for alternatives assessments under several state programs. While the standard GreenScreen ecotoxocity evaluation includes acute and chronic aquatic toxicity, GreenScreen guidance also states that when relevant, additional ecotoxicity endpoints such as avian or bee toxicity may be incorporated using the EPA's Design for the Environment (DfE) Program Alternatives Assessment Criteria for Hazard Evaluation. At the request of the Natural Resources Defense Council, ToxServices incorporated terrestrial toxicity data into GreenScreen assessments of three widely used neonicotinic pesticides, thiamethoxam, imidacloprid, and clothianidin, that are known to be highly hazardous to terrestrial invertebrates such as bees. All three pesticides were assigned Benchmark scores of 1 (Avoid-Chemical of High Concern) due to their very high persistence in combination with hazards for ecotoxicity (clothianidin and thiamethoxam) or ecotoxicity and neurotoxicity (imidacloprid). All three pesticides received the highest hazard scores for acute aquatic toxicity and acute foliar invertebrate (i.e. bee) toxicity, but only clothianidin and imidacloprid received the highest scores for chronic aquatic toxicity. Clothianidin and imidacloprid received moderate and high scores for acute terrestrial vertebrate (i.e. bird) toxicity. Therefore, evaluation of terrestrial toxicity endpoints illustrated differences in the overall ecotoxicity profile that are not apparent in an evaluation of only the standard GreenScreen endpoints. Given the application of GreenScreen for comparative hazard and alternatives assessments, incorporation of terrestrial toxicity produces a more robust hazard characterization for informed decision making.

Use of Modeling Tools to Determine Environmental Concentrations from Environmental Passive Samplers

RP103 Ambient Air Monitoring for an Expanded List of PAHs in an Urban and Rural Area Using Passive and Active Methodologies

K. Ellickson, Minnesota Pollution Control Agency / Environmental Analysis and Outcomes; M. Krause, Minnesota Dept of Health / Public Health Laboratory Organic Chemistry; C. McMahon, Minnesota Pollution Control Agency / Environmental Analysis and Outcomes Division; C. Herbrandson, Minnesota Dept of Health / Environmental Health retired; C. Schmitt, Minnesota Dept of Health / Public Health Laboratory Organic Chemistry; C. Lippert, Mille Lacs Band of Ojibwe Dept of Natural Resources and Environment / Air Quality; G. Pratt, Univ of Minnesota / School of Public Health Division of Environmental Health

This interagency project aimed to characterize air concentrations of vapor and particle-phase PAHs in an inner city and a rural setting, to investigate sources, estimate Benzo[a]pyrene equivalent cancer potency, and compare measured and modeled concentrations. Three existing ambient air monitoring sites were chosen for active air samplers. Siting of 20 cylindrical passive air samplers (Wania et al 2003, Schrlau et al. 2011) was determined by modeled concentrations, community input, potential Environmental Justice areas, and proximity to known pollutant sources and sensitive receptors. Air sampling began in June 2013, the beginning of meteorological summer. Active samples were collected for 72 hours every 12 days, and passive samplers were deployed continuously for a sampling duration of 3 months, over a total sampling period of 2 years. PAHs were extracted (size-fractionated XAD-4, Quartz Microfibre filters) using a Dionex ASE-350, separated using a Varian Select PAH, 30m x 0.25mm (0.15µm film thickness) analytical column, and analyzed by Agilent 5977 GC/MS. The PAH analyte list was selected to maximize inhalation risk assessment and source apportionment information. The passive sampler mass loading was calculated based on the seasonally averaged total (gas plus particle) active sampler results. Annual and whole study upper 95th

confidence limits of the arithmetic mean of air concentrations were calculated without detection limit substitution and compared to Benzo[a]pyrene potency equivalence to assess potential inhalation human health risks. Benzo[c]fluorene was the most potent c-PAH, but requires analysis of a mass interferent Dibenzothiophene sulfone. Several localized events were observed in the PAH concentration data, helping to identify PAH profiles from these sources. Gas-particle partitioning was a function of temperature, sub-cooled vapor pressure, and octanol-air partitioning coefficient, in keeping with previous studies. Retene, a wood smoke marker, is somewhat anomalous because it's vapor pressure is high compared to other PAHs of similar molecular weight. The individual PAHs, and cumulative potency do not exceed human health risk guidelines. Source apportionment work underway will provide source contribution estimates that can be used to inform agency priorities.

RP104 Benzo[c]fluorene Potency in Ambient Air and Dibenzothiophene Sulfone as a Mass Interferent and Potential Gas Phase Diesel Marker

K. Ellickson, Minnesota Pollution Control Agency / Environmental Analysis and Outcomes; M. Krause, Minnesota Dept of Health / Public Health Laboratory Organic Chemistry; C. McMahon, Minnesota Pollution Control Agency / Environmental Analysis and Outcomes Division; C. Herbrandson, Minnesota Dept of Health / Environmental Health retired; C. Schmitt, Minnesota Dept of Health / Public Health Laboratory Organic Chemistry; C. Lippert, Mille Lacs Band of Ojibwe Dept of Natural Resources and Environment / Air Quality; G. Pratt, Univ of Minnesota / School of Public Health Division of Environmental Health

Cancer potency may not be fully assessed for airborne c-PAHs if air monitoring is limited to the EPA 16 priority PAHs. An expanded list of PAHs was measured in ambient air using active and passive sampling in an urban and rural setting. Air sampling began in June 2013, the beginning of meteorological summer. Active samples were collected for 72 hours every 12 days, and passive samplers were deployed continuously for a sampling duration of 3 months, over a total sampling period of 2 years. PAHs were extracted (size-fractionated XAD-4, Quartz Microfibre filters) using a Dionex ASE-350, separated using a Varian Select PAH, 30m x 0.25mm (0.15µm film thickness) analytical column, and analyzed by Agilent 5977 GC/MS. In the urban area, passive samplers were sited based on modeled results, known potential Environmental Justice areas, and community input. Air concentrations were summarized by study year, and for the entire study for cancer potency comparisons. Upper 95% confidence limits of the annual arithmetic mean were calculated without detection limit substitution for comparison to estimated inhalation health benchmarks based on Benzo[a]pyrene cancer potency equivalents. Benzo[c]fluorene had the highest BaP equivalent potency of any other PAH, and therefore drove the inhalation cancer potency for the air mixture. However, Benzo[c]fluorene has a mass interferent of Dibenzothiophene sulfone (DBTS). DBTS is an intermediate in the desulfurization process of diesel fuel from Dibenzothiophene (DBT). Dibenzothiophene is used as a model sulfur-containing diesel fuel component, as the sulfur is less reactive because it is stabilized by the aromatic structure of DBT. Energy is required for the desulfurization of DBT, generally, an oxidant, chemical catalyst, higher than ambient temperature heat or biological reactions with the sulfur in DBT. There is potential, therefore, that DBTS could be monitored as a gas phase diesel marker. It is also possible that DBTS is a sampling artifact created on the XAD-4 surface. A multiple measures model was conducted for DBT/DBTS ratios, proximity to major roadways, comparisons with ambient oxidant concentrations (ozone), ambient temperatures, home heating days, and winter vs summer diesel fuel blend seasons. The statistical analysis was different for passive and active samplers. Our preliminary results are suggestive of a gas phase diesel marker that is detectable using both active and passive samplers.

RP105 Spatial variations of porewater and bulk sediment concentrations in complex sediment matrices

S. Yan, Texas Tech Univ / Chemical Engeneering; M. Rakowska, T. Hussain, D.D. Reible, Texas Tech Univ / Dept of Civil Environmental and Construction Engineering

Background. Sediment porewater concentrations of hydrophobic organic contaminants measured by passive sampling are often used to indicate bioavailability and potential risks to aquatic organisms over more traditional bulk solid concentration measurements. Due to the cost and complexity of in-situ monitoring, the sorbents are often placed at a small number of locations at a given site and generally measure only a small volume of interstitial water. This leads to concerns that the individual measurements of passive samplers are less representative than bulk solids. The definition of uncorrelated areas, e.g. "hot spots", is also of interest for both solid and porewater concentrations. Objective. The aim of this study was to evaluate and compare the spatial correlations of in situ hydrophobic organic compound (HOC) porewater concentrations determined by passive sampling and the bulk sediment concentrations to evaluate representativeness and hot spots using geostatistical analysis at several contaminated sediment sites. Methods. Porewater and bulk solid samplers were analyzed from three different field studies conducted at Roxana Marsh, Grand Calumet River, Indiana, Hunters Point Naval Shipyard (HPNS), San Francisco, California and Columbia Slough, Portland, Oregon. Solid phase microextraction (SPME) fibers (approximately 30 µm polydimethyl siloxane (PDMS) coatings were preloaded with performance reference compounds (PRCs) inserted in shielded or unshielded holders, and embedded vertically into the sediment. After equilibrating the fibers were retrieved, sectioned and analyzed for PRCs, 15 PAH compounds or 111 PCB congeners using HPLC with fluorescent detector or GCTQMS. Surficial bulk sediment samples were taken from the same locations and the concentrations were also analyzed. The measured concentrations were subjected to statistical analysis including semivariogram analysis. Results. Data analysis showed that the spatial correlations typically exhibit an equal or longer range in porewater than in solid sediments, which suggest that point porewater measurements are potentially more representative of the surrounding area than bulk solid concentrations. The porewater is itself an integrative medium while HOCs in solids are often associated solely with the organic matter in the solids. The analysis was also used to identify spatially correlated versus uncorrelated (i.e. areas influenced by different sources) locations at the sites.

RP106 Measuring DDT, DDD, and DDE in sediments with passive sampling: implications for reactive compounds

A. Tcaciuc, J.K. MacFarlane, Massachusetts Inst of Technology / Dept of Civil and Environmental Engineering; R. Borrelli, Renewable Energy & Environmental R&D Center, Istituto eni Donegani; P. Cesti, Renewable Energy and Environmental R&D Center – Istituto eni Donegani; P. Gschwend, MIT / Dept of Civil and Environmental Engineering

DDT and its degradation products, DDD and DDE, remain pollutants of concern at various sites in the world. Passive samplers are promising tools for evaluating freely dissolved concentrations of hydrophobic organic chemicals in sediment beds. In conjunction with performance reference compounds (PRCs), passive samplers have been successfully used to determine freely dissolved concentrations of PCBs and PAHs in contaminated sediment beds. However, using passive samplers for DDT, DDD and DDE poses the challenge that depending on the conditions in the sediment, DDT may be reacting to produce DDD and/or DDE. This reactivity can in turn affect the transport of PRCs and the ability to determine the freely dissolved concentrations of DDT, DDD and DDE using passive samplers. To address this issue, we developed a 1-D reaction-diffusion model for chemicals exchanging between PE and the sediment bed. While the transfer of non-reactive compounds such as PCBs was well described by existing 1-D diffusion models, the reaction-diffusion model better captured the transfer of the reactive DDT PRCs. We employed this reaction diffusion model for evaluating the fractional equilibrium of the native DDT, DDE and DDD in passive samplers deployed at a DDT contaminated site. We also used the reaction diffusion model to infer in situ degradation rates of DDT. The high in situ degradation rates determined from the DDT PRC loss suggested that the presence of parent DDT in the sediments is indicative of a recent or ongoing source of "fresh" DDT. Our results suggest that passive sampling in combination with mass transfer models of PRCs, could be used to obtain quantitative information about the biogeochemical processes governing the fate of contaminants. Freely dissolved concentrations in combination with degradation rates can then be used as inputs in larger scale mass balance models to inform decisions about risk management and remediation.

RP107 Cross-validation of equilibrium sampling and non-equilibrium passive sampling methods in PCB contaminated sediments

A. Wang, Northeastern Univ / Civil & Environmental Engineering; S.N. Schmidt, Technical Univ of Denmark / Dept of Environmental Engineering; T.S. Bridges, US Army Engineer Research and Development Center; P.T. Gidley, Engineering Research and Development Center; G.R. Lotufo, C.E. Ruiz, US Army Corps of Engineers ERDC; A.J. Kennedy, CEERD-EPR / Environmental Laboratory; N.S. Rogers, US Army Corps of Engineers ERDC; U. Ghosh, Univ of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering; R.M. Burgess, USEPA / Atlantic Ecology Division; L. Fernandez, Northeastern Univ / Civil and Environmental Engineering; P. Mayer, Technical Univ of Denmark / Dept of Environmental Engineering

Equilibrium and non-equilibrium sampling methods using well characterized polymers have been developed for measuring sediment porewater concentrations within environmental monitoring and site specific risk assessments. Straight-forward calculation of sediment porewater concentrations from polymer concentrations is possible when sediment slurries are allowed to equilibrate with polymer films in the laboratory (i.e., ex situ). In situations where in situ sampling is desired, non-equilibrium passive sampling methods may be preferable. In this case, mathematical models of Fickian diffusion are used to determine correction factors for the disequilibrium condition before conversion of polymer concentrations to porewater concentrations, which can introduce additional error and uncertainty. In this work ex situ equilibrium sampling with silicone coated jars and in situ non-equilibrium sampling methods low density polyethylene (PE) strips were used to determine porewater concentrations of polychlorinated biphenyls (PCBs) in New Bedford Harbor (Massachusetts, USA) sediments. Mesocosms were prepared by placing well-mixed sediment and water in glass aquaria. Strips of PE were inserted directly to the sediment bed while cores of the sediment were collected and subsamples of them tumbled in silicone coated jars. Freely dissolved concentrations measured by the two approaches were in very good agreement and on average differed by a factor of less than 2. Precision was higher for equilibrium sampling using silicone coated jars ($RSD_{avg} \leq 4.6\%$, n=9) compared to in situ non-equilibrium sampling using PE strips ($RSD_{avg} \leq 18\%$, n=3). These results support the use of in situ deployments when there is a need to capture concentration profiles in intact sediment beds while demonstrating the ease-of-use and precision of ex situ sampling methods.

RP108 Fatty acid binding protein in oyster Crassostrea gigas as a binding site to pharmaceuticals

J.F. Tisca, F.S. Soares, A. Bainy, G. Razzera, Univ Federal de Santa Catarina / Bioquimica

Toxic substances, including some polycyclic aromatic hydrocarbons (PAHs), pharmaceuticals, trace metals, among others, are frequently present in sanitary sewage and can be detected in estuaries, which may affect the homeostasis of organisms. Over the last two decades, pharmaceuticals, considered as emerging contaminants, have been receiving increased attention as potential hazardous to marine organisms. Some widely used pharmaceuticals, such as ibuprofen, paracetamol and diclofenac, can be assimilated by marine organisms and their effects in those species require more studies, particularly in sessile and filter-feeding organisms, such as bivalves. These sentinel organisms, such as Crassostrea gigas, have been used to evaluate environmental contaminant effects. Understanding the xenobiotic metabolism, such as pharmaceuticals substances, in this species is highly relevant for biomonitoring programs and oyster farming purposes. Previous studies have shown a significant up-regulation of the fabp gene which codifies one fatty acid binding protein (FABP) in C. gigas exposed to sanitary sewage effluents. FABP protein family possesses a hydrophobic pocked where fatty acids usually bind as primary ligands. The aim of this work was to evaluate the potential interactions of pharmaceutical with the binding pocket of a specific FABP isoform. We selected a C. gigas fabp isoform (ABU41520.1) homolog to human intestinal fabp, which has been previously proposed as a molecular biomarker of exposure to xenobiotics. Swissmodel and Swissdock softwares were used for modeling C. gigas FABP and molecular docking analysis of interactions to pharmaceutical substances (ibuprofen, paracetamol and diclofenac) and endogenous ligand (palmitate and oleate). All tested ligands showed negative free energy levels (ΔG) compatible with stable ligands. Particularly, palmitate and ibuprofen showed the most favorable interaction with the lowest energy. FABP protein was successful heterologously expressed in E. coli cells and purified by using affinity chromatography. Palmitate and ibuprofen, ligand-binding assays were carried out by fluorescence techniques (1,8ANS) and circular dichroism spectroscopy. Palmitate and ibuprofen appear to interact with the hydrophobic cavity of fabp. Our findings strongly suggest that fabp could be an ibuprofen binding protein in C. gigas after exposure to this contaminant in the environment. Financial support: CNPq.

Methods and Applications of Non-targeted Mass Spectrometry for Environmental Characterization

RP109 An integrated approach to study the formation and environmental behavior of transformation products from organic micropollutants

Z. Li, Stockholm Univ / ACES; A. Sobek, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry ACES; M. Radke, Inst for Hygiene and Environment / Environmental Laboratory

A holistic assessment of environmental fate of organic micropollutants requires comprehensive information on their transformation products (TPs) since TPs may be less degradable and/or more toxic than the parent compounds. However, the fate of TPs has been scarcely investigated, much due to conventional target analytical approaches being limited by the absence of information on TP identities. The presented work addressed these knowledge gaps with a tiered workflow, with which we first identified TPs by combining laboratory incubations and non-targeted screening with high resolution mass spectrometry (HRMS), then investigated the behavior of identified TPs both in the lab and in situ. Water/sediment tests were carried out in bottles spiked with 9 pharmaceuticals. Water samples were taken and analyzed by UHPLC/QToF-MS under full scan data acquisition mode. A HRMS data-processing method was established, which enabled identification of 11 TPs that were formed with increasing concentration trends along the dissipation of their parent compounds. Experiments were then conducted using a flume to examine the behavior of TPs in a simulated river system. The same parent pharmaceuticals were spiked in surface water and the 11 TPs identified from the bottle incubations were monitored. Generally, TP formation and behavior were found consistent with the observations from the bottle incubations, indicating the TP information generated from static batch experiments can be qualitatively transferred to more complex systems. Thereafter, field studies were carried out in four rivers over a period of one week and the behavior of these 11 characteristic TPs was determined in a river stretch downstream of a sewage treatment plant (STP) outfall. The TPs formed in the lab-controlled experiments were also detected at the sampling sites close to the STP effluent, with the highest concentration of 0.89 µg/L found for metoprolol acid in a small river containing high proportion of treated

wastewater. Significant loss along the stretch was observed for most of the detected TPs. The results suggest STPs a pronounced source for TPs to surface water. TPs may be formed during wastewater treatment and then emitted into recipients, where they can undergo further transformation. Overall, the presented approaches provide a systematic workflow to identify environmentally relevant TPs and allow for comparisons between observations from lab-based experiments and field studies.

RP110 The use of non-targeted metabolomics profiling to study associations between POP exposure and biomarkers of human health in elderly California women

S. Salihovic, California Environmental Protection Agency / Dept of Toxic Substance Control; M. Wang, ECL California Dept of Toxic Substances Control / Dept of Toxic Substances Control Environmental Chemistry Laboratory; S. Anand, California Environmental Protection Agency / Dept of Toxic Substance Control; S. Hurley, D. Nelson, Cancer Prevention Inst of California; J. Park, M. Petreas, California Environmental Protection Agency / Dept of Toxic Substances Control Environmental Chemistry Laboratory; P. Reynolds, Cancer Prevention Inst of California

Basic fundamentals of mass spectrometry have, in the last decade, allowed for a global characterization of the human metabolome, enabling researchers to study individual metabolic profiles at a new and unprecedented detail.More recently this approach has been combined with the analysis of environmental pollutants with the overall aim to study the associations between human exposure to persistent organic pollutants and biomarkers (i.e. circulating metabolites) of human health. Persistent organic pollutants (POPs) are known toxicants and have been linked to numerous adverse effects in humans. Metabolites in the human circulation (e.g. fatty acids, glycolipids) play a key role in human health and have been shown to be important in disease development. Non-targeted metabolomics provides a tool to unravel which processes are playing a key role in this development. Therefore, the main aim of this study is to investigate the associations between POPs concentrations and metabolic profiles in serum samples from a group of 325 elderly California women. POPs were determined using GC-HRMS and LC-MSMS and quantified using isotope dilution. Metabolites were determined using LC-QTOFMS and when possible quantified using isotope dilution. A broad range of metabolites were detected and further studies to perform metabolite characterization are ongoing. Preliminary results show that human POP exposure might be associated with lipid-related metabolites. This initial investigation demonstrates the use of non-targeted metabolomics profiling in providing a more complete understanding of the relationship between human POP exposure and biomarkers of human health. The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

RP111 Towards benchmark suspect screening and non-targeted analysis methods

E.M. Ulrich, USEPA / Office of Research and Development /National Exposure Research Laboratory; J. Sobus, USEPA / ORD / NERL / EMMD; A. Richard, C. Grulke, A. Williams, USEPA / ORD / NCCT; A. Guiseppi-Elie, USEPA / IO / ORD / NERL

Suspect screening (SSA) and non-targeted analysis (NTA) methods offer new approaches to efficiently generate exposure data for a growing number of chemicals in commercial use worldwide, for which there is a dearth of information. High-resolution mass spectrometry (HRMS) provides a practical means to characterize xenobiotic chemicals in a variety of environmental and biological media efficiently and broadly. These relatively new approaches use a variety of analytical instrumentation, data processing methods, acceptance criteria, and reporting standards. We are conducting a round-robin collaborative trial to evaluate a range of approaches currently used in SSA and NTA. Three categories of experiments are being used: 1) ten standard chemical mixtures from the EPA's ToxCast library, 2) standardized environmental matrices, and 3) standardized environmental matrices spiked with known chemical mixtures. The ToxCast library mixtures include a structurally diverse set of compounds, focused on environmental chemicals with exposure potential. Extracts of standardized environmental matrices including house dust (NIST SRM 2585), human serum (NIST SRM 1957), and environmentally deployed silicone passive samplers are being provided to each participating laboratory to eliminate most aspects of pre-analysis variability. Gas and/or liquid chromatography with HRMS are used in an attempt to maximize chemical space coverage. Initial results will be discussed including (but not limited to): methods, software, and databases used; identified chemicals with level of certainty; percent correct identifications, false negatives, and false positives. Heat maps, concentration estimates and hierarchical clustering of the data will be used to prioritize chemicals to confirm in environmental samples, which will be enhanced by the ToxCast mixtures of known chemicals. The goal of this work is to produce benchmark methods for analytical, reporting, and data analysis to facilitate further analyses and identify areas for improvement.

RP112 Screening of Pesticide Residues and Fluorochemicals using LC-HR-MS/MS and Product Ion Libraries

S. Roberts, Sciex / Environmental and Food Analysis; F. Zhong, A. Quinn-Paquet, J. Stahl-Zeng, A. Schreiber, Sciex

Pesticides and fluorochemicals pose a potential threat to environmental and human health. Modern LC-MS/MS analytical techniques allow quick and efficient screening for hundreds of pollutants with excellent sensitivity and selectivity to meet global reporting guidelines and regulations. Recent advancements in LC-MS/MS technology, including hybrid systems such as quadrupole-quadrupole time-of-flight (QTOF), now provide the ability to perform targeted and non-targeted screening in food samples on a routine basis. Here, we present results using a new method to identify pesticides and fluorochemicals in environmental samples using the SCIEX X500R QTOF system. For pesticide analysis, samples were extracted using a QuEChERS method (Quick, Easy, Cheap, Effective, Rugged and Safe), and extracts were diluted 10x to minimize possible matrix effects. For fluorochemical analysis, samples were diluted 1:1 with methanol and directly injected. LC separation was achieved using a polar modified reversed phase column and a mobile phase consisting of water/methanol and ammonium formate buffer. MS detection was performed using information dependent acquisition to simultaneously collect accurate mass MS and MS/MS information using positive and negative electrospray ionization. Target compounds were automatically identified in a variety of food and water samples by matching retention time (when available), accurate mass, and isotope pattern of the molecular ion and confirmed using MS/MS library searching with SCIEX OS software and SCIEX product ion libraries for pesticides and fluorochemicals.

Fate and Effects of Metals: Regulatory and Risk Assessment Perspective

RP113 Comparison of EPA Estimated vs. Field-Collected Inputs for the Biotic Ligand Model

C. Olson, Middle Tennessee State Univ / Biology; G. Beaubien, MTSU / Biology; E.J. Van Genderen, International Zinc Association / Assistant Manager Environment; A.C. Ryan, Windward Environmental LLC; R.R. Otter, Middle Tennessee State Univ / Biology

The Biotic Ligand Model (BLM) is a regulatory model widely used for estimating metal toxicity in aquatic systems, based on water chemistry and geochemical properties. Since these models rely on water parameters that are not always readily available, the USEPA recently released a draft Technical Support Document (TSD) which provided an approach for estimating missing water quality parameters to supplement incomplete data sets. The TSD presents calculated values for eight of the ten required parameters for BLM modeling, suggesting pH and temperature should always be measured, based on level III ecoregions and stream order. Although the TSD was immediately intended for criterion calculation and implementation for copper, this study compared BLM outputs for a suite of dissolved metals for which BLMs are currently available (Al, Cd, Cu, Ni, and Zn). Measured water quality parameters and metals concentrations of four first order streams located in the Blue Ridge ecoregion were used to perform BLM simulations, and the resulting criterion values were compared to EPA supplemented values. Outputs for dissolved metals showed differences within and among sites for both estimated and field-collected data.

RP114 Implementation options for water quality standards for nickel in Australia

A. Peters, G. Merrington, wca; C. Schlekat, NiPERA, Inc.

The European Community recently adopted a Water Quality Criteria (or Environmental Quality Standard, EQS) for nickel which is based on bioavailability, and uses a Biotic Ligand Model (BLM) based approach for its implementation. A programme of testing of the applicability of the BLM approach for nickel was undertaken in Australia in collaboration with local research organisations. Initial testing of nickel toxicity to Australian test species in field collected Australian surface waters revealed some limitation in the ability of the existing individual species BLMs to predict nickel toxicity in some of these waters. Testing was also performed on a soft water tolerant hydra which indicated increased importance of competition from hardness cations (Ca^{2+} and Mg^{2+}) in extremely soft waters (Ca < 2 mg l^{-1}). This study presents a comparison between several different possible approaches towards the implementation of a bioavailability based standard for nickel in Australia. Available possibilities for the derivation of an environmental threshold for nickel, and various other trace metals, include the use of a single value standard, a hardness corrected standard, a standard based on another single water quality parameter such as DOC, and a standard based on an integrated bioavailability approach similar to that applied in Europe. Each of these possibilities for the derivation of a standard for nickel are comsidered an dassessed against one another in order to identify which approach provides the most appropriate compromise between complexity and ecological relevance.

RP115 Mercury concentrations in fish from three major lakes in north Mississippi: Spatial and temporal differences and human health risk assessment

C.E. Thornton, Univ of Mississippi / Pharmacology; S. Wolff, G. Brown, Univ of Mississippi / Chemistry; J. Chen, Zhejiang Univ of Technology / Chemical Engineering; K. Meals, Mississippi Dept of Wildlife Fisheries and Parks; S. Brewer, Univ of Mississippi / Biology; J.V. Cizdziel, Univ of Mississippi / Chemistry; K.L. Willett, Univ of Mississippi / Pharmacology

The goal of this study was to compare total mercury (Hg) concentrations in fish muscle tissue and assess consumption risks of fish collected from three north Mississippi lakes (Sardis, Enid and Grenada) that are extensively used for fishing and recreation. Largemouth Bass (LMB; n=64, Channel Catfish (CC; n=72) and White Crappie (WC; n=100), that represent a range of trophic levels, were collected during Spring 2013 and 2014. Creel data estimated that anglers harvested approximately 370,000 kg of WC, 27,000 kg of CC, and 15,000 kg of LMB from the lakes annually. Median Hg wet weight concentrations were highest in LMB (443 ng/g), followed by CC (211 ng/g), and WC (192 ng/g). Fish-Hg concentrations were lower than those reported in fish >10 years ago. There were significant differences between lakes consistent across species. Grenada length normalized fish-Hg concentrations were higher than those from Enid and Sardis. Because existing consumption advisories for CC are length-based, the lack of relationship between length and Hg concentration indicated that the recommendations may not be sufficiently protective. Further, five different risk assessment paradigms yielded hazard quotient (HQ) values suggesting that existing fish consumption advisories may be insufficient to protect adults and especially children from exposure to Hg. Supported by U.S. Geological Survey and Mississippi Water Resources Research Institute.

RP116 Revising EPA's National Copper Ambient Water Quality Criteria for the Protection of Estuarine/Marine Aquatic Life Using the Biotic Ligand Model

M. Elias, J.R. Beaman, K. Gallagher, USEPA / Office of Water; G. Smith, Ohio Valley Regional Chapter; C. Voros, Great Lakes Environmental Center

EPA's National Recommended Water Quality Criteria for aquatic life were first developed for copper in estuarine/marine environments in the mid-1980s and were last updated as draft criteria in 2003. Consistent with provisions in the Clean Water Act, National Recommended Water Quality Criteria are periodically revised to ensure they incorporate the latest scientific information and are protective of aquatic life. The 2016 update of the copper estuarine/marine criteria represents a substantial change in the way this criteria is calculated by incorporating use of the saltwater biotic ligand model (BLM), a bioavailability model that relies on water quality input parameters to estimate copper criteria that is protective of aquatic life in estuarine/marine environments. Incorporation of the BLM allows users to account for individual water quality variables (temperature, pH, dissolved organic carbon, and salinity) that influence the bioavailability and toxicity of copper in estuarine/marine environments. Use of the BLM will allow users to develop values that better target environmental protection by focusing on the fraction of copper that is bioavailable and can exert a toxic effect. In addition to the BLM, the 2016 update incorporates a more robust toxicity database supporting the updated criteria. A total of 78 genera are used to derive the 2016 estuarine/marine criterion maximum concentration in comparison to the 44 genera used for the 2003 draft criterion. Although limited additional toxicological data were available to directly derive an estuarine/marine chronic criterion, the acute-to-chronic ratio was revised using data for a broader range of marine and representative freshwater species to provide a more robust criterion continuous concentration value. In addition to cumulative nonpoint source releases, antifouling paints (used as coatings for ship hulls, buoys, and underwater surfaces) and CCA-impregnated timbers (used in decking, pilings and some marine structures) represent major sources of copper to the estuarine/marine environment, and the updated criteria will be beneficial for the protection of estuarine/marine aquatic life, particularly those occurring in and around coastal harbors and marinas. Details of the BLM approach, toxicological data used, and criteria derivation process are presented for this forthcoming criteria, which is scheduled to be published as final in late 2016.

RP117 Toxic effect of heavy metals from reused mine wastes on environment and human health

W. Ju, Seoul National Univ / Dept of Civil and Environmental Engineering; S. Hwang, E. Jho, Hankuk Univ of Foreign Studies / Departmenf of Environmental Science; K. Nam, Seoul National Univ / Dept of Civil and Environmental Engineering; B. Jeong, Seoul National Univ

With the current movement towards the increasing reuse of solid wastes such as mine waste in soil, it is necessary to understand leaching potentials of heavy metals from mine wastes that could contaminate environment, and the subsequent environmental and human health effects. The study investigates the leaching potentials of heavy metals from mine wastes and the ecological toxic effects and human health risk of heavy metals in mine waste leachates. Mine waste samples were collected from five metal mines (two different Pb-Zn mines, two different Fe mines, and a Mo mine) in South Korea. The Korea Standard Test Methods for Solid Waste (STM) and the synthetic precipitation leaching procedure (SPLP) were performed to figure out if heavy metal concentrations of leachates from mine wastes meet the regulatory levels for waste reuse in Korea. The SPLP was conducted to generate leachate that would be formed on exposure to acid rain. The heavy metal concentrations of the STM leachates and the SPLP leachates did not exceed the Korea regulatory levels. Based on a conservative assumption that these leachates flow into water streams, the leachate heavy metal concentrations were compared with the Korea effluent water quality standards, but they did not exceed the standards. However, one of the mine waste samples exceeded the standard for the toxic effects on Daphnia magna (TU>1). The Solubility/Bioavailability Consortium (SBRC) method was used to determine the bioaccessible forms of metals from mine waste. Carcinogenic and noncarcinogenic risks of the bioaccessible metals are to be calculated to see if the leachates impose any toxic effects on human. The leaching potential and ecological toxic effects show that a proper post-management of mine wastes such as heavy metal removal might be necessary to prevent harmful effects on environment. Overall, it is necessary to assess ecological and human health risk of reusing mine wastes in order to promote mine waste reuse.

RP118 Application of the Transformation/Dissolution Protocol to determine the rate of metal removal from the water column for chronic hazard classification

P. Huntsman-Mapila, J. Skeaff, R. Beaudoin, CanmetMINING / Natural Resources Canada

The UN Globally Harmonized System (GHS) and the EU Classification, Labelling and Packaging (CLP) hazard classification schemes include the concept of degradation whereby rapid degradation from the water column (greater than 70% removal in 28 days) results in different classification cut-off values and categories. For metals and inorganic metal compounds, the rapid and irreversible removal from the water column is analogous to the rapid degradation concept for organics, recognizing that metal ions can be made non-available from the water column by a number of processes (e.g. precipitation and mineralization). This work is aimed at adapting the UN Transformation/Dissolution Protocol (T/DP) to establish the rate and extent of partitioning of metals from the water column so that the resulting data can be used in metals chronic classification. The T/DP is carried out under aqueous conditions representative of those generally found in the aquatic environment. Through the addition of sediments, data on water column residence times and processes can be generated. We have examined the rate of removal of Ni (1000 µg/L) and Co (500 µg/L) in the presence of two different sediments at pH 6. Following the addition of 1, 100 and 10,000 mg/L of either Raisin River (RRS) or Buffalo River (BRS) sediment to the individual T/D solutions, we agitated the jars at 100 rpm for one minute to suspend the sediments, then allowed the sediments to settle. At 24, 48, 96, 168, 336 and 672 h intervals, we then sampled the solutions for analysis of the dissolved concentrations of Ni and Co as a function of time. The results for the Raisin River sediment, which could be described as a medium grain sand with 0.8 C% and ~2% Fe, revealed 72% removal of Ni from the water column and 76% removal of Co for the 10,000 mg/L sediment loading over the 28 day period. The Buffalo River sediment, with 3.4 C% and 4.0% Fe, resulted in an 88% removal of Ni from the water column and 89% removal of Co for the 10,000 mg/L sediment loading over the 28 day period. Partition half-times ($t_{1/2}$) for Ni and Co for the 10,000 mg/L loading of RRS were 15 days for Ni and 13 days for Co. For the BRS sediment, $t_{1/2}$ was nine days for both Ni and Co. These values compare favourably with $t_{1/2}$ values calculated from experimental field data in freshwater lakes. The T/DP adapted to measure the rate of metal removal from the water column offers an experimental resolution to the issue of chronic classification for metals.

