SETAC®

abstract book

7th SETAC World Congress
SETAC North America 37th Annual Meeting

Table of Contents

Platform Abstracts

Poster Abstracts

Indices

This book comprises the abstracts of the presentations for the platform and poster sessions of the 7th Society of Environmental Toxicology and Chemistry (SETAC) World Congress/SETAC North America 37th Annual Meeting, conducted at the Rosen Shingle Creek in Orlando, Florida, 6–10 November 2016. The abstracts are reproduced as accepted by the Scientific Program Committee and appear in numerical order.

In each abstract, the presenting author's name is underlined. The author index cross-references the corresponding abstract numbers. Affiliation, session and keyword indices are also included.

International Standard Serial Number 1087-8939

About SETAC

The Society of Environmental Toxicology and Chemistry (SETAC), with offices in North America and Europe, is a non-profit, professional society established to provide a forum for individuals and institutions engaged in the study, analysis and solution of environmental problems, the management and regulation of natural resources, environmental education, and research and development.

Specific goals of the society are:

- Promote research, education and training in the environmental sciences
- Promote the systematic application of all relevant scientific disciplines to the evaluation of chemical hazards
- Participate in the scientific interpretation of issues concerned with hazard assessment and risk analysis
- Support the development of ecologically acceptable practices and principles
- Provide a forum (meetings and publications) for communication among professionals in government, business, academia and other segments of society involved in the use, protection and management of our environment

These goals are pursued through the conduct of numerous activities, which include:

- Conduct meetings with study and workshop sessions, platform and poster presentations, and achievement and merit awards
- Publish scientific journals, a newsletter and special technical publications
- Provide funds for education and training through the SETAC Scholarship/Fellowship Program
- Organize and sponsor chapters and branches to provide a forum for the presentation of scientific data and for the interchange and study of information about local and regional concerns
- Provide advice and counsel to technical and nontechnical persons through a number of standing and ad hoc committees

SETAC membership currently comprises more than 6,000 individuals from government, academia, business and non-governmental organizations with backgrounds in chemistry, toxicology, biology, ecology, atmospheric sciences, health sciences, earth sciences, environmental engineering, hazard and risk assessment, and life cycle assessment.

If you have training in these or related disciplines and are engaged in the study, use or management of environmental resources, SETAC can fulfill your professional affiliation needs.

All members receive the SETAC Globe newsletter highlighting environmental topics and SETAC activities, reduced fees for meetings and discounts on SETAC books. All members receive online access to *Environmental Toxicology and Chemistry* (ET&C) and *Integrated Environmental Assessment and Management* (IEAM), the peer-reviewed journals of the society. Members may hold office and, with the Emeritus Members, constitute the voting membership.

If you desire further information, contact the Pensacola office if you are in Latin America, Asia/Pacific or North America, or the Brussels office if you are in Europe or Africa.

ENVIRONMENTAL QUALITY THROUGH SCIENCE®

Bioavailability of Organic Chemicals for Retrospective Risk Assessment: Measurement, Applications and Communication

1 Presentation of the newly standardized soil quality TRIAD approach, with special focus on the inclusion of bioavailability

J. Roembke, ECT Oekotoxikologie GmbH; J. Bernard, DIN Berlin; J. Harmsen, Alterra, Wageningen-UR / CALM

Recently, ISO standardized the performance of the TRIAD approach as a method to ensure the quality of the site-specific ecological risk assessment of soil contamination (originally, the TRIAD was developed for sediments). The norm ISO 19204 is based on experiences made in The Netherlands, Great Britain and Denmark as well as in other parts of the world (e.g. Brazil). The term TRIAD relates to three Lines of Evidence (LOE): chemistry, toxicology and ecology. Each of these LOEs is performed on three tiers (screening, refined screening, detailed assessment) with increasing complexity of the tests to be performed. In view of the nature of this International Standard the investigation procedure is described on a general level, but details of technical procedures for the actual assessment are given in related technical standards (e.g. ISO 15799, ISO 17616). In ecological risk assessment, the effects of soil contamination on the ecosystem are related to the intended land use and the requirements that this use sets for properly functioning soil. The ISO Standard describes the basic steps relating to a coherent tool for a site-specific risk assessment with opportunities to work out site-specific details. Inclusion of bioavailability improves the applicability of the TRIAD approach. In this contribution we will give a short overview on the soil quality TRIAD ISO standard, starting with simple approaches to link it with existing generic soil values (based on total concentrations) in the screening tier. Indicators for actual and potential bioavailability refine the tier. For organic chemicals passive sampling and Tenax/cyclodexrine are suitable tools comparable to 0,001 mol/l CaCl2 and 0,43 mol/l HNO3 for heavy metals. Because the two other LOE's (toxicology and ecology) are also directly related with bioavailability a more balanced TRIAD is obtained. Finally, on the detailed assessment level more complex methods might be used, such as chemical models, or the use of more site specific organisms. Advanced or complex methods and experimental designs are not excluded. Currently, practical experience with the soil quality TRIAD approach is still limited, but in the light of a growing tendency to skip the use of total concentrations in soil ecological risk assessment (e.g. in the context of prospective risk assessment) it is expected that this situation will change in the foreseeable future. However, this expectation depends highly on further legal developments.