RP119 Evaluation of USEPA's draft "missing parameters" technical support document for application of the biotic ligand model

A.C. Ryan, K.E. Croteau, D.K. DeForest, R.C. Santore, Windward Environmental, LLC

The biotic ligand model (BLM) requires 11 input parameters for calculation of site-specific water quality criteria (WQC). At some sites, complete sets of BLM inputs may not be available, and this has raised questions about BLM applicability at those sites. In 2015, the United States Environmental Protection Agency (USEPA) released a draft technical support document that provides Level 3 Ecoregion default values for BLM inputs, with the intent of using these values when measured values are not available. The default parameters represent the 10th percentile values estimated on an Ecoregion-specific basis. We conducted an analysis to evaluate the effect of using some or all of the Ecoregion default values on BLM-based WQC for copper. Similarly, we evaluated the effect of the Ecoregion default parameters on BLM predictions representing the 5th percentile of chronic species sensitivity distributions (i.e., consistent with WQC) for lead and zinc. To evaluate the effect of using the default parameters on BLM predictions, complete sets of water chemistry data were obtained from the NWIS database for more than 1,000 sites around the United States. More than 20,000 complete sets of co-located (i.e. consistent in time and location) BLM inputs were compiled. Four scenarios of BLM calculations were evaluated: 1. WQC were calculated using reported values for all BLM inputs; 2. WQC were calculated by substituting Ecoregion-specific dissolved organic carbon (DOC) defaults; 3. WQC were calculated by substituting Ecoregion-specific calcium and magnesium; and 4. WQC were calculated by substituting all inputs (except pH and temperature). Results indicate that use of DOC defaults decreases the BLM-predicted WQC by generally less than 10-fold, but decreases of 100-fold were observed. Compared to DOC, use of calcium and magnesium default values had minor effects on BLM predictions. Lead and zinc predictions were more affected by calcium and magnesium substitution than were copper predictions. When default values were used for all parameters (except pH and temperature), BLM-based WQC were most conservative, although values were generally comparable to the scenario where DOC was the only substitution. These results suggest that it is advisable to use measured values for all BLM inputs, but that avoiding use of default values for DOC is most important.

Scientific Integrity Issues and the Applied Environmental Sciences

RP120 Removal of health care products in the tertiary polishing with constructed wetlands of conventionally treated municipal wastewaters

J.H. Cardenas, E. Torres Ramirez, Benemerita Universidad Autónoma de Puebla / Posgrado en Ciencias Ambientales Instituto de Ciencias; A.E. Navarro Frometa, Universidad Tecnologica de Izucar de Matamoros / Procesos Alimentarios

Currently the use of personal and health care products has growth and intensified which in turn has also increased the release of the substances which fall in their composition to environment, especially to the water bodies. Since two decades ago these compounds have aroused the interest of scientific community because of the insufficient knowledge on their transport and fate in the acuatic environment and the insufficient information regarding their effects on the different trophic levels and in general in the health of the ecosystems. The objetive of this study was to evaluate an alternative for the tertiary polishing of the effluent from the conventional municipal water tretament systems, due to the fact that these systems do not remove some of these organic micropollutants with the required efficiency. With this purpose, at the end of the final sedimentation tank of the wastewaters treatment plant of the city of Izucar de Matamoros, were installed 15 constructed wetland (at mesocosm level) with different combinations of variables: Porous medium (Pm: gravel-G, medium and fine volcanic gravel TG and TF respectively), macrophyte (Pl: Phragmites australis,-Phr, Cyperus papirus- Cy, Thypa latifolia- Ty) and hydraulic residence time (HRT: 1, 3 and 5 days). To assess the removal capacity of the systems, the input and outputs loads of triclosan, diclofenac and naproxen were determined by gas chromatography coupled to mass spectrometry in 15 sampling campaigns. Removal percentages (PlPmHRT) were obtained between 38 (TyTF1) and 86% (CyTF5) for naproxen, 53 (PhrTG1) and 93% (CyTF5) for triclosan and 58 (PhrTG1) and 83% (CyTF5) for diclofenac. The statistical analysis showed a significant effect in the removal percentage of the three target analytes ($p < 0.05$) only for the HRT. However, removals above 57, 73 and 72% for naproxen, triclosan and diclofenac were obtained with different combinations of Pl and Pm for HRT 1. It is concluded that constructed wetlands are an efficient alternative for the tertiary treatment of conventionally treated municipal wastewater, improving its quality before its disposal to surface water bodies. Furthermore its construction materials can be tailored to the resources available in each region.

RP121 Designing, Performing, and Reviewing Toxicity Tests for Effective Presentation in Reports and Journals

W.L. Goodfellow, Exponent, Inc. / BioSciences Practice; M.E. McArdle, K.J. Kulacki, Exponent, Inc.

Arguably, the experimental design and performance of the toxicity tests are critical to the validity and usability of toxicity test results, but few consider the importance of peer-review in this process. The backbone of the scientific process is founded on the requirement of transparency of the methods and results employed such that another rearcher has sufficient information to reproduce the study. Often, individuals believe that the peer-review process is only needed to publish a paper in a peer-reviewed journal. It is often believed that research submitted to non-peer-reviewed journals and books, or research in stand-alone reports does not need the same degree of transparency and reproducibility. This is one reason that there is a mountain of poorly-executed studies with inadequate (if not incorrect) data and conflicting results that often leave data users baffled and confused. Screening the literature and only using studies from peer-reviewed outlets that are held to the highest levels is one way to address this concern; however, many chemicals or test species lack sufficient studies from peer reviewed sources. Although established practices, such as "Good Laboratory Practices" (GLP), typically result in using appropriate protocols and promote transparency through documentaion requirements, they may not always ensure that the study was adequately performed despite a solid track record of past performances. Through the use of case examples, this paper will discuss important considerations for the design and performance of toxicity tests as well as the presentation of the results, discussion, and conclusions. Additionally, we will recommend internal and external review strategies for all types of communication, not just papers for peer-reviewed journals.

PAHs in the Real World: Sources, Sinks, Bioavailability and Toxicity

RP122 A Comparative Developmental Toxicity Study on Embryonic Flounder Exposed to Crude Oils of Different Geological Origin

J. Jung, M. Kim, E. Lee, K. Choi, S. Ha, J. An, U. Yim, Korea Inst of Ocean Science and Technology / Oil and POPs Research Group

Crude oils from different origins have distinct chemical compositions, hence might produce different toxicity. In the study, embryonic flounder were independently exposed to four crude oils, Basrah Light (Iraq), Pyrenees (Australia), Sakhalin Vityaz (Russia) and MFO-380 (processed fuel oil), with oiled gravel effluent. Total PAH concentrations were highest in MFO-380 (82,600 ng/mg), followed by Sakhalin Vityaz (25,600 ng/mg), Basrah Light (13,200 ng/mg), and Pyrenees (2100 ng/mg). Pyrenees was characterized by its relatively higher compositions of three to four ring PAHs, while two ring PAHs (C0 – C3 naphthalenes) highly dominated in Sakhalin Vityaz. MFO-380 and Basrah Light showed similar relative compositions except that Basrah Light had relatively high concentrations of dibenzothiophene and its alkylated homologues. Overall, the two types of crude oil (Basrah Light and MFO-380) produced highly similar gene expression pattern, primarily characterized by the well-known effects on biotransformation, immune response, cardiac function and oogenesis. Responses also included cardiac edema, spinal curvature and tail fin defect. High frequency percentage of cardiotoxicity and the low level of nkx expression were detected in embryonic flounder exposed to pyrenees which have higher composition of three to four rings. The expression level of CYP1A was highest in embryonic flounder exposed to Sakhalin Vityaz and MFO-380. This study has value in continued comparisons of crude oils from a wider range of sources. The results also indicate that differences in PAH composition from different crude oil origin can be an important factor understanding the impacts of other crude oil spills.

RP124 Ecotoxicological Risk of PAHs Released from Contaminated Sediments in Owen Sound, ON, Canada

M. Buell, Trent Univ / Environmental and Life Sciences Graduate Program; K.G. Drouillard, Univ of Windsor / Great Lakes Inst for Environmental Research; C.D. Metcalfe, Trent Univ / Water Quality Centre

As a result of historical industrial activity, the sediments in the inner harbor of Owen Sound in Ontario, Canada are contaminated with PAHs, as well as other inorganic and organic contaminants. There is recent interest in evaluating the ecotoxicological risks associated with these in-place pollutants because of a proposal to dredge the harbor to restore navigation for deep-draught vessels in this Great Lakes port. We initiated a study to evaluate the levels and the distribution of PAHs and other contaminants in sediments in Owen Sound and the potential for these contaminants to be released into the water column at levels that are toxic to early life-stages of fish. Concentrations of total PAHs in sediments in the inner harbour were well above the sediment quality guidelines for the province of Ontario, with mean total PAH concentrations at the most contaminated site of 9,400 ppb dry weight. We deployed semi-permeable membrane devices (SPMDs) in the inner harbor to estimate the average concentrations of PAHs in the water column and the estimated concentrations for several compounds were above provincial water quality guidelines, including levels of fluoranthene, chrysene, benzo(a)anthracene and benzo(k)fluoranthene. In order to determine whether these contaminants in the water column are present at concentrations that pose a risk to fish, we exposed early life stages of two species of fish, Japanese medaka (Oryzias latipes) and lake whitefish (Coregonus clupeaformis) to extracts from the SPMDs deployed in the inner harbor. The medaka exposed to SPMD extracts developed yolk sac edema, which is a commonly observed developmental response in early life stages of fish exposed to PAH compounds. The whitefish did not show the same response, but these fry are currently being evaluated to determine whether they show more subtle toxicological effects.

RP125 Effects of dissolved organic matter on bioavailability and biodegradation of PAHs

J. Ortega-Calvo, Instituto de Recursos Naturales y Agrobiologia / Agroquimica y Conservacion del Suelo; C. Jimenez Sanchez, Inst de Recursos Naturales y Agrobiol. de Sevilla / Agroquimica y Conservacion de Suelos; R. Posada-Baquero, IRNAS CSIC / Agroquimica y Conservacion del Suelo; J. Garcia, Instituto de Recursos Naturales y Agrobiologia de Sevilla CSIC; M. Cantos, CSIC – Spanish National Research Council

In environmental sciences, dissolved organic matter (DOM) is usually differentiated from particulate organic matter as the size fraction of organic matter smaller than 0.45 µm. This fraction typically consists of a multitude of structurally different compounds, all typically present at low concentrations, although it can differ significantly in quality (or biodegradability) and quantity in time and space. The environmental fate of organic pollutants, such as PAHs, can be affected by DOM via increased apparent solubility, desorption, transport and biodegradation. This overview presentation will focus on the recent research efforts in our group, where we have specifically addressed the influences of DOM quality on bioavailability-related phenomena, as connected with biodegradation of PAHs: chemotaxis, attachment and solubilisation. We used, for our studies, different experimental models to assess bioavailability, and these included Tenax extraction, dual 14C/residue analysis of microcosm samples, dynamic passive dosing with PDMS, biphasic NAPL/water systems, and column systems. Different model DOM sources, of dissimilar quality, were used, and included humic acids, root exudates, biosurfactants and organic fertilizers. We found that biodegradation of poorly bioavailable PAHs was enhanced by (bio)surfactants (Environ. Sci. Technol. 48:10869-10877, 2014), the targeted fertilization of free-oil phases or NAPLs (Environ. Sci. Technol. 45:1074-1081, 2011), by modulating the deposition and tactic motility of microbial degraders in porous media (Environ. Sci. Technol. 46:6790-6797, 2012), and by root exudates (Soil Biol. Biochem. 57:830-840, 2013; Environ. Sci. Technol.

49:4498–4505, 2015). However, a negative influence on biodegradation of PAHs by humic acids (Environ. Pollut. 184:435-442, 2014) and biosurfactants (Environ. Pollut. 205:378-384, 2015) was found if they prevented cell attachment to the PAH-loaded PDMS sources. These influences of DOM on bioavailability are relevant not only for innovation efforts in bioremediation but they have also connections with the determination of bioavailability of organic chemicals in retrospective and prospective risk assessment and regulation (Environ. Sci. Technol. 49:10255-10264, 2015).

RP126 Exposure to PAHs in Swedish Seafarers

B. Strandberg, Univ of Gothenburg / Occupational and Environmental Medicine; J. Moldanova, C. Österman, IVL Swedish Research Inst; H. Koca Akdeva, Univ of Gothenburg; S. Langer, IVL Swedish Research Inst

The purpose of this project was to investigate indoor air quality and measure personal exposure to polycyclic aromatic compounds (PAHs) on Swedish ships. Indoor air quality is important aspects of the environment which has not been studied extensively on ships. For seafarers' good indoor environment becomes particularly important as it represents both the working and living environment. On long trips that last for weeks to several months there is no way to change the indoor environment, and no exit from the ship. Air quality on a ship is characterized almost exclusively by the presence of substances that originate in the ship's fuel, lubricants and engine exhaust. Example of air pollutants are PAHs and this group of air toxics is of special concern since they may give an increased risk of cancer. Monitoring of PAHs is mainly studied with active sampling in workplaces. However, to simplify routine monitoring, passive air samplers may be the only option since they are cheap, easy to handle, and less disturbing. Best risk assessment is done using personal sampling. In this presentation, polyurethane foam (PUF) was used both as stationary, and for the first time as personal samplers for a three to seven days sampling period at different workplaces and on various job categories on a cruise ship. Measurements were carried out on two occasions: before and after the change of the fuel. We found a considerable wide range of PAH exposure levels for the various workplaces and occupational categories on the ship. However, all measurements were well below the Swedish occupational exposure limits (OEL) for benzo(a) pyrene and naphthalene. This study contributes to increased knowledge of exposure, sources and health effects to PAHs for Swedish seafarers.

RP127 Fate of polycyclic aromatic hydrocarbons in urban lake sediment

V. Boyd, Univ of Illinois / Civil and Environmental Engineering; C.J. Werth, Univ of Texas Austin / Dept of Civil Architectural and Environmental Engineering

The concentration of polycyclic aromatic hydrocarbons (PAHs) in urban lake sediments has increased in some catchments undergoing rapid urbanization by as much as two orders of magnitude over the last 20 to 40 years (Van Metre et al., 2000). One of the primary contributors to PAH loadings in urban lakes are coal tar pitch particles originating as runoff from paved surfaces, which were shown to significantly contribute to overall PAH loading in lake and streambed sediment (Van Metre et al., 2010; Yang et al, 2010). When these particles enter an urban lake the PAHs in the coal tar pitch are redistributed to more strongly sorbing carbonaceous materials (e.g., soot, charcoal), taken up by aquatic organisms, or released to the water column. An in situ tracer study was conducted in a lake near Milwaukee, WI to measure the fate and transport of PAHs in sediments originating from coal tar pitch. Sediment cores taken from the lake were amended with particles of coal tar pitch, asphalt, charcoal, and soot, and then placed back into the top layer of sediment. These cores were retrieved over a two year period and the exchange of PAHs between the different materials was quantified. PAHs were detected to move to and from all materials, with the greatest concentrations moving from coal tar pitch and asphalt particles, to the charcoal and soot particles. While soot and charcoal accumulated the greatest concentrations of PAHs, the sediment accumulated more mass than any other material. Transport of PAHs was measured to occur at least three times more in the horizontal direction (i.e. away from the cores) compared to the vertical direction (i.e. between different layers of the cores). Lab studies are being conducted to mimic field conditions under a more controlled environment.

RP128 Importance of Source Preparation and Selection Strategies in Chemical Mass Balance Modeling: Source Identification of PAHs in Urban Sediments

S. Ahn, Exponent, Inc. / Environmental and Earth Science; K. O'Reilly, Exponent / Environmental and Earth Science

EPA's Chemical Mass Balance (CMB) model is one of several receptor models used to identify the potential source(s) and quantify source contributions to receptor (environmental sample) concentrations. Originally developed by the USEPA for allocation of contaminants in air, CMB is now widely accepted and used for chemical apportionment in various media including sediment. The CMB model seeks a solution that can best fit the composition of chemicals in a sample via the linear sum of specified group of sources. Successful CMB application requires identification of the important sources that are relevant to the site under investigation along with the model's other underlying assumptions: source profiles are known and stable; and there are sufficient differences between sources so that they are linearly independent of one another. Ultimately, the value of the model's output depends on the quality of the source inputs. When CMB is applied for source identification and contribution of polycyclic aromatic hydrocarbon (PAH) contamination in urban lake sediment, caution is required in source selection strategy because there are many sources of PAHs in urban areas, and the PAH profiles of different sources are often similar. As a case study, CMB was used to identify sources and estimate source contributions to PAH-contaminated urban sediment impacted by multiple potential sources, including vehicle emissions, a coal-fired power plant, parking lot dusts, urban background sources, and more. This presentation demonstrates the impact of differently prepared and selected sources, and similarities between selected samples, on CMB model results. The relationship between the proposed sources and receptor samples is described using statistical tools such as principal component analysis and Pearson correlation. This case study provides an opportunity to review pros and cons of CMB application in PAH source identification in complex urban settings.

RP129 Incorporating contaminant matrix effects enables prediction of in vivo PAH bioavailability from in vitro digestor results

K.J. James, Univ of Saskatchewan / Toxicology Centre; M. Cave, British Geological Survey; S. Siciliano, Univ of Saskatchewan / Toxicology Group and Dept of Soil Science

Polycyclic aromatic hydrocarbons (PAHs) are carcinogenic pollutants found in soil worldwide. Soil physio-chemical properties have large variability, therefore predicting PAH bioavailability from ingested soil is an arduous task. Furthermore, individual PAHs have the potential to influence the physio-chemical properties, such as the solubility, of other PAHs. Here we quantify the solubility of 4 PAH compounds and compare single PAHs to multiple PAH mixture solubility in both water and bile fluids. Notably, the single compound solubility of benzo(a)pyrene and phenanthrene in either water or bile fluids were significantly ($p < 0.05$) different compared to multiple compound solubility. Given these results, the in vivo bioavailability matrix of 11 PAHs across 14 soils is compared to the in vitro bioaccessiblility matrix using co-inertia analysis to determine the principle PAHs affecting the bioavailability of other PAHs. Co-Inertia analysis reveals that the principle PAHs include benzo(a)anthracene, fluoranthene, chrysene, and anthracene. Including these PAHs as predictive variables in a linear model significantly improves the in vitro bioaccessibile predictive ability of in vivo bioavailability ($P < 0.05$). The predicted-observed linear models have a slope of 1.0, $p < 0.005$, and r^2 ranges between 0.65 for benzo(a)pyrene to 0.87 for anthracene. In conclusion, co-inertia analysis identifies the primary PAHs affecting PAH release from soil, allowing for improved bioaccessible predictions of bioavailability.

RP130 Lake-sediment record of PAH, mercury, and fly-ash particle deposition near coal-fired power plants in Central Alberta, Canada

B.D. Barst, McGill Univ / Dept of Natural Resource Sciences; J.M. Ahad, Natural Resources Canada / Geological Survey of Canada; N.L. Rose, Univ College London / Environmental Change Research Ctre; J.J. Jautzy, Univ of Ottawa / Dept of Earth and Environmental Sciences; P.E. Drevnick, Univ of Michigan School of Natural Resources Environment / Biological Station; P.R. Gammon, H. Sanei, M. Savard, Natural Resources Canada / Geological Survey of Canada

We report a historical record of atmospheric deposition in dated sediment cores from Hasse Lake, located near both current and previously operational coal-fired power plants in Central Alberta, Canada. The vertical distributions of spheroidal carbonaceous particles (SCPs), an unambiguous marker of high-temperature fossil-fuel combustion, polycyclic aromatic hydrocarbons (PAHs), and mercury (Hg) were used to evaluate the extent of contamination related to the coal-fired power plants in the region. Total organic carbon (TOC), C/N and stable carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) isotope ratios of organic matter were determined to further examine anthropogenic inputs and changes in lake productivity over the past century. Accumulation rates of SCPs in the early part of the Hasse Lake record (pre-1955) compare well with the history of coal combustion to the east of the lake in the city of Edmonton, whereas accumulation rates in the latter part of the record (post-1955) suggest inputs from coal-fired power plants in the Wabamun Region to the west of the lake. Increasing accumulation rates of SCPs, PAHs, and Hg also coincide with the period of peak pollution in the Wabamun Region. Changes in TOC, C/N, and $\delta^{13}C$ and $\delta^{15}N$ ratios of organic matter indicate increases in lake productivity which may be related to anthropogenic atmospheric deposition.

RP131 PAH monitoring in the Great Lakes: What do dreissenid mussels tell us?

A.P. Jacob, K. Kimbrough, E. Johnson, E. Davenport, NOAA National Ocean Service / National Centers for Coastal Ocean Science / Center for Coastal Monitoring and Assessment; M. Edwards, NOAA National Ocean Service

NOAA's National Centers for Coastal Ocean Science Mussel Watch Program (MWP) has been using dreissenid mussels to monitor chemical contamination in the near shore zones of Great Lakes since 1992. Dreissenid mussels are abundant in the outer harbors on breakwaters and other hard substrates in the Great Lakes. These sessile, filter-feeders bioaccumulate contaminants, possess limited ability to metabolize contaminants, shed light on the bioavailability of contaminants to higher trophic levels, and serve as surrogates for benthic and wildlife health, thus making them an excellent tool for contamination monitoring and assessment. Beginning in 2009, MWP expanded its monitoring efforts by adding numerous sites within Areas of Concern and conducting place-based contamination assessments to address the issues under 'Toxics Substances and Areas of Concern' focus area under Great Lakes Restoration Initiative. MWP also began incorporating newer approaches such as the use of caged mussels and bivalve health metrics (biomarkers, genomics and metabolomics) into its routine protocol to aid contaminant characterization and link exposure to measurable effects in mussels. PAH is one class of compounds that have been routinely measured by MWP at all of its sites to date. We will present basinwide baseline PAH data from Great Lakes sites in relation to land use and population data, provide PAH distribution and fingerprinting results, and additional enhanced efforts of Great Lakes MWP achieved through numerous collaborations and partnerships with other federal, state, local agencies and academic institutions.

RP132 Polycyclic aromatic hydrocarbon accumulation in soil receiving rooftop runoff

S. Hileman, J.B. Belden, Oklahoma State Univ / Integrative Biology; J. Vogel, Oklahoma State Univ

Rooftop runoff, especially in urban areas, may carry contamination into the receiving soil. For instance, polycyclic aromatic hydrocarbon (PAH) contamination from atmospheric deposition or leaching from building materials may accumulate in the soils under downspouts or drip lines. The magnitude of contamination likely varies based on roof type and age of building. To gain a better understanding of the potential for PAH contamination, we measured PAHs in soil within 1m of drain spouts or roof edges at 92 structures, including single house residential buildings, industrial buildings, and institutions such as schools. More than 65% of the samples collected had higher levels of benzo[a]pyrene (a priority PAH) than the recommended soil screening level of 15.7ng/g. Several sites, which greatly exceeded soil screening levels, were locations where older buildings had roofing components covered with sealant, presumably containing coal tar. These preliminary findings are significant because buildings with particularly high PAH levels may put children at risk for additional exposure to carcinogenic PAHs, by either ingestion or contact with contaminated soil. These data also suggest potential contamination issues for harvested rainwater using rooftop runoff catchment systems.

RP133 Predicting Passive Sampler Equilibration Times for PAHs in an Amended Sand Cap

J. Roberts, SiREM; M. Vanderkooy, J.M. Conder, Geosyntec Consultants; M. Healy, SiREM; J. Thompson, C. Thompson, Geosyntec Consultants

PAHs in sediment pore water can be sequestered before upwelling water reaches the sediment-water interface using amended sand caps with amendments such as activated carbon and biochar. Passive samplers offer a method to monitor remedy effectiveness. A key condition for using passive samplers to directly estimate hydrophobic organic compounds (HOCs) pore water concentrations is that the concentrations of the HOCs being sampled are in equilibrium between the sampler and the pore water. The time to achieve equilibrium between the passive sampler and the surrounding pore water is dependent on both the hydrophobicity of the HOC and the surrounding chemical environment. The loss of performance reference compounds (PRCs) during deployment of a passive sampler allows for the estimation of the degree of equilibrium achieved or confirmation of the achievement of equilibrium. If the passive sampler is found not to be at equilibrium with the surrounding pore water, then the PRC data can provide an estimation of passive sampler uptake rates for calculation of the equilibrium pore water HOC concentrations. This presentation will show theoretical and empirical data demonstrating the difference in estimated equilibration times for various PAH compounds in different amended sediment cap environments. The equilibration times measured ranged from ~20 days in a powdered activated carbon (PAC) amended cap environment to ~200+ days in a sand only cap with no flowing water. Equilibration times were determined using deuterated PAH and hydrophobic dye PRCs. The results of the research can be used to determine if PRCs are required in passive sampling programs depending on the cap conditions (e.g. PAC or no PAC), HOCs of interested being measured and estimated sample deployment time.

RP134 The Application of Monoclonal Antibody-Based Biosensor Analysis for Quantifying PAHs in Sediment Pore Waters

M.A. Unger, G.G. Vadas, M. Vogelbein, Virginia Inst of Marine Science / Aquatic Health Sciences; L.T. Yonkos, Univ of Maryland / Environmental Science and Technology; S.E. Hartzell, Univ of Maryland, College Park

Hydrophobic contaminants such as polycyclic aromatic hydrocarbons (PAH) accumulate in sediments and may pose significant ecological and human health risk. Contaminant bioavailability is governed by partitioning but multiple chemical and physical factors influence bioavailability in natural systems. Because measuring contaminant exposure and uptake in biota is time consuming and expensive, multi-phase models have been developed to predict contaminant bioavailability. The heterogeneity of natural habitats makes it difficult to reliably predict bioavailability from measured bulk sediment concentrations and properties. Ultimately, site-specific pore water measurements are needed to accurately predict contaminant fate and bioavailability but these measurements are difficult to obtain by standard analytical methods. Advances in biosensor technology allows near real-time measurement of contaminants at sub ppb

concentrations in small volume (< 5 mL) aqueous samples. A quantitative, monoclonal antibody (mAb)-based sensor was used to measure PAH concentrations in sediment pore water collected at various PAH contaminated sites in the Elizabeth River, VA and Baltimore Harbor, MD. PAH concentrations in pore water samples were measured in the field within minutes of collection with the biosensor to map the spatial distribution of PAHs at contaminated sites in the Elizabeth River, VA. Sampling of pore water concentrations with depth by drive-point piezometer allowed vertical profiling of PAH concentrations within sediments to evaluate the input of contaminated groundwater and document mixing of surface water within the sediments. Analysis of PAH concentrations in pore waters from sediment cores collected in Baltimore Harbor was used to evaluate PAH toxicity to benthic amphipods. Correlations between PAH concentrations measured by the biosensor (< 1 µg/L to > 800 µg/L) and those measured by GC-MS were excellent and the results are being used to help develop sediment remediation strategies.

RP135 The Interactive Role of Fate Processes in the Overall Aquatic Fate of Polycyclic Aromatic Sulfur-Containing Hydrocarbons (PASHs)

P. Saranjampour, Louisiana State Univ / Dept of Environmental Sciences; K. Armbrust, Louisiana State Univ / Environmental Sciences School of the Coast and Environment; B. Marx, Louisiana State Univ / Experimental Statistics Dept

Crude oil spills release significant amounts of polycyclic aromatic sulfur-containing hydrocarbon (PASHs) and their alkyl homologous into aquatic systems. Dibenzothiophene (DBT) and its homologous, C1-, C2- and C4- DBT, were chosen as model compounds to investigate possible fate pathways of PASHs after a crude oil spill. Loss due to reaction with hydroxyl radical (indirect photolysis), volatilization from water and biological uptake were investigated by measuring their physicochemical properties. The EPA Exposure Analysis Modeling System (EXAMS) was used to estimate the relative impacts of these properties to overall chemical fate as a function of depth (10 cm, 1 m and 2 m) and salinity. The hydroxyl radical rate constant ($K_{\cdot OH}$), Henry's law constant (H), and n-octanol/water partition coefficient (K_{ow}) of PASHs were determined in distilled water. The K_{ow} which is an indicative of biological uptake, was also determined in artificial seawater to investigate the salinity impact on bioavailability of the PASHs. The analogue C1- DBT reacted faster with ·OH compared to other PASHs. The C2- and C4-DBT analogues had higher H compared to other homologues. Furthermore, PASH K_{ow}'s were increased as their molecular weight and water salinity increased. These results suggest that reaction with ·OH might be a significant dissipation pathway for smaller and more polar PASHs in shallow aquatic systems. In addition, high H and K_{ow} suggest that volatilization or uptake by aquatic organisms might be an additional potential fate pathway for high molecular weight and less polar PASHs. The overall half-lives of PASHs, assuming only dissipation due to indirect photolysis and volatilization, were estimated to increase as a function of depth in the water column. The decreasing order of half-lives of PASHs at 10 centimeters depth are DBT > C1-DBT = C4-DBT > C2-DBT which are 4.2 > 0.9 > 0.5 days, respectively. However, the decreasing order of half-lives of PASHs at 2 meters depth are changing to C4-DBT > DBT > C1-DBT > C2-DBT which are 15.1 >13.7 > 11.4 > 9.7 days, respectively. The C2-DBT half-life was estimated to be the shortest in either depths possibly due to higher contribution of volatilization than indirect photolysis in overall PASHs aquatic fate.

RP136 The polycyclic aromatic hydrocarbon 2-naphthol accelerates adipogenesis in the 3T3-L1 model

R. Attanasio, J. Wang, Georgia State Univ / Biology

Polycyclic aromatic hydrocarbons (PAHs) are known carcinogens and suspected endocrine disruptors. 2-naphthol is one of the important metabolites of naphthalene, which is the simplest PAH. Indeed, urinary 2-naphthol is used as a biomarker of exposure to PHAs in humans. Results from epidemiological studies show associations between exposure to 2-naphthol and obesity, a condition characterized by excess adipose tissue. In this study, we evaluated the effects of 2-naphthol on adipogenesis using mouse 3T3-L1 cells. These cells, under certain conditions, differentiate from fibroblasts to adipocytes, and are widely used for studying adipogenesis. Thus, 3T3-L1 cells were exposed to different doses of 2-naphthol. Cell differentiation was evaluated by cell morphology, lipid production, and mRNA expression of marker genes characteristic of either early adipocyte differentiation: CCAAT-enhancer-binding protein β (C/EBPβ), insulin receptor substrate 2 (IRS2), and sterol responsive element binding protein 1 c (SREBP1c); or terminal differentiation: C/EBPα, peroxisome proliferator-activated receptor-γ (PPARγ), and fatty acid binding protein 4 (aP2). Production of the antimicrobial peptide cathelicidin (Camp), which is produced by differentiating adipocytes and modulates inflammation and immunity, was also evaluated. Cell morphology changes and increased lipid accumulation indicated that 2-naphthol induced 3T3-L1 differentiation. During early differentiation, 2-naphthol stimulated C/EBPβ, IRS2, and SREBP1c expression, whereas during terminal differentiation, 2-naphthol increased C/EBPα, PPARγ, and aP2 expression. Moreover, 2-naphthol elevated Camp expression in a dose-dependent manner. In conclusion, our results show that 2-naphthol accelerates adipocyte differentiation and induce Camp production in 3T3-L1 cells, thus indicating that 2-naphthol might play potential roles in the development of inflammation and obesity.

RP137 Analysis of incense by headspace-gas chromatography-mass spectrometry (HS-GC/MS) and thermogravimetric-gas chromatography-mass spectrometry (TGA-GC/MS)

M.R. Schnyder, Texas Southern Univ / Dept of Environmental Science and Technology / Environmental Toxicology; M. Saleh, Texas Southern Univ / Chemistry Dept

Twleve incense samples, six stick incense and six dhoop style, from four different manufacturers were characterized by headspace-gas chromatography/mass spectrometry (HS-GC/MS) and thermogravimetric analysis-gas chromatography/mass spectrometry (TGA-GC/MS) under pyrolysis conditions. Burning incense is a popular practice around the world across all races, religions, ethnicities, nationalities, and ideologies. There are numerous studies which show the chemical composition of incense before burning or after burning. However, there are few studies that investigate the chemical composition both before burning and after burning. A chemical fingerprint for the incense before burning was determined using HS-GC/MS and many hazardous compounds were found. The TGA-GC/MS was used to determine the products of pyrolysis and combustion under helium and oxygen atmospheres respectively. The TGA-GC/MS analysis showed the presence of benzene for four out of six samples and the different chemical compositions of incense after thermo gravimetric analysis were suspected to be a result of distinct smoke-generating compounds used in the manufacturing of incense. This research provides preliminary evidence on the harmful emission products and their relationship to incense ingredients.