2 Use of Equilibrium Passive Sampling Devices for Measuring Bioavailable PAH and Related Heterocyclic Compounds

K. O'Neal, CH2M; X.R. Xia, North Carolina State Univ / CCTRP/CVM; X. Kong, P. Lazaro, D. Shea, North Carolina State Univ

Passive sampling devices (PSDs) that are allowed to reach equilibrium with water or water-particle slurries have shown promise in estimating the readily desorbable and potentially bioavailable fraction of polycyclic aromatic hydrocarbons (PAHs). To make further progress toward this goal, we measured the equilibrium polymer-water partition coefficients for 85 PAHs and related heterocyclic compounds and for 27 oxygenated- and nitro-PAHs (O/N-PAH) using polyoxymethylene (POM) as a non-depleting sorbent phase. Our measured partition coefficients (KPOM) are in good agreement with previously published values for the USEPA "PAH-34" list and our data set extends the values to a much larger and more useful group of PAH and O/N-PAH degradation products. We used both a static-renewal water-only exposure and a sediment-water slurry exposure to measure KPOM and found good agreement between the two methods. Our measured log KPOM values were linearly correlated to log KOW ($r2 = 0.96$ for static-renewal experiment and $r2 = 0.93$ for sediment-water slurry). We then measured dissolved PAH in a sediment-water slurry, using PAH-contaminated sediment from the field, and compared the POM method to solid-phase microextraction (SPME) for measuring freely dissolved PAH. The POM provided data for 72 PAH and O/N-PAH compounds compared to only 3 PAH for the SPME owing to the much lower detection limits of the POM method. Furthermore, to provide toxicological relevance to our chemical measurements, we conducted experiments with oil and creosote contaminated sediment pre- and post-remediation and found, with some exceptions, that the PAH concentrations in sediment-water slurry measured using the POM was well correlated with accumulation in freshwater mussels, providing strong evidence that the POM method measures only the bioavailable fraction of PAH in the sediment.

3 Using Passive Sampling to Measure Site Specific Partitioning and Refine Sediment Risk Assessment

H. Xia, U. Ghosh, Univ of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering

PAHs and PCBs are listed as the chemicals of potential ecological concerns for South Wilmington Wetlands. The objectives of this study were to evaluate the site specific porewater concentration and sediment partitioning constants for PAHs and PCBs using polyethylene passive samplers, and to assess the site-specific bio-concentration factor (BCF) through PCB bioaccumulation in freshwater invertebrates. Results were used to refine the sediment preliminary remediation goals (PRG) based on two ecological receptors: toxicity to benthic invertebrates and bioaccumulation in the Spotted Sandpiper. Finally, a steady state cap design model was used to examine the performance of a soil cap, as a potential remediation approach. For PAHs, the site specific sediment partitioning constants (Koc) were 1-2 orders of magnitude higher than the generic values used in preliminary assessments, which resulted in higher revised PRGs than initial ones based on the protection of benthic invertebrates. The estimated PRG based on benthic exposure is more restrictive compared to exposure to the Spotted Sandpiper as PAHs do not bio-magnify and primarily pose problems for benthic invertebrates. For PCBs, nearly 1 order of magnitude higher site-specific Koc was observed than generic values. Bioaccumulation of PCBs in worms followed the typical behavior and was consistent with generic correlations for organism uptake, which could be largely explained based on PCB sediment porewater concentration. For PCBs, exposure to the Spotted Sandpiper resulted in a more restrictive PRG compared to benthos based PRGs. Overall, site-specific assessment of PAH and PCB partitioning in sediments was able to refine risk assessment for South Wilmington Wetlands and develop more realistic PRGs. Conventional estimation of porewater concentration using generic organic carbon partition constants was not predictive of bioaccumulation in worms. PRG derived from generic values could be orders of magnitude different from those based on site specific measurement. Also, the PRG for the same contaminant could be orders of magnitude different based on different receptors. Thus, selection of appropriate ecological receptor is crucial in risk assessment. Finally, the cap modeling results indicated that application of a soil cap with 5% organic carbon was able to achieve the revised remediation goals, by reducing (over 90%) of the sediment toxicity, and exposure of benthic and avian species to PAHs, PCBs and pesticides.

4 A probabilistic framework for evaluating the likelihood of toxicity in sediments based on site-specific partitioning and passive sampling methods

A.A. Brennan, Univ of Minnesota Duluth; N.W. Johnson, Univ of Minnesota Duluth / Civil Engineering

A probabilistic decision framework was developed to demonstrate how SPME-derived C_{free} measurements for PAHs can be used to evaluate the accuracy of risk management decisions in moderately contaminated sites where the toxicity of sediments is uncertain. The framework builds upon tiered assessment approaches by incorporating a measure of the likelihood that concentrations found at moderately contaminated sites are protective of benthic organisms. Results of a probabilistic analysis illuminate large variability in the effective partitioning values for total organic carbon and black carbon, and demonstrate that any single, deterministic partitioning prediction implicitly provides protection to some likelihood. Until standard passive sampling methods are widely accepted and implemented or partitioning behavior of PAHs is understood more fully and can accurately predict porewater concentrations for all sediments, a statistical framework for using site-specific SPME-derived K_{OC} partitioning distributions can provide a cost-effective, nuanced option for predicting risk in a range of sediment types. The proposed decision framework provides flexible statistical guidance for moving through tiered assessment approaches that incorporate 1) screening level targets of predicted interstitial water concentrations (C_{free}) from bulk sediment concentrations (C_{total}) and site-specific SPME-derived K_{OC} partitioning distributions 2) SPME-derived C_{free} estimates of bioaccumulation and toxicity and 3) actual biological (toxicity or bioaccumulation) testing. The decision framework was developed and applied in the context of data collected from a pilot project utilizing navigational dredged materials for creation of shallow water habitat in one of the Great Lakes Areas of Concern: the St. Louis River Estuary in Duluth, MN, USA. Results suggest that areas of moderate contamination stand to gain the most from direct measures of C_{free} during initial stages of assessment.