RP138 PAH Phototoxicity on Porites divaricata corals

M. del Carmen Guzman Martinez, Universidad Autonoma Metropolitana / Hydrobiology; P. Ramirez Romero, U.A.M. Iztapalapa / Hidrobiologia

PAHs are a group of toxic substances, with a wide environmental distribution, produced by incomplete combustion processes of natuaral and anthropogenic origin. These compounds pose a risk to aquatic organisms because of its potential to produce phototoxicity when combined with solar UV radiation. Coral reefs are located in areas where the transparency of the water allows solar UV radiation to penetrate deep in the water column. In Mexico, the Caribbean Sea is a natural area of great value in terms of biodiversity, but the rapid tourism development threatens this ecosystem. In the present study the reef zone of Puerto Morelos, Quintana Roo, Mexico was chosen as a study area due to its environmental significance. The aim of this work was to evaluate the median lethal concentration (LC50) of anthracene, Benzo[α]pyrene and fluoranthene on Porites divaricata corals. Samples were collected at a depth of 1 m and transproted to the laboratory where 120 branches (1-2 cm long) were distributed in 10 aquarium. PAHs were dissolved in HPLC grade acetone to obtain the following nominal concentrations: 0.95 and 1.9 of benzo[α] pyrene, 15 mg/L, 30 mg/L and 60 mg/L of fluoranthene and anthracene plus two controls with acetone and two controls with seawater. Coral samples were kept in the aquariums for 10 hours inside the laboratory. Followed by a SUVR exposure period in which the aquariums were put in fiberglass tanks (0.7 x 2.0 x 0.6 m) with a constant water flow to maintain temperature at 30 ° C. In situ chlorophyll measurements were taken at 6:00 am and at noon using a pulse amplitude modulation fluorometer. After 6 days of experimentation signals bleaching or mortality were observed. Mortalities were used to determine LC50. Results showed that Porites divaricata presented a decrease in the photochemical efficiency, bleaching and mortality in the presence of environmentally relevant levels of SUVR, which means that in areas of high boating activities PAHs may represent a risk factor for corals living in shallow areas.

Engineering, Toxicology and Risk Assessment Guidance for Sediment Evaluation at Dam Removal Sites

RP139 Best practices for sediment assessment: Lessons from five dam removals in North Carolina

T. Augspurger, US Fish and Wildlife Service / Ecological Services

A decision to proceed with dam removal needs a case-by-case assessment of environmental and economic costs and benefits. One component is evaluating the chemical nature of accumulated sediments. In North Carolina, dam removal guidance notes the need to evaluate contaminants but there are not established methods. Accordingly, dam owners were reluctant to conduct expensive testing without a certain regulatory framework, and the lack of a framework hampered efforts to manage analytical costs. In five dam removal projects since 2004, we used the framework of the USEPA/USACE technical guidance manual on disposal of dredged material in inland waters to evaluate sediments. Assessment areas were defined as the stream-reach impounded by the dams, plus a one-mile buffer laterally and upstream consistent with the ASTM International Standard Practice for Environmental Site Assessments: Phase I Environmental Site Assessment Process. Evaluations start with a tier 1 assessment of existing information to assess the potential for current and historic contaminant inputs to the impounded reaches. GIS maps were populated with information from USEPA's Facility Registry System, Toxics Release Inventory and Envirofacts databases and records maintained by State water, air, and waste management agencies. Sites within the assessment area were screened-in or screened-out for further evaluation. For facilities that needed more inquiry, we gathered information on pollutants discharged and pathways to the assessment areas. Database reviews were augmented with review of any water and sediment chemistry data. We conducted a recon of each site and interviewed staff knowledgeable on the land uses and history. Results were synthesized for stakeholders with a recommendation on concluding assessment or proceeding through tiers of additional data collection, including sediment chemistry and toxicity testing to the extent necessary to inform decision-making. Absence of pollutant sources indicated little need for more work to characterize potential contaminants. Specific issues identified in tier 1 reviews guided any additional sampling. While there is no standard method for evaluating potential sediment contamination at dams, the step-by-step approach of synthesizing contaminant source data, sharing that with stakeholders for a discussion on how to proceed, and collecting site-specific sediment data if needed effectively and efficiently addressed concerns of regulated and regulatory entities.

Strategies for Assessing Chemicals for Endocrine Activity: Making the Best Use of Screening-Level Information

RP140 Behavioral toxicity of mixtures of endocrine disrupting chemicals in Zebrafish (Danio rerio) larvae

L. Birgersson, Univ of Gothenburg / Biology and Environmental Science; G. Asmonaite, Univ of Gothenburg / Dept of Biological and Environmental Sciences; B. Carney Almroth, Univ of Gothenburg / Biology and Environmental Sciences; E.J. Sturve, Univ of Gothenburg

The presence of endocrine disrupting chemicals (EDCs) in the aquatic environment can have severe effects on the health of aquatic organisms. Numerous anthropogenic EDCs, such as plasticizers, fire retardants and antibacterial agents, enter the aquatic ecosystems via effluents from wastewater treatment plants and land runoff. Many of these chemicals have been shown to have adverse effects on fish, including disruption of reproduction, as well as effects on neurodevelopment and brain formation. Previously, studies have mainly focused on single compound exposures or simple mixtures at high doses which does not reflect the complex mixtures of EDCs at low concentrations present in the aquatic environment. Hence, the challenge today is to assess the effects of more complex mixtures of EDCs in low doses, which is the basis for the EU financed Horizon 2020 project EDC-MixRisk. EDC- MixRisk is an interdisciplinary project where epidemiological and bio statistical methods have been used to identify EDCs that are correlated with endocrine disruption in two pregnancy cohort studies. EDCs linked to three different health domains (metabolism, reproduction and neurodevelopment) were identified and mixtures of these bad actors (phthalate metabolites, phenols and PFASs) were synthesized and are presently being tested in experimental model systems. The current study aimed to determine the behavioral toxicity of low doses of the EDC mixtures on zebrafish (Danio rerio) during early development. Alterations of larval behavior caused by the EDC exposure were studied as an endpoint for neurodevelopment since behavior integrates many biochemical processes and can be a sensitive endpoint for sub-lethal toxicity of endocrine disruptors. Zebrafish were exposed to sub lethal doses of the mixture targeting neurodevelopment (found to be correlated with adverse neurological effects in the epidemiological study) and larval locomotion was tracked using the ViewPoint ZebraBox revolution software. Additionally, quantitative PCR (qPCR) was used to determine the effects of the EDC mixture on the expression of thyroid related genes. Our results indicate that low doses of the neurological mixture caused adverse effects on the of behavior zebrafish larvae. Preliminary results also show that several of the thyroid related genes (including Deiodinase 2) are negatively impacted by the low dose exposure.

RP141 Considerations for Developing, Validating and Implementing Performance Based Test Guidelines

S.L. Levine, Monsanto Company / Global Regulatory Sciences; E.M. Mihaich, ER2

To manage teh ongoing development of test guidelines that evaluate the same endpoint, OECD developed guidance on a new concept known as Performance Based Test Guidelines (PBTG). The PBTG concept creates a grouping of test methods, with similar essential components and endpoints, to ensure that the methods have equivalent performance. This concept is not entirely foreign to ecotoxicologists, where many guidelines have historically included the option of testing any one of a number of species provided they adhered to specific performance standards. However, it is a relatively new concept for in vitro assays and it is being implemented to manage the proliferation of in vitro test systems. In addition, EPA is interested in adopting performance based standards to manage acceptance criteria for high-through-put in vitro screening assays that will inform the EDSP. An overview and analysis will be drawn from the two initial PBTGs developed by OECD, the estrogen receptor transcriptional activation assays and the in vitro skin corrosion assay. This presentation will provide an overview of the general approach to implement PBTGs and standards, examples of assay types where PBTGs have been applied, approaches and considerations to cross-validate mechanistically and functionally equivalent "me too" assays, learnings from these first two efforts, and a discussion of advantages and disadvantages to applying PBTGs.

Chemical and Microbial Environmental Health Threats Associated with Disasters

RP142 Comparison of Wastewater-Associated Contaminants in the Bed Sediment of Hempstead Bay, New York, before and after Hurricane Sandy

S.C. Fisher, P.J. Phillips, USGS / New York Water Science Center; B.J. Brownawell, Stony Brook Univ / School of Marine and Atmospheric Sciences; J.P. Browne, Town of Hempstead / Dept of Conservation and Waterways

Wastewater infrastructure situated along the coast proved particularly vulnerable to coastal storms. Inundation brought by Hurricane Sandy caused widespread failures and overloads of wastewater treatment systems resulting in the discharge of billions of gallons of untreated and partially-treated sewage into the sensitive ecosystem of Hempstead Bay, New York, in the weeks following landfall. To assess the impact these discharges may have had on the benthic environment, bed sediment samples from sixteen sites collected and archived before the storm (2010-12) were analyzed and compared to samples collected after the storm (2013). Samples were analyzed for 74 compounds that are typically associated with wastewater, including sewage tracers (skatole, acetophenone, and indole), polycyclic aromatic hydrocarbons (anthracene, fluoranthene, and phenanthrene), human [steroid] hormones (3-beta-coprostanol and estriol), and personal care and domestic use products (caffeine and bisphenol a). Data from eight sites were used for statistical comparisons (Wilcoxon signed-rank test) of pre- and post-storm conditions—data from an additional eight sites with only pre- or post-storm samples were evaluated for regional context. Results from the most frequently detected wastewater tracers and ratios of steroid hormone and of polycyclic aromatic hydrocarbon concentrations indicate an increased sewage signal near the Bay Park sewage treatment plant outfall in Reynolds Channel (median percent change of +116% using 23 paired compounds) and downstream of Powell Creek, where raw sewage was discharged during emergency clean-up (median percent change of +240% using 24 paired compounds). At four sites further from the outfall, median concentrations were lower in samples collected after the storm (median percent change ranging from -70% to -25%), possibly because of sediment redistribution observed throughout the bay. The final two sites in the comparison did not have statistically significant differences in concentrations of compounds compared; however, relative to other sites, concentrations of wastewater tracer compounds were higher in both pre- and post-storm samples. Overall, this analysis indicates changes in bed sediment quality of Hempstead Bay resulted from a combination of additional sewage inputs, sediment redistribution, and stormwater runoff carrying sewage overflow and burned and unburned petroleum products in the days and weeks following the storm.

RP143 The impact of onsite wastewater disposal systems on groundwater in areas inundated by Hurricane Sandy in New York and New Jersey

I. Fisher, USGS; P.J. Phillips, USGS / New York Water Science Center; K. Colella, USGS; S.C. Fisher, USGS / New York Water Science Center; T. Tagliaferri, USGS; W.T. Foreman, E.T. Furlong, USGS / National Water Quality Laboratory

Thousands of coastal onsite wastewater disposal systems (OWDS) were inundated by Hurricane Sandy's storm tide. Inundation of community infrastructure or OWDS facilities during coastal flood events can damage OWDS, and may increase the load of poorly treated sewage into the shallow groundwater flow system and adjacent coastal waters. The presence of OWDS in areas inundated during Hurricane Sandy in 2012 has raised concerns over whether saltwater inundation affected 1) the presence of wastewater-associated compounds in the near shore shallow groundwater flow system and 2) the ability of the shallow groundwater flow system to attenuate wastewater-associated compounds. The high hydraulic conductivity of the sandy surficial aquifer of the New Jersey-New York coastal region makes these areas particularly vulnerable to organic wastewater contamination. This study compares the shallow groundwater quality downgradient of OWDS before and after Hurricane Sandy in the barrier island communities of Fire Island National Seashore, NY, and establishes a baseline for wastewater influence on groundwater in other NY (Long Island) and NJ (Sandy Hook) coastal communities inundated by Hurricane Sandy. Nutrients and contaminants of emerging concern (CECs; such as pharmaceuticals and hormones) were detected in shallow groundwater downgradient of OWDS in two settings along the New Jersey and New York coastlines: 1) a single, centralized OWDS serving a park facility; and 2) multiple, single-family home OWDS (cesspools) in areas with land use ranging from low-density residential to mixed use (residential and institutional). The most frequently detected pharmaceuticals were lidocaine (40%), carbamazepine (36%), and fexofenadine, bupropion, desvenlafaxine, meprobamate, and tramadol (24-32%). Land use settings with the greatest influence on downgradient wells were in locations that catered to the greatest number of people, regardless of the type of OWDS (centralized or cesspools/septic systems). These data demonstrate the importance of analyzing for a wide variety of CECs in regional studies to account for varied demographics. Comparisons between groundwater data collected before and after Hurricane Sandy at Fire Island, NY, show increases in the number of pharmaceuticals and the total concentration of pharmaceuticals after Hurricane Sandy, but those increases may reflect other factors (seasonality, usage) besides inundation.

RP144 Regional assessment of persistent organic pollutants in resident mussels following Hurricane Sandy

K.L. Smalling, USGS / NJ Water Science Center; A. Deshpande, USDOC-NOAA-NMFS-NEFSC / Sandy Hook Laboratory; H. Galbraith, USGS; B.L. Sharack, USDOC-NOAA-NMFS-NEFSC / Sandy Hook Laboratory; D. Timmons, USDOC-NOAA-NMFS-NEFSC; R.J. Baker, USGS

Resident mussels are effective indicators of ecosystem health because contaminant concentrations in their tissues quickly respond to changes in ambient environmental levels, accumulation occurs with little metabolic transformation, and more than 20 years (1985-2012) of historical contaminant data within the United States are available. Mussels have been used worldwide to monitor changes in contaminants in the coastal environment but results from this and other studies suggest that they also have the potential to detect short and long-term impacts of episodic events as well as long-term impacts of incremental changes (sea level rise and land-use change). Blue and ribbed mussels were collected from 10 previously studied locations approximately a year after Hurricane Sandy and analyzed for a suite of persistent organic pollutants (POPs) including polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), polycyclic aromatic hydrocarbons (PAHs) and organochlorine pesticides (OCPs). A subset of shells from each site was also aged by thin-sectioning to determine if there were site-specific or local differences in mussel populations. No relation between length or age and latitude was observed indicating a similar distribution of ages across the sampled mussel populations. Regionally, concentrations of PCBs and PAHs decreased significantly, while concentrations of OCPs remained unchanged, and PBDEs significantly increased compared to historic concentrations. Although concentrations of PCBs, OCPs and PAHs were at or near record low concentrations, regional trends did not significantly change after Hurricane Sandy. At some locations, however, observed concentrations were an order of magnitude lower than pre-Sandy concentrations, indicating that the current study did provided a new baseline in POPs for select areas following a major coastal storm. A combination of tissue analysis, chronology and histology immediately following a major event (e.g. natural disaster) would be valuable and necessary to establish a link between contaminants and the resulting ecological effects. This study demonstrates that to effectively measure storm induced impacts it is necessary to understand the factors influencing changes in mussel body burdens, have a long-term monitoring network, and to have the ability to mobilize quickly post event.

RP145 Resetting the Bar: Establishing Baselines for Persistent Contaminants after Hurricane Sandy in the Coastal Environment of New Jersey and New York, USA

T. Reilly, USGS / New Jersey Water Science Center

Hurricane Sandy (often informally referred to as "Superstorm Sandy") was the second costliest hurricane to make landfall in the United States since 1900. In the immediate aftermath of Hurricane Sandy, it was readily apparent that long-term contaminant threats were possible due to a myriad of factors including the extent of compromised infrastructure, beach erosion, and sediment disturbance and the proximity of the storm track to population centers and vulnerable ecosystems. Although supplemental funding sources became available to U.S. Geological Survey (USGS) many months after the storm, scientists applied retroactive approaches to assess the potential contaminant impacts to public spaces and ecosystems. These approaches included: 1) the regional collection of environmental samples in locations (estuaries, bays, beaches) and media (sediment and tissue) including stations sampled prior to Hurricane Sandy; 2) the assessment of specific sources of contaminants particularly partially and untreated wastewater, 3) the potential for mitigation activities themselves to exacerbate the release of contaminants in, and near, public spaces; 4) the novel application of young-of-the-year bluefish as a sentinel species of contaminant mobilization and uptake; and 5) the evaluation of new remote sensing platforms to identify contaminant plumes in the environment. The results of these studies will published in a forthcoming special issue of Marine Pollution Bulletin providing resource managers and researchers with a comprehensive baseline dataset describing post-Hurricane Sandy contaminant levels throughout coastal New Jersey and New York and insights into the impacts of this event on wildlife and the built environment. Progress on the USGS strategy to define baseline and post-event sediment-bound environmental health stressors (SCoRR) and the ongoing assessment to compare storm-derived changes to long-term trends in sediment quality within the region in collaboration with the U.S. Environmental Protection Agency will be presented.

Integrating Chemistry and Biology in a Landscape Context to Reveal Potential Causes of Endocrine Disruption

RP146 Strategies to Address Endocrine Disruption in Fish and Wildlife in the Chesapeake Bay Watershed

K.L. Smalling, USGS / NJ Water Science Center

U.S. Geological Survey (USGS) scientists have established a national framework to evaluate endocrine disrupting chemicals (EDCs) and their effects on fish and wildlife. The four strategic goals for EDCs outlined by the framework were to 1) identify and quantify sources, fate, transport, distribution and exposure; 2) evaluate their effects on fish and wildlife; 3) determine their mechanism(s) and thresholds for adverse effects and 4) develop appropriate assessment tools and models to evaluate risk. The framework and strategic goals were applied directly to ongoing research in the Chesapeake Bay watershed to assess the exposure and potential effects of EDCs on fish and wildlife. The Chesapeake Bay is the largest estuary in the United States, and provides critical resources to fish, wildlife and people that use the 64,000 square mile watershed. For more than a decade, adverse effects associated with exposure to EDCs have been observed including intersex (testicular oocytes) in bass and plasma vitellogenin in male fishes (bass and sucker species). Skin lesions and mortalities of both adult and young-of-year bass have also been observed in fish from the same locations where the prevalence of intersex was high. Currently, emphasis is being placed on aquatic ecosystems with a focus on the identification of relevant EDCs, how they enter waterbodies, and how they affect aquatic organisms. Studies are investigating key pathways of EDC transport and exposure including the mechanisms and chemical thresholds associated with observed effects. Controlled laboratory and environmental field sampling approaches are being applied in tandem at six integrator sites that are dominated by agricultural land use. EDC research in the Chesapeake Bay Watershed was designed as a coordinated and collaborative effort between Federal, State and academic research partners to fill data gaps and synthesize findings. This study will provide a scientific basis for resource managers to consider strategies to reduce the occurrence of EDCs and their effects on fish and wildlife in this, and other, valuable ecosystems.

RP147 Effects of early life stage exposure of largemouth bass to a common Chesapeake Bay contaminant (atrazine) or a model estrogen (17α-ethinylestradiol)

J.K. Leet, C.A. Richter, USGS / Columbia Environmental Research Center; R. Bhandari, Univ of North Carolina at Greensboro / Biology; D.K. Nicks, V. Velez-Rivera, USGS / Columbia Environmental Reserach Center; D.E. Tillitt, USGS / Columbia Environmental Research Center

Field studies have shown high prevalence of intersex in smallmouth bass (Micropterus dolomieu), and to a lesser extent largemouth bass (Micropterus salmoides), populations in the Chesapeake Bay watershed. This observed phenotype has been correlated with the presence of the agricultural pesticide atrazine, which is widely used and one of the most commonly detected pesticides in the watershed. Our objective was to investigate the mechanisms of intersex formation in largemouth bass (LMB). An experiment was conducted in which LMB were exposed to either atrazine (1, 10, or 100 μg/L) or the model estrogen 17α-ethinylestradiol (EE2, a strong estrogen known to induce intersex and sex reversal in fish; 1 or 10 ng/L). Fry were exposed directly after hatch from 5 days post spawn (dps) through early gonad development (80 dps). The initial histological analysis of sex ratios indicated the 10 ng/L EE2 treatment resulted in all females indicating complete male sex reversal; however, there was no apparent sex reversal at 1 ng/L EE2. Additional analysis of sex identification by the presence of SOX9 and β-CATENIN as markers of "male" and "female" gonadal tissue, respectively, will be compared to histological results to determine any potential effects on sex differentiation. Future analysis will focus on potential biomarkers of intersex development and endocrine disruption (e.g., vtg, cyp19a, vasa, dazl, zp3, sf1, cyp17,dmrt1, foxl2). This study will shed light on the sensitivity of LMB to estrogens during sex differentiation, and potential effects of atrazine on gonad development in this species.

RP148 Time course of transcriptomic alterations in the adult fathead minnow (Pimephales promelas) ovary in response to atrazine exposure

C.A. Richter, J.K. Leet, R. Bhandari, USGS / Columbia Environmental Research Center; R.S. Cornman, USGS / Fort Collins Science Center; D.E. Tillitt, USGS / Columbia Environmental Research Center

Agricultural land use is associated with increased concentrations of nutrients and pesticides in surface waters, as well as symptoms of endocrine disruption including reproductive abnormalities and disease outbreaks in resident populations. The herbicide atrazine is the second highest-use pesticide in the United States and is frequently detected in surface waters of the Chesapeake Bay watershed. Atrazine has been implicated in reproductive dysfunction and decreased egg production in fathead minnows (Pimephales promelas) during 30 d exposures at concentrations of 0.5, 5, and 50 μg/L. Here we evaluated the time course of transcriptomic alterations in ovarian tissue of adult fathead minnow exposed to 50 μg atrazine/L for 4, 14, or 30 d. Our objectives were to evaluate possible adverse outcome pathways underlying the observed reduction in egg production and identify putative biomarkers of exposure for future evaluation in the field. The ultimate aim is to determine whether the concentrations of atrazine observed in the Chesapeake Bay watershed could be contributing to declines in health of fish and wildlife. We observed over-representations of genes with altered expression in gene ontology categories including lipid metabolism, steroid metabolism, cell surface receptor signaling pathway, cell adhesion, and signal transduction. These changes suggest a challenge to regulatory feedback loops of the hypothalamus-pituitary-gonad axis. Future investigations will focus on candidate adverse outcome pathways involving the maturation-inducing hormone pathway, cell membrane estrogen receptor pathway, and SF-1 pathway.

RP149 Assessing the Effect of Early Life Exposure to EE2 on the Innate Immune Response of Largemouth Bass

J. Hansen, USGS WFRC / Western Fisheries Research Center; S.R. Das, Pacific Northwest Diabetes Research Inst; J.C. Woodson, USGS / Western Fisheries Research Center; R.S. Cornman, USGS / Fort Collins Science Center; D.E. Tillitt, C.A. Richter, USGS / Columbia Environmental Research Center

Exposure to estrogenic endocrine disrupting compounds (EDCs) such as 17a-ethinylestradiol (EE2) has been associated with reproductive failure and developmental abnormalities in both largemouth and smallmouth bass in US watersheds. In this study, we addressed the impact of EE2 exposure on the initiation of innate immunity in largemouth bass larvae using RNAseq. For the first 70 d of life, largemouth bass larvae were either exposed to an environmentally relevant concentration of EE2 (1ng/L) or vehicle control. On day 70 pf, fish were then injected with either bacterial or viral mimics or saline for 24 hrs while still in the presence of EE2. Individual hepatic mRNA libraries (n=18, PE200) were sequenced at a depth of >40M reads which were then used for de novo assembly to generate a reference transcriptome for largemouth bass. The hepatic transcriptome consisted of over 130,000 contigs, which upon Blast2GO annotation against other fish led to the prediction of roughly 35,000 ORFs. The reference transcriptome was then used to measure differential expression of the control and experimental groups. Initial analysis of EE2 exposure alone to vehicle control demonstrated that over 630 mRNAs were differentially expressed ($p < 0.05$). Current research includes assessing and validating genes and pathways involved in innate immunity that were dysregulated upon stimulation with the microbial mimics and how chronic EE2 exposure modified the expression of these genes. The availability of the annotated reference transcriptome for largemouth bass will complement studies designed to assess how EDCs may lead to increased disease susceptibility.

RP150 Determining the estrogenicity of wastewater effluents and low concentration hormone treatments in chinook salmon and their recovery following exposure

H. Osachoff, BC Ministry of Environment / Land Remediation Section; V. Furtula, Environment and Climate Change Canada; J. Harkness, Urban Systems Ltd.; A. Goulding, Univ of British Columbia; G.C. van Aggelen, Environment and Climate Change Canada / Toxicology; C.J. Kennedy, Simon Fraser Univ / Dept of Biological Sciences

Considerable information exists about the estrogenicity of waste water effluents (WWEs) and their potential to feminize male fish; however, WWEs in many jurisdictions have not been characterized with respect to their constituents, estrogenicity, or potential for environmental impacts to aquatic life. In this study, two tertiary waste water treatment plant (WWTP) effluents from British Columbia, Canada were evaluated. Little is known regarding the estrogenic potential of these complex mixtures; initial chemical analyses indicated estrone (E1) and 17α-ethinylestradiol (EE2) may be present. Both WWTPs discharge to freshwater environments where culturally and economically-important Pacific salmon spawn, hatch, and spend the majority of their freshwater life stage as juveniles before migrating to the ocean. This study had two goals: (1) to determine the contribution of natural or synthetic estrogen hormones to the overall estrogenicity of the WWEs, and (2) to evaluate the effects and recovery of juvenile chinook salmon exposed to either these WWEs or pure estrogen hormones. Chinook were exposed to environmentally-relevant concentrations (1% and 5%) of WWEs for 7 d and then transferred to clean water to recover for a further 7 d. The WWEs were evaluated for sterols (hormone) composition and chinook were then exposed (same exposure regimen) to similar estrogen hormone concentrations: E1 (2 ng/L), EE2 (0.5 ng/L, the local water quality guideline), 17β-estradiol (E2; 1 µg/L, +ve control). Using hepatic vitellogenesis-related transcript expression, the estrogenicity of the E1 treatment was shown to be similar to one of the WWEs in terms of estrogenic potential. Numerous molecular and biochemical endpoints were evaluated to examine the ability of fish to recover from hormone or WWE-induced effects. Fish were able to recover from alterations to liver somatic index, and plasma [glucose] and [lactate]. However, endpoints that remained/became altered after 7 d of recovery in clean water included gill Na^+/K^+ ATPase activity, [leukocytes], gonadal somatic index, plasma [vitellogenin protein], and hepatic transcripts of estrogen receptor isoforms, vitellogenin and vitelline envelope proteins. These results show that not all altered endpoints in fish exposed to WWEs and estrogen hormones recover in the short term following exposure, which indicates the health and fitness of juvenile salmonids could possibly be impaired by environmentally-relevant WWEs or hormone exposures.

RP151 Are responses of wild fish to wastewater effluent consistent? An assessment of spatial and temporal variability of biological endpoints

M. Fuzzen, Univ of Waterloo / Biology; G. Tetreault, Enviroment Canada / Water Science and Technology Directorate; L. Bragg, Univ of Waterloo / Dept of Biology; P.A. Bahamonde, Univ of New Brunswick / Biology; R.N. Tanna, WorleyParsons Advisian / Environment and Society; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate Aquatic Contaminants Research Division; M.R. Servos, Univ of Waterloo / Dept of Biology

It is well established that exposure of aquatic organisms to endocrine disrupting chemicals (EDCs) contained in municipal wastewater effluent (MWWE) can have deleterious effects on the health of fish populations. While this has been well demonstrated in the laboratory, it remains difficult to associate EDCs in MWWE with impacts on the health of wild fish populations. Our ability to detect change in exposed ecosystems is currently limited by our poor understanding of how responses to EDCs vary across levels of biological organization. The purpose of this study was to evaluate biological indicators of EDC exposure by observing their annual variability in a wild population of fish exposed to MWWE. The system used to conduct this study was the central reach of the Grand River in Kitchener, Ontario, where two municipal wastewater treatment plants are located. Rainbow darter (Etheostoma caeruleum) were collected from sites across an urban gradient in the spring and fall between 2007 and 2012. Analysis of selected pharmaceuticals, liver gene expression, gonadal sex steroid production, gonad histology, and somatic indices were compared across years and seasons. We found that in this system the consistency of biological responses varies according to the level of biological organization. Exposure and biological measures at the lower levels of organization (e.g. gene expression) are highly variable while measures that were at the middle of the biological scale (e.g. gonad histology) were the most consistent between seasons and years. Although endpoints representing higher levels of biological organization (e.g. somatic indices) are desirable because of their relevance, they are influenced by natural variability and more difficult to link to specific stressors. The findings of this study have important implications for future research efforts on environmental impacts of contaminants, as well as for the design and interpretation of biological monitoring programs globally.

RP152 Effects of thyroid hormones, thyroid hormone disruptors, and treated wastewater effluent on chemosensation in Lithobates catesbeianus tadpoles

J. Heerema, Univ of Lethbridge / Biological; G.G. Pyle, Univ of Lethbridge / Biological Sciences; C.C. Helbing, Univ of Victoria / Dept of Biochemistry Microbiology

Endocrine disrupting compounds (EDCs) represent a large group of chemicals that have widespread use in our everyday lives, ranging from pharmaceuticals to personal care products. Consequently, EDCs enter municipal wastewater but are not fully removed by conventional wastewater treatment processes. Therefore low concentrations of EDCs are persistent in treated wastewater effluent. These low concentrations of EDCs in effluent may be biologically active and disruptive to the endocrine system in aquatic vertebrates. Some EDCs are able to disrupt the normal functioning of the thyroid system in vertebrates through agonism and antagonism of thyroid hormones (THs). Tadpoles are valuable sentinels for studying the effects of TH disruption because THs are the main drivers of metamorphosis. During metamorphosis the whole tadpole body plan is remodeled as the developing tadpole prepares for a semi-terrestrial and semi-aquatic lifestyle as an adult. In particular, THs trigger major structural and functional changes in the whole olfactory system. Therefore, TH disruption could lead to changes in chemosensory acuity in tadpoles. In this study, we exposed premetamorphic North American bullfrog (Lithobates catesbeianus) tadpoles to environmentally relevant concentrations of one of THs thyroxine (T_4), triiodothyronine (T_3); a cocktail of known EDCs; treated municipal wastewater effluent; or a negative control of 17β-estradiol (E_2). Chemosensory mediated avoidance responses to a stimulus (mixture of amino acids) were subsequently measured using an I-maze choice assay. The results show that T_3 impaired avoidance responses to the stimulus, but conversely T_4, E_2 and the cocktail of known EDCs had no effect on behavioral responses. Exposure to treated wastewater effluent however, did impair the chemosensory mediated avoidance responses to the stimulus. These results indicate that EDCs present at low concentrations in treated effluent may be able to mimic T_3, as avoidance responses to the stimulus were disrupted in both these treatments. It is important that chemosensory function remains intact in tadpoles, as it allows them to locate food and avoid predators. Therefore, chemosensory mediated behavior can serve as a sensitive environmentally relevant endpoint to detect TH disruption, and can be informative of the potential effects of EDCs in treated wastewater effluent receiving waters.

RP153 Toxicity of Triphenyltin on the Development of Retinal Axons in Zebrafish at Environmentally Relevant Concentrations

Y. Xiao, Peking Univ

The impacts of triphenyltin (TPT) on ecological health are of particular concern due to the unexpectedly high levels found in wild fish around the world. Here, zebrafish embryos were exposed to TPT via in ovo nano-injection to study its toxicity on the development of retinal axons in fish. Lipophilic dye labeling revealed obvious defects in retinal axon development in larvae with normally shaped eyes, with incidences of 0, 1.08%, 2.66%, 4.26%, and 6.85% observed in the control, 0.8, 4.0, 20.0, and 100 ng/g ww exposure groups, respectively, showing a dose-dependent increase. Larvae with retinal axon development defects exhibited dark coloration, indicating vision loss. Since the lowest observable effective concentration of TPT to induce retinal axon development defects was 0.8 ng/g ww, which is lower than the concentrations in wild fish eggs, this defect could occur in wild fish larvae. Alterations in the expressions of pax6 and ephrinBs, which regulate the establishment of retinal polarity, were correlated with defect incidence. Expression levels of the CYP26A1 gene and protein were significantly up-regulated in all exposure groups, which may lead to significant decreases in concentrations of retinoic acid (RA) precursors, retinol and retinal, though the sensitivity of the present LC-MS-MS method was insufficient to detect the concentrations of RAs in the zebrafish larvae. Such a disruption of retinoid homeostasis would, at least partly, contribute to the incidence of developmental defects in retinal axons. This study is the first to report that TPT at environmentally relevant concentrations can interfere with development of retinal axons in fish.

"One Health": Opportunities for SETAC Leadership in Integrating Environmental, Human and Animal Health

RP154 A One Health Approach To Study Mercury In Traditional Foods Of Bigstone Cree First Nation (Alberta, Canada)

N. Golzadeh, McGill Univ / Natural Resource Sciences; J. Baker, McGill Univ; M. Beaver, Bigstone Cree First Nation Community; N. Basu, McGill Univ / Dept of Environmental Health Sciences

Mercury (Hg) is a global pollutant of concern since it can affect public health and ecosystem quality. First Nations communities are particularly susceptible to mercury contamination given that their traditional foods, which play a significant role in their health, culture, recreation, and spirituality, are known to be contaminated with mercury. Most studies concerning mercury contamination in First Nations communities have focused on seafood, with relatively few studies on other food sources. Further, there can be great variability in mercury contamination across communities, and thus there is a need for site-specific information. The objective of this study is to characterize mercury (total and methylmercury) levels in 150 traditional food items of concern to the Bigstone Cree Nation (Alberta, Canada). Through a participatory research activity, we identified and collected 13 different categories of animal and plant items of concern (Labrador tea, Berries, Rat root, Moose, Soil, Mountain-ash, Grouse, Hare, Fish, Mint, Duck, Water lily and, miscellaneous meat and plant samples). The food samples were processed, dried, and then analyzed for total mercury using a Direct Mercury Analyzer (DMA-80). In the plant samples the highest average mercury levels were in old man's beard (145.7 ppb) followed by Labrador tea (20.7 ppb) and mint (20.5ppb). Analyses of the meat samples are currently in process, as well as the methylmercury determinations. The work is particularly suited for analysis through a One Health perspective, a perspective shared by Aboriginal communities worldwide. As such, the data will be analyzed with respect to potential impacts on humans, organisms, and ecosystems.