5 Development of Invertebrate Bioaccumulation Factors for Polychlorinated Biphenyls

H. McChesney, ARCADIS; N. Bonnevie, ARCADIS / Environmental Sciences, Assessment, and Planning; P. Anderson, S. Walls, ARCADIS

Predictive ecological risk assessments rely on numerous assumptions regarding the uptake of chemicals by receptors. Bioaccumulation of chemicals from soil to biotic tissue is a primary uncertainty when predicting exposure to receptors in the food web. In the absence of site-specific tissue data, an increased understanding of chemical bioaccumulation at lower trophic levels can greatly increase the predictive ability of ecological risk assessments to allow for more refined evaluation of potential ecological risk. When evaluating potential ecological risk to PCBs in soil, it is often necessary to derive estimates of PCB concentrations in invertebrates, such as earthworms. At the base of the trophic pyramid, estimates of PCB concentration in earthworms and other invertebrates affect predicted exposure and potential risk associated with PCBs at all trophic levels. Commonly used literature-based BAFs have been developed from PCB uptake data derived from limited laboratory and field datasets. However, these BAFs may not account for site-specific factors that can significantly alter uptake of PCBs such as congener composition, weathering, and site-specific abiotic or biotic factors. To evaluate the potential effect of these considerations on uptake estimates, we reviewed the literature on PCB bioaccumulation by invertebrates and assembled a database of PCB bioaccumulation data that included information regarding specific congeners or Aroclors, as well as weathering, biotic, and abiotic parameters. We used available data from sites with similar PCB structure and site conditions to model soil-invertebrate bioaccumulation. As it is not always feasible to obtain site-specific uptake data and develop site-specific soil to earthworm BAFs, the use of BAFs modeled for specific congeners and site conditions can reduce uncertainty and increase the predictive ability of ecological risk assessments.

6 Assessing Bioavailability of High Molecular Weight Hydrocarbons in Weathered Soils from Intra-aggregate Pore Size Distributions

S. Ghoshal, A. Akbari, McGill Univ / Civil Engineering

The assessment of bioavailability of hydrophobic organic contaminants (HOCs) to microorganisms is of great interest in a priori assessments of bioremediation rates and extents. Several different paradigms have been used to assess the microbial availability of HOCs and to estimate remediation endpoints. For example, the rate and extent of physicochemical mass transfer of HOCs from contaminated soils to the aqueous phase have been commonly used to assess bioavailability, because it is generally understood that only aqueous phase contaminants are bioavailable to microorganisms. However, poorly soluble high molecular weight organic compounds, such as those present in certain fractions of petroleum liquids, are often degraded only by direct contact of bacteria with the oil-water interface or by micellar solubilization and/or emulsification by biosurfactants excreted by bacteria near oil-water interfaces. In weathered petroleum-contaminated soils, a significant fraction of poorly soluble hydrocarbons reside in sub-micron sized pores of soil aggregates. Given that the bacteria are typically larger than these pores, direct contact with those hydrocarbon fractions are not expected, and hydrocarbons present in larger pores are not considered as bioavailable. We have developed a X-ray microcomputed tomography technique, supplemented by gas adsorption and mercury porosimetry measurements, that can be used to characterize a broad range pore size distributions in soil aggregates to enable estimation of bioaccessible pore volumes. Our recent investigations however suggest that an approximate size of bacteria may results in incorrect estimation of microbial bioavailability. Our detailed experimental studies demonstrate that certain growth conditions and bacterial properties cause aggregation of bacteria, which results in bacterial entry only into pores 5 microns and larger; while in situations where there is active bacterial growth near pore mouths, bacteria in early growth stages can enter pores as small as 0.4 microns. These findings provide a basis for estimating bioaccessible pore volumes which can then be used towards rational assessments of bioremediation endpoints in porous soil aggregates.

7 Are depletive and passive samplers interchangeable exposure metrics to estimate interstitial water concentration?

S. Nutile, Southern Illinois Univ Carbondale / Zoology; A. Harwood, Alma College / Environmental StudiesBiology; F.L. Sinche, K. Huff Hartz, Southern Illinois Univ Carbondale / Center for Fisheries Aquaculture and Aquatic Sciences; P.F. Landrum, Southern Illinois Univ; M.J. Lydy, Southern Illinois Univ-Carbondale / Center for Fisheries Aquaculture and Aquatic Sciences

It is well recognized that defining bioavailability is essential for accurately estimating exposure in risk assessments. Bioavailability- and bioaccessibility-based metrics, such as passive samplers and Tenax extractions, respectively, provide accurate exposure estimates of contaminants in sediments by representing the chemical fraction that is, or will, become available for biological uptake. Use of passive samplers under equilibrium conditions is time consuming, but use under non-equilibrium conditions requires modeling and extrapolation. Additionally, defining the bioaccessible fraction through estimates of the rapidly desorbing fraction (F_{rap}) with sequential Tenax extractions can take days to weeks. Single-point Tenax extractable concentrations, however, represent F_{rap} and provide accurate estimates of bioaccessibility. As the link between Tenax extractable concentrations and interstitial water concentration at equilibrium (C_{IW}) is not well defined, few risk assessments utilize this method. This study examined the relationship between bioavailability- and bioaccessibility-based techniques by comparing F_{rap}, SPME fiber concentrations, and 24 h single-point Tenax extractions by using estimates of C_{IW} as a comparative media. Comparisons of SPME fibers at equilibrium to F_{rap} estimated from full desorption curves by calculating C_{IW} yielded a strong linear regression, suggesting both bioavailability and bioaccessibility are driven by F_{rap}. Since single-point Tenax extractions are more convenient than quantifying F_{rap} using full desorption curves or using SPME fibers at equilibrium, comparisons of C_{IW} calculated using single-point Tenax extractions and SPME fibers were made to understand if estimates of F_{rap} provided by single-point extractions were comparable to full desorption curves and passive samplers. A significant linear regression was found, demonstrating that 24 h single-point Tenax extractions provide operationally defined estimates of C_{IW} at equilibrium similar to that of passive samplers. The slope of this regression line, however, is dependent on the length of the Tenax extraction, as 24 h extractions represent desorption from F_{rap} as well as the slow and very slowly desorbing fractions. Therefore, both bioavailability- and bioaccessibility-based exposure metric estimates are controlled by F_{rap}, provide similar estimates of C_{IW} at equilibrium, and as such, should be considered complementary tools for use in risk assessments.