RP155 Quantitative analysis of 296 antibiotic resistance and related genes in human impacted environments

M. Virta, Univ of Helsinki; A. Karkman, Univ of Helsinki / Dept of Food and Environmental Sciences; T.A. Johnson, Michigan State Univ / Center for Microbial Ecology Dept of Civil and Environmental Engineering; K. Pärnänen, W. Muziasari, Univ of Helsinki; J. Muurinen, Univ of Helsinki / Food and Environmental Sciences; C. Lyra, M. Tamminen, Univ of Helsinki; R.D. Stedtfeld, J.M. Tiedje, Michigan State Univ / Center for Microbial Ecology Dept of Civil and Environmental Engineering

The origins of antibiotic resistance in the environment is relevant to human health because of the increasing importance of zoonotic diseases as well as the need for predicting emerging resistant pathogens. Antibiotics are used in diverse settings for food production. Domestic animals are treated with antibiotics for both curing disease and promoting growth. Moreover, aquaculture relies on antibiotics to manage infectious disease. Wastewater treatment plants receive sewage from various sources, including hospitals and households which are both important sources of antibiotics and their residues, and antibiotic resistant bacteria. We have characterized the antibiotic resistance gene profiles by using parallel quantitative PCR array targeting 296 genes. Samples were collected from different locations in Finland: manure from cattle and pig farms, soil that received the manure as fertilizer, sediments from aquaculture farms and effluent, influent and activated sludge from waste water treatment plant. Total DNA was isolated and the genes were quantified using highly parallel qPCR array on Applied Biosystems OpenArray platform and normalized with 16S rRNA gene numbers. Altogether 184 genes were found from the waste water treatment plant. Untreated inflow water contained the highest number of genes, followed by the final effluent and sludge. 71 of the genes were found in aquaculture sediments. The antibiotic resistance genes against to the antibiotics that have been used in the aquaculture farms were clearly enriched. The numbers of the antibiotic resistance genes was increased in the cattle and pig manure in the farms that used antibiotics and the spreading of the manure increase that amount of antibiotic resistance genes in the soil. In addition to the antibiotic resistance genes, the genes related to the genetic mobility were enriched by human impact which may implicate increase in the horizontal gene transfer by human activities. Our results demonstrate that human activities can results to the increase to the abundance of antibiotic resistance genes which may lead to the enrichment of the resistance and transfer of the resistance genes to the pathogens.

Passive Sampling in the Aquatic Environment: Recent Developments and Advances

RP156 Evaluation of porewater reductions due to carbon placement via sedimite and aquagate at a contaminated sediment site

M. Rakowska, Texas Tech Univ / Civil Environmental and Construction Engineering; S. Yan, Texas Tech Univ / Chemical Engeneering; T. Hussain, Texas Tech Univ / Dept of Civil Environmental and Construction Engineering; X. Shen, Texas Tech Univ / Environmental Engineering; D.D. Reible, Texas Tech Univ / Civil and Environmental Engineering; T. Himmer, CH2M; C.A. Irvine, CH2M / Ecosystem Services; J. Eby, CH2M; D. Janda, Navy Base San Diego

Activated carbon is increasingly used to reduce contaminant bioavailability in sediments as a remedial measure. Activated carbon is often placed as a composite material to aid in settling and retention at the sediment surface. A demonstration of two such composite materials, Sedimite and Aquagate, was conducted in PCB contaminated sediments in open water near Hunters Point, CA. The materials were allowed to settle directly to the sediment surface. Here the changes in porewater concentration in the surface sediments and in deeper layers up to 40 cm below the sediment surface were evaluated by passive sampling using polydimethylsiloxane (PDMS) coated fibers to measure porewater concentrations of PCBs. Our goal was to evaluate and compare changes to in situ hydrophobic organic compound (HOC) porewater concentrations before and after activated carbon placement and between the two different activated carbon placement methods. The pilot study was conducted at Hunters Point Naval Shipyard (HPNS). For passive sampling, SPME fibers (34.5 µm PDMS coating) were preloaded with 7 C^{13} PCB congeners as performance reference compounds (PRCs). PDMS fibers were inserted to unshielded holders, attached to a tripod frame and embedded vertically 30 cm into the sediment for triplicate measurement of porewater concentration at the 20 sampling locations. After 28 days the fibers were retrieved, sectioned into a 1-6, 11-16 and 21-26 cm segments below the sediment surface and analyzed for PRCs and 111 PCB congeners using GCTQMS. Bulk sediment samples were also collected and the concentrations quantified by GCTQMS. Baseline sampling showed uniform porewater concentrations across the site with lower concentrations in the near surface versus the deeper layers due to exchange with the overlying water from the shallower zone. Statistical analysis showed that the porewater samples were well correlated with nearby samples. After AC placement, porewater concentrations decreased from a baseline average of 2.2 ng/L to 0.35 ng/L in the surficial layer. Smaller but significant reductions in porewater concentration was noted at the deeper depths. AC also influenced the approach to steady state of the passive samplers with more rapid approach to steady state post-placement. The influence of nonlinear sorption on the PRC analysis was evaluated by modeling and indicated that the presence of activated carbon can cause traditional analyses to overestimate the fractional approach to steady state.

RP157 In situ porewater sampling of PCDD/Fs and PCBs to predict their bioaccumulation in Passaic River benthic invertebrates

M. Khairy, Univ of Rhode Island; R. Lohmann, Univ of Rhode Island / Graduate School of Oceanography; D. Adelman, Univ of Rhode Island

Polyethylene samplers were deployed four times at four different locations along the lower Passaic River in sediment and water column from June, 2015 to February, 2016. At the same time, sediment and benthhic invertebrates were collected from the deployment sites. All samples were analyzed for mono- through octa-chlorinated dioxins and furans, and polychlorinated biphenyls, PCBs. Concentrations of sum 89 PCBs in the porewater as obtained from the in situ sampler ranged from 2.0 ng/L (site S1) to 5.0 ng/L (site S2) with an average concentration of 3.0 ng/L. PCDD/F concentrations in porewater generally ranged from 24 pg/L (Site 1) to 41 pg/L (Site 3) with an average concentration of 32 pg/L. In both cases, in situ porewater concentrations were in the same range as laboratory eqiulibrations of those sediments with passive samplers. For the in situ eqiulibrations, the use of PRCs was of critical importnace to correct for non-eqiulibrium attained during field deployments.Three different PRC combinations were compared to laboratory-obtained porewater results. For the in situ multisampler deployments, there is some benefit of using both d-PAHs + $^{13}C_{12}$-PCDDs for PCDD/Fs quantitation. Freely dissolved concentrations of PCBs in the river water ranged from 1.3 ng/L to 1.8 ng/L, with no statistical significant difference between the different sampling sites. Lipid normalized concentrations of PCBs and PCDD/Fs were estimated from sediment, porewater and river water and compared to measured lipid normalized concentrations in the benthic species. Porewater and sediments using the black and organic carbon scenario were generally better predictors of lipid concentrations of PCBs and PCDD/Fs. Additionally, good prediction of the lower chlorinated PCBs (mono- through tetra-) were also obtained from the river water (polyethylene deployed in the water column above the bottom sediments). Based on our results, exposure to porewater and to a lesser extent river water and the probable ingestion of sediment particles are the possible sources of bioaccumulation of PCBs and PCDD/Fs in the lower Passaic River, which indicates that deployed olyethylene samplers (either in the river water or the sediments) are good predictors of tissue concentrations of the benthic species.

RP158 Passive samplers for in situ measurement of pyrethroid insecticides in surface water

J. Gan, Univ of California, Riverside / Dept of Environmental Science; A. Xue, Univ of California Riverside; C. Liao, Univ of California Riverside / Dept of Environmental Science; Z. Cryder, Univ of California Riverside

Pyrethroid insecticides are widely used in urban environments, and their occurrence in urban surface streams has been associated with acute aquatic toxicity to invertebrates, especially in regions such as California. Pyrethroids are strongly hydrophobic compounds, and studies have shown that the freely dissolved concentration (C_{free}) is more predictive of their bioavailability and toxicity to aquatic species. In this study, we developed a passive sampling approach for in situ monitoring of low levels of pyrethroid insecticides under field conditions. Evaluation of a series of polymers suggested that polyethylene film (PE) exhibited the highest uptake capacity for pyrethroids. To overcome the slow uptake kinetics and circumvent the requirement of long time interval to reach equilibrium, isotope-labeled permethrin and bifenthrin were used as performance reference compounds (PRC) to preload the PE sampler. Desorption of isotope-labeled pyrethroids and absorption of non-labeled analytes were isotropic, validating the assumption for the PRC method. The PRC-PE calibration method was then validated in large tanks under simulated flow conditions, where the effect of salinity and dissolved organic matter on bioavailability was also determined. The optimized method was further deployed for 7 d at multiple locations in southern California for in situ monitoring of pyrethroids. The results indicated that the PRC-PE sampler may be used for in situ monitoring of pyrethroids in surface streams under field conditions with flexible sampling intervals and sufficient sensitivity.

RP159 Using a Commercially-available Passive Sampling Device To Monitor Hydrophobic Organic Contaminants in the Laboratory and the Field

J. Roberts, SiREM; J.M. Conder, M. Vanderkooy, Geosyntec Consultants; M. Healy, SiREM; J. Thompson, C. Thomas, M.M. Grover, Geosyntec Consultants

Passive sampling devices (PSDs) present many advantages over conventional aqueous samples for quantifying hydrophobic organic compound (HOCs) concentrations in pore water (sediment and soil), surface water and storm water in terms of cost and data usability. They provide data to estimate contaminant bioavailability and toxicity to environmental receptors that is more representative than conventional grab samples, as it quantifies contaminants only in the dissolved form. In the field, PSDs enable collection of representative- and depth-discrete data without the need to collect large volume aqueous samples. Similarly, in laboratory treatability studies to evaluate remedial options for contaminated sediments or soils, passive samplers help to decrease the volume and number of samples required. Passive samplers deployed in these studies provide the ability to compare different treatment technologies in a relatively short time frame, test multiple conditions concurrently, and enable the flexibility to allow changes to a remediation strategy that would be impractical at field-scale. This presentation will highlight the benefits of using PSDs in both laboratory treatability studies and field applications as well as discuss the practical lessons learned from applying passive sampling techniques, drawing from several case studies using a commercially-available PSD. In one study, PCB availability of a sediment amended with activated carbon, zero valent iron, siderite and sulfur was measured with PSDs. The results were used to determine the most effective commercial amendment for decreasing PCB concentrations in pore water, with PSDs demonstrating that the selected remedy achieved a >95% reduction in PCB availability. In another study, PSDs were used to characterize PCB concentrations in sediment pore water amended with different amounts of activated carbon and the results were used to determine the optimal dose of carbon for the field application, with PSDs demonstrating that the optimal activated carbon application rate resulted in a 98% reduction in PCB availability. At this same site, PSDs were deployed in the field to provide baseline PCB availability data prior to activated carbon amendment, and the PSDs will be used for post amendment monitoring to document remedial success. It is clear that currently-available passive sampling approaches are ready for widespread application and can provide high-quality data to aid environmental decision makers.

RP160 Sensing organic pollutants in aquatic environment by passive sampling techniques

E.Y. Zeng, Jinan Univ / School of Environment

Organic contaminants, such as persistent organic pollutants, have the potential to cause adverse effects on humans and wildlife because of their toxicity and bioaccumulation and/or biomagnification through the aquatic foodweb. Measurement of dissolved organic contaminants in water can provide important information for predication of organic contaminants in aquatic species, as well as the magnitude of human exposure. Passive sampling techniques are easy to operate and cost-effective, hence create new opportunities for monitoring organic contaminants in aquatic environment around the world. Among the available passive samplers, polyethylene (PE) devices have been recommended as preferred alternatives for sensing organic contaminants in aquatic environment because they are biomimetic, inexpensive, and convenient for field deployment. A self-developed passive sampler with PE as sorbent phase has been demonstrated to be capable of reasonably quantifying dissolved organic contaminants in coastal seawater and in freshwater lakes in Antarctica and China. The highest level of PAHs in Antarctica and in China was found around Russian Progress II Station and Southern Lake in Wuhan, respectively, both indicating the significance of human activities to the loadings of PAHs. In China, the concentrations of PAHs gradually increased from Western China (Xinjiang and Tibet) to Eastern China (Liaohe River, Songhua River and the lower reaches of the Yangtze River), showing a similar strong correlation with population density. The composition profiles of PAHs in Antarctica indicated that PAHs in the inland lakes were derived mainly from local oil spills, while mixed PAH sources, i.e., coal combustion, refined fossil fuel combustion and oil spills, occurred in China. Our results indicate the feasibility of establishing a global aquatic network of organic contaminants with PE passive samplers, which is critical for enhancing the long-term health risk assessment for humans and wildlife.

RP161 Passive sampling for priority substances at semi polluted River Porvoonjoki, Finland

P.T. Kajankari, Univ of Helsinki / Dept of Environmental Sciences; O. Penttinen, Univ of Helsinki / Faculty of Biological and Environmental Sciences; A. Rantalainen, Univ of Helsinki / Dept of Environmental Sciences

European Union has set the water policy directive 2008/105/EC which classifies 45 substances or substance groups as priority substance list. It sets environmental quality norms for annual average and maximum allowable concentration for inland and other surface waters and biota. From a monitoring perspective simple and reliable method is of major importance. In this study the performance of specific passive sampling device for the monitoring of dissolved concentrations of three priority substances was assessed through a field deployment of samplers along slightly polluted river in Southern Finland. Selected substances are commonly used in Finland for different purposes. Polybrominated diphenyl ethers (PBDE) are used as flame retardants. Neurotoxic cypermethrin is a pesticide that belongs to pyrethroids. Nonylphenol is used by chemical industry and is endocrine disruptor. They are all in the priority substance list and are considered toxic. They are all also lipophilic (log K_{ow} >3), and therefore they should accumulate in lipid passive samplers. River Porvoonjoki is 143 km long and its drainage basin is 1273 km^2. The river is located in Southern Finland and runs from the Lahti region to the Gulf of Finland. Three wastewater treatment plants along the river are the major source of chemical input to natural watercourse including a discharge of treated wastewaters of 150 000 citizens. The natural flow of the river is low and from time to time one third of the river's water can be treated wastewater. Passive sampling devices accumulate chemicals continuously from water providing a measure of average river conditions and pollution status over the exposure period of 30 days instead of active water sampling that only gives information of exact moment. The sampling was taken with passive sampling devices (PSDs) from water. The PSDs were 48 cm long low-density polyethylene (LDPE) layflat tubing filled with 0.5 mL of triolein. Specific sampler type was chosen because the chosen chemicals have high log K_{ow}, thus highly lipophilic, and are uptaken by triolein. The samples were taken from water because the EU's WPD gives quality norms for waters. The samplers were deployed to the river Porvoonjoki on September 2015 and the study was repeated on summer 2016. The chemicals were analysed with GC-MS. Uptake rates of the chemicals were either taken from the literature (nonylphenol and PBDE) or uptake rates were determined at laboratory (cypermethrin).

RP162 Field evaluation of membrane assisted passive sampler for isolation and identification of pharmaceutical and personal care products in natural waters

H. Nyoni, B. Mamba, T. Msagati, Univ of South Africa / Nanotechnology and Water Sustainability Research Unit

One of the major challenges in routine monitoring programmes is the isolation and identification of substances whose fate, behaviour and (eco) toxicological effects are not well understood. Pharmaceuticals and personal care products and their degradation products exhibit adverse effects on biota and human health, yet their occurrence, distribution and fate is not well understood. This work reports findings on the use of passive sampling devices in addressing the challenge of isolation and identification of selected emerging pharmaceuticals and personal care products and their degradation products in natural waters. Aqueous sampling rates for selected pharmaceuticals and personal care products were determined on the membrane assisted passive sampling device (MAPS) and commercially available Polar Organic Chemical Integrative Sampler (POCIS). Field calibration studies of the passive sampling devices spiked with performance reference compounds were performed, and the resulting time-weighted average concentration estimates were compared with laboratory derived values.

RP163 Fugacity gradients of hydrophobic organics across the air-water interface measured with a novel passive sampler

W. Chen Chou; L. Bao, E.Y. Zeng, Jinan Univ / School of Environment

Mass transfer of hydrophobic organic contaminants (HOCs) across the air-water interface is an important geochemical process controlling the fate and transport of HOCs at the regional and global scales. However, few studies have characterized concentration or fugacity profiles of HOCs near both sides of the air-water interface, which is the driving force for the inter-compartmental mass transfer of HOCs. Herein, we introduce a novel passive sampling device which is capable of measuring concentration (and therefore fugacity) gradients of HOCs across the air-water interface. Laboratory studies indicated that the escaping fugacity values of polycyclic aromatic hydrocarbons (PAHs) from water to air were negatively correlated to their volatilization half-lives. Results for field deployment were consistent between the passive sampler and an active method, i.e., a combination of grab sampling and liquid-liquid extraction. In general, the fugacity profiles of detected PAHs were indicative of an accumulation mechanism in surface microlayer in the study regions (Haizhu Lake and Hailing Bay of Guangdong Province, China), while p,p'-DDD tended to volatilize from water to the atmosphere in Hailing Bay. Furthermore, the fugacity profiles of the target analytes generally decreased and then increased towards the air-water interface, reflecting the complexity of environmental behavior of the target analytes near the air-water interface. Overall, the passive sampling device provides a novel means to better characterize the air-water diffusive transfer of HOCs, facilitating the understanding of the global cycling of HOCs.

RP164 Temporal and spatial monitoring of persistent organic pollutants on the Palos Verdes Shelf using two passive sampling methods

G. Flavetta, Northeastern Univ / Civil and Environmental Engineering; W. Lao, Southern California Coastal Water Research Project; K.A. Maruya, SCCWRP; R.M. Burgess, USEPA; L. Fernandez, Northeastern Univ / Civil and Environmental Engineering

Passive sampling methods now allow for the collection of large amounts of data with minimal effort. Because large data sets are necessary to determine spatial and temporal trends in the concentrations of persistent organic pollutants (POPs) in the coastal ocean, passive sampling tools are ideally suited to these types of studies. In September 2010 and 2013, polyethylene films (PE) and solid-phase microextraction fibers (SPME) were co-deployed to determine the dissolved concentrations of POPs on the Palos Verdes Shelf (PVS) Superfund site. During the 2010 sampling event, the two types of samplers produced similar but offset results. The goals of the 2013 sampling campaign were to (1) investigate the potential sources of the offset between results from the two sampler types, and (2) investigate the temporal and spatial stability of concentrations at the Superfund site. Results from both sampling campaigns indicated increasing dissolved concentrations of POPs with proximity to sediment bed, and in a north-west direction along the shelf for several km before the concentrations began to decrease. Temporally, concentrations between the two sampling events were within a factor of three. Additionally, the use of temperature correction factors to PE and the use of performance reference compounds for SPME impacted the concentrations by factors of two and three, respectively. Despite two successful congruent sampling events, additional monitoring will be needed to determine long-term trends or statistically significant changes in dissolved POPs on the PVS.

RP165 Reducing the Impact of Flow on the Sampling Rate of POCIS

J.B. Belden, S.A. Morrison, Oklahoma State Univ / Integrative Biology; G.H. Rosen, SPAWAR Systems Center / Energy and Environmental Sustainability; G.R. Lotufo, U. S. Army ERDC / Environmental Laboratory; R.D. George, Us Navy Spawar Systems Center / Environmental Sciences

Polar Organic Chemical Integrative Samplers (POCIS) have been demonstrated as a promising technique for measuring water concentration of many organic compounds. However, current sampler designs and technology do not account for variations in sampling rate due to changes in flow velocity and turbulences near the sampler. Thus, our research targeted two different approaches to improve calibration of samplers including: 1) placement of flow restrictive screens around the sampler to cause a stable boundary layer to develop around the sampler; and 2) test potential performance reference compounds (PRCs) to measure in-situ sampling kinetics allowing adjustments of sampling rates. Moderately high flow (10 cm/s) resulted in 466 and 418 % higher sampling rates for TNT and atrazine, respectively, with no modification to the POCIS. However, placement of a nylon mesh screen (0.100 mm mesh) on the outside of the POCIS reduced differences in sampling rates across flow to less than 25%. In a separate experiment, stable isotope labelled caffeine was used as a PRC. Through correction of the sampling rate based on the rate of loss of caffeine from each sampler, differences in sampling rates across flow were reduced to less than 30% for TNT and atrazine. However, the PRC did not perform as well for all analytes tested. Both techniques are promising for increasing the accuracy of POCIS.

RP166 Calibration of Organic-Diffusive Gradients in Thin Film (o-DGT) Passive Samplers for Perfluorinated Chemicals (PFCs) in Water

K. Luong, Univ of Winnipeg / Richardson College for the Environment; T.C. Vera, Univ of Winnipeg; J.K. Challis, Univ of Manitoba / Chemistry; C.S. Wong, Univ of Winnipeg / Richardson College for the Environment

The calibration of perfluorinated compounds (PFCs) was assessed with the organic-diffusive gradients in thin films (o-DGT) passive sampler. Monitoring for PFC contaminants in waters is important given their environmental persistence and bioaccumulation. The few attempts at passive sampling for PFCs have largely relied on the polar organic chemical integrative sampler (POCIS). While successful, determination of chemical concentrations with POCIS can be plagued by significant uncertainties given limitations in predicting effects of environmental variables (e.g., water flow rate, temperature, etc.) on POCIS sampling rates. The main advantage of o-DGT is its insensitivity in sampling rate towards flow rate of water, eliminating the need for extensive in situ calibration. Six PFCs were studied: perfluoro-n-decanoic acid, perfluoro-n-nonanoic acid, perfluoro-n-undecanoic acid, perfluoro-n-octanoic acid, perfluoro-1-octanesulfornic acid, and perfluorobutane-1-sulfonic acid. A diffusive cell experiment showed that diffusion coefficients of these PFCs through the diffusive gel layer ranged from 2.20 to 3.88×10^{-6} cm^2/s at 23°C. A calibration test was performed to determine the kinetic uptake of PFCs to o-DGT; these experimental sampling rates were compared to theoretical values (i.e. Hayduk-Laudie model) and to the measured diffusion coefficients. The sampling rates calculated from measured diffusion coefficients were in general agreement with the sampling rates measured in the calibration experiment (relative errors < 40%). This result indicates that diffusion coefficients alone can estimate sampling rates for o-DGT, thus eliminating the need for full scale laboratory calibration required in POCIS.

RP167 Extending the scope of passive sampling for contaminated sediments: standardizing methods for moderately hydrophobic organic contaminants

K.A. Maruya, SCCWRP; W. Lao, D. Tsukada, D. VanDervort, Southern California Coastal Water Research Project; Y. Hong, SCCWRP, UCR, Inst of Urban Environment, Chinese Academy of Sciences; J. Gan, Univ of California, Riverside / Dept of Environmental Science

Passive sampling methods for determining the freely dissolved concentrations (Cfree) of organic contaminants in sediment are focused on those that are highly hydrophobic (e.g. log Kow > 5). However, organic contaminants of concern are not limited to only those that meet this criteria. In this study, we propose standardizing and validating protocols that utilize different polymeric materials to target chemicals of concern in sediment that exhibit a wide range of hydrophobicity (i.e. 3

RP168 Accessibility of Diffusive gradient in thin films (DGT) Samplers to representative Hg forms in sediments

B. Anandha Rao, Texas Tech Univ / Civil and Environmental Engineering; G. Bland, Texas Tech Univ; D.D. Reible, Texas Tech Univ / Civil and Environmental Engineering

Interstitial or sediment pore water concentrations have been demonstrated to relate with bioavailability and bioaccumulation. However, traditional techniques used for pore-water sampling such as the Henry's sampler have severe limitations (e.g., inability to obtain uncompromised sample at multiple depth intervals) resulting in inadequate sediment characterization. Recent development and application of passive sampling devices such as diffusive gradient in thin film (DGT) samplers has mitigated many of the addressed issues. DGTs can profile in-situ Hg pore-water in sediments at relatively high resolution and at time scales relevant to biological processing. Despite its advantages, the question still remains on what DGT really measures and how it relates to the 'truly' bioavailable mercury fraction in sediment pore-waters. Particulate Hg (> 0.45 µm) is neither expected to be bioavailable nor accessible by DGTs, whereas, the truly dissolved (< 1 nm) are readily accessible by both biota and DGT. The bioavailability of intermediate sizes is unknown but colloidal particles > 20-50 nm in size are unlikely to pass a cell wall without active transport processes. Similarly, colloidal particles in this size range have diffusivities 10-100 times are unlikely to diffuse into a DGT at significant rates. To explore this hypothesis, different molecular sizes of Hg inorganic/organic complexes (from 'dissolved' to high molecular weight colloids) were prepared followed by measurement of the Hg uptake by DGTs. The Hg-organic colloids included both broadly size fractioned natural organic matter and distinctly sized synthetic polymers containing strong Hg binding sites. The measured diffusion coefficient of these colloidal-Hg forms through the DGT gel layer were then correlated to the size fractions accessible by the DGTs. Finally, the results from these studies will be used to discuss the biological relevance (e.g., methylation potential) of different Hg size forms taken up by DGTs.

RP169 Polyethylene: An Alternative Passive Sampler for Monitoring Fluorotelomer Alcohols

E. Dixon-Anderson, R. Lohmann, Univ of Rhode Island / Graduate School of Oceanography

Fluorotelomer alcohols (FTOHs) and other poly-fluorinated alkyl substances (PFASs) are common and ubiquitous by-products of various industrial telomerization processes. This class of volatile and semi-volatile compounds has been shown to degrade into a wide variety of perfluorinated carboxylic acids (PFCAs) including perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS), persistent organic pollutants. Recent atmospheric studies have shown the presence of fluorotelomer alcohols and their degradation products present in high concentrations spreading out from point sources in North America, Europe, and Asia. This study develops a method for the widespread monitoring of fluorotelomer alcohols in air and water through the use of polyethylene (PE) passive samplers and gas chromatography-mass spectrometry (GC/MS). To achieve this, PE-water and PE-air partitioning coefficients need to be known. Kpe-w's were determined via a time series of water-PE exposures using known concentrations of PFASs including FTOHs, sulfonamides (FOSAs), and sulfonamidoethanols (FOSEs). A field validation study in Providence was set up to determine the Kpe-a's via a time series of exposure. Log Kpe-w's, for FTOHs were found to range from 2.8-5.3 while sulfonamides (FOSAs) and sulfonamide ethanols (FOSEs) were found to range from 4.9 to 5.4.

RP170 Field Evaluation of organic-DGT and POCIS: Presence and Sources of Pesticides and Pharmaceuticals in the Lower Red River

J.K. Challis, Univ of Manitoba / Chemistry; K. Luong, Univ of Winnipeg / Richardson College for the Environment; M.L. Hanson, Univ of Manitoba / Dept of Environment and Geography; C.S. Wong, Univ of Winnipeg / Richardson College for the Environment

Current passive sampling designs for polar organic contaminants in water lack the ability to easily adjust uptake rates under varying environmental conditions (e.g., flow rate, temperature), often leading to large uncertainties in measurements. This issue significantly reduces the overall applicability of polar passive samplers (e.g., Polar Organic Chemical Integrative Samplers; POCIS). The diffusive gradients in thin films (DGT) sampler, popular for metals sampling, is largely insensitive to effects of flow on sampler uptake and allows for simple measurement/modelling of temperature-specific sampling rates. Our previous work successfully adapted and calibrated DGT samplers for a suite of polar organic contaminants (hence, organic-DGT), demonstrating that uptake by o-DGT was linear over 3-4 weeks at environmentally relevant concentrations, and compound specific sampling rates were largely independent of water flow. We evaluated the utility of the o-DGT passive sampler in the Red River, a large river system originating in the United States and emptying into Lake Winnipeg, Canada, the 10th largest freshwater lake in the world. A total of six sampling sites along the Red River were monitored continuously from April to September (2-3 week deployments) to assess transport of pesticides and pharmaceuticals from the US-Canada border into Lake Winnipeg. To validate o-DGT, samplers were co-deployed with POCIS to highlight the benefits and limitations of both. The herbicide atrazine was detected at all sites over the entire season, with concentrations ranging from 10-30 ng/L. Neonicotinoid insecticides, including thiamethoxam and clothianidin were only detected at the agricultural dominated sites where concentrations from 5-50 ng/L were observed. Various pharmaceuticals, including trimethoprim, sulfamethoxazole, and carbamazepine, were generally detected only downstream of the city of Winnipeg at concentrations up to 15 ng/L. In most cases o-DGT and POCIS were in general agreement, however at certain sites and times POCIS appeared to systematically underestimate water concentrations compared to o-DGT, likely a result of POCIS uptake being highly variable with water flow and temperature. This study illustrates the promise of o-DGT as a robust, widely applicable monitoring tool with the ability to account for flow-rate and temperature effects in-situ, two factors plaguing the reliability of current polar passive samplers.

RP171 o-DGT passive sampler for in situ sampling of antibiotics in waters

C. Chen, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry; H. Zhang, Lancaster Univ / LEC; K.C. Jones, A.J. Sweetman, Lancaster Univ / Lancaster Environment Centre; G. Ying, Chinese Academy of Sciences / State Key Laboratory of Organic Geochemistry

Passive water sampling has several advantages over active methods: providing TWA data, saving time and cost and yielding high spatial resolution data. One problem of many current samplers is that their sampling rates for are flow-rate dependent, thereby requiring calibration data and other information to enable water concentrations to be derived. A novel passive sampler (called o-DGT) for organic chemicals (antibiotics as model compounds) based on diffusive gradients in thin-films (DGT) was developed[1] and tested[2] to overcome some drawbacks of current samplers, and then employed to assess the removal of antibiotics in WWTPs[3]. DGT can be extended to organic chemicals with XAD18 as the new binding phase and agarose as the novel diffusion gel. The measured diffusion coefficient (D) with a diffusion cell allows temperature correction and derivation of aqueous concentrations. o-DGT sampler was then tested in a waste water treatment plant (WWTP) for a range of antibiotics. Fourteen antibiotics were detected in the actively sampled water samples, with 10 of the 14 detected in o-DGT deployed for more than 7 days. This time interval is recommended to integrate aqueous concentrations over time, without risks of reaching capacity and significant biofouling. DBL thickness had less effect on the o-DGT measurement than reported for other passive samplers. o-DGT gave comparable results to the automatic sampling but is more cost effective; both were more satisfactory than grab sampling. Sampling in two WWTPs (Chinese and British) showed that Neither of the WWTPs was very effective at removing antibiotics: ~40–50% (overall) was removed by the two plants, with the rest being discharged into the receiving rivers. o-DGT is useful and cost-effective tool for routine environmental monitoring and can highlight the effectiveness of treatment steps, which can be applied to wastewater based epidemiology studies.

RP172 Development of a novel passive sampling strategy for methylmercury in sediments and soils

J.P. Sanders, U. Ghosh, Univ of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering; A. McBurney, C.C. Gilmour, Smithsonian Env. Research Center

Mercury in sediments can pose a significant risk to ecological and human health when it is converted to the more toxic and bioaccumulative methylmercury (MeHg) by anaerobic microorganisms near the sediment-water interface. Benthic organisms exposed to MeHg in this zone represent an important link in the process of MeHg bioaccumulation in aquatic food webs. As such, quantitative measures of the bioavailability of MeHg to benthos are important for contaminated site risk assessment. To date, no passive sampling strategy has achieved wide acceptance for generating such measurements. Existing equilibrium technologies such as "peepers" are based on size exclusion, while the diffusive gradient in a thin film (DGT) approach employs high-affinity chemisorption and operates in a continuous, kinetic mode. We are working to develop a novel passive sampling technology for MeHg using a hybrid accumulation strategy to emulate the steady-state (pseudo-equilibrium) mode of bioaccumulation by benthos. A target for sampler partitioning of MeHg was established at log K between 3.0 and 4.5, to approximate typical benthic bioaccumulation factors and sediment-water partitioning constants. A variety of custom materials consisting of either thiolated sorbents or activated carbon embedded in support polymers was prepared and evaluated in increasingly environmentally realistic experiments. In initial tests in 3 ppt Instant Ocean solution, many of the materials showed strong, linear partitioning of MeHgCl across a relevant range of concentrations. Subsequent tests in the presence of MeHg complexed to dissolved organic matter found somewhat decreased accumulation by polymers, but log Ks remained in or near our target range. The most promising polymers were exposed in contaminated soil slurries. Polymer log K values were within 0.5 log units of soil K_d. Pore water MeHg concentrations estimated using polymer accumulation and measured partitioning constants for the MeHg-DOM complex agreed within a factor of one to four with direct measurements of centrifuged pore water. An experiment is now underway to characterize the kinetics of uptake by polymers. Future work will attempt to correlate MeHg bioaccumulation by the amphipod L. plumulosus with measurements by our sampling polymers deployed alongside the organisms in test microcosms. Sampling measurements will be used as input for a bioaccumulation model to validate the predictive capability of the device.

RP173 Next-generation environmental passive sampler materials: Electrospun nanofiber mats (ENMs)

A. Martinez, Univ of Iowa / Civil and Environmental Engineering IIHRHydroscience and Engineering; J. Qian, B. Jennings, The Univ of Iowa; D.M. Cwiertny, Univ of Iowa / Dept of Civil and Environmental Engineering

Using electrospinning, we synthetized seven electrospun nanofiber mats (ENMs) from polymers (ethylene-vinyl-acetate, polyacrylonitrile, polyethylene terephthalate, polymethylmethacrylate, polystyrene, polyvinyl acetate and polyvinylidene fluoride) and investigated their performance as next-generation passive sampling materials. Given the ease of material fabrication, we were able to tune the physical-chemical properties of ENMs to produce robust materials with improved selectivity and enhanced sorption capacities for polar and nonpolar pollutants. We tested ENM in homogeneous aqueous systems and heterogeneous systems (model soils) against aniline and nitrobenzene, and PCBs and dioxin. Aqueous uptake experiments yielded very fast rates of partitioning with equilibration times < 1 d. Equilibrium partition coefficients (L/kg) for ENMs ranged from 0.7 to 3 log units for aniline and nitrobenzene, suggesting uptake via partitioning into the bulk nanofiber (i.e., absorption) and specific binding interactions (e.g., H-bonding, Coulombic interactions). PCBs and dioxin yielded very fast equilibrium uptake (< 18 h), with equilibrium partition coefficients ranging from 3 to 6 log units. The partition coefficients measured for the best performing ENMs often exceeded partition coefficients achieved with available passive sampling materials (e.g., LDPE, PDMS glass fiber). Across a range of experimental conditions (pHs, analyte concentration and mixtures), little change in ENM performance was observed. We also found promising performance in heterogeneous systems with model soils, where polystyrene, not only yielded reproducible measurement of nitrobenzene pore water concentration but also allowed ease of handling by minimizing unwanted ENM-soil organic matter interactions. Further efforts improved performance via fabrication of novel ENM composites and surface-chemical functionalized ENMs. The inclusion of carbon nanotubes or anionic surfactants could be used to promote uptake of aniline (by as much as 1 log unit in partition coefficient). Further, integration of Ag nanoparticles to ENMs can be used to impart biocidal activity, thus slowing biofouling during deployment. We also fabricated novel multilayer ENMs, in which layer-by-layer combinations of different polymers impart multi-target capabilities (e.g., simultaneous uptake of polar and nonpolar species) and greater ease of application and handling in complex media (e.g., protective surface layers that limit fouling).

RP174 Bioanalytical Effect-Balance Model to Determine the Bioavailability of Organic Contaminants in Sediments Affected By Black and Natural Carbon

J. Bräunig, National Research Centre for Environmental Toxicology (Entox) / National Research Centre for Environmental Toxicology Entox; J.Y. Tang, The Univ of Queensland / ENTOX; M.S. Warne, Coventry Univ / Centre for Agroecology Water and Resilience; B. Escher, Helmholtz Centre for Environmental Research GmbH – UFZ / Cell Toxicology

Several important binding entities in sediments dictate the fate and availability of organic contaminants in marine sediment water systems. Black carbon (BC) has been shown to have a high sorptive capacity for organic contaminates and to limit their bioavailability and thus the risk of exposure to organisms, while the fraction bound to organic carbon (OC) is considered to readily desorb and thus this fraction is bioavailable. So far, binding of single compounds or defined compound classes to BC in natural sediments has been investigated using chemical analysis. In this study we expand the investigation to mixtures of chemicals by combining passive sampling with in vitro bioanalytical tools. The advantage is that these tools will not only give information on the bioavailability of sediment-associated contaminants but also their mixture toxicity. As a case study we investigated sediments from an Australian coal-exporting harbour with high BC load, and sediments from a tropical agricultural area and a subtropical urban area with lower BC contents as reference sites. Accelerated solvent extraction was used to exhaustively extract sediments. Tenax extraction and PDMS (polydimethylsiloxane) passive sampling were used to differentiate total from readily desorbable (bioavailable) concentration, and overlaying water was extracted with solid phase extraction and served as a proxy for pore water. All extracts were characterised with two cell-based bioassays, the AhR-CAFLUX, which measures dioxin-like activity, and the AREc32 bioassay, which quantifies the induction of the adaptive stress response to oxidative stress. The resulting bioanalytical equivalents, which are effect-scaled concentrations, were applied in an effect-balance model, consistent with a mass balance-partitioning model for single chemicals. Sediments containing BC had most of the bioactivity associated with the BC fraction, while the OC fraction played a role for sediments with lower BC. As effect-based sediment-water distribution ratios demonstrated, most of the bioactivity in the AhR-CAFLUX was attributable to hydrophobic chemicals, while more hydrophilic chemicals activated AREc32, even though bioanalytical equivalents in the aqueous phase remained negligible. This approach can be used to understand the fate and effects of mixtures of diverse chemicals in sediments and make informed risk based decisions concerning the fate of contaminated sediments.

RP175 Evaluating the Relationship between Equilibrium Passive Sampler Uptake and Aquatic Organism Bioaccumulation

R.M. Burgess, USEPA / Atlantic Ecology Division; A. Joyce, National Research Council/ USEPA / Atlantic Ecology Division

This review evaluates passive sampler uptake of hydrophobic organic contaminants (HOCs) in water column and interstitial water exposures as a surrogate for organism bioaccumulation. Fifty-four studies were found where both passive sampler uptake and organism bioaccumulation were measured and 19 of these investigations provided direct comparisons relating passive sampler uptake and organism bioaccumulation. Polymers compared included low density polyethylene (LDPE), polyoxymethylene (POM), and polydimethylsiloxane (PDMS), and organisms ranged from polychaetes and oligochaetes to bivalves, aquatic insects, and gastropods. Regression equations correlating bioaccumulation (C_L) and passive sampler uptake (C_{PS}) were used to assess the strength of observed relationships. Passive sampling based concentrations resulted in logarithmic predictive relationships, most of which were within one to two orders of magnitude of measured bioaccumulation. Mean coefficients of determination (r^2) for LDPE, PDMS and POM were 0.68, 0.76 and 0.58, respectively. For the available raw data, the mean ratio of C_L and C_{PS} was 10.8 ± 18.4 (n = 609). This review concludes that in many applications passive sampling may serve as a reliable surrogate for biomonitoring organisms when biomonitoring organisms are not available. When applied properly, passive sampling based estimates of bioaccumulation provide useful information for making informed decisions about the bioavailability of HOCs in aquatic environments.

RP176 A Novel Approach to Assess and Quantify Mass Flux of Groundwater Discharge into Surface Water

D. Lavoie, P. Favara, CH2M; M. Annable, K. Hatfield, Univ of Florida Gainesville

Discharge of contaminated groundwater to surface water occurs at many sites adjacent to water bodies. Due to a lack of cost-effective methods to quantify mass-flux, cleanup objectives for groundwater are typically very conservative resulting in unnecessary treatment costs. There is a need for cost effective and accurate hyporehiec zone characterization tools to better estimate contaminant level impacts, verify natural attenuation, and measure groundwater mass-flux over broader space and time dimensions. With support from CH2M, the University of Florida (UF) has developed a sediment-bed passive flux meter (SBPFM) to address these needs. The SBPFM in an evolution of UF's Passive Flux Meter (PFM) that is well established in the remediation field. The main design challenge in developing the SBPFM was converting the PFM, which measures horizontal groundwater flux, to a vertical configuration for hyporhiec and groundwater/surface water transition zone application. UF developed the SBPFM through lab bench-scale testingthat has assessed its design efficacy in measuring contaminant flux. The SBPFM was designed to passively and directly measure local contaminant and water fluxes and provide more accurate information on the temporal mass flux distribution through the sediments in order to better design site remedial and closure strategies. Once lab tests of the SBPFM were completed, field tests were conducted by CH2M and UF at several sites. The field deployments were designed to both refine the logistics of deployment processes through optimal device configurations, and obtain data that could identify groundwater flux (detection of contaminants and estimates of mass flux). The field deployments showed that the SBPFMs could be easily deployed near shore and provide results for both tidal and non-tidal conditions. Additionally, both activated carbon and ion-exchange resins were used to measure organic (VOCs) and inorganic (chloride) contaminants, respectively. The deployment results demonstrate that reliable measurements could be achieved since time-averaged flux was estimated as opposed to short-term or "point-in-time" measurements. An economic assessment of a SBPFM deployment relative to other sediment flux tools also demonstrates potentially significant cost savings.

Deepwater Horizon Oil Spill – The Discoveries and Outreach

RP177 Characterization of Dioctyl Sodium Sulfosuccinate as an Obesogen In Vivo

A. Temkin, Medical Univ of South Carolina / Marine Biomedicine and Environmental Studies; R. Bowers, Medical Univ of South Carolina / Pathology and Laboratory Medicine; J. Baatz, Medical Univ of South Carolina / Pediatrics; D. Spyropoulos, Medical Univ of South Carolina / Pathology and Laboratory Medicine

Childhood, adolescent and adult obesity rates in the United States and worldwide have been increasing since the 1970s and have reached epidemic proportions. While genetic predisposition, diet and exercise are known factors in obesity development, recent studies have focused on elucidating environmental exposures associated with obesity.
Our specific focus is on exposures to endocrine/metabolic disrupting chemicals known as obesogens, which can increase stem cell to fat cell differentiation, and have other metabolic effects that collectively promote obesity development. Recently, our lab identified dioctyl sodium sulfosuccinate (DOSS) as a PPARg agonist and a probable obesogen and wanted to further validate its obesogenic potential in vivo using dosing and exposure routes common to human scenarios. DOSS is a commonly used non-ionic surfactant, present in Corexit dispersants that were used during the Deepwater Horizon oil spill, and is also present in a variety of consumable and personal care products as an emulsifying agent. Pregnant women often become constipated at midgestation and are prescribed as the standard of care stool softeners that are essentially DOSS (500mg/day) through nursing. To parallel this scenario, pregnant female mice were orally dosed with either 30ug/mL DOSS in carboxy methylcellulose (0.5% CMC) vehicle or vehicle control alone in their drinking water from midgestation (day E11.5) through weaning. F1 offspring were then given untreated water until they were 16 weeks old and end point analysis for obesity markers was performed including glucose tolerance, DEXA scans for fat content and bone density, liver and fat pad histology and gene expression and bone marrow mesenchymal stem cell gene expression and differentiation potential. Our results indicate that DOSS is a bona fide obesogen in vivo and displays a sexually dimorphic phenotype. Most significantly, we observe that DOSS exposed males had a significantly higher fat percentage and significantly lower bone area when compared to vehicle treated controls. Additionally, treated males responded different to the glucose tolerance test, displaying a significantly higher spike in glucose blood level after glucose gavage despite similar baseline levels. Cellular and molecular changes were also observed that are indicative of DOSS' obesogenic potential in vivo. Together, these data suggest that DOSS can act as an obesogen in vivo at physiological levels of exposure.

RP178 Identifying and characterizing Deepwater Horizon oil's toxic effects across taxa

R. Takeshita, J.M. Morris, Abt Associates; K.D. Dean, Stratus Consulting Inc. / Dept of Animal and Avian Sciences; M.L. Gielazyn, NOAA / co USEPA Region IV; R.W. Ricker, NOAA / Office of Response and Restoration; P.L. Tuttle, US Fish and Wildlife Service / Deepwater Horizon NRDAR Field Office; J. Lipton, Abt Associates

As part of the Deepwater Horizon Natural Resource Damage Assessment (NRDA), the Natural Resource Trustees conducted a comprehensive laboratory toxicity testing program with fish, zooplankton, phytoplankton, amphipods, mollusks, crustaceans, birds, turtles, and mammalian cell lines. Across tests, the Trustees found a considerable degree of consistency among types of toxic responses observed in different organisms. Cardiotoxicity, poor reproduction, abnormal growth/development, disruption of blood cells and function, oxidative damage, immune system dysfunction, impairment of stress responses and adrenal function, and effects on locomotion were observed across a variety of taxa. This consistency points to the conservation of mechanisms of action and disease pathways across a range of vertebrate and invertebrate species. Results from field studies on wildlife from habitats contaminated with DWH oil demonstrate similar manifestations of toxic effects. From a toxicological perspective, we observed a logical progression of physiological perturbation from molecular and cellular effects that manifest as organ disease, to systemic effects that compromise fitness, growth, reproductive potential, and survival. From a clinical perspective, the breadth of adverse health effects and symptoms associated with exposure to Deepwater Horizon oil forms a coherent suite of symptomatic responses to petroleum toxicity. The availability of data from the large number of laboratory and field studies focused on DWH oil toxicity provides an unprecedented opportunity for scientists to investigate the mechanisms behind oil toxicity, and for decision makers and the public to gain a broader, ecosystem wide understanding of how oil spills affect natural resources.

RP179 The impact of crude oil exposure on the prey capture and male aggression behavior in sheepshead-minnow (Cyprinodon veriegatus veriegatus)

D. Philibert, D. Lyons, K. Tierney, Univ of Alberta / Biological Sciences

From April to July 2010, the Deepwater Horizon oil spill released 3.19 million barrels of crude oil into the Gulf of Mexico that then spread to the surrounding tributaries and wetland habitats. In an attempt to reduce the effects of an oil slick on coastal habitat, dispersant was applied both at the wellhead and at the slick surface to break oil into smaller droplets to expedite microbial degradation. Though the effects of crude oil on survival and cardiac development of early life stages of marine fishes has been established, few studies have looked at the impact of developmental exposure on ecologically relevant behavioral endpoints that relate to both fish feeding and reproduction. Male aggression in the defense of breeding territory, and feeding behavior, play critical roles in both the growth and reproductive success of marine fishes. In our study, sheepshead minnow (Cyprinodon veriegatus veriegatus) embryos were exposed from 1-10 dpf to water accommodated fractions (WAFs) of crude oil, weathered crude oil, crude oil and dispersants, weathered oil and dispersants as well as dispersants alone. Prey capture efficiency was quantified at 60 dpf using brine shrimp nauplii. At 8-11 months the male fish were assessed for aggression-based behavior, using strikes against a mirror. Exposure to the various WAFs had no direct impact on the latency to prey capture, but caused a shift in the bold and shy behavioral phenotypes normally found. Ecologically relevant endpoints such as feeding behavior and male-type aggression behavior on marine model species, such as the sheepshead minnow, will allow for more accurate predictions of the impact of crude oil release on fish populations.

RP180 The Influence of Mixing Energy on the Concentration and Composition of Oil in Laboratory Toxicity Tests

S.B. Kane Driscoll, Exponent, Inc. / EcoSciences; J. Hauri, Assumption College; K. Kulacki, Exponent Inc.; A. Morrison, Exponent / EcoSciences; M.E. McArdle, Exponent, Inc.; P. Schierz, Exponent Inc. / EcoScience; K.L. Yozzo, None / Environmental Health Sciences; M. Edwards, Exponent / Environmental and Human Health Consulting

Water accommodated fractions (WAFs) are laboratory preparations used to simulate oil exposure in aquatic toxicity testing. Standard protocols for preparing WAFs use low- or medium-energy mixing. More recently, a high-energy mixing technique (HEWAF) was developed and used to evaluate the potential toxicity of oil spills, such as the Deep Water Horizon release. Concentrations of total polycyclic aromatic hydrocarbons (TPAH) in unfiltered HEWAFs were one to two orders of magnitude higher than WAFs prepared using established protocols. In addition, HEWAFs had larger percentages of potentially toxic high molecular weight PAHs and alkylated PAHs in comparison to other WAFs. This compositional shift was conserved over a wide range of dilutions. Only a small percentage of the surface water samples collected in the Gulf of Mexico during the active spill period in 2010 were similar in concentration and composition to laboratory HEWAFs. The implications of these compositional differences on potential toxicity will be discussed.

RP181 Comparing the toxicity of crude oil in fresh and saltwater systems: linking chemistry and gene expression

D. Lyons, Univ of Alberta; D. Philibert, K. Tierney, Univ of Alberta / Biological Sciences

Crude oil is highly toxic to fish during early life stages. As an exceptionally complex mixture, oil induces numerous abnormalities in developing fish including cardiac and morphological deformities. This study compares the molecular responses of saltwater and freshwater fish species (sheepshead minnow and zebrafish) to crude oil exposure. We exposed sheepshead minnow and zebrafish embryos to water accommodated fractions (WAFs) of crude oil, weathered crude oil, crude oil plus dispersant, and dispersant alone. We measured gene expression levels in both sheepshead minnow and zebrafish embryos after exposure, targeting genes involved in neurological and cardiac development as well as biotransformation. In our exposures, source oil WAFs had a higher concentration of polycyclic aromatic hydrocarbons (PAHs) than weathered oil WAFs. The combination of dispersant and oil vastly increased the amount of PAHs in the WAFs when compared to oil alone. This increase in PAHs occurred to a greater extent in saltwater than freshwater, indicating that oil and dispersant interact differently in these two aquatic environments. Due to the increase in PAHs, the oil plus dispersant WAF was more toxic to developing fish embryos than the other exposures. Though biotransformation gene expression levels were upregulated in both species in response to oil exposure, they were induced to different extents with zebrafish having a much higher expression level. The results of this study enable us to compare and contrast the consequences of oil spills in both freshwater and saltwater as well as demonstrate the implications of using a chemical dispersant in these environments. We were also able to help establish whether zebrafish, a common model species, are valid models for studying marine oil spills.

Mixtures: Exposure and Toxicity from Combinations of Stressors

RP182 Incoporating bioavailability-based measurements into whole-sediment toxicity identification: An application in South China

X. Yi, H. Li, Guanzhou Inst of Geochemistry / Chinese Academy of Sciences; J. You, Jinan Univ / School of Environment

Sediments in urban waterways of Guangzhou, China were contaminated by a variety of chemicals and showed prevalent toxicity to benthic organisms. A combination of whole-sediment toxicity identification evaluation (TIE) procedure and bioavailability-based extraction approaches was used to identify the causes of sediment toxicity. Four of the six sediment samples collected caused 100% mortality to Chironomus dilutus in 10-d bioassays and the potential toxicants were assessed using TIE testing in these sediments after dilution. The results of phase I characterization showed that organic contaminants were the principal contributors to the mortality of the midges in two sediments, and metals and organics jointly caused the mortality in the other two sediments. Ammonia played no role in the mortality for all the samples. Conventional toxic unit analysis in phase II testing identified Cr, Cu, Ni, Pb and Zn as the toxic metals while cypermethrin, lambda-cyhalothrin, deltamethrin and fipronils being the toxic organics. To improve the accuracy of identifying the toxicants, four-step sequential extraction and Tenax extraction were conducted to analyze the bioavailability of the metals and organics, respectively. Bioavailable toxic unit analysis narrowed the list of toxic contributors and the principal toxicants included three metals (Zn, Ni and Pb) and three pesticides (cypermethrin, lambda-cyhalothrin and fipronils). Metals contributed to the mortality in all sediments, but sediment dilution reduced the toxicity and caused metals' contribution to the mortality in two sediments being overlooked in phase I characterization. Incorporating bioavailability-based measurements into whole-sediment TIE testing improved the accuracy of identifying the causative toxicants in urban waterways where multiple stressors occurred and contributed to sediment toxicity jointly.

RP183 Toxicity of manganese in the presence of cadmium or lead to the nematode Caenorhabditis elegans

H. Ma, C. Lu, C. Pattison, Univ of Wisconsin Milwaukee / Zilber School of Public Health; K.A. Lenz, UWM-ZSPH / Environmental Health Sciences

Manganese (Mn) contamination from mining industry poses a significant public health concern as Mn is a neurotoxicant and can induce a Parkinson-like syndrome called “manganism”. Existing literature on Mn neurotoxicity as well as regulatory guidance on human exposure mainly focus on single element, without considering the co-occurring metals. Mn contamination sites are usually accompanied with other toxic metals such as Pb and Cd; however, toxicity of Mn in combination with these metals are not well-understood. The current study examined the toxicity of Mn in the presence of Cd or Pb, the two most commonly found companying metals in Mn contamination sites, using a model organism the nematode C. elegans. The central hypothesis is that the presence of Pb or Cd will induce additive or synergistic effects in the toxicity of Mn in C. elegans. C. elegans were exposed to Mn with or without the presence of Cd or Pb, and a series of toxicity endpoints were evaluated, including lethality, reproduction, behavior, lifespan, neurotoxicity, and oxidative stress. Neurotoxicity was evaluated using a dat-1::GFP transgenic strain of C. elegans that expresses GFP in dopaminergic neurons of the worm, which enables in vivo imaging of the neurons for structural and morphological alterations. Overall oxidative stress was assessed using a daf-16::GFP transgenic strain of the worm. Exposure to Mn alone from low µM to low mM levels caused significant toxicity in reproduction, locomotion behavior, lifespan, neurotoxicity and oxidative stress in the worm. The neurotoxicity effects included neuronal body shrinkage, breakage in neuronal processes, and errors in axonal pathfinding in dopaminergic neurons. The oxidative stress was indicated by translocation of GFP from cell cytoplasm to nucleus in the worm. Adding Pb or Cd to Mn induced significant synergistic toxicity effects in C. elegans as shown in most of the endpoints examined. For example, LC10 Mn together with LC10 Cd induced a 65% mortality and LC10 Mn together with LC10 Pb caused a 90% mortality in the worm. Similar synergistic effects were also seen in lifespan, reproduction, neurotoxicity and oxidative stress. These findings suggest that accompanying metals may significantly increase the toxicity of Mn, and hazard and risk evaluation of Mn must take into consideration of the potential synergistic effects with other co-occurring metals.

RP184 Multivariable analysis of ecotoxicity and basic water quality parameters in two watershed areas in Japan: effects of concentration process

H. Yamamoto, National Inst for Environmental Studies / Faculty of Integrated Arts and Sciences; M. Mitsuyama, M. Enyama, S. Nishiie, Tokushima Univ; N. Shinoka, I. Tamura, Okayama Univ; N. Tatarazako, National Inst for Environmental Studies / Environmental Risk

We have attempted to find a trend in various ecotoxicity and basic water quality items in two river watersheds in Japan, one in Yoshino River, Tokushima, and the other in Yodo River, Kyoto-Osaka of Japan. Over three years, we conducted short-term chronic toxicity tests for whole water samples using fish (Danio rerio), daphnia (Ceriodaphnia dubia), and alga (Pseudokirchneriella subcapitata), and Microtox test was also conducted. Basic water quality items such as BOD, COD, NH_4^+-N, and hardness were determined as well as on site measurements of DO, pH, and electric conductivity (EC). This year, we also used two solid-phase cartridges, one is Oasis HLB to concentrate organic contaminants and the other is Nobias Chelate column to concentrate cationic metals to more frequently detect the ecotoxicity, which we failed to detect in most of the samples. Several multi-variable analyses such as principal component analysis (PCA), factor analysis, clustering analysis, and regression analysis were used to find out a trend in spatial variation and in the selected parameters. As with those results we reported last year, we found from the PCA results that BOD, COD, hardness, NH_4^+-N, and EC are in the similar area with relatively high primary principle component while DO is in negative side. Similar trend was found for the factor analysis and the organic compounds originated from human activities such as domestic wastewater are probably the major factors. In contrast, the secondary principle component was higher only for daphnia reproduction/survival, which suggests the toxicity for C. dubia is the very specific item with little correlation with the other basic water quality items and toxicity. The clustering analysis roughly showed the trend with separation of upstream and downstream sites. The regression analysis did not find any significant correlations between water quality items and the C. dubia and algal toxicity. The frequency of detecting toxicity was jumped up by the concentration process but it needs special cautions for concentrating cation metals due to the use of acid and neutralization, which results in the increase of salt concentration to interfere the C. dubia reproduction.

RP185 Real Metals for the real world: A Comparison of Dosing Methods to Determine Soil Quality Guidelines

M.J. Cousins, Univ of Saskatchewan / Dept of Soil Science; J. Renaud, Univ of Coimbra; K. Jegede, Univ of Saskatchewan / Toxicology Centre; K. Awuah, E. Elikem, D. Peak, Univ of Saskatchewan; B.A. Hale, Univ of Guelph / School of Environmental Sciences; J. Sousa, Univ of Coimbra / Dept of Life Sciences; S. Siciliano, Univ of Saskatchewan / Toxicology Group and Dept of Soil Science

Standard soil dosing methods for metal toxicity research poorly represent real world contamination. While laboratory soil toxicity assays involve dosing soils with aqueous metal salts, field contamination is almost exclusively caused by deposition of smelter emissions as complex metal mixtures. Fixed-ratio ray dosing regimens can be used to test the toxic effects of these complex mixtures, whether they are based on regulatory limits, relative toxicities, or environmental concentrations. The metals are mixed in their relative concentrations and toxicity is tested against an organism. Currently, metal salts are added to test soils in a fixed-ratio ray and then the soils are leached with artificial rainwater to remove excess salinity. Unfortunately, metal that has been added to the soil is also leached. While this is not so much an issue for single metal tests, mixtures lose individual metals in disproportionate amounts. The fixed-ratio ray is no longer fixed and therefore flawed, making metal toxicity guidelines based on this approach inappropriate. To remedy this issue we evaluated three methods of creating metal mixtures of lead, copper, cobalt, nickel, and zinc in four soils. The mixtures were applied in three ways: (i) pipetting in aqueous nitrate salts and leaching, (ii) adding commercially purchased metal oxides as dry powders, and

(iii) adding synthetic minerals produced via annealing. The synthetic minerals are created in three steps. First, aqueous nitrate metal salts are mixed in the desired mixture ratio. Ferric nitrate solution is then added to the mixture in a 2:1 molar ratio of iron to the sum of the other metals. A small sample of the mixture is removed and titrated to pH 7.5 using ammonium hydroxide and centrifuged. The remaining metal concentrations in the supernatant are used to adjust the main mixture, and it is then also brought to pH 7.5 and centrifuged. The precipitate is heated to 600?C to remove excess nitrates, and then tested for metal concentrations and added to soil. Metal toxicity will be tested using F. candida, O. nitens, and E. crypticus to see how the different dose methods affect toxicity, possibly through different metal complexes being formed. Solid phases of the metals in each sample will be examined using XRD and compared to field contaminated soil. This study will demonstrate the strengths and weakness of these three different methods of creating metal mixtures in soils for fixed ray analysis.

RP186 Putative mechanisms of atrazine's toxic interactions with other chemicals

A. Schmidt, Clemson Univ ENTOX / Dept of Biological Sciences; N. Sengupta, Clemson Univ / Dept of Biological Sciences; C. Saski, Clemson Univ / Dept of Genetics and Biochemistry; W.S. Baldwin, Clemson Univ / Biological Sciences

Atrazine is an herbicide with several known toxic effects, including interactions with other chemicals. For example, atrazine increases the toxicity of several organophosphates in some invertebrates and conversely reduces the toxicity of triclosan and DHA to D. magna in a concentration dependent manner. Our preliminary research suggests atrazine provides protection from triclosan through induction of glutathione S-transferases (GSTs), potentially due to activation of the xenobiotic-sensing nuclear receptor, HR96. We performed RNA-seq to determine if atrazine is inducing protective effects by inducing several detoxification enzymes and to estimate other interactions. Our RNA-seq analysis demonstrates induction of GSTs and several other detoxification enzymes including CYP370A9, glucosyltransferases, and alcohol dehydrogenase. Pathway analysis is underway and we have confirmed induction of GSTS1, GST1-1, CYP370A9, and ALDH by qPCR. Based on our RNA-seq data, we can hypothesize as to which environmentally relevant toxicants may have interactions with atrazine depending on whether they are activated by CYPs or detoxified by CYPs and other detoxification enzymes. We recently performed acute toxicity tests to determine individual LC_{50} and hillslope values. We are currently performing toxicity tests with binary mixtures containing atrazine. Therefore, we can compare observed toxicity with expected toxicity using the Computational Approach to the Toxicity Assessment of Mixtures (CATAM) independent joint action model and assess whether atrazine is exerting antagonism, additivity, or synergistic toxicity in accordance with our hypothesis.

RP187 Developmental and interactive effects of arsenic and chromium to developing Ambystoma maculatum embryos: toxicity, teratogenicity, and uptake

S. Gardner, G. Cline, Jacksonville State Univ / Biology; N. Mwebi, Jacksonville State Univ / Physical and Earth Sciences; J.R. Rayburn, Jacksonville State Univ / Biology

Anthropogenic activity has contributed to elevated concentrations of arsenic 12 and chromium in the environment. Both arsenic and chromium are known to induce toxic effects in exposed organisms, including amphibians. The spotted salamander, Ambystoma maculatum, may be useful for showing developmental effects caused by exposure to these metals as larvae develop in water that may contain arsenic or chromium. After exposure to environmentally relevant arsenic and chromium concentrations using Na2HAsO4 * 7H2O and Na2Cr2O7 * 2H2O, larvae showed a different pattern of whole-body arsenic and chromium from individual and mixture19 exposure. 12 day LC50 concentrations from individual As(V) and Cr(VI) exposure in Ambystoma maculatum larvae were 261.17 mg/L and 71.93 mg/L, respectively, while 12 day EC50 concentrations were 158.82 and 26.05 mg/L, giving teratogenic indices of 1.64 and 2.76. A mixture of arsenic and chromium yielded a teratogenic index of 2.78, indicating that these metals are also teratogenic when exposed as a mixture. These results show that Ambystoma maculatum may be a useful indicator of environmental toxicity from arsenic or chromium exposure.

RP188 Time to sampling after capture impacts site-specific ovarian steroid production in rainbow darter (Etheostoma caeruleum)

S. Deeming, Wilfrid Laurier Univ / Biology; A.L. Lister, Wilfrid Laurier Univ / Dept of Biology; M.R. Servos, Univ of Waterloo / Dept of Biology; D. MacLatchy, Wilfrid Laurier Univ / Biology

Studies on male fish in the Grand River (Southern Ontario, Canada) have shown a variety of reproductive issues such as increased intersex condition (ova-testes) and vitellogenin production, and decreased gonadsomatic index and testosterone production. Many of these effects have potentially been linked to proximity to the effluent outflows of wastewater treatment plants (WWTP). WWTP effluents are complex mixtures that contain numerous chemicals with the potential to disrupt the endocrine systems of exposed fish. This study investigated the sex steroid production levels of female rainbow darter (RBD, Etheostoma caeruleum) at two locations in the Grand River: a location upstream (reference) of the Waterloo WWTP effluent outflow and a site that is downstream of the outflow (exposed). Secondly, this study examined the impact of the collection method on the steroid production. Given that field collections of small-bodied fish in rivers often employ electrofishing methods and that stress is known to affect steroid levels, collected fish from both locations were sacrificed and ovaries removed at 1, 7, and 24h after electroshocking. Ovarian tissue was cultured in vitro for 24h with or without the addition of human chorionic gonadotropin (hCG), an analog to endogenous luteinizing hormone that stimulates steroid production. Reference fish sacrificed 1h post-collection had stimulated ovarian estradiol production levels of 54.4 ± 4.8 pg/mg of tissue, which was significantly higher than exposed fish sampled after 1hr (34.3 ± 2.2 pg/mg). After 7h post-collection, basal estradiol production levels for reference fish ovarian tissue (5.0 ± 0.44 pg/mg) were significantly higher than those of exposed fish (3.1 ± 0.40 pg/mg). Over the 24h, stimulated estradiol levels decreased significantly in reference fish ovaries (1h 54.4 ± 4.8, 7h 40.7 ± 4.0, and 24h 25.6 ± 2.9 pg/mg). After 24h, there were no significant differences in basal or stimulated estradiol production levels between the reference and exposed fish ovaries. These results suggest that standardized collection and sampling methods may be important to interpreting reproductive steroid levels of fish collected through electrofishing and in the identification of site-specific differences. The impact of time held post-shock may be a stress-related response with enough magnitude to impact the ability to detect reproductive endocrine impacts of point/non-point sources on small-bodied fish and is being further investigated.

RP189 Evaluation of Chemical Mixture Toxicity Predictability with High Dimensional Toxicogenomic Data Using Parallel Factor (PARAFAC) Analysis

S. Rahman, Northeastern Univ / Civil Environmental Engineering; C. Gao, Northeastern Univ / Bioengineering; N. Gou, Northeastern Univ / Civil and Environmental Engineering; A. Gu, Northeastern Univ / Dept of Civil and Env Engineering

Predictive toxicity assessment of chemical mixture is challenging and complex due to unknown interactive modes of action (MoA) including concentration addition, independent action, synergistic, or antagonistic models. Toxicogenomic technology combined with bioinformatics have the potentials to transcend the limitations of conventional toxicological approaches for predicting mixture toxicity. However, toxicogenomic based mixture toxicity prediction has hardly been explored due to limitations including lack of quantitative dose-dependent toxicogenomic data, limited established theoretical and modeling framework, data complexities due to large no. of variables associated with small sample size, and lack of consensus in computational methodologies. Here we apply tensor decomposition method- Parallel Factor (PARAFAC) to toxicogenomic data (temporal transcriptomic data of 120 biomarkers of all known stress pathways, over 2-hr exposure time at 5-min interval, generated by GFP-fused whole-cell array of E.coli K12, MG1655) for predicting molecular toxicity of a binary mixture of two metals- As and Cr. PARAFAC model decomposes 3-D toxicogenomic data (biomarker x time x chemical dose) of the mixture and individual chemicals separately into multiple components/factors. Decomposed PARAFAC factors represent chemical-specific distinct fundamental biological and molecular features, which are further characterized via gene set enrichment analysis to reveal significantly impacted pathways (e.g., DNA damage, protein damage, and so on) and therefore implied dominant toxicity mechanisms represented by each factor. We have further demonstrated the efficacy of biomarker factor loads of individual chemical models as prediction parameters to predict mixture toxicity. Significant prediction models with higher confidence ($p< 0.05$) have been found to estimate quantitative mixture toxicity endpoint from biomarker factor loads of individual chemical models using linear regression. However, estimation models at the pathway level using pathway loads, achieved by aggregating biomarker loads, as prediction parameters are not significant ($p>0.05$). This study explored a novel application of PARAFAC analysis in predicting mixture toxicity at molecular level that can provide significant insight into toxicogenomic based mixture toxicity. Further study is on-going to include more mixtures with different MoA, and varying biomarkers to contribute to the knowledge gap in predictive mixture toxicity.

RP190 Too thick to drink, too thin to plow: Chemical mixtures in the Elkhorn River, Nebraska

A.S. Kolok, Univ of Nebraska – Omaha / Nebraska Watershed Network; J.M. Ali, Univ of Nebraska Medical Center / Environmental, Agricultural and Occupational Health

Agrichemical loading to surface waters in the Midwestern United States is driven by surface runoff. From April until July, agrichemical concentrations in surface waterways, such as the Elkhorn River, peak following rainstorm events. During dry years, the rain events are discrete, and episodes of chemical exposure are separated by periods during which the chemical exposure returns to baseline conditions. During wet years, the series of episodic exposures fuse into a continuous exposure of lower concentration. In both cases, runoff does not contain one agrichemical, but rather a suite of co-occurring herbicides. Furthermore, the overall concentration of the suite of herbicides is influenced by abiotic factors including water temperature, photoperiod and the overall load of suspended sediments. The primary biological impacts of the herbicide mixture are reproductive, as fish exposed to the raw water and sediment experience reductions in the expression of estrogen responsive genes. Biological impacts are not uniform across the entire spring season, but rather are influenced by rainstorm runoff and river discharge. Our research on the Elkhorn River suggests that regulation of herbicide concentration in surface waters in Nebraska needs to take episodic events into consideration along with overall average chemical concentration. In keeping with the session's theme, the presentation will address the integration between the chemical mixture found in the Elkhorn River and the environmental conditions (temperature, discharge, suspended solids) that influence the behavior of those chemicals.