8 Single-point Tenax extractions: An effective but underutilized tool in sediment risk assessments

A. Harwood, Alma College / Environmental StudiesBiology; S. Nutile, Southern Illinois Univ Carbondale / Zoology; F.L. Sinche, K. Huff Hartz, Southern Illinois Univ Carbondale / Center for Fisheries Aquaculture and Aquatic Sciences; P.F. Landrum, Southern Illinois Univ; M.J. Lydy, Southern Illinois Univ-Carbondale / Center for Fisheries Aquaculture and Aquatic Sciences

Numerous studies have utilized the single-point Tenax extractable concentration to evaluate bioaccumulation potential of hydrophobic organics. Ultimately, the Bioaccumulation Tenax Model, which relates the 24 h Tenax extractable concentration to lipid normalized tissue concentrations, was developed. This model now contains over 750 data points, representing several compound classes and species. Despite the apparent robustness of this model, Tenax is still not a widely recognized method for sediment assessments. One reason for this is the limited information on the consistency of this method across sediments, experimental methodologies, and compound classes. The objective of the current study was to evaluate which variables can influence the consistency and applicability of Tenax extractable concentrations to evaluate bioaccumulation. We determined that in most cases the Tenax extractable concentrations were consistent regardless of Tenax to organic carbon ratios or Tenax mass. The relationship between the 24 h Tenax extractable concentration and the rapidly desorbing fraction also was unaffected by Tenax to organic carbon ratios, hydrophobicity, organic carbon content of sediments, and only slightly impacted by aging time. However, while Tenax extractable concentrations can be related to mortality, caution is advised when using Tenax extractable concentrations to estimate bioaccumulation when sediments are toxic; therefore, selection of appropriate endpoints is essential to optimally utilizing this technique. This further demonstrates that 24 h single-point Tenax extractions are a robust method for evaluating bioaccumulation potential in sediments and are a powerful underutilized tool for risk assessments of hydrophobic organics.

Uncharted Waters: Field Ecotoxicology in Remote Locations on Limited Resources

9 An Ecotoxicological Voyage into Central Asia

D.D. Snow, Univ of Nebraska / School of Natural Resources; A.S. Kolok, Univ of Nebraska – Omaha / Nebraska Watershed Network; S. Bartelt-Hunt, Univ of Nebraska-Lincoln / Civil Engineering; B. Uralbekov, al-Farabi Kazakh National Univ; N. Mamilov, al-Farabi Kazakh National Univ / Biology and Biotechnology; M.K. Sellin Jeffries, Texas Christian Univ / Dept of Biology

When conducted in developing countries, ecotoxicological research may be particularly challenging. Here, we present lessons learned from a recent reconnaissance mission to Kazakhstan to highlight such challenges and offer potential solutions. In our experience, the researcher is likely to confront an environment in which there is little technical or logistic support for field work. Furthermore, extensive and sophisticated sample collection, preparation and processing that field scientists typically enjoy in developed countries is often not possible. Even the taken for granted background information, such as maps and traveling details, may either be unavailable or available only in a language and format that dramatically limits utility. Due to these limitations, it is important to plan ahead early, and to incorporate the expertise of locals into the travel plans and coordination. If the travelers include those who have not experienced the culture, landscapes and uncertainty of an expedition to a foreign country, then it is also critical that group members be continually involved in the planning and inevitable change of plans. With respect to data collection, it may be important to collect data that encompasses trace level organic and inorganic contaminants, as well as biological tissues and field measurements, particularly if the expected contaminants are uncertain. In spite of the risks, the rewards of a successful field expedition to a foreign country are considerable and the lessons learned will ultimately pave the way to better understanding of how to best manage aquatic ecosystems both for a growing global community and shrinking planet.

10 Documenting water quality in the Syr Darya River Basin – the utility of passive sampling

S. Bartelt-Hunt, Univ of Nebraska-Lincoln / Civil Engineering; D.D. Snow, Univ of Nebraska / School of Natural Resources; B. Uralbekov, al-Farabi Kazakh National Univ; A.S. Kolok, Univ of Nebraska – Omaha / Nebraska Watershed Network; M.K. Sellin Jeffries, Texas Christian Univ / Dept of Biology; N. Mamilov, al-Farabi Kazakh National Univ / Biology and Biotechnology; E. Hoehn, Univ of Nebraska-Lincoln; J. Sallach, Univ of Nebraska-Lincoln / Civil Engineering

The Syr Darya River originates in the Tian Shan Mountains in Kyrgyzstan and eastern Uzbekistan and flows through southern Kazakhstsan to what remains of the Aral Sea. The river basin in Kazakhstan and Uzbekistan is an area of intensive agricultural production, and annual use of pesticides and insecticides in the lower region has been estimated at 34,000 to 52,000 metric tons. In June and October 2015, we conducted a sampling campaign along the Syr Darya to evaluate the occurrence of pesticides, insecticides, metals and radionuclides to better eludicidate the water quality impacts from intensive agricultural practices and mining activity in the region. A variety of metals were detected including vanadium, uranium, iron, copper and zinc, generally showing increasing concentrations with distance downstream. Analysis of water and sediment samples demonstrated the occurrence of lindane, trifluralin and residues of legacy pesticides including 4,4-DDE. Passive organic chemical integrative samplers (POCIS) were deplyed in the Syr Darya. A variety of compounds were detected in both grab samples and POCIS including neoicotinoid and organophosphorus insecticides, as well as triazine and chloroacetanilide herbicides. Though a POCIS was lost at one location, a larger number of compounds were detected in the POCIS extracts when compared to the grab samples, indicating the potential utility of passive sampling in remote locations or when contaminant concentrations are not well understood.