RP191 Does competition for food influence the toxicity of heavy metal mixtures?

J. Renaud, Univ of Coimbra; M. Cousins, Univ of Saskatchewan; K. Jegede, Univ of Saskatchewan / Toxicology Centre; K. Awuah, Univ of Saskatchewan; S. Siciliano, Univ of Saskatchewan / Toxicology Group and Dept of Soil Science; J. Sousa, Univ of Coimbra / Dept of Life Sciences

The toxic effects of metals on individual species of soil invertebrates are well documented in the literature. However, impacted soils typically contain a mixture of metals and impact a community of invertebrates. Here, we evaluated the effects of individual metals and metal mixtures of Cu, Co, Ni, Zn and Pb in a fixed-ratio ray dosing regimen on the reproduction of Folsomia candida and Oppia nitens. Mites and collembolans were tested for their response to metals separately as well as with both organisms present in the test vessel. Single metals were dosed with 11 different concentrations determined based on F. candida EC50 for each metal and mixture dosing were performed with 10 different ratios simulating the ratios observed in contaminated sites and guideline values each with 8 different doses. The selected dosing regimen will allow the calculation of dose and ratio dependant deviations from concentration addition and the single vs. combined exposure will allow observation of any indirect effects due to competition. This experiment is the first study on the role of competition in soil invertebrate reproduction and survival when exposed to both single and mixtures of metals. The total metal exposure experiments should be finalized in the July 2016.

Linking Science and Social Issues – Poster Only

RP192 Bridging the Gap Between Cannabinoid Toxicity and Public Perception

D. Carty, Univ of Mississippi / Biology; C.E. Thornton, K.L. Willett, Univ of Mississippi / Pharmacology; S. Cutler, Univ of Mississippi / The School of Pharmacy and Biomolecular Sciences

Cannabis has been used for several millennia as a medicinal therapeutic. Until the enactment of the 1937 Marijuana Tax Act, cannabis was being used widely across the United States and found in numerous pharmaceuticals. Currently, medical cannabis has shown potential in many areas of treatment (i.e. insomnia, loss of appetite, cancer, Dravet syndrome, etc), however, it is a Schedule I drug in the United States and illegal under Federal Law. While public perception of medical cannabis varies, empirical toxicological data is lacking and widely conflicting. Therefore, the consequence of developmental exposure to cannabinoids on the potential etiology of subsequent adult or multigenerational toxicity is currently unknown. Herein, we examined the potential toxicities of two cannabinoid constituents currently being used for therapeutic purposes, Δ9-tetrahydrocannabinol (THC) and cannabidiol (CBD), on zebrafish morphology, behavior, and morphogenesis/neurogenesis. Our results indicate phenotypic dysmorphologies, enhanced locomotion, and differentially expressed genes imperative for normal development. THC and CBD shared similar adverse morphologic and behavioral outcomes, but lacked similarity in terms of differential gene expression in key morphogenesis/neurogenesis genes. For example, c-fos was significantly upregulated in THC and CBD exposed zebrafish, while dazl was significantly upregulated following only THC exposure. Additionally, CBD was greater than 6 times more potent than THC, LC_{50} 0.53 ± 0.19 mg/L and 3.65 ± 0.67 mg/L, respectively. Through this work we are gaining additional insight into potential mediating mechanisms of cannabinoid toxicity which can be used to influencing public perception via empirical evidence. Supported by NIGMS, Grant Number P20GM104932.

RP193 Evolving Products of Consumer Convenience and their Environmental Implications

A. Hicks, Univ of Wisconsin – Madison / Civil and Environmental Engineering

Products of consumer convenience have and are continuing to change the consumer landscape. These products have a common thread of saving time and effort while producing a similar end result or experience when compared to their conventional counterparts. Modern day examples in various stages of technological development and consumer adoption include disposable diapers, single serve coffee pods, and compostable silverware. At the same time, these products have the potential to exhibit significantly different environmental, economic, and social impacts when compared to their conventional counterparts. A midpoint life cycle assessment was completed to evaluate the environmental impacts of consumer convenience on coffee. Three generalized coffee brewing systems were evaluated: drip filter, french press, and single serve coffee pod (a product of consumer convenience). Inventory data with respect to the raw materials and use phase were collected through tear-down and experimentation with the three brewing systems. Potential for material change and alternate end of life scenarios for the coffee pods is also discussed. In evaluating the environmental impact of growing and processing the coffee in Brazil (one of the major coffee producers) the most significant contributors to the life cycle impact were found to be fertilizer, pesticide, and diesel utilized in the growing and harvesting of the coffee plants. As expected, for the conventional coffee brewing methods (drip filter and french press) the most significant environmental impacts across all of the impact categories considered were due to the coffee grounds themselves and the electricity utilized to brew the coffee. It was expected that for the single serve pod style coffee that that additional materials required to produce the pod (foil and plastic cup) would dominate the life cycle impact, however, that was found not to be true. In fact, brewing coffee with a single serve pod was found to have a lower environmental impact in all of the impact categories considered than the conventional brewing methods. This is largely due to the coffee pod containing less ground coffee to produce the volume of coffee drink, and using less energy during the brewing process. This is a valuable case study in that it suggests that products of convenience do not inherently have a larger environmental footprint than their conventional counterparts.

RP194 Impact of Environmental Contaminants on Childhood Education; Synthesis of Ecological Systems theory, Piaget and Vygotsky Education theories

C. Onwurah, Univ of Nigeria / Dept of Educational Foundation; U.E. Uzodinma, Univ OF NIGERIA, NSUKKA / Dept of Educational Foundations; I.N. Onwurah, Univ of Nigeria / Biochemistry

The impact of environmental contaminants on childhood education is becoming very obvious in the developing countries like Nigeria. Mining may cause environmental issues ranging from waste rock and tailing disposal, land disturbance, dust and noise, to environmental pollution. If not managed well, any of these could adversely affect the health and educational development of the children living near mining operations. Miners and their families are exposed to harsh working conditions for minimal income in a high risk context, endangering their health as well as often the surrounding environment. These contaminants, such as lead, have been reported to create very serious impediment in childhood education, particularly their cognitive experiences. In this work, we evaluated lead concentrations in soil and plants in a lead mining community of Ebonyi State, Nigeria. We also reviewed the literature on the effect of environmental lead in other to link environmental contaminants with the mechanisms of motor development, which promotes participation and active learning in children, in accordance with Piaget's theory of cognitive development, an extremely important domain in early childhood education. In Vygotsky's wiew, childhood development was a process and could be a period of crisis in cognitive development in an event that can create a perturbation on the child. For example a qualitative transformation in the child's mental functioning could be underpinned by toxic substances in the environment. All these are wrapped up in The Ecology of Human Development. Through this work, an approach or forum for a coordinated assessment of environmental contaminants as it affects childhood education would be developed for the purpose of solving the problems and needs of the environmental pollution-endangered communities, since it has been posited that environmental contaminants, exemplified by lead, have a persistent and irreversible effect on intelligent quotient (IQ) even during the adult years.

RP195 Land Use-Sustainability Browser: A Decision Support Tool Linking Enviromental Science to Social Outcomes

B.T. Walton, USEPA / ORD, NHEERL; E. HALL, USEPA; L. Cox, Oak Ridge Inst for Science and Education / Research Laboratory

With the increasing scale, scope, and complexity of problems addressed by environmental toxicologists and chemists, the profession has welcomed and benefited from the input and perspectives of social scientists. The influence of the social sciences is evidenced, in part, by the development of decision support tools (e.g., EnviroAtlas[1] and the EcoHealth Relationship Browser[2]) and indices (e.g., Environmental Quality Index, Human Well-Being Index) to quantify and substantiate the interconnections between environmental, social and health indicators. These tools are designed to better communicate these interconnections and many allow comparisons between locations over a range of metrics. A number of decision support tools developed by EPA provide ready access to information, references, and facilitate visualization of data to inform community choices regarding sustainability and the resilience of urban and rural environments. We report the development, status and functionality of a new relational browser on land use and sustainable development. The Land Use-Sustainability Browser is supported by a data base of more than 1,200 peer-reviewed publications on the importance of land use as both a positive and negative driver of sustainable development. Linkages between land use and transportation, materials and waste management, buildings and infrastructure are included as major influences on sustainable development. More than 200 references are cited as evidence to support summaries of the literature related to land use and sustainability. We demonstrate the functional capability of the browser for scenarios relevant to environmental toxicology, chemistry and social outcomes. [1]www.epa.gov/enviroatlas [2]https://www.epa.gov/enviroatlas/enviroatlas-eco-health-relationship-browser

RP196 Modern history of hypoxia in Narragansett Bay: the geochemical record

W.S. Boothman, USEPA / Atlantic Ecology Division National Health and Environmental Effects Research Laboratory Office of Research and Development; L. Coiro, USEPA / Office of Research and Development National Health and Environmental Effects Research Laboratory Atlantic Ecology Division

Increased inputs of nitrogen and other nutrients to estuarine and marine ecosystems from agricultural runoff, urbanization and suburbanization have resulted in degradation of water quality, including increased frequency and severity of hypoxia. While much work has been conducted in recent years to characterize the spatial and temporal extent of hypoxia in coastal systems, the historical record of hypoxia in such systems is much less well known. The current work examines the history of hypoxia in upper Narragansett Bay and nearby Greenwich Bay, an urbanized estuary in the northeastern U.S., through vertical profiles of geochemical markers in sediment cores. Concentrations of molybdenum (Mo), a quantitative surrogate for direct measurement of hypoxic conditions in overlying waters, reveal periods of more frequent hypoxia that vary spatially and temporally throughout the Bay. Variations in the degree and extent of hypoxia are related to changes in the population and anthropogenic inputs to the Bay from the surrounding watersheds, as well as estuarine circulation patterns within the Bay. The more urbanized upper bay shows greater frequency of hypoxia at the turn of the 20th century with conditions improving through mid-century and recurrent hypoxia thereafter. Hypoxia was less prevalent in the early 20th century and increased substantially from ~1950 to the present in Greenwich Bay, which has a more suburban watershed. Carbon and nitrogen concentrations and isotope values reflect increased nitrogen enrichment and productivity in the Bay in the 2nd half of the 20th century. These results can help inform study of the environmental responses to societal activities that may degrade or improve water quality.

RP197 Risk Assessment on four Artificial Sweeteners, alternatives to reduce excessive Sugar consumption

J. Lee, J. Kwon, G. Song, M. Hwang, I. Hwang, Ministry of Food and Drug Safety

Food industry is gradually developed, and the use of food additives that are necessary to improve the food preservation and distribution has been incresed too. Standards and specification of Food additives have been established and managed by the Ministry of Food and Drug Safety(MFDS) in Korea. The interest in safety of food additives also has been increased because of the potential health hazardous risk from the use of synthetic addivies. There was an issue that excessive sugar intake might cause adverse effets on blood glucose by generating diabetics, metabolic syndrome and obesity. As the result, the interest in sweeteners has been raised, but some reports that artificial sweeteners may cause adverse effects including fetus obesity are increasing the anxiety on health effects otherwise. Even though some sweeteners were already permitted to use in food, and certified its safety by the MFDS in Korea, Joint FAO/WHO Expert Committee on Food Additives(JECFA) and European Food Safety Authority(EFSA), safety reassessment on four sweeteners (Sodium saccharin, Acesulfame potassium, Aspartame, Sucralose) was conducted to relieve the public from safety anxiety. The hazard identification of the sweeteners was come up with summarizing the safety information from JECFA and EFSA New information of the sweeteners was gathered by research papers. Based on the large number of toxicological studies requesting the safety evaluation of the sweeteners, the No Observed Adverse Effect Level (NOAEL) is identified for the most sensitive effect in the most proper animal species. A safety factor of 100 is normally applied to the NOAEL in order to establish the ADI for humans. The level of safety on these sweeteners was evaluated by comparing among the ADI data established by the JECFA or EFSA. For the exposure assessment of the sweeteners, we used poundage method based on Korea National Health & Nutrition Examination Survey and guidelines on safe use of sweeteners. In this study, four sweeteners, Sodium saccharin, Acesulfame potassium, Aspartame, Sucralose, reassessed were all evaluated as not hazardous to human.

RP198 The importance of medication disposal for consumers. (But they don't know or seek information about proper methods)

J.S. Punzi, CHPA / Regulatory and Scientific Affairs

Over-the-counter (OTC) products comprise the majority volume of pharmaceuticals and personal care products purchased by consumers. Proper disposal OTCs is important for safety and environmental concerns. To identify consumer awareness, knowledge and behavior of disposal practices, the CHPA and its Educational Foundation engaged Nielsen Research/Harris Poll for a national survey During February 3-9, 2015, of adults age 18 years and older who used/purchased OTC medicines in the past 6 months. The online survey instrument included 49 questions, 9 regarding disposal. Data were weighted for propensity to be online and U.S. proportions for all demographic variables. From 2002 respondents (54% female), 95% had used/purchased medical pills/tablets/capsules, 92% personal hygiene drugs,73% vitamins/supplements, 50% medical liquids, 48% topical medical creams/ointments. We determined that 50% of the respondents "typically" dispose of expired/unwanted in the household trash and 20% flush them down the sink or toilet. Only 7% return them to local take-back programs or pharmacies (6%). While 90% of the respondents agreed "the way someone disposes" is important, and 49% "wish they knew more" about "proper" disposal, 62% have "never sought" information. Even though half of consumers currently dispose of OTCs in household trash which usually terminates in EPA- regulated landfills, too many continue to dispose of unused/unwanted OTC's by flushing, and even fewer utilize existing "take-back" programs. There is clearly a need for better public education about proper disposal of pharmaceuticals and personal care products.

RP199 Tox on Tap: Changing Public Perceptions of Science

L.P. D'Silva, D. Green, Univ of Saskatchewan – Toxicology Centre / Toxicology; E. Maloney, Univ of Saskatchewan / Toxicology; C.R. Labarrere, Univ of Saskatchewan / Toxicology Centre; S.E. Crawford, Univ of Saskatchewan – Toxicology Centre / Toxicology Centre

Public perception of science is heavily influenced by the way in which research and scientific development is communicated. Though always present to some degree, in the previous few years the communication gap between scientific researchers and the general public has widened significantly. This has contributed to a general negative shift in the public perception of science, especially in emerging and controversial areas of scientific development. Tox on Tap (ToT) aims to combat this communication gap, by bringing scientists from academia, government, and industry together with members of the local community to discuss scientific developments and recent issues in hot-topic toxicological and environmental areas. A non-profit, volunteer-run initiative, ToT aims to make science interesting and understandable to the general public by using a storytelling/discussion-based approach mirroring that of Café Scientifique. Primarily run during the academic year at a local pub, these events have been met with great public interest. Attendance has ranged from 40-120 individuals per event, with topics discussed having included mercury exposure via seafood, rhino poaching, prion diseases, and environmental teratogens. The informal and friendly atmosphere of these discussions has promoted audience participation and education about current scientific research. We would like to share our successful stories of effectively communicating science, inspiring the public through our events, and increasing perception of the scientific community.

RP200 Environmental Implications of Efficiency: Fuel Efficient Vehicles and the Rebound Effect

J. Mahoney, Univ of Wisconsin – Madison / Civil Environmental Engineering; A. Hicks, Univ of Wisconsin – Madison / Civil and Environmental Engineering

One of the pressing problems facing humanity in the 21st century is a changing climate, with the transportation sector emitting approximately a quarter of all emissions. Efforts to reduce emissions from transportation fall into two camps: market-based approaches of increasing fuel prices and improving fuel efficiency standards through legislation. Producing vehicles with improved efficiency allows consumers to travel a given distance using less fuel, leading to decreased emissions. An important consideration while quantifying the fuel savings from more efficient vehicles is to determine the rebound effect. The rebound effect occurs when an increase in efficiency of a good leads to increased consumption of that good. Accurately estimating the rebound effect in vehicles will show what percentage of the theoretical fuel savings is realized. This determination will offer insight into whether regulations pertaining to efficiency will lead to overall fuel savings. To gain understanding into the fuel efficiency rebound effect, consumer surveys were administered to gather data on driving habits and demographics. This study utilized the data to estimate the transportation rebound effect for various groups of participants. Groups were established based on demographic data, such as comparing rural and urban households and various income levels. The variations in the magnitudes of the rebound effect among the groups were analyzed to investigate factors that influence driving behavior and to what extent they affect fuel price elasticity. It is anticipated that comparing the rebound for households on different ends of demographic categories will reveal significant differences in their respective rebound effects. Of particular interest was comparing rural and urban households and investigating the rebound differences. An important factor in this comparison is the availability of alternate modes of transportation, or lack thereof; when fuel prices increase, urban households can readily adopt alternate transportation or revert from it when fuel prices fall, whereas rural households may not have that option. These findings can be used to identify how different groups of drivers respond to improvements in fuel efficiency. Better understanding this behavior will provide discernment into the efficacy of using fuel efficiency mandates to reduce transportation emissions.

Aquatic Toxicology and Ecology – Poster Only – Part 4

RP201 Water supply resilience through watershed management under climate change regime: An excerpt from the Brahmaputra River watershed of India

P. Mazumder, Tezpur Univ / Molecular Biology and Biotechnology; M. Kumar, Tezpur Univ / Environmental Science

In the present era of high population growth, rapid urbanization and climate change, uncertainty of natural phenomenon and land use pattern are rapidly increasing and posing serious threat on drinking water supply from both quantity and quality perspectives especially in a country like

India. The aim of this study was to achieve sustainability in the water resource management by understanding the governing processes of water storage and supply on watershed scale followed by developing integrated efficient operating system. The study has been carried out in the Brahmaputra Basin by assessing the current urban water use in the river watersheds through questionnaire survey, review of available scientific and government organization's reports. Further, health risk from the current water sources was estimated through measuring concentrations of fecal coliform and E. coli so that a new strategies of sustainable water supply under climate change scenario may be evolved. Results suggest that the most crucial step for managing the water resource would be an extensive and in-depth study of the impact of climate change on water resources on watershed scale. Urbanization results in severe environmental deterioration because countermeasures, which need to wait for policy-makers' decision, cannot catch up with the change.Much advancement has been made in this field but the difficulty lies in the application of the existing information to arrive at a solution for this. Decision-making needs to consider several aspects of health, environment, economy, socio-culture and technical function within a framework that includes interactions between users, organizations and technology. Applicability of results seems universal as the climate change evidently affects the global precipitation pattern which can lead to societal conflicts. Hence the need of the hour is to adopt mitigatory approaches which can at least diminish the effect of climate change to a certain extent.

RP202 Is harmonization of the number of test concentrations possible in the OPPTS and OECD fish bioconcentration tests?

A. Samel, DuPont Crop Protection; M. McCoole, Bayer CropScience / Environmental Toxicology and Risk Assessment; A.J. Jones, DuPont Crop Protection / Inst of Environmental Toxicology; T.S. Kung, FMC Corporation/Global Regulatory Sciences / Dept of Biochemistry and Microbiology; F. Kee, FMC Corporation; H.O. Krueger, Wildlife International / Aquatic Plant and Insect Toxicology; K. Henry, NovaSource / Tessenderlo Kerley, Inc. / Ecological Sciences

In 2012 the OECD fish bioconcentration test guideline (TG 305) was revised to incorporate a dietary bioaccumulation test and to utilize fewer fish by providing the option of decreasing the number of test concentrations, from two to one, where appropriate. Until this revision the USEPA OPPTS 850.1730 and OECD TG 305 test guidelines were fully harmonized. The OPPTS test guideline was written in 1996 and, to this date, remains a draft test guideline. An analysis by Crop Life America (CLA) of the results of fish bioconcentration studies with crop protection products compared the bioconcentration factors (BCFs) derived from two test concentrations. This augments a similar effort conducted in Europe which resulted in the revision of OE CD TG 305 to include an option for reducing the number of test concentrations required. The hypothesis is that it is sufficient to conduct the fish bioconcentration test with one test concentration based on supporting data from studies previously conducted with two test concentrations. The use of one test concentration provides acceptable and relevant fish bioconcentration results and reduces the number of vertebrate organisms tested.

RP203 An evidence base to support the one concentration approach in fish bioconcentration studies for plant protection products and general chemicals

N. Burden, NC3Rs; S.K. Maynard, Syngenta / Environmental Safety; L. Weltje, BASF SE / Crop Protection Ecotoxicology; J. Wheeler, Dow Agrosciences

Fish bioconcentration studies are conducted to address various regulatory requirements. These tests result in the generation of a bioconcentration factor (BCF), which is used to determine whether substances are bioaccumulative and/or need further consideration regarding accumulation in the food chain and for secondary poisoning assessments. Bioconcentration tests are resource and animal intensive, often requiring more than 100 fish per study. Replacing, reducing or refining the use of fish for BCF testing would therefore have multiple benefits, including improved efficiency, reduced costs and supporting animal welfare considerations. Since its revision in 2012, the OECD Test Guideline 305 'Bioaccumulation in fish' includes the option to use one exposure concentration rather than two, providing there is scientific justification. However, two concentrations may still be required for some regulatory purposes. To determine whether the one concentration approach could be justified for plant protection product (PPP) actives and general chemicals, BCF values resulting from low and high exposure concentrations were compared for 55 PPP actives and 236 general chemicals. Within this dataset we also explored the BCF values generated for ionisable substances. Overall, there was no statistically significant difference in the BCF values from low and high exposure concentrations. This suggests that the testing of one exposure concentration is sufficient to reliably estimate the BCF value. The relationship between the low and high exposure concentration BCF values was particularly strong for BCFs $\geq$ 1000 L/kg, which is beneficial as only chemicals with relatively high BCFs (e.g. > 2000 L/kg, for the EU 'B' criterion) may require regulatory action. This analysis provides a data-driven rationale for using the one test concentration approach for PPP actives and general chemicals, and where applied would decrease the numbers of fish used by one third.

RP205 Evaluation of the Daphnia magna Four-Day Survival and Growth Test Method

N. Love, S. Skigen, D. McCausland, GEI Consultants, Inc.

In 2009 James Lazorchak, Mark Smith, and Herman Haring presented a new test method based on the growth endpoint for the Daphnia magna species. The Daphnia magna four-day survival and growth test method was developed to provide an additional option to evaluate the potential for sublethal toxicity in the aquatic environment (Lazorchak, 2009). Current methods for the species involve an acute exposure of only 24 to 96 hours, or long-term chronic exposures of 21 to 28 days. The proposed method would allow a shorter duration test while still incorporating the sublethal endpoint. Recently, many dischargers in the Western United States have been struggling to meet whole effluent toxicity (WET) sublethal limits for C. dubia due exclusively to interference from the total dissolved solids (TDS) components in their effluent. While the four-day D. magna method has not been approved by the USEPA, we have begun to evaluate concurrent chronic C. dubia and four-day D. magna tests in various waters in Colorado to determine whether the method could potentially isolate the TDS component while still providing an estimation of true toxicity. Through the expanded use of the method, we have conducted an extensive evaluation of the method requirements and, in turn, have formulated several key observations and various suggested modifications to the method should it ever be considered as an alternate test method for WET testing. Our evaluation focused primarily on control performance criteria requirements and the data required to demonstrate good performance will be presented.

RP206 Microtox: Bioanalytical Tool in Water Quality assessment. Evaluation of toxicity of samples from Cauca-River-Colombia

R. Sarria, Universidad del Cauca; J.A. Gallo Corredor, Universidad del Cauca / Dept of Chemistry

Bacterial Bioluminescense inhibition assays (Microtox) are the most widely used assay for measurement of citotoxicity in water samples. This type of assays utilises the light emission in naturally bioluminescent bacteria (Vibrio Fischeri) as a measure of overall celular energy status and health. A decreased light output indicates interference with energy metabolism and overall celular health, reflecting the combined baseline toxicity of all chemicals in the sample. Bacterial Bioluminescense inhibition assays are therefore very suitable for screening of overall non-specific toxicity. In addition to the low cost and simplicity of these assays, their applications in water quality testing are wide ranging and well represented in the literature providing a large volume of comparative information. The water types tested with the Microtox, for example, span across efluents of coal gassification, oil refineries, pulp mills and sewage treatment plants as well as environmental waters and drinking water. Microtox was used to evalueted the quality of Cauca River from

Colombia. In Colombia, the Cauca River is the second most important artery fluvial. The Valley formed by the Cauca River constitutes the axis of development of different socioeconomic activities in the southwestern region of Colombia, as are power generation, sand extraction, drinking water supply, agricultural, domestic and industrial use. However, these activities impact negatively the ecosystem causing deterioration of the quality of river water. Sediments samples were taken from eight sampling points in across of the Cauca River in the Colombian southwest. Considering the presence of potentially toxic substances, such as pesticides, PAHs and heavy metals, aqueous and organic extracts from Cauca River were used to assess toxicity in sediments by using the photo-luminescence bacteria Vibrio Fisheri as screening response variable. Overall, the Microtox approach appears to be rapid and cost effective for on-site hotspot identification, and may increase understanding of hazards associated with heavy metal and organic contaminants in these waterways.

RP207 Rapid ecotoxicological bioassay using delayed fluorescence in the marine cyanobacteria Cyanobium sp. (NIES-981)

T. Yamagishi, National Inst for Environmental Studies; M. Katsumata, Hamamatsu Photonics / Central Research Laboratory; H. Yamaguchi, Y. Shimura, M. Kawachi, H. Koshikawa, Y. Horie, N. Tatarazako, National Inst for Environmental Studies

@font-face font-family: “Cambria Math”; @font-face font-family: “Yu Mincho”; @font-face font-family: “@Yu Mincho”; @font-face font-family: “Osaka”; @font-face font-family: “@Osaka”; p.MsoNormal, li.MsoNormal, div.MsoNormal margin: 0mm 0mm 0.0001pt; text-align: justify; font-size: 12pt; font-family: “Yu Mincho”; .MsoChpDefault font-family: “Yu Mincho”; div.WordSection1 A general method for testing the toxicity of chemicals on algae was described in the 1984 OECD test guidelines (algal growth inhibition test TG201), in which growth inhibition at 72 h after exposure is used to estimate the effective concentration (i.e., EC_{50}) of chemical. Although this test reliably and directly measures algal growth, it is time consuming and expensive because it requires counting the cells every 24 h for up to 72 h of exposure, or more, using an electronic particle counter or under a microscope. The use of delayed fluorescence (DF) intensity as an endpoint for rapid estimation of the effective concentration (EC_x) has been reported as an alternative to standard growth inhibition (at 72 h after exposure) in some fresh water algae including Pseudokirchneriella subcapitata. In marine algae, although an approach of bioassaying using DF measurements has not been performed yet, its development would provide many benefits for marine environmental risk assessment. In this study, we selected marine cyanobacteria Cyanobium sp. (NIES-981) as a test algal species, which is closely related to genera Synechococcus/Prochlorococcus known as major primary producer in marine environment. We knew that this species grows with high efficiency under a culture condition in the preliminary study, and therefore considered that it is candidate for the test species. As a first step, we showed that this species is valid for a standard growth test (72-h growth inhibition test) using five chemicals (3,5-DCP, simazine, diflufenican, $K_2Cr_2O_7$,and $CuSO_4$). Next, we compared EC_{50} values and low-toxic-effect values (EC_{10}, EC_5, and NOEC) of five test chemicals based on the standard growth test with EC_{50} values obtained by a test with a 24-h time period using DF intensity. Finally, we discuss the possibility of rapidly estimating the toxicity of chemicals by DF measurement in Cyanobium sp.. Based on comparisons of the two dose-response curves and the EC_{50} values, we conclude that DF intensity is useful as an endpoint for rapid estimation of EC_{50} in Cyanobium sp..

RP208 Conversion of estrone to estradiol in male fathead minnows: Implications for assessing risk

D. Feifarek, E.C. Randolph, USEPA / National Health and Environmental Effects Research Laboratory; R. Milsk, ORISE; J.E. Cavallin, USEPA / Mid-Continent Ecology Division; S. Poole, USEPA / National Health and Environmental Effects Research Laboratory; T. Saari, USEPA / ORD, NHEERL; K.M. Jensen, USEPA / National Health and Environmental Effects Research Laboratory; B.R. Blackwell, ORISE / National Health and Environmental Effects Research Laboratory; D.L. Villeneuve, G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory

Estrogens are frequently observed in aquatic environments associated with anthropogenic influence, such as agricultural runoff and wastewater treatment effluent. While 17β-estradiol (E2) is the most potent naturally-occurring estrogen, estrone (E1) is often found at higher environmental concentrations. However, exogenous sources of E1 could potentially be converted to the more potent E2 through the action of endogenous 17β-hydroxysteroid dehydrogenase activity, specifically, the 17β-hydroxysteroid dehydrogenase type 1 isoform (HSD17B1). Observation of increased plasma E2 concentrations without measureable changes in aromatase (cytochrome P45019a) expression in male fish caged in ambient waters containing elevated concentrations of E1, but low or non-detectable concentrations of E2, suggested this may be occurring in the field. If so, exogenous E1 may have a greater impact on reproductive function in aquatic vertebrates than previously assumed. The present study was conducted to evaluate this hypothesis. Male fathead minnows (Pimephales promelas) exposed to aqueous concentrations of 16.7, 50, and 150 ng E1/L in the laboratory exhibit significantly ($p< 0.05$) elevated plasma E2 concentrations relative to control. Plasma testosterone (T) was elevated at a low E1 exposure concentration (1.8 ng E1/L) and depressed at the highest level of exposure (150 ng E1/L). Additionally, vitellogenin (VTG) mRNA expression was significantly elevated at concentrations of 50 and 100 ng E1/L. Results suggest that when assessing potential risks of environmental estrogen mixtures to fish, it may be necessary to assume that potency of measured E1 is, in fact, equivalent to that of E2. The contents of this abstract neither represent, nor necessarily reflect official USEPA policy.

RP209 Preparation of Water Accommodated Fractions Using a Passive Dosing Technique

C. Mead, Envigo Research Limited / Ecotoxicology Dept.; D. Mullee, Envigo Research Limited / Dept of Residue Analysis; D. Sacker, Envigo Research Limited / Dept of Ecotoxicology; M. Glazier, Envigo Research Limited / Dept of Residue Analysis

In the assessment of the toxicity of complex mixtures (UVCBs) with limited aqueous solubility, the preparation of Water Accommodated Fractions (WAFs) is the generally advocated method of test solution preparation (OECD 23). The preparation of WAFs is not without its difficulties as great care needs to be taken to ensure that undissolved, dispersed test item is not present in the final WAF used for testing as this can exert physical effects on the test organisms. Chemical stability of the WAF is also an area where questions can arise as the method of preparation does not lend itself to the use of continuous flow-through dosing techniques. The use of a passive dosing technique to prepare WAFs of various petrochemicals was investigated to determine whether this technique would allow for the easy preparation of WAFs where undissolved/dispersed test item would not be present. Chemical analysis of WAFs prepared using both the traditional approach and the passive dosing technique was performed to determine whether similar chemical profiles in the WAFs prepared using the different methods were obtained. Stability of the WAFs was also determined over a suitable time period to be used in standard aquatic toxicology studies.

RP210 Toxicity Identification Evaluation of Textile Dyeing Effluents Treated by Fenton Process

J. Na, Korea Univ; J. Jung, Korea Univ / Environmental Science and Ecological Engineering; G. Nam, Korea Univ / Dept of Environmental Science Ecological Engineering

Textile dyeing wastewater contains many recalcitrant compounds including dyes, surfactants, resins, synthetic sizing compounds, resulting in a threat to human and animal health. This wastewater is commonly treated by biological treatment followed by an advanced oxidation process such as Fenton oxidation. Most of previous studies have been conducted to evaluate the removal of organic compounds and color, without consideration of toxicity of textile dyeing effluents. In this study, ecotoxicity of textile dyeing effluent was identified using Daphnia magna by the TIE (toxicity identification evaluation) procedures. Overall, the analysis showed that Fe and Zn are the key toxicants in textile dyeing effluents, which may be originated from the Fenton process. In addition, ill-defined organic toxicants likely dyes and surfactants also contributed to the observed toxicity of effluents significantly.

RP211 Reducing the number of fish used in acute toxicity testing: Incorporation of the Fish Embryo Acute Toxicity test into the threshold approach

P. Bishop, PETA International Science Consortium Ltd.; G. Stoddart, PETA International Science Consortium Ltd., London UK; D. Altmann, M. Paparella, Environment Agency Austria, Vienna, Austria; S. Walter-Rohde, Environment Agency Germany, Dessau-Roßlau, Germany; C. Fassbender, PETA International Science Consortium Ltd., London, UK; S.E. Belanger, The Procter & Gamble Company / Environmental Stewardship and Sustainability Organization; J. Rawlings, The Procter & Gamble Company / Global Product Stewardship; T. Braunbeck, Univ of Heidelberg / Centre for Organismal Studies

The assessment of aquatic toxicity is required in various regulatory frameworks and has a huge impact on the number of fish used around the world. In 2011, nearly 180,000 fish were used for toxicological and other safety assessments in Europe. Large numbers of aquatic toxicity tests are required for REACH and, with the 2018 registration deadline fast approaching, strategies to reduce the number of aquatic toxicity tests are urgently needed. The acute fish toxicity test (AFT, OECD Test Guideline [TG] 203) is one of the most frequently used aquatic toxicity tests worldwide. Because death is the endpoint, animal welfare is a significant concern, making the goal of reducing the number of animals used a priority. Applying the threshold approach (OECD Guidance Document 126), where an initial fish test is conducted at one concentration derived from test responses in Daphnia and algae and continued testing is triggered only if mortality is observed at this threshold concentration, can significantly reduce the number of fish used in the AFT. Furthermore, the Fish Embryo Acute Toxicity Test (FET, OECD TG 236) provides a significant refinement to the AFT, as embryos are used instead of adult/juvenile fish. We are developing a strategy for incorporating the FET into the threshold approach to provide a means for reducing the number of fish used in acute aquatic toxicity testing. This strategy is building on extensive earlier work and drawing upon the work of three individual efforts.A new database containing acute toxicity data for adult/juvenile fish, fish embryos, Daphnia and algae has been constructed to analyse how the FET can be incorporated into the threshold approach. The applicability domain of the FET will be clarified, and the uncertainties of the FET (focusing on metabolism) will be compared to the uncertainties of the AFT for the protection of the aquatic ecosystem. On this basis, a concept for defining acceptance criteria for the new approach will be proposed. A recently published report by the European Chemicals Agency on the use of the FET for REACH is being considered. This poster presents progress to date. The views, conclusions and recommendations are those of the authors and do not necessarily represent the policies or positions of the organisations to which the authors are affiliated.