11 An ecotoxicological reconnaissance in Central Asia: Assessment of biomarker responses in wild-caught roach (Rutilus rutilus)

G.S. Nystrom, Texas Christian Univ / Biology; D.D. Snow, Univ of Nebraska / School of Natural Resources; A.S. Kolok, Univ of Nebraska – Omaha / Nebraska Watershed Network; S. Bartelt-Hunt, Univ of Nebraska – Lincoln / Dept of Civil Engineering; B. Uralbekov, al-Farabi Kazakh National Univ; N. Mamilov, al-Farabi Kazakh National Univ / Dept of Biology and Biotechnology; M.K. Sellin Jeffries, Texas Christian Univ / Dept of Biology

With increasing global demand for agricultural products, countries of the developing world, such as Kazakhstan, have been pressured to implement strategies for intensive agricultural production. Some strategies have led to a variety of environmental disasters, one of the worst being the recent dewatering of the vast Aral Sea. Water diversion from the Syr and Amu Darya rivers since the 1950s to supplement agricultural production in the arid region has not only caused the subsequent dewatering of the Aral Sea, but has led to the wholesale collapse of the Sea's historically important fishery. Recent investigations have revealed the residues of both modern and legacy pesticides (e.g. 4,4-DDE, a metabolite of the pesticide DDT), heavy metals (e.g. vanadium), and radionuclides in the Syr Darya watershed, potentially arising from agricultural runoff, mining and changing land uses. The goal of this reconnaissance project was to assess the biological implications of contaminants in the Syr Darya watershed. This was accomplished by taking physical measurements (i.e. mass, length, condition factor, GSI, and HSI) and tissue (i.e. liver, brain, gonad, gill) samples from roach fish (Rutilus rutilus) at three sites along the Syr Darya. Tissue samples were analyzed for genes considered to be biomarkers of chemical exposure. Quantitative PCR analysis of these tissues revealed the altered expression of genes perceived as indicators of a generalized stress response (e.g. heat shock protein 70, superoxide

dismutase), and xenobiotic metabolism (e.g. cytochrome p450 enzyme 1A). The implications of these findings will be discussed in the context of land use and chemical residues. In keeping with the session's theme, we will also discuss some of the difficulties and resolutions associated with collecting biological samples in remote regions of Kazakhstan.

12 Development of a native pencil catfish (Trichomycterus areolatus) as a freshwater environmental sentinel of pollution in Chile

J.M. Ali, Univ of Nebraska Medical Center / Environmental, Agricultural and Occupational Health; A.S. Kolok, Univ of Nebraska – Omaha / Nebraska Watershed Network

Much of the country of Chile is a desert environment with unique and challenging problems relative to the discipline of ecotoxicology. Here, the rivers run a relatively short distance from their origins in the Andean Mountains to the Pacific Ocean and are separated by miles of desert. Despite their remote locations in the Andes many of these river systems are subject to intensive utilization by mining, industry and agriculture that contribute to their degradation. We have identified a native environmental sentinel for investigating pollutants in the scarce freshwater ecosystems of Chile. Trichomycterus areolatus, is a native pencil catfish found in streams throughout Central Chile and is an ideal candidate for a sentinel organism due to its relative abundance and intimate interaction with both the sediment-water interface. We sequenced the adult transcriptome of T. areolatus using tissue samples collected from the Choapa River in Coquimbo (Region IV), Chile. Based on this data, we identified differences in hepatic gene expression downstream of pollution sources along the Choapa River in January 2015. Among other site specific changes in hepatic gene expression, we found defeminization of female specimens collected downstream of areas with intense agricultural activity. Additionally, male specimens collected near the city of Salamanca showed an upregulation in hepatic expression of CYP1A. However, challenges remain with implementing this species as an environmental sentinel including a lack of knowledge about its reproductive strategy, typical feeding behaviors and life history.

13 Vitellogenin detection and quantification in blood plasma and surface mucus of a range of Australian freshwater and marine fishes

K.L. Hassell, J. French, The Univ of Melbourne / Centre for Aquatic Pollution Identification and Management CAPIM; V.J. Pettigrove, The Univ of Melbourne / Zoology; R. Moeller, TECOmedical AG; M. Hennies, TECOdevelopment GmbH; M. Wippermann, TECOmedical AG

Research on the impacts of endocrine disrupting chemicals (EDCs) to Australian fishes is restricted to just a few studies due largely to a lack of tools, resources and limited local expertise. Australia, like many other locations that have limited ecotoxicology resources, also exhibit harsh environmental conditions (ie. long periods of drought) and have unique flora and fauna. For these reasons, research to establish the sensitivities of local, native species is necessary to determine realistic estimates of risks from EDCs in these environments. However, there are currently no specific tests for Australian species, which, combined with an underlying lack of fundamental knowledge of the reproductive physiology in most native fishes, creates challenges when trying to measure endocrine disruption in environmental monitoring and laboratory-exposure studies. Measurement of the yolk-protein precursor, vitellogenin (VTG) is a widely used and well established biomarker for assessment of exposure to estrogenic endocrine disrupting chemicals. Globally, the induction of VTG in juvenile and male fish is used in standardised testing guidelines (eg. OECD, USEPA) to infer exposure to sewage-derived estrogens and other xenoestrogens (eg. Bisphenol A, nonylphenol), in well described, model species such as zebrafish, fathead minnows, carp, roach and rainbow trout. The measurement of VTG is predominantly carried out by enzyme-linked immunosorbent assay (ELISA), using antibodies that have been developed for specific test species, however, the production of VTG antibodies is costly, time consuming and has animal ethics considerations and is therefore not a viable option for development in multiple Australian fish species. Here we report the use of two commercially available ELISA kits for quantitative measurement of VTG in blood plasma and surface mucus of several fish species sampled from rivers and estuaries around Melbourne, Australia. Successful testing has been done on native species from several fish families, including Sparidae, Tetraodontidae, Percichthyidae, Gobidae and Eleotridae, as well as introduced species from Cyprinidae and Percidae. This study demonstrates the utility of applying existing tools to non-standard test species in order to progress research into endocrine disruption impacts in Australia, despite the lack of local tools and resources.