RP212 Methodology to visualize skeletal defects in inland silverside Menidia beryllina exposed to levonorgestrel

M.M. McConville, Univ of North Carolina, Wilmington / Marine Biology; B. DeCourten, Univ of North Carolina, Wilmington / Biology and Marine Biology; B. Woodall, UNCW; A. Taylor, Univ of North Carolina Wilmington; S.M. Brander, Univ of North Carolina, Wilmington / Dept of Biology Marine Biology

The inland silverside Menidia beryllina is zooplanktivorous and inhabits rivers and estuaries along the East, West, and Gulf coasts. Their high sensitivity to chemicals, small body size, short generation time, and small-batch fecundity make them an ideal toxicological study species. Toxicological studies have been conducted on abnormal skeletal development of the inland silverside after exposure to certain chemicals; however, to the best of our knowledge no studies have used calcein staining to visualize the resulting abnormalities in this species. Calcein (CAS 1461-15-0) is a fluorochrome dye that binds to calcified structures. When excited with blue light (of ~488 nm), it emits a green fluorescence (~520 nm). Calcein has been successfully used in aquaculture to non-invasively mark juvenile fish, and to examine skeletal development in the model zebrafish. The goal of this study was to determine whether calcein has the potential to be a useful tool to better understand the effects of environmental contaminants on bone development in M. beryllina. Previous work in our laboratory demonstrated that skeletal abnormalities occur after exposures to ng/L concentrations of endocrine disrupting chemicals (EDCs). We therefore designed a series of tests to elucidate the best methodology for calcein staining of M. beryllina skeletal structures in order to examine such abnormal skeletal development. After immersing live larvae in 2-g/L of calcein for 7 minutes, calcification of major bone structures were successfully seen between 9-21 days post fertilization. We subsequently exposed M. beryllina embryos to environmentally relevant concentrations of levonorgestrel from 5 hpf to hatch (168-192 hpf). Fish were immediately stained with calcein and imaged using a confocal microscope to quantify skeletal abnormalities in the craniofacial region. This method will be useful for better understanding skeletal abnormalities in larval stages of this model fish species resulting from exposure to environmentally relevant concentrations of EDCs.

RP213 Strategies for Characterizing Species Sensitivity in Screening Level Assessments for Data Poor Industrial Chemicals

K. Moran, USEPA / OCSPPOPPTRAD; K.E. Mayo-Bean, USEPA / OPPT

The EPA Office of Pollution Prevention and Toxics (OPPT) is responsible for implementing the Toxic Substances Control Act (TSCA) which regulates industrial chemicals in the US. Under TSCA, the notifier is not required to conduct any “new” ecological or human health testing before submitting a PMN and, thus, many substances are submitted with little or no experimental data. To conduct risk assessments with little or no data, OPPT has developed a strong knowledge base in quantitative structure activity relationships (QSARs) based on available laboratory data. These QSARs represent a collection of curated experimental data that are categorized by chemical class and taxa for the standard aquatic toxicity endpoints used in screening level risk assessments. The endpoints represent hazard potential to three levels of taxa including vertebrates (fish), invertebrates, and algae. The species included in the curated data sets for each taxa are those allowed under the standard test guidelines (i.e., OCCSP and OECD Guidelines). Although many species are represented in a QSAR, often data available for a chemical are for a single species within the taxa. In the new chemicals program, potential variability in toxicity between species is addressed using a standard set of assessment factors that are applied to the estimated or measured effect levels. However, if a QSAR class is sufficiently robust (i.e., Neutral Organics, Esters, Phenols, Aliphatic Amines), plotting effect levels against Log Kow can inform on the class-specific species variability represented by the spread of data across the regression lines. USEPA is investigating the usefulness of class specific assessment factors developed from this demonstrated spread of data to better account for species variability within a specific class and taxa in conjunction with updates to the USEPA

ECOSAR program as more robust data sets become available. For each chemical class where sufficient data are available, the data will be plotted and the spread of data around the trend line will be depicted and discussed. The views expressed in this abstract are those of the authors and do not represent Agency policy or endorsement.

RP214 Passive Dosing Functional Water Solubility and Implications for Aquatic Toxicity Testing

R.J. Guinn, Eastman Chemical Company / Product Stewardship Regulatory Affairs; T. Lloyd-Saylor, Eastman Chemical Comany / Corporate Analytical Division

Over the last few years techniques to introduce and maintain stable saturation concentrations of substances and mixtures for aquatic toxicity tests using passive dosing have been reported. These techniques typically utilize silicone tubing or solid silicone O-rings as the reservoir for the test material, and the dosing in water follows partitioning equilibrium theory. The technique also provides an opportunity to quantify the saturation water solubility of substances that are difficult to measure using standard water solubility methods. However, caution must be exercised for multi-component substances or mixtures as minor constituents or impurities may be the most water soluble components and may introduce analytical quantification issues, as well as issues for aquatic toxicity testing. Examples of solubility experiments of multi-component substances using different passive dosing techniques, along with discussions of analytical challenges and implications for aquatic toxicity testing using these techniques will be presented.

RP215 Development of Culturing and Rearing Methodology for Ephemeroptera Taxa

G. Edwards, D. Brady, Marshall Univ / IST; M.Y. Armstead, Marshall Univ / Integrated Science and Technology; M. Wilson, Marshall Univ / IST

Mayfly taxa may be more sensitive to aquatic pollutants than standard test organisms used to determine anthropogenic effects on aquatic ecosystems. Mayflies, however, are not frequently used in toxicity testing and few studies have addressed culture methods for mayfly taxa. Additionally, while larger mayflies can be field collected for use in bioassays, the most sensitive stage may be newly hatched individuals and the relative sensitivity has not been established for most species. To answer these questions, and to provide organisms of consistent health for use in toxicity testing, mayflies are being reared in the laboratory. Culture methods for rearing larval mayflies to emergence, collecting viable eggs sexually and parthenogenetically, and rearing eggs to hatch have been developed in the Marshall University Lab. Currently, evaluations are underway to determine if hatch rate can be manipulated in developing egg clutches to synchronize hatching and be more for conducive for use in toxicity testing. Further development of the methods in order to conduct native mayfly toxicity testing is dependent on a suitable food source being established for cultured mayfly nymphs. The objective of the study described herein was to investigate adequate food alternatives that will lead to a minimum of 80% survival in juvenile mayflies the first 48 hours after hatch. This endpoint was selected because standard toxicity testing requires an 80% survival within the control organisms for the test to be considered valid. Tests were conducted using a variety of diets incorporating laboratory cultured algal alternatives and natural and artificial foods options such as ground fish food, yeast-cereal leaves-trout chow and leaf disks. Diet treatments were given to individual nymphs in separate chambers throughout the course of a 36-day test. Mortality rates from preliminary testing with 11 feeding treatments were used to narrow food types to the ones yielding the best results for further testing. Success was evidenced by the growth and development of the nymphs, measured as number or exuvia shed and survival with the goal of 80% survival in the first 48 hours after hatch. Two of the four feeding treatments provided over 80% survival of newly hatched mayfly nymphs in 48 hours. The other two provided over 70% survival in 48 hours. A diet of laboratory cultured Navicula sp. and leaf disks supported the greatest survival over the 36 day study.

RP216 A comparison of the survival of Leptocheirus plumulosus and Corophium volutator in the 10-day Sediment Toxicity Test using Formulated Sediment

J. Griffith, Environmental Enterprises USA, Inc. / Drilling Fluids; D. Daniel, Environmental Enterprises USA, Inc.

Synthetic based fluids slated for use in the Gulf of Mexico must pass the 10-day Sediment Toxicity test, EPA Method 1644, using L. plumulosus. The Offshore Chemical Notification Scheme requires several different types of testing to be completed on chemical components designated for use in the exploration, exploitation and associated offshore processing of petroleum on the UK Continental Shelf. If the chemical or component is a “sinker”, has a Log Pow >4, or is in any other way known to adsorb to particles or end up in the sediment, or contain surfactants, a sediment re-worker test using C. volutator must be performed. This study evaluates the performance of L. plumulosus and C. volutator using EPA Method 1644. The toxicant used was a C16/18 IO which is also used as the standard reference material for the test method. Six treatments were prepared with formulated sediment, five test substance concentrations and a negative control. Twenty organisms were exposed to each test treatment for 10 days. The endpoint for each test was survival.

RP217 The Uncertainties Associated with Detection and Quantification of Intersex (Testicular Oocytes) in Fish

A. MacLeod, Univ of Maryland, College Park / Environmental Science and Technology; L.T. Yonkos, Univ of Maryland / Environmental Science and Technology

Over the last two decades, several teleost fish species have been detected with testicular oocytes (TO), resulting in a variety of techniques to characterize the occurrence and severity of the condition. Primary methodological differences relate to the orientation of histologic sections (transverse vs. longitudinal), number and spatial distribution of histological sections observed, and quantification of TO severity (direct enumeration of observed TO vs. application of a ranking system to describe number, relative proximity and, where appropriate, developmental stage of oocytes). Resulting estimates of TO prevalence and severity will often differ in meaningful ways so care must be taken to recognize these distinctions when comparing study results and when designing studies. To address the benefits and caveats of each method, largemouth bass Micropterus solamoides testes were subjected to transverse, longitudinal, and biopsy sectioning (biopsies collected via laparoscopy, a non-lethal surgical technique). It is paramount to understand the implications of each available technique to collect tissue (lethal vs. non-lethal) and each subsequent methodological step when designing an investigation to ensure its comparability to findings in the scientific literature. With few exceptions, correlations of TO metrics should be investigated at the population level rather than the individual level due to variability in sub-samples and ability to detect TO. Data was analyzed across sample sites by comparing TO prevalence and severity from each step-section singly, and across all step-sections, to determine the variability based on level of observational effort and method employed. Detailed results and implications will be discussed.

RP218 Development of quantitative structure activity relationship models to predict the toxicity of fluorinated chemicals to aquatic organisms

J.L. Newsted, Natural Resource Technology

Over the last 12 to 15 years, a concentrated effort has been made to identify and quantify fluorinated compounds in the aquatic and terrestrial environments. Initially, these programs focused on perfluoroalkyl sulfonic acids (PFSAs) and perfluorocarboxylic acid (PFCAs). However, as analytical methods and instrumentation have improved, the number of fluorinated classes that have been identified in environmental matrices has increased dramatically to include fluorotelomers, polyfluorinated phosphate esters (PAPs) and perfluorophosphonates (PFPAs). In contrast, the assessment of the potential risks these fluorochemicals pose biota has progressed much more slowly. With the exception of perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) few fluorochemicals have been tested sufficiently to support many regulatory needs including the support of pre-manufacturing notices, water quality criteria and ecological risk assessment. One means to address this lack of data is to develop quantitative structure activity relations (QSAR) that can be used to screen and rank the fluorochemicals as to their potential environmental risks. Studies have shown that within different classes of fluorochemicals, the toxicity to aquatic organisms tend to increase with the length of the fluorinated carbon chain. However, branching, inclusion of heteroatoms and differences in terminal functional groups in the non-fluorinated portion of theses compound can also alter toxicity making it difficult to predict toxicity across the various classes of fluorochemicals. To address this issue, a systematic evaluation of available ecotoxicological data for fluorochemicals was conducted. For fluorochemicals with adequate toxicological data, molecular descriptors were determined that included topographical, geometrical, electrostatic, and quantum chemical endpoints. QSAR models were developed using multiple linear regression (MLR) and principal component analyses (PCA) methodologies. Preliminary results from these models indicate that reasonable estimates of acute toxicity to several species can be made using this type of approach. Results from these analyses will be presented and uncertainties and areas of future research will be discussed.

RP219 Mosquitofish as a model for endocrine disruption; the impacts of exposure to arsenic on reproductive function and development

R. Smith, Northern Arizona Univ / Biology; C.R. Propper, Northern Arizona Univ / Biological Sciences

A wide range of contaminants can interfere with hormonal regulation in vertebrates. These endocrine disrupting compounds (EDCs) are of high relevance for human and wildlife health. Endocrine signaling controls essential physiological processes, which have an impact on an individual's health, such as growth and development, stress response, and ultimately reproduction and population development. The metalloid, arsenic, is known to cause various detrimental health problems including cancer and non-cancer illnesses and has a regulatory limit of 10 ppb in drinking water. At low environmentally relevant levels, arsenic has been identified as an EDC that disrupts normal function of thyroid, adrenal, and gonadal axes. Arsenic has been shown to inhibit androgen receptor (AR) recruitment to AR target genes in sertoli and prostate cells. For males, EDCs that have anti-androgenic activity may lead to alterations in genetic signaling pathways, hormonal profiles, and subsequently, secondary sex characteristics. To determine potential health outcomes from arsenic exposure, juvenile male mosquitofish (Gambusia affinis) were collected and exposed to sodium arsenate (0 ppb, 0.7 ppb, 7 ppb, 74 ppb) in the lab for 30 days. Morphological endpoints including body length, body mass, gonopodium somaticindex (GSI), and gonopodial lengths, indicative of androgen-dependent secondary sex characteristic development, were evaluated. Total length, standard length, condition factor, and mass did not differ among treatment groups. Using geometric morphometric analysis, we found that body shape was significantly narrowed in the 74 ppb group. GSI and gonopodial lengths were significantly lower, showing a reduced growth effect, in the 7 ppb and 74 ppb treatment groups. However, differences in the 4:6 ratio among treatments were not significant suggesting that the overall fin growth is being inhibited. Our results suggest that arsenic exposure below current regulatory limits affects general growth and reproductive development in a sentinel fish species. Future work will determine whether molecular reproductive endpoints can also act as biomarkers for arsenic exposure in Western mosquitofish under both laboratory and field conditions.

RP220 Potential Aquatic Toxicity of Petroleum Biodegradation Metabolites in Groundwater Samples from Fuel Release Sites

A. Tiwary, Chevron / HES; R.I. Magaw, Chevron ETC; D.A. Zemo, Zemo & Associates; R.E. Mohler, Chevron ETC / PAD; K. O'Reilly, Exponent / Environmental and Earth Science; C. Espino Devine, Chevron ETC

Petroleum hydrocarbons biodegrade in the environment and are converted to polar (non-hydrocarbon) metabolites. These metabolites are extracted from groundwater samples and quantified as Total Petroleum Hydrocarbons (TPH) unless a silica gel cleanup (SGC) step is applied to the sample extract prior to the TPH analysis. The polar metabolites can be separated from the non-polar hydrocarbons by incorporating the SGC step; however, some regulatory agencies are hesitant to adopt this method, citing the unknown nature and toxicity of these complex mixtures. Using state-of-the-art non-targeted GCxGC-MS analyses of groundwater samples from historic fuel release sites, we tentatively identified thousands of polar metabolites representing many distinct structural classes of chemicals including acids/esters, alcohols, phenols, ketones, and aldehydes. The potential toxicity of polar metabolites to freshwater aquatic organisms has been investigated as part of this study. Briefly, upgradient (representing local background conditions) and downgradient groundwater samples were collected from several representative biodegrading fuel release sites, and submitted to a contract laboratory for chronic aquatic toxicity testing for freshwater organisms using EPA test methods 1000 (Fathead Minnow), 1002 (Daphnid) and 1003 (Green Algae). Results show that aquatic toxicity of groundwater samples from fuel release sites are primarily due to background water quality, and not from biodegrading petroleum metabolites. Overall, the complex mixtures of polar metabolites, at concentrations typically found at petroleum release sites, are unlikely to pose a significant risk to aquatic life.

RP221 Dredging and seasonality effects on nutrient concentrations and ecoenzymatic activity in agricultural drainage ditch sediments

M. Moore, M.A. Locke, USDA-ARS National Sedimentation Laboratory / Water Quality and Ecology; M.B. Jenkins, USDA-ARS National Sedimentation Laboratory; R.W. Steinriede, USDA-ARS National Sedimentation Laboratory / Water Quality and Ecology Research Unit; D.S. McChesney, USDA-ARS National Sedimentation Laboratory

Agricultural drainage ditches are conduits between production acreage and receiving aquatic systems. Often overlooked for their mitigation capabilities, agricultural drainage ditches provide an important role for nutrient transformation via microbial metabolism. Variations in ecoenzyme activities have been used to elucidate microbial metabolism and resource demand of microbial communities to better understand the relationship between altered nutrient ratios and microbial activity in aquatic ecosystems. Two agricultural drainage ditches, one in the northeast portion of the Arkansas Delta and the other in the lower Mississippi Delta, were monitored for a year. Sediment samples were collected prior to each ditch being dredged (cleaned), and subsequent post-dredging samples occurred as soon as access was available. Seasonal samples were then collected throughout a year to examine effects of dredging and season on nutrient concentrations and ecoenzymatic activity recovery in drainage ditch sediments. Significant differences in phosphorus concentrations were noted at almost every location and sediment depth, primarily between the pre-dredge and post-dredge samples. Dredging decreased sediment phosphorus concentrations between 33-51%, depending on sample location and depth. Likewise, ecoenzymatic activity was significantly decreased after dredging in most samples. Fluorescein diacetate hydrolysis activity in one ditch decreased 56-67% after dredging. Many sample sites also had significant phosphorus and ecoenzymatic activity differences between the post-dredge samples and the year-long follow-up samples. Results indicate microbial metabolism in dredged drainage ditches may take up to a year or more to recover to pre-dredged levels. Likewise, while sediment nutrient concentrations may be decreased through dredging, runoff and erosion events over a year tend to quickly replenish nutrient concentrations in sediments. Understanding microbial metabolism and nutrient dynamics within agricultural drainage ditches is a first step toward addressing issues of nutrient enrichment in aquatic receiving systems, such as the Gulf of Mexico.

RP222 Endocrine disruptors and parasitism: what effects on the sex behaviour of the amphipod Gammarus pulex ?

A. Fivet, S. Horion, J. Thome; E. Gismondi, Univ of Liege / Laboratory of Animal Ecology and Ecotoxicology

Endocrine disruptors (EDCs) are well known to disrupt the development and the reproduction of exposed organisms. Although this point has been studied in vertebrate models, the limited knowledge of the endocrine system of invertebrates makes the evaluation of EDCs effects difficult. However, invertebrates represent the major part of aquatic ecosystems, such as amphipods Gammaridea, which are crucial for their functioning (e.g. litter degradation, food resource). Moreover, gammarids are hosts of parasites such as vertically-transmitted microsporidia (microsporidia VT), which could be confounding factors in assessment of EDC effects. Indeed, some microsporidia VT could have endocrine effects by their own present in the host, since it was observed for example, a feminisation of juvenile males, which become phenotypic females. This study aimed to assess the effects of the ethinylestradiol (EE_2) and the cyproterone acetate (CPA), EDCs commonly studied in vertebrates, and the presence of microsporidia VT, on the sex behaviour and the fitness of the freshwater amphipod Gammarus pulex during a 30 days-exposure. Several parameters were recorded such as: the time of amplexus formation, the mate-guarding time, and numbers of spermatozoa and oocyte produced. Results revealed that less amplexus were formed when G. pulex were exposed to EDCs, especially to EE_2. However, G. pulex exposed to EE_2 0.05 $\mu g.L^{-1}$ took less time to form amplexus than controls, whereas G. pulex exposed to EE_2 5 $\mu g.L^{-1}$ took longer time. About parasitism, when exposed to EE_2 0.05 $\mu g.L^{-1}$, parasitized G. pulex were more in amplexus than respective control. Moreover, whatever the exposure condition, the percentage of parasitized females in amplexus were higher than in controls. Finally, no significant effect of EDCs was observed on the spermatozoa and oocyte in unparasitized gammmarids, but weaker spermatozoa counts were measured in presence of microsporidia VT. Under CPA stress, parasitized males produced significantly less spermatozoa than respective controls. Results highlight that EE_2 and CPA caused low effects on the sex behaviour and the fitness of G. pulex, unlike microsporidia VT presence, which decrease the amplexus time formation, increase the percentage of females in amplexus, and reduce the spermatozoa production, in stress conditions. Thus, results suggest that the parasite presence affected the gammarids behaviour in order to tend to increase its own fitness (e.g. transmission).

RP223 Infradian control of Daphnia magna molt cycle and its disruption by nitric oxide

S. McKnight, North Carolina State Univ; S. Eytcheson, NCSU Toxicology / Biological Sciences; G.A. LeBlanc, North Carolina State Univ / Biological Sciences

Internal molecular clocks control influential biological processes and environmental cues aid in the regulation of the timing of these rhythms. Environmental chemicals may disrupt these rhythms resulting in profound adverse consequences. The molting in arthropodsis initiated by the synthesis and inactivation of 20-hydroxyecdysone. Disruption in the timing of the 20-hydroxyecdysone peak can adversely impact both growth and reproduction. We hypothesized that the overall duration of the molt cycle in crustaceans is dictated by a cascade in the sequential expression of several nuclear receptors and cytochrome p450 (CYP) enzymes. Further, we propose that pulses in nitric oxide control the availability of one of these proteins, HR3, and as such, acts as a fine-tuner of the timing of the molt cycle, perhaps in response to environmental cues. Lastly, we propose that exposure to exogenous sources of nitric oxide such as nitrate and nitrite can disrupt the timing of the molt cycle resulting in adverse impact on growth and reproduction. Analysis of mRNA expression of relevant proteins during the molt cycle of adult daphnids (Daphnia magna) revealed the sequential production of E75, HR3, FTZ, 20-hydroxyecdysone-synthesizing CYPs, and 20-hydroxyecdysone-inactivating CYP. Early exposure to a nitric oxide donor sodium nitroprusside (SNP) resulted in a significant increase in the magnitude and delay in timing of peak expression of FTZ and CYP18a1 mRNA expression as well as a delay in molting. CYP18a1 is the CYP enzyme responsible for inactivation of 20-hydroxyecdysone. We conclude that exposure to an exogenous source of nitric oxide caused excess availability of free HR3 protein resulting in excess expression of downstream proteins. This may ultimately result in a prolongation of the duration of the molt cycle with negative consequences on growth and reproductive rates.

RP224 The Effects of Aquatic Nitrate Pollution on Zebrafish (Danio rerio) Embryo Respiration

S.M. Conlin, H.J. Hamlin, The Univ of Maine / School of Marine Sciences

Nitrogenous compounds naturally cycle through the air, aquatic systems, and soil. Global nitrogen has been increasing in quantity due to anthropogenic sources, whether intentional or unintentional, that include agricultural fertilizer, fossil fuel combustion, and exhaust gasses. Excess nitrogen in agricultural fertilizers can leach into groundwater and presents the potential for contaminating drinking water and affecting aquatic wildlife. To assess the effects of nitrate pollution, zebrafish embryos are used as a model organism. This research seeks to understand nitrate's function in zebrafish embryo respiration as measured by oxygen consumption rates. Oxygen consumption rates (OCR) are determined using a novel approach Seahorse Bioscience XF^{e}96 extracellular flux analyzer specially designed for use with zebrafish embryos. OCR analyses were performed for five nitrate treatment concentrations that included 0, 5, 10, 50 and 100 mg/L NO_3-N with both sodium nitrate or potassium nitrate. To separate the effects of nitrate from the carrier ion, whether sodium or potassium, OCR analyses were also performed for four vehicle control treatment concentrations equivalent to the amount of sodium or potassium within each of the nitrate treatments with sodium chloride or potassium chloride, respectively. Zebrafish embryos were chronically immersed in the respective treatment concentrations for 24 hours post fertilization before 75 minutes of OCR measurements were recorded. OCR measurements were averaged and normalized to a 0.05µM FCCP positive control treatment. Dunnett's multiple comparisons test following a significant one-way ANOVA was used to compare treatment OCR values to control OCR values. Sodium nitrate treatments of 50 and 100 mg/L NO_3-N, as well as the corresponding vehicle controls for each treatment significantly reduced OCR compared to control. Potassium nitrate treatments of 10 and 50 mg/L NO_3-N, as well as the 50 mg/L and 100 mg/L vehicle control treatments significantly reduced OCR compared to control. Significant vehicle control OCR analyses represent an often-overlooked aspect of laboratory nitrate research, as the carrier ion is often not examined for its effects. In addition to immersion OCR analyses, injection of potassium and sodium nitrate through the zebrafish embryo chorion will be investigated for its effects on embryo respiration and to investigate how different routes of laboratory nitrate exposure may impact embryo respiration.

RP225 Development of an in vivo anti-androgenic activity detection assay using fenitrothion (MEP) in Japanese medaka (Oryzias latipes)

N. Tatarazako, National Inst for Environmental Studies / Environmental Risk; Y. Horie, National Inst for Environmental Studies; H. Watanabe, National Inst for Environmental Studies / Health and Environmental Risk Research Center; H. Takanobu, National Inst for Environmental Studies / Center for Environmental Rsik Research; T. Iguchi, National Inst for Basic Biology / Molecular Environmental Endocrinology

The effects of endocrine disruptors, such as anti-androgenic chemicals, on aquatic environments, has caused increasing concern in recent years. Currently, the method used to screen chemicals for anti-androgenic activity is called the androgenised female stickleback screen (AFSS), and it was established by the Organization of Economic Cooperation and Development (OECD) in 2011 using the stickleback. However, screening assays have not been developed in other fish species. In this study, we present the detailed description of the development and evaluation of a screening method for anti-androgenic activity in chemicals by utilizing Japanese medaka (Oryzias latipes). Using this model, we focused on the number of papillary processes as an indicator of a chemical's anti-androgenic activity. Thus, at 35 days post fertilization, medaka were exposed to fenitrothion (MEP), an anti-androgenic compound, for 28 days. In the control group, the formation of papillary processes was observed in XY medaka, but not in XX medaka. However, after MEP exposure, the number of papillary processes were significantly decreased in a dose-dependent manner in XY medaka; in the 300 µg/L concentration group, four out of 11 XY medaka showed no papillary processes even if there were no significant effects on total length and wet body weight compared with the control group. Our results indicate that the number of papillary processes in Japanese medaka can be used as an indicator of anti-androgenic activity and that this model may prove useful as a chemical screening method.

RP226 Combined effects of endocrine disruptors and parasitism on the molting process of the invertebrate amphipod Gammarus pulex?

Q. Langevin, Univ of La Rochelle; C. Adam, Univ of Liege; J. Thome, Liege Univ / Laboratory of Animal Ecology et Ecotoxicology; E. Gismondi, Univ of Liege / Laboratory of Animal Ecology and Ecotoxicology

Endocrine disruptors (EDCs) are known to modify population dynamics of exposed organisms. In amphipod Gammaridea, growth and reproduction are linked to the molt process; hence, EDCs could affect populations through molt disruptions. However, Gammaridea are hosts of parasites, such as vertically-transmitted microsporidia (microsporidia VT), which could be confounding factors in assessment of EDC effects. Indeed, some microsporidia VT could have endocrine effects by their own present, as it was observed a feminization of juvenile males (e.g. disruption of androgen gland). This study aimed to assess the effects of ethinylestradiol (EE_2), cyproterone acetate (CPA), 4-hydroxytamoxifen (4HT) and 17α-methyltestosterone (17MT), and the presence of microsporidia VT, on the 20-hydroecdysone concentration (20-HE, molt hormone) and the chitobiase activity, enzyme involved in the degradation of the old cuticle, in Gammarus pulex males and females, after a 96h laboratory exposure. Results revealed that only EE_2 and CPA impacted the 20-HE concentration in uninfected males, and no effects were observed in parasitized males. In uninfected females, no effects were measured, but 20-HE concentrations increases were observed after EDC exposures. For chitobiase analyses, no differences were observed in uninfected males after EDC exposures, but a trend to increased activity was measured in infected males. The opposite result was highlighted in females, since significant increases of chitobiase activity were measured in uninfected females exposed to 4HT and 17MT, and trends to increased activity were observed in infected females. Results also underlined no difference between the 20-HE concentration in uninfected and infected individuals. However, parasitized males and females had lower chitobiase activities than uninfected individuals. The study shown that EDCs affected the 20-HE concentrations and the chitobiase activity of G. pulex, differently according to the gender and parasitism. This suggest that EDCs, proved in vertebrates, could also disrupt the population dynamic of invertebrates such as G. pulex. Moreover, EDCs effects, more important on the 20-HE concentrations than on the chitobiase activity, suggest that EDCs disturb the molt mechanism by its first stages. Finally, results revealed low chitobiase activities in parasitized G. pulex, which could leading to a slower molt, thus a slower reproduction, contrasting with the parasite fitness (transmission by reproduction).

RP227 Inhibition of swim bladder inflation in Japanese medaka (Oryzias latipes) larvae in the absence of an air-water interface

Z.P. Pandelides, Univ of Ontario Inst of Tech; M. Overturf, Univ of Louisiana at Monroe / Biology; E. Ussery, Univ of Ontario Inst of Tech / Faculty of Science Biology; J. Guchardi, Univ of Ontario Inst of Technology / Faculty of Science Aquatic Toxicology; D.A. Holdway, Univ of Ontario Inst of Tech / Science

Physostomous fish maintain their embryonic connection between the gut and the gas bladder via a pneumatic duct, whereas this connection degenerates in physoclistous fish resulting in a closed swim bladder. In physoclistous larval fish, the pneumatic duct only exists for a short period of time before it regresses. Therefore, swim bladder inflation must occur by ingesting air at the water surface during this time. Japanese medaka (Oryzias latipes) are physoclistous fish and were used to assess the time needed to inflate the swim bladder before the closure of the pneumatic duct. Control Japanese medaka larvae have a swim bladder inflation rate of 99.6 +/- 1.4 % within 3 days of hatching. Covered larvae, denied an air-water interface (4-8 days), were completely unable to inflate their swim bladders post hatch until they were uncovered. Furthermore the amount of time post hatch which the larvae were denied an air-water interface had a significant reduction on their ability to inflate their swim bladders when they were exposed to an air-water interface. This effect was time dependent with significant effects being observed from 4-8 days covered. The longer the fish were denied an air-water interphase the less fish were able to inflate their swim bladders when uncovered. A significant increase in mortality was also observed in all the treatments that were covered for four or more days. These results indicate that access to an air-water interface is crucial for the initial inflation of Japanese medaka. Inhibition of swim bladder inflation of larval Japanese medaka has the potential to cause population level effects by reducing growth and survival.

RP228 Effects of Temperature on the Endocrinology of Smoltification in Juvenile Rainbow/Steelhead Trout (Oncorhynchus mykiss)

M. Giroux, Univ of Maine / School of Marine Sciences; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences

The San Francisco Bay Delta is experiencing seasonally warmer waters and salt water intrusion into historically freshwater ecosystems due to climate change. Juvenile endangered Steelhead Trout (Oncorhynchus mykiss) inhabit this system from juvenile development through the smoltification process. It is possible that juvenile fish experience premature hypersaline acclimation due to seawater intrusion (PHA), and the effects of increased temperature and PHA on pre-smolt Steelhead are unknown. Rainbow trout (Oncorhynchus mykiss) were used as a genetic model for Steelhead, since they are the same species. Juvenile fry were exposed to 110C, 16.40C and 190C temperatures (n=12) for two weeks and then challenged for 24 hours to 32ppt seawater. Estradiol-17? (E2), cortisol, triiodothyronine (T3), thyroxine (T4) levels were measured in blood/plasma or whole animal homogenates using Enzyme Linked Immunnosorbent Assays. Gill Na+/K+ ATPase mRNA levels were measured using qPCR. Preliminary results show 50% survival and a hepatosomatic index (HSI) of 0.89% in fish exposed at the highest temperature compared to an average HSI of 1.24% in fish exposed to the optimal temperature. Ongoing studies will explore the impacts of PHA and pesticides on smoltification and osmotic stress in multiple life stages of salmonids. This material is based upon work supported by the Delta Stewardship Council Delta Science Program.

RP229 Effects of ALCOA Solid Waste Leachate on Water Quality of the Yadkin River: A Badin, NC Case Study for Ecotoxicology's Role in Social Justice

T.M. Early, Appalachian State Univ / Environmental Science; S. Tuberty, M. Ezzell, J. Parnell, Appalachian State Univ / Biology; R. Longest, D. Schwartz, Duke Environmental Law and Policy Clinic; W. Scott, Yadkin RiverKeeper; M. Hinson, Badin Concerned Citizens

Social justice is one of the three pillars of the Sustainability movement spreading across academic institutions worldwide. Here we introduce an aquatic ecotoxicology/social inequality case study in which an underprivileged community in Badin, NC is forced to contend with toxic leachate from one of the only retired ALCOA plants not designated as a USEPA Superfund site in the US. Site designation under Superfund provides funding for and oversight of cleanup activities. Often problems that exist in lower income communities are overlooked by political and/or government entities and therefore continue on indefinitely. The Badin Works facility was operated as an aluminum smelting plant by Aluminum Company of America (ALCOA) from 1916 to 2007. During that time cyanide, fluoride, PCBs, PAHs and other toxins, including arsenic, were released through ALCOA's 13 outfall pipes into Badin Lake and into Little Mountain Creek, which is listed as impaired by NCDENR due to poor bioclassification. Additionally, hazardous materials were buried in unlined landfills at 44 known locations. For the last 3 years the Appalachian State University Aquatic Ecotoxicology Lab has partnered with the Duke Environmental Law and Policy Clinic, Badin Concerned Citizens, and the

Yadkin RiverKeeper to analyze water, sediments, fish and macroinvertebrates from Badin to support elevation of the contaminated Badin sites to Superfund status. Studies have consistently shown elevated levels of cyanide in water and soil (22 ppb and 1.8 ppb, respectively) and fluoride in water (26 ppm). Also, elevated levels of PCB's in soil (53 ug/kg Aroclor 1248) and fish tissue (as high as 340 ug/kg of Aroclor 1248) and PAH levels in soils (29 ug/kg Benzo(a)pyrene) were reported. Although results of NC DWQ benthic macroinvertebrate bioindicators have consistently shown excellent water quality, the fish community IBIs have shown declines from Good/Fair to Poor over the three years of sampling. Because our data supported the Badin community's request for Superfund status, in November 2014 the USEPA agreed to conduct a preliminary assessment for Superfund status of the retired ALCOA smelter site. Through a diverse partnership that strategically combined complementary resources we have made great strides towards the goal to correct this long overlooked issue.