14 Grocery Store Ecotoxicology: Mercury in food fish from two major river systems in Colombia

A.S. Kolok, Univ of Nebraska – Omaha / Nebraska Watershed Network

It is not uncommon for modern mining to occur in remote regions of the world. One such region is the Nechi River near El Bagre in northeastern Colombia. The Nechi River watershed is known for its gold deposits and both artisanal and industrial mining operations extract the resource from the river sediments. A considerable amount of elemental mercury is used in the extraction process, and there is concern that mercury contamination can occur both occupationally and environmentally. Relative to environmental contamination, it is possible that large predatory fish, such as whiskered catfish, can biomagnify mercury in their muscle making the meat toxic if consumed. Efforts to sample large fish from the local rivers are thwarted by the lack of reliable transportation locally and by the limitations in the type of equipment that can reliably be transported to such remote regions. Under these conditions, a successful strategy that can be employed is to sample fish collected for human consumption, either by the local fishers as they bring their catch to market or directly from the market place itself. Using this strategy, we attempted to determine whether fish from the Nechi River were more contaminated with mercury than the nearby La Miel River, a tributary of the Magdalena River where there are no pronounced gold deposits. Six different fish species were collected from each river system and in general the fish from the Nechi had higher levels of mercury in their tissues than did those from La Miel. More importantly, the levels of mercury found in the Nechi were highest in muscle tissue from two different species of Pimelodid, or whiskered, catfish. It seems likely that species from the Pimelodid family can be used as environmental sentinel organisms relative to mercury contamination. Furthermore, it seems plausible that fish collected at local fish markets can be very useful to evaluate mercury contamination on a watershed scale.

15 Challenges in assessing chemical contamination of water in resource poor countries: Lessons learned during field sampling in Haiti

J.H. Bisesi, H. Sit, L.L. Jackson, Univ of Florida / Environmental and Global Health; S. Robinson, Univ of Florida / Envirionmental and Global Health; N. DeStefano, Duke Univ; L. Ferguson, Duke Univ / Dept of Civil and Environmental Engineering; T. Sabo-Attwood, Univ of Florida / Environmental Global Health

The large majority of outreach efforts in resource poor countries are focused on infectious diseases that plague these areas. But unregulated chemical use and discharge, and inadequate treatment infrastructure may also lead to chemical contamination risks to aquatic organisms as well as animals and humans that use contaminated water sources for drinking, cooking, and cleaning. Additionally, many chemical contaminants are known to exacerbate infectious disease, which may contribute to the epidemic disease outbreaks around the world. Yet little work has been done to characterize the presence and potential environmental health risks of aquatic chemical contaminants in resource poor countries. Haiti is located on the island of Hispaniola and is recognized as the poorest country in the western hemisphere. It has been plagued with widespread environmental health issues resulting from poor infrastructure, little regulation, lack of education, and a receding economy. In Haiti, little attention has been paid to chemical contaminants in aquatic systems, therefore, our team set out in the spring of 2015 and 2016 to conduct small scale surveys of contaminants in surface and subsurface waters. Two techniques were implemented to assess the presence of organic

contaminants: high throughput hormone receptor bioanalytical assays for screening of endocrine activity and non-target mass spectrometry for identification of chemicals present in these waters. Initial results from these assays indicate the presence of low levels of numerous chemical contaminants including estrogenic chemicals, pesticides, pharmaceuticals, and plasticizers. Results from these studies will be used to prioritize future sampling and be matched with future exposure assessments to inform risk analysis for Haitian populations. Many challenges were encountered during these studies including import/export, logistical, and infrastructure issues that will be addressed during this presentation. Lessons learned from our work in Haiti are useful as toxicological assessments in underdeveloped settings gain traction in support of improving ecosystem and human health.

16 Ecotoxicological Research in Remote and International Settings: Challenges and Solutions

C.R. Propper, F.A. von Hippel, M. Shuman-Goodier, C.L. Buck, Northern Arizona Univ / Biological Sciences

Ecotoxicological research in remote and/or international settings is fraught with challenges and rewards. However, research efforts in these locales is critical to establish the effects of contaminants on both human and environmental health. We will discuss lessons learned from three investigator perspectives including both obstacles and solutions while working in remote areas around the world. Establishing collaborations across distance and culture involves language, technical, legal, and cultural challenges. Working with local collaborators with culturally relevant experience is critical. Second, training in cross-cultural sensitivity relevant to the research site, as well as basic language skills, build foundations with local research partners and the community. Gaining the confidence of the support people on site is fundamental to navigating the regulatory rules involving transportation, permitting, and sample collection. Planning needs to include concrete emergency preparation for potentially life threatening situations such as infectious diseases, political instability, catastrophic events, and dangerous animals. Building a knowledge-base and support system requires site visitation, collaborator and support staff meetings, and evaluation of field conditions. Site visitation also enables the collection of preliminary data and the identification of suitable model species necessary for successful grant applications. Creative funding solutions often require combinations of support from diverse granting resources to promote project sustainability; grant resource examples include non-governmental organizations, international aid agencies, local and federal grant programs, and the home institution. A challenge for the research community is educating funding agencies regarding the hurdles and need for ecotoxicological research in remote locations and developing countries. Collectively these approaches will facilitate research and therefore broaden our understanding of the impact of pollution on a global scale.

Exposure, Effects and Fate of New Organic Contaminants in Aquatic Ecosystems

17 Advances in the fugacity modeling of emerging substances in aquatic ecosystems

M.J. Bock, P.C. Fuchsman, Ramboll Environ

Fugacity modeling was proposed by Don Mackay as a comprehensive framework to model the fate of substances in the environment. In fugacity modeling virtually all important processes can be included: (1) partitioning, (2) bioaccumulation, (3) degradation and synthesis reactions, (3) advection and diffusion, (6) loadings to the environment, and many other processes. Since its inception, the application of fugacity modeling has evolved from simpler to more complex systems. Early fugacity models described processes on a continental scale. Later models moved to smaller units such as lakes, drainage basins and watersheds. Other fugacity models have been developed to characterize processes such as wastewater treatment and the land application of biosolids. In recent years we have applied fugacity based models to the prediction of the ecological risks due to the disposal of consumer products and substances of emerging concern. Substances such as triclosan and bisphenol A have been recently evaluated to characterize risks to aquatic systems. Earlier models utilized WWTP models, watershed scale fate and transport models to predict the steady state concentrations in abiotic media, and food web based bioaccumulation models to predict dietary and tissue concentration. In an effort to more accurately capture geographic variability we have moved to smaller model units, and more recent models have been reparametrized to link the units together using a flow network. The flow network links upstream model units to downstream model units and more faithfully simulates the movement of substances through a drainage basin. We have also developed additional model algorithms that not only incorporate the degradation of substances but also include the fate of these degradation products in the simulations. The primary challenges to effective fugacity modeling are (1) the accurate estimation of chemical characteristics such as K_{oc} and media specific degradation rates, (2) pathway specific loadings of point and diffuse sources to abiotic media, and (3) the characterization of the model units including the volume of surface water, surface soil, and sediment, surface water flow and flow pathways, and the boundaries of each model unit. The use of these models provides a means by which the risks associated with substance can be assessed in the absence of comprehensive monitoring data.

18 Temporal trends of PBDEs and emerging flame retardants in endangered beluga whales from the St. Lawrence Estuary (Canada)

A. Simond, UQAM / Biological Sciences; M. Houde, Environment and Climate Change Canada / St Lawrence Center; V. Lesage, Fisheries and Oceans Canada; J. Verreault, Université du Québec à Montréal / Dept of Biological Sciences

Located downstream of several large cities, the St. Lawrence Estuary (Eastern Canada) has over the years become a highly contaminated area by halogenated flame retardants (HFRs). Each summer, many whale species migrate into the St. Lawrence Estuary for feeding. Due to their high trophic level, certain toothed and baleen whales from this area are highly exposed to HFRs including polybrominated diphenyl ethers (PBDEs) and several other HFRs. A study reported a significant increase in blubber PBDE concentrations in stranded beluga whales (Delphinapterus leucas) from the St. Lawrence Estuary between 1987 and 1997, followed by a plateau up until 2007. Although St. Lawrence belugas have been protected from hunting since 1979, this population has not recovered and was reclassified as endangered in 2014. This might be partly explained by high exposure to HFRs and other contaminants. We investigated the variations of 35 PBDE congeners and 12 emerging HFRs (e.g., Hexabromobenzene (HBB) and dechlorane-related compounds) in the blubber of 50 stranded male belugas found along the Estuary and Gulf of St. Lawrence between 1997 and 2013. We also examined the occurrence of these HFRs in 11 stranded male and female minke whales (Balænoptera acutorostrata) from the St. Lawrence as well as 6 male belugas from Nunavik (Canadian Arctic) collected as part of the traditional hunt. PBDEs were the most abundant HFRs in all three whale populations and 6 emerging HFRs were quantified in the majority of samples. ΣPBDE concentrations in blubber of St. Lawrence belugas were 3- and 5-fold greater than minke whales and Arctic belugas, respectively. Overall, concentrations of emerging HFRs in belugas from the St. Lawrence were notably greater compared to the two other populations, with the exception of Dechlorane plus (DP) and Dec-604 Component B that were greater in Arctic belugas. No significant trend of PBDEs was found in St. Lawrence belugas during this 17-year period. In contrast, concentrations of HBB and Chlordene plus decreased slightly from 1997 to 2013, while DP increased up until 2000 and decreased slightly thereafter. Age and diet (i.e., stable carbon and nitrogen isotope signatures) of whales did not influence HFR concentrations. Despite several years of PBDE regulations, blubber levels of PBDEs in St. Lawrence belugas have remained unchanged. The occurrence of alternative HFRs in these cetaceans warrants continuous monitoring of these substances.

19 Mass Balance Study of Lake Michigan for Organic Pollutants in 2010-2015

J. Guo, Univ of Illinois – Chicago / School of Public Health; M. Venier, Indiana Univ / SPEA; S. Westenbroek, USGS / Wisconsin Water Science Center; A. Li, Univ of Illinois at Chicago / School of Public Health; R.A. Hites, Indiana Univ / School of Public Environmental Affairs

This study revisits and updates the Lake Michigan Mass Balance Study that was conducted by federal, state, university, and private-sector researchers between 1994 and 1996. The current work combines recent data from Lake Michigan tributary water, air, open lake water, and sediment to calculate an updated mass balance for polychlorinated biphenyls (PCBs), brominated flame retardants (BFRs), and organophosphate esters (OPEs). The fluxes or loads of tributary, open lake water, air, and sediment sources were calculated and compared to produce an approximate present-day mass balance. Water samples, including both the dissolved and particle phases, were collected every three weeks in 2015 from the Grand, Kalamazoo, St. Joseph, and Lower Fox Rivers and from the Indiana Harbor and Ship Canal. Air samples, including both particle and vapor phases, were obtained from Chicago and Sleeping Bear Dunes every 12 days as part of the United States' Integrated Atmospheric Deposition Network (IADN). Open lake water samples were previously analyzed in the Hites laboratory in conjunction with Environment Canada. Sediment data were obtained from the Great Lakes Sediment Surveillance Program. Tributary sample concentration ranges in 2015 for PCBs, BFRs, and OPEs were 0.5-50 ng/L, 0.2-3.7 ng/L, and 0.4-150 ng/L, respectively. Significant differences in mean concentrations were found among the five rivers; the Indiana Harbor and Ship Canal had the highest mean concentrations for the three groups of compounds. Preliminary results suggest that the Chicago remains the main source of atmospheric deposition to Lake Michigan for many of these compounds. The concentrations of PCBs and some BFRs measured in our study were less than that measured/computed by previous studies, possibly indicating a downward trend.