RP230 A short summary of environmental fate (biodegradability) and ecotoxicity data for ENORDET O-series surfactants

D. Lyon, Shell Oil Co. / Shell Health Risk Science Team; J. Dawick, Shell Health / Shell Health Risk Science Team

A host of chemical enhanced oil recovery (cEOR) technologies are currently being evaluated to extend the life and maximise production of oil from new and existing reservoirs. Shell Chemicals is developing two general classes of surfactant for enhanced oil recovery: alcohol alkoxy sulfates (ENORDET J- and A-series) and internal olefin sulfonates (ENORDET O-series). These products are currently being evaluated in pilot projects around the world to demonstrate the potential of surfactant-based cEOR technology. Shell has commissioned a range of baseline environmental fate and ecotoxicological effect studies on selected products from within the ENORDET surfactant portfolio to assist and comply with global regulatory notification and registration requirements. The objective of this poster is to provide an overview of the experimental environmental fate and effects data currently available for ENORDET O-Series surfactants and how this compares with analogous classes of anionic surfactants (e.g. detergent range surfactants). The challenges faced with generating scientifically robust and relevant environmental test data for ENORDET surfactants along with potential opportunities for future research and testing will also be addressed.

RP231 Comparative Toxicity Of Sodium Carbonate Peroxyhydrate To Freshwater Organisms

T. Geer, Clemson Univ / Dept of Forestry and Environmental Conservation; C.M. Kinley, Clemson Univ / School of Agricultural Forestry and Environmental Sciences; K. Iwinski, A.J. Calomeni, J. Rodgers, Clemson Univ / Dept of Forestry and Environmental Conservation

Episodic exposures of sodium carbonate peroxyhydrate (SCP) algaecides in aquatic systems prompt the need to understand innate sensitivities of aquatic organisms to exposures of the active ingredient, hydrogen peroxide. Measurements of the relative sensitivities of algal, invertebrate, and vertebrate species to laboratory exposures of hydrogen peroxide can be used to interpret potential risks from SCP applications in aquatic environments.The objective of this study was to measure and compare responses of a cyanobacterium (Microcystis aeruginosa), a eukaryotic alga (chlorophyte Pseudokirchneriella subcapitata), invertebrates (microcrustacean Ceriodaphnia dubia and benthic amphipod Hyalella azteca), as well as the vertebrate fathead minnow (Pimephales promelas) to exposures of hydrogen peroxide as SCP. Hydrogen peroxide exposures were confirmed using the I_3^- method. Measured relative sensitivities of organisms exposed to SCP were compared with published toxicity data to provide context for other algaecides and herbicides (e.g. copper formulations, endothall, and diquat dibromide). Algal responses (cell density and chlorophyll a concentrations) and animal mortality were measured after 96-h aqueous exposures to SCP in laboratory-formulated water to estimate EC_{50} and LC_{50} values, as well as potency slopes. M. aeruginosa was more sensitive to hydrogen peroxide as SCP (96-h EC_{50}: 0.9-1.0mg L^{-1} H_2O_2) than the eukaryotic alga P. subcapitata (7-d EC_{50}: 5.2-9.2mg L^{-1} H_2O_2), indicating potential for selective use of SCP exposures to control prokaryotic algae. For the vertebrate and invertebrate organisms evaluated, measured 96-h LC_{50} values ranged from 1.0 to 19.7mg L^{-1} H_2O_2. C. dubia was the most sensitive species, and the least sensitive species was P. promelas, which is not likely to respond to concentrations of hydrogen peroxide as SCP affecting cyanobacteria (e.g. M. aeruginosa). Based on information from peer-reviewed literature, exposures of other algaecides could cause similar differential responses of prokaryotic algae compared to eukaryotic algae. Of the algaecides compared, exposures of SCP can mitigate risks associated with noxious cyanobacterial growths (e.g. M. aeruginosa) while minimizing potential risks for other species (e.g. P. promelas).

RP232 Effects of Industrial Activity on Trace Element Accumulation, Community Composition, and Population Structure of Lotic Dragonfly Nymphs

D.E. Fletcher, A.H. Lindell, J.C. Seaman, P.T. Stankus, D.B. Pitt, J.V. McArthur, Univ of Georgia – Savannah River Ecology Laboratory / Savannah River Ecology Laboratory

Evaluating impacts of environmental contamination is an essential component of assessing a stream's need of and potential for restoration or enhancement. Presented results are a portion of an overall integrated assessment of the hydrology, geomorphology, biology, and contaminant accumulation in Coastal Plain streams on the Savannah River Site, SC, USA. We used 7 genera of dragonfly nymphs as biomonitors of contaminants entering the aquatic food web and impacts of excessive stormwater runoff. Two reference streams were compared to 3 streams receiving varying amounts of stormwater runoff and effluents with two streams being more severely scoured. Dragonfly nymph generic richness and diversity were reduced in the two most scoured streams as more sensitive species were missing and others reduced in relative abundance. Life history differences between disturbed and reference streams also included missing or poorly represented cohorts based on size frequency analyses. Additionally length-weight relationships differed between disturbed and reference streams in some genera. Variation in element accumulation among genera clearly exceeded variation within genera suggesting that genus is a reasonable taxonomic level for both spatial and taxonomic comparisons. Patterns of trace element accumulation in biota tended to be element and taxa dependent, but patterns of elements frequently accumulating to higher concentrations in the disturbed sites were evident. Some elements such as Mn, Co, Ba, and Ni showed particular taxonomic variability that was compounded in disturbed sites. Boyeria, Hagenius, Macromia, and Erpetogomphus accumulated higher concentrations of these elements than Dromogomphus, Gomphus, and Cordulegaster. In contrast, Se and As tended to accumulate higher in Dromogomphus and were elevated in most genera at the two most disturbed sites. Al, V, and Fe were also consistently elevated in all three disturbed sites in most genera. Influences of body size, trophic level, carbon sources and surface area to mass ratios on trace element accumulation were evaluated. Overall, dragonfly nymph community and population structures were altered in the two most scoured streams and several trace elements were accumulating to higher levels in all three disturbed systems.

RP233 Spatial Analysis Methods for Assessing Sediment Injury in Natural Resource Damage Assessment

P.N. Booth, Ramboll Environ / Ecological Sciences; J. Ma, Exponent; M.W. Kierski, Exponent / Ecological and Biological Services Practice

Natural Resources Damages Assessments (NRDAs) for injury to sediment typically rely on the use of Habitat Equivalency Analysis (HEA) as a means of determining the scope of compensatory mitigation necessary to offset lost services due to a release. HEA, in turn, is a tool for estimating the spatial dimension of service loss over time and expresses service losses and gains in units of service-acres-years (SAYs) defined as the level of ecological services provided by one acre of sediment habitat over a one year period under baseline conditions. Application of HEA involves two fundamental steps: 1) development of quantitative relationships between concentrations of one or more constituents in sediment and inferred ecological service loss, and 2) use of geographical information systems to conduct spatial analysis of sediment chemistry to determine service losses by unit area (SAYs)—and the outcome of any HEA analysis is highly sensitive to the assumptions inherent in each of these steps. This presentation compares and contrasts the effects of two spatial analysis methods (Thiessen polygon and Inverse Distance Weighting) using a real-world data set, presents strengths and weaknesses of the two approaches, and discusses ways in which uncertainty can be minimized.

RP234 Bioaccumulation and toxic effects of resin acid for microalgae and microcrustaceans

c. soares, Univ Federal de Santa Catarina / Biochemistry Dept; M.L. Rocha, I. Baptista, Univ Federal de Santa Catarina

Pulp and paper production process generate a great variety of compounds that can cause adverse effects on several organisms. The resin acids such as abietic acid are among those compounds that exhibit high resistance to chemical and biological degradation that associated with their hydrophobic nature can exhibit increased toxicity due to bioaccumulation effect. This study aimed to evaluate the toxic effects of different concentrations abietic acid (10 ug/L and 50 ug/L) in organisms from different trophic levels (microalgae – Scenedesmus subspicatus and microcrustacean – Daphnia magna) and bioaccumulation potential for both. Bioassays with Daphnia magna were carried out according to OECD – Test No. 211 (OECD, 2012). Bioassays were performed with Scenedesmus subspicatus according to ISO 8692 (ISO 2012). Abietic acid exhibited no toxicity for microalgae. The results showed that daphnideos that were fed with algae (106 células.mL-1) that grew up in different abietic acid concentrations showed a reduction in the number of pups compared to controls, a reduction of up to 83%. Additionally, significant morphological changes of daphnideo spine were observed in all tested abietic acid concentrations, and it was absent in controls. The presence of males was also observed, especially for higher concentration of abietic acid. Chromatographic analysis by GC/ MS were able to detect abietic acid in microalgae cell at 3h-exposure period and no abietic acid was detected in the 24 and 48h-period, although toxicity has been high in the same period. In conclusion, preliminary results showed that the algae were able to bioaccumulate abietic acid/or a metabolite and the biomagnification phenomenon can be observed along the food chain. Support: Fapesc/CNPq

RP235 Comparison of Statistical Approaches for Count Data from Ecotoxicity Studies

J.W. Green, DuPont / Applied Statistics Group

There are two types of count data of that arise in ecotoxicity studies. Quantal data is based on a fixed number of subjects that are exposed and the interest in is the number of those subjects that respond, e.g., die or develop a specific type of lesion or condition. The type of count data to be discussed here can take on a wide range of possible values that vary by individual subject. Examples include the number of eggs laid and the number of live young produced. Typically, count data have been analyzed as though they are continuous, often after a square-root transform. Advances in statistical methodology and software have made it possible to use a generalized linear models (GLMM) approach using a Poisson or negative binomial error structure. In doing so, it is possible to accommodate overdispersion in a direct manner. This approach has intuitive appeal and has recently attracted much interest in ecotoxicology. Both NOEC and regression approaches to data interpretation are considered. For the NOEC approach, the power of various tests to find effects will be explored through extensive computer simulations and through a large database of guideline studies. Results from GLMM models with Poisson error structure will be compared to the previous standard approach of approximating a normal error structure on (possibly transformed) replicate counts and applying Williams' or Dunnett's test or applying a non-parametric alternative using the stepdown Jonckheere-Terpstra or Shirley test or a Dunn or Mann-Whitney pairwise analysis. For the regression approach, a comparison will be made of the quality of ECx estimates, in terms of precision, bias, uncertainty, and goodness of fit, from GLMMs with Poisson error structure and gamma priors to accommodate overdispersion, to familiar non-linear models based on an approximate normal distribution of (possibly transformed) within-treatment replicate proportions. An application will be made to the recently issued mollusc reproduction test guideline. The choice of analysis has important risk assessment implications and it is important to understand the strengths and weaknesses of various approaches in order to make scientifically sound and practical choices.

RP236 Comparison of Statistical Approaches for Quantal Data from Ecotoxicity Studies

J.W. Green, DuPont / Applied Statistics Group

Quantal data is a type of count data that often arises in ecotoxicity study. A fixed number of subjects are exposed and the interest in is the number of those subjects that respond, e.g., die or develop a specific type of lesion or condition. There numerous ways to analyze quantal data. For NOEC determination, these include the Cochran-Armitage test, with a Rao-Scott adjustment in case of overdispersion, Williams' or Dunnett's test on transformed data to approximate normality. Recently, there has been much interest in applying generalized linear mixed models (GLMM) using a binary error structure (that accommodates overdispersion where needed) to quantal data. Williams' beta-binomial tests is an older approach that is a specific way to implement GLMM. GLMM models have good conceptual appeal and provide natural extensions to regression from which a percent effects level (ECx) can be estimated. This paper will explore through extensive computer simulation modeling and a substantial database of guideline studies the relative merits of these alternative approaches in terms of their power and sensitivity to find effects. For the regression approach, a comparison will be made of the quality of ECx estimates, in terms of precision, bias, uncertainty, and goodness of fit, from probit or logistic models based on binary distributions, familiar non-linear models based on an approximate normal distribution of (possibly transformed) within-treatment replicate proportions, and the same non-linear models for the mean response but using GLMMs with binary error structure that accommodate overdispersion. The choice of analysis has important risk assessment implications and it is important to understand the strengths and weaknesses of various approaches in order to make scientifically sound and practical choices.

RP237 Issues for ECp Estimation

R.J. Erickson, B. Forsman, T.L. Highland, R. Hockett, D.J. Hoff, C.T. Jenson, D.R. Mount, T.J. Norberg-King, USEPA / ORD NHEERL Mid-Continent Ecology Division

For chronic toxicity to aquatic organisms, the past 30 years have seen a growing interest in the estimation of concentrations causing a certain percentage effect (ECp) rather than using highest no-observed effect concentrations (HNOEC) or lowest observed effect concentrations (LOEC) as the basis for risk characterizations. Although ECp estimation has certain advantages for better defining risk, it involves various issues regarding estimation methodology, model selection, and data sufficiency. Using a "mega" dataset regarding the chronic toxicity of NaCl to Ceriodaphnia dubia, various issues and potential problems in ECp estimation for more typical data sets will be explored.

RP238 Bayesian modeling of the co-occurrence of aquatic species and contaminants: Model evaluation and case study application

R. Martin, USEPA / Office of Research and Development; E. Waits, USEPA / National Exposure Research Laboratory; R.J. Miltner, Ohio Environmental Protection Agency; C.T. Nietch, USEPA / Water Supply and Water Resources Division; D. Zimmerman, Ohio Environmental Protection Agency

Risk managers would greatly benefit from modeling tools that facilitate probabilistic assessment of potential ecological exposures in natural ecosystems at the landscape or watershed scale. For aquatic systems, empirical data on contaminants (e.g., metals, pesticides, invasive species) and species distributions (e.g., fishes) are often readily available from sources such as agency bioassessment programs. Such data could be utilized to model and map exposure risk in terms of the probability of co-occurrence of target species and contaminants across the landscape. For this paper, we evaluated a Bayesian model utilizing Hamiltonian Monte Carlo (HMC) for application of the multivariate probit (MVP) model to the problem of modeling the joint occurrence of contaminants and species distributions using empirical data. As an alternative to developing individual models (e.g., logistic regression) for each response (i.e., chemical occurrence and fish occurrence) and multiplying the probabilities to arrive at a conditional probability of co-occurrence, the MVP model estimates the joint distributions for multiple responses in a single, multivariate model; accounting for the potential dependence between empirical contaminant and species occurrences. We first evaluated the model using simulated data and then applied it to a case study watershed, where we predicted and mapped the probability of co-occurrence of agricultural pesticides and sensitive stream fishes.

RP239 Genotoxic response assessment in the Neotropical fish by alkaline unwinding assay using methyl methane sulfonate (MMS) as chemical model

E.J. de San Benito, Universidad Nacional de La Plata; P.V. Gonzalez, Universidad Nacional de la Plata – CONICET / Centro de Investigaciones del Medio Ambiente; J.I. Quelas, Universidad Nacional de la Plata – CONICET / Instituto de Biotecnología y Biología Molecular; P. Carriquiriborde, Centro de Investigaciones del Medio Ambiente, Universidad Nacional de la Plata – CONICET – Comisión Administradora del Río Uruguay / Centro de Investigaciones del Medio Ambiente CIMA

The aims of this study was to assess the genotoxic response, single-strand (SSB) and double-strand breaks (DBS), in Cnesterodon decemmaculatus by a fluorometric microscale alkaline unwinding assay using MMS as reference compound. Assay was first set up in vitro generating single strand-breaks by enzymatic digestion with calf thymus endonuclease I on DNA samples obtained from control fish skeletal muscle. Then, in vivo assays were performed exposing fish to 0, 3.75, 7.5, and 15 mg L^{-1} MMS to build the dose-response curve. Sybr Green I was used as fluorochrome and DNA unwinding was performed on a multi-mode microplate reader. The strand scission factor (SSF) was assessed as endpoint in both assays. Good correlation between digestion time and SSF was observed from 0 to 30 min and 0.65 to 2.17 arbitrary DNA damage units. Clear genotoxic induction was also observed in fish muscle during in vivo assays. The SSF value was increased from 0.15 in controls to 0.45, 0.50 and 0.54 in 3.75, 7.5, and 15 mg L^{-1} MMS expose fish, respectively. Significant effects were observed earlier from 3.75 mg L^{-1} (LOEC), and the EC_{50} was estimated between 0 and that value. In conclusion the developed fluorometric microscale alkaline unwinding assay was sensitive to assess genotoxic effects induced by the reference chemical in the tested South American fish. Therefore, it appears as an easy, quick and reliable tool for assessing genotoxicity in the lab, and potentially in the field using a local species.

RP240 Drug resistance-related major vault protein (MVP) and cellular vault particles in fish: A piece of the puzzle in understanding multi-drug resistance?

A.L. Margiotta, L.J. Bain, C.D. Rice, Clemson Univ / Biological Sciences

Cellular vaults are ubiquitous 13 mega Da multi-subunit organelles that may have a role in nucleo-cytoplasmic transport. Seventy % of the vault's mass consists of a ≈100 kDa protein, the major vault protein (MVP). Earlier work in our lab sequenced MVP from channel catfish, Ictalurus punctatus, monocytes (42TA cells). We recently expressed channel catfish MVP as a recombinant protein for generating a panel of specific mAbs, resulting in hybridoma 3F9 secreting a mAb that recognizes MVP in all fish examined to date, as well as mammalian cells. Using immunohistochemistry, we show that mAb 3F9 staining for MVP (and presumably intact vaults) is highly expressed in epithelial, immune system, and endothelial cells. Using qPCR, MVP mRNA expression is induced in channel catfish ovarian cells by ethidium bromide, which damages DNA. We also examined MVP protein expression in tissues from Atlantic killifish collected in situ at the Atlantic Wood (AW) EPA superfund site. Killifish from the AW site display a PAH-resistant phenotype, and had a high incidence of liver lesions and neoplasia. Through immunoblotting and IHC, we show that MVP protein expression is highly variable in AW fish compared to fish from a reference site. Also, MVP is highly expressed in many advanced neoplastic liver lesions, with nuclear location in the most advanced lesions. The true function of cellular vaults remains unknown, but the results of this study support a possible role in acquired resistance to intracellular toxic compounds, and or their metabolites.

RP241 Aquatic insects as a mechanism of dispersal for antibiotic resistance genes in the environment

C. Lobson, Univ of Manitoba / Dept of Environment and Geography; L.G. Chaves-Barquero, Univ of Manitoba / Dept of Chemistry; C.S. Wong, Univ of Winnipeg / Richardson College for the Environment; C.W. Knapp, Univ of Strathclyde; M. Hanson, Univ of Manitoba / Environment and Geography

Human-use antibiotics are commonly released into aquatic ecosystems from wastewater effluents emanating from lagoons on the Canadian Prairies. This can lead to selection for antibiotic resistant gene-bearing bacteria (ARGs) in these environments (both lagoons and receiving waters). We hypothesize that as aquatic insects emerge from these lagoons, they could be a vector for ARGs into surrounding environments. To test this, we deployed emergence traps in three wastewater lagoons and the effluent-receiving creek at Dunnottar, MB to determine the type and abundance of aquatic insects emerging from wastewater lagoons. The ARGs were measured on emerged insects, in the water and were quantified using qPCR. The antibiotic resistance genes targeted were sul1, sul2, and sul3 and were compared to 16S-rRNA to calculate the proportion of resistant genes relative to total bacterial genes. The concentrations of sulfonamide antibiotics were characterized as well. The greatest proportion of sulfonamide resistant genes relative to 16S-rRNA was 9.3% and was measured in the primary lagoon, with lesser amounts observed in the rest of the wastewater system. We were not able to detect sul-type resistant genes within emerging insects, suggesting that this mechanism of spread is unlikely to be significant compared to other means (e.g., direct release of improperly treated wastewaters).

RP242 Assessment of biochemistry and genotoxicity in Rhamdia quelen feed with residual algae biomass from biodiesel production

A.M. Marques, UFPR / Genetics; R.E. Balen, UFPR / Dept of Zoology; C.M. Motta, UFPR / Dept of Genetics; L.d. Fernandes, UFPR / Pharmacology; A.B. Mariano, J.V. Vargas, UFPR / Dept of Mechanical Engineering; H. Silva de Assis, UFPR / Pharmacology; F. Meurer, UFPR; M. Cestari, UFPR / Genética

Climate change caused by the release of greenhouse gases by burning of fossil fuels has created an appeal for sustainable energy production. The difficulty of obtaining renewable fuels is the application of energy-compensating systems to meet the demand. The cultivation of microalgae is an alternative for the production of biodiesel. Microalgae can be created in different culture media, including industrial effluents. After processing of microalgae, a residue called defatted biomass waste (RBD) is obtained, and it can be used as an ingredient in animal feed production. The microalgae Acutodesmus obliquus (Green algae) (Scenedesmus obliquus) was cultivated in medium (Chu), and it was used in the production of feed. 60 fingerlings of the species Rhamdia quelen (Catfish) were used. Four groups (n=15) were created: control (normal feed – 0%) and other 3 groups with feed enriched with RDB in the proportion of 1%, 2% and 3%. The feed lasted 60 days (the fish were fed three times daily ad libitum). The biomarkers were comet assay (for erythrocytes, hepatocytes and brain cell analyses), piscine micronucleus and halo assay (for erythrocytes), acetylcholinesterase (AChE) for the brain and muscle analyses. For liver cells, the biochemical biomarker used were catalase (CAT), glutathione S-transferase (GST), superoxide dismutase (SOD) and lipid peroxidation (LPO). Normal data were analyzed using one-way variance (ANOVA). Non-normal data were analyzed using Kruskal-Wallis. In the comet assay, it was not observed brain tissue damage. A significant decrease in DNA damage in erythrocytes from concentrations 2% and 3% was observed, as well as in concentrations 3% RBD liver tissue. No difference was observed between the groups in the piscine micronucleus. There was an increase in AChE enzyme activity in the brain for the 3% group, and there was an increase of muscle activity in groups with 2% and 3% RBD. The degradation of intracellular hydrogen peroxide (CAT) was not changed. The GST enzyme also showed no change. SOD metaloenzyme, which catalyzes the dismutation of the superoxide, showed an increase in activity for groups with 2% and 3% of RBD. The measuring of the LPO showed no loss of cell membrane integrity. Microalgae are major producers of antioxidants and a food containing these antioxidants are known to be beneficial. The evaluation of safety in the use of RBD in fish feed is important to prevent future risks to the health of its consumers.

RP243 The Effect of Starvation and Refeeding on Global Gene Expression in Livers of Rainbow Trout (Oncorhynchus mykiss)

M. Overturf, Univ of Louisiana at Monroe / Biology; D.A. Holdway, Univ of Ontario Inst of Tech / Science

During their life cycle, salmonids may face extended periods without food. Fish depend on body energy reserves during these periods of starvation. An effective way to identify the relationships between major metabolic pathways and body processes is to examine changes in metabolism during starvation followed by a refeeding. The present study investigated the global gene expression following a 14 day starvation period and a 14 day refeeding period in rainbow trout. While no significant effects were seen in length and body weight following the 14 day starvation period, hepatosomatic index (HSI) was significantly reduced. Length and body weight of rainbow trout were significantly increased following the 14 day refeeding period while HSI increased to pre-starvation levels. RNA-seq analysis was utilized to determine the differentially expressed genes in liver extracts. Results from the present study will provide possible mechanisms of metabolic adaptation of liver tissues to starvation and refeeding of rainbow trout. In addition, the results may provide an indication into whether starvation can lead to enhanced toxicity of environmental contaminants.

RP244 Use of siRNA to Understand the Role of Hemoglobin in the Toxicity of Nitrite

S. Eytcheson, NCSU Toxicology / Biological Sciences; G.A. LeBlanc, North Carolina State Univ / Biological Sciences

Hemoglobin levels in some aquatic species vary with oxygen availability. Environmental nitrogenous compounds, such as nitrate and nitrite, can bind to the heme moiety of hemoglobin resulting in toxicity. We hypothesized elevated hemoglobin levels resulting from low oxygen conditions can increase the tolerance of daphnids (Daphnia magna) to nitrite by sequestering the nitrite yet providing ample unaltered hemoglobin to meet the oxygen transport needs of the organisms. We investigated this by: 1) comparing the toxicity of nitrite to control daphnids and daphnids with chemically (pyriproxyfen)-induced hemoglobin levels; and, 2) evaluating the restoration of sensitivity to nitrite in pyriproxyfen-treated daphnids by suppressing translation of the hemoglobin hb1 and hb2 genes using small interfering RNA (siRNA). Pyriproxyfen exposure increased hemoglobin levels as evidenced by increased hb1 and hb2 mRNA levels and increased red coloration of the organisms. Pyriproxyfen exposure also increased the tolerance of daphnids to the acute toxicity of nitrite. Feeding daphnids siRNA that specifically targeted hb1 and hb2 mRNA significantly attenuated the induction of hemoglobin by pyriproxyfen and the tolerance of these organisms to nitrite toxicity. The suppression of hemoglobin expression was monitored throughout the experiments by noting the reduced red coloration of the daphnids and was confirmed at the end of the experiments by quantitative real-time PCR. Results support the hypothesis that the induction of hemoglobin serves to protect daphnids from the toxicity of some environmental chemicals. Further, results of this study demonstrate that feeding of siRNA is an efficient, non-invasive means to knock down specific gene products in daphnids.

RP245 Identification and evaluation of reference genes for the normalization of qRT-PCR analysis in Crassostrea brasiliana

G. Muller, Federal Univ of Santa Catarina / Biochemistry; F.L. Zacchi, Univ Federal de Santa Catarina / Departamento de Bioquímica; D.d. Lima, Univ Federal de Santa Catarina / Bioquimica; R.S. Piazza, Unviersidade Federal de Santa Catarina / Bioquimica; K.H. Luchmann, UDESC Laguna / Engenharia de Pesca; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences; A. Bainy, Univ Federal de Santa Catarina / Bioquimica

Accurate quantification of transcripts using quantitative real-time PCR (qRT-PCR) depends on the identification of reliable reference genes for normalization. Despite the lack of studies on reference genes selection in bivalves, gene transcription studies using real-time quantitative reverse transcription PCR (qRT-PCR) have notably increased in these organisms. For oysters, a systematic evaluation of reference genes under environmental stressors and contaminant challenges is required. The present study aimed to contribute to the identification of the most suitable reference genes for normalization of mRNA transcription data in qRT-PCR analysis of Crassostrea brasiliana. For this purpose, mRNA expression of nine candidate genes were analyzed in the gills of oysters under three different experimental conditions: (i) different temperatures (18°C, 24°C or 32°C) and phenanthrene (100 $\mu g.L^{-1}$) combined exposure; (ii) different salinities (10, 25 or 35) and phenanthrene (100 $\mu g.L^{-1}$) combined exposure and (iii) 10% of diesel fuel water-accommodated fraction (diesel WAF) exposure. Reference gene transcription stability was calculated using four algorithms (geNorm, NormFinder, BestKeeper, comparative delta Ct), and the recommended comprehensive ranking was provided using RefFinder tool. The geometric means of ranking values using the RefFinder tool identified several optimal sets of genes that are suitable for qRT-PCR data normalization: transcripts of ankyrin-like, GAPDH-like and α tubulin-like genes had the three lowest variations in temperature and PHE combined exposures; transcripts of ankyrin-like, β actin-like and β tubulin-like genes were optimal for salinity and PHE combined exposure; and transcripts of α tubulin-like, 28S ribosomal protein-like and ankyrin-like genes were the most stable reference genes for diesel WAF exposure. Throughout all experimental conditions, the genes with the lowest global variability were ankyrin-like and α tubulin-like across all durations of exposure. These results revealed that the reference genes ankyrin-like and α tubulin-like reported here could be employed for differential expression in future studies using qRT-PCR with similar exposure conditions in C. brasiliana. Supported by: CNPQ/INCT-TA, CAPES/ CNPq

RP246 Tissue-based mapping of the fathead minnow (Pimephales promelas) transcriptome and proteome

L. Smith, C. Lavelle, Univ of Florida / Physiological Sciences; F. Yu, C. Silva-Sanchez, Univ of Florida / Interdisciplinary Center for Biotechnology Research; N. Vinas, Midsouth Regional Chapter / Inst for Genomics Biocomputing and Biotechnology; J. Bisesi, Univ of Florida; N.D. Denslow, Univ of Florida / Physiological Sciences; T. Sabo-Attwood, Univ of Florida / Environmental Global Health

The fathead minnow (FHM, Pimephales promelas) is used extensively to explore effects of contaminant exposure in both field and laboratory settings due to its regulatory importance, ease of culture, and the existence of extensive species-specific biology and toxicity data. The availability of genetic information and molecular tools specific to the FHM pales in comparison to that of the zebrafish (Danio rerio) despite its limited ecological relevance and regulatory importance. As such, there has been increased interest to bring the FHM into the genomic era to increase our understanding of complex mechanisms of action of environmental contaminants through the use of functional genomic applications, particularly in the development of adverse outcome pathways. To address this gap in genetic information, we sought to build a FHM transcriptomic and proteomic sequence database. For the transcriptome sequence database construction, RNA was collected from gut, liver, gonad, brain, blood, heart, and kidney from one healthy adult male fish, a cDNA library was constructed and then sequencing was performed on a PacBio instrument. Transcripts were mapped using publicly available zebrafish and human databases resulting in over 70,000 annotated genes. Protein sequences were generated and the largest open reading frame for each gene was selected and annotated using Blast2Go, resulting in 65,000 mapped protein sequences. To create transcriptomic and proteomic maps, we collected RNA and protein, respectively, from gut, liver, telencephalon, and hypothalamus tissues. Global RNA expression was measured by RNAseq and global protein expression was measured by iTRAQ labeling followed by LC-MS/MS analysis. Transcripts and proteins were mapped using the sequence databases generated in house and their relative expression levels in each tissue were compared. Results revealed differential expression of transcripts and proteins across tissues that in some cases were not consistent at the gene and protein levels. These results highlight the need for comprehensive transcriptomic and proteomic analyses of contaminant effects as changes in expression may not be conserved across all levels of regulation. These results also provide the first tissue-based transcriptomic and proteomic maps for FHMs that will have importance in functional genomic applications in ecotoxicology.

RP247 The role of mitochondrial dysfunction in the adverse outcome pathway for impaired growth

D.G. Bolser, Univ of Florida; D.A. Dreier, Univ of Florida / Physiological Sciences; E. Li, K. Kroll, Univ of Florida; J. Schmidt, C.J. Martyniuk, N.D. Denslow, Univ of Florida / Physiological Sciences

Several studies suggest that many chemicals in the environment alter mitochondrial function. Changes in mitochondrial function, such as those related to basal metabolism and ATP production, may affect ecologically relevant endpoints such as growth. Although there are robust models to assess mitochondrial function for human health, there remains a critical research need to address these effects in ecologically-relevant species like the fathead minnow, which is found throughout North America. Thus, the objectives of this study were to: (1) Develop an assay to measure mitochondrial function in fathead minnow embryos and (2) Link mitochondrial function and growth in an adverse outcome pathway. Here, the Seahorse XFe24 Extracellular Flux Bioanalyzer was used to measure oxygen consumption rate (OCR) in embryos at various life stages. Our optimization studies have determined that one embryo per well is sufficient to detect an OCR of 200 (24 hr stage) to 250 (48 hr stage) pmol/min, which is within the dynamic range of the instrument (50-400 pmol/min). Similarly, basal respiration and ATP production increased with age. Next, a known mitochondrial toxicant, 2,4-dinitrophenol, was used to assess changes in mitochondrial function and growth. Fathead minnow embryos were exposed at three doses (1, 10, and 100 μg/L) for 24 hours and assayed for changes in basal respiration, ATP production, maximal respiration, and spare capacity. Fathead minnows were also exposed to these conditions for 7 days and measured for total length using ImageJ. Basal and maximal respiration decreased for all doses of 2,4-dinitrophenol and demonstrated a dose-dependent relationship. Similarly, there was also a decrease in growth at higher doses of 2,4-dinitrophenol after 7 days of exposure. Thus, results indicate an association between mitochondrial dysfunction and growth, which may be used to develop an adverse outcome pathway for this important ecological endpoint.

RP248 A new genomic resource for the fathead minnow (Pimephales promelas): Development and application of a genetic linkage map

E. Waits, USEPA / National Exposure Research Laboratory; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory; J. Martinson, USEPA; T. Saari, USEPA / ORD, NHEERL; K.M. Jensen, USEPA / National Health and Environmental Effects Research Laboratory

The fathead minnow (Pimephales promelas) is the most widely-used small fish model for regulatory ecotoxicology in North America. However, the genome-scale resources and molecular genetic tools needed to exploit the full potential of this aquatic toxicological model are lacking. Specifically, the absence of structural genome information for the fathead minnow currently limits its use in the dissection of complex traits, genetic marker discovery, identification of gene regulatory domains, and elucidation of directed biological networks that underlie response to chemical stress. To overcome this deficit, we developed a novel, SNP based consensus genetic linkage map based on three independent genetic crosses. The resulting genetic architecture defines 25 major linkage groups, consistent with the number of chromosomes in the fathead genome. To illustrate the utility of this newly developed tool, we performed a quantitative trait loci (QTL) analysis of the phenotype SEX. Multiple QTL were identified, which together, explain the majority of genetic variance (77%, p = 6.34 x 10⁻¹²) observed for fathead gender. These genetic markers may have utility for determining the genetic sex in intersex individuals by distinguishing feminized males from masculinized females. This will be of paramount interest to ecotoxicologists using the fathead minnow as a model to investigate sensitivity to endocrine disruption and sex-reversal.