20 Linear and cyclic volatile methylsiloxanes in blood of freshwater and marine piscivorous wildlife from Canada

D.G. Wang, Dalian Maritime Univ / Dept of Environmental Science and Engineering; S. de Solla, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; M. Lebeuf, Maurice Lamontangne Inst. / Maurice Lamontagne Inst; T. Bisbicos, Environment and Climate Change Canada / Water Science and Technology Directorate; G. Barrett, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate; M. Alaee, Environment and Climate Canada / Water Science and Technology Directorate

Cyclic and linear volatile methylsiloxanes (VMS) substances are widely used as ingredients for cosmetic and personal care products including anti-perspirant, baby products, shampoo, nail polishes, etc. Blood of piscivorous wildlife (snapping turtles, double-crested cormorants, and grey seals), was collected in Canadian freshwater and marine ecosystems. A modified quick, easy, cheap, effective, rugged, and safe (QuEChERS) method was developed to measure VMS in blood, using large-volume injection with gas chromatography-mass spectrometry (LVI-GC-MS). Cyclic VMS hexmethylcyclotresiloxane (D3), octamethylcyclotetrasiloxane (D4), decamethylcyclopentasiloxane (D5), and dodecamethylcyclohexasiloxane (D6) were present in blood of all three species. Linear VMS were only found in seal blood in one contaminated site. For most animals, D5 was the dominant compound, with mean concentrations ranging between 0.143 and 7.39 ng/g ww. Further, D5 showed the largest spatial variation for each species, as all showed elevated D5 concentrations in contaminated sites compared to the reference sites. Our data indicated that local urban sources of VMS contribute significantly to the observed D5 concentrations in free ranging wildlife. Given that the blood:air partition coefficient of VMS is low but the lipid:water partition coefficient is very high, diet is likely the main source of VMS to piscivorous wildlife. The presence of cyclic VMS in the blood of three species from different taxonomic groups in marine vs freshwater ecosystems demonstrates that these chemicals are ubiquitous in aquatic biological systems.

21 Scenario analysis of the persistence of linear and cyclic volatile methylsiloxanes in aquatic environments using multimedia models

D. Panagopoulos, Stockholm Univ / Dept of Applied Environmental Science; A.H. Kierkegaard, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry ACES; A. Jahnke, Helmholtz Centre for Environmental Research – UFZ / Cell Toxicology; M. MacLeod, ITM – Stockholm Univ / Dept of Environmental Science and Analytical Chemistry ACES

Volatile methylsiloxanes (VMS) are a group of organosilicon chemicals that consist of SiO-chains in cyclic or linear ordinance and have methyl groups attached to the silicon atoms. Because of their widespread use in personal care products, cyclic and linear volatile methylsiloxanes (cVMS and lVMS) have been found at considerable levels in air, surface waters, sediments and aquatic organisms. In surface waters and sediments, the residence times of VMS are primarily controlled by their sorption to organic carbon, characterized by their organic carbon/water partition ratio (K_{OC}). Kozerski et al.[1] reported a log K_{OC} value of 5.17 for decamethylcyclopentasiloxane (D_5) and in a previous study[2] we measured log K_{OC} of 6.12. To explore the implications of such differences in partitioning behavior, we modeled the fate of cVMS and lVMS in generic scenarios using the equilibrium criterion model (EQC) and in a regional scale scenario in Adventfjorden, Svalbard, Norway. Using the K_{OC} measurements of Kozerski et al.[1] in the EQC model the overall residence time for D_5 was 203 d, while using the K_{OC} measurements of Panagopoulos et al.[2] the overall residence time was more than 3 times longer at 676 d. Similarly, in the regional scenario when using a log K_{OC} of 5.17 the overall residence time for D_5 was 225 d, while using a log K_{OC} of 6.12 the overall residence time was 534 d. The one log unit higher K_{OC} substantially increased the residence times of D_5 such that their residence times in sediment exceeded the persistence (P) criterion for sediment set by REACH and the 100-day criterion for overall persistence suggested by Webster et al.[3] The modeling results underline the large influence of K_{OC} when estimating the persistence of VMS in aquatic environments.

22 Polyhalogenated carbazoles in sediments of the Great Lakes: natural or anthropogenic?

A. Li, J. Guo, Univ of Illinois at Chicago / School of Public Health; S. Zhou, Zhejiang Univ of Technology / School of Environment; T. Lin, Univ of Illinois Chicago / School of Public Health; H. He, Nanjing Univ / School of the Environment; Z. Li, Univ of Illinois at Chicago / School of Public Health; P. Ranasinghe, Clemson Univ / School of Public Health; S. Hosseini, S. Bonina, Univ of Illinois Chicago / Dept of Civil and Materials Engineering; M.B. Corcoran, Univ of Illinois Chicago / Dept of Earth and Enviromental Science; C. Smalley, Univ of Illinois at Chicago / Dept of Earth and Enviromental Science; K. Rockne, Univ of Illinois at Chicago / Dept of Civil and Materials Engineering; N.C. Sturchio, Univ of Delaware / Dept of Geological Sciences; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre

Aromatic organohalogens may originate from both natural and anthropogenic sources, and can be either detrimental or beneficial to the ecosystem and humans. To date, synthesized persistent and bioaccumulative organohalogens have received most attention in environmental monitoring. Evidence is mounting that known anthropogenic organohalogens compose only a small fraction of the total organohalogens found in the environment. In recent years, increasing detection of polyhalogenated carbazoles (PHCZs) has caused concern. PHCZs resemble polyhalogenated dibenzofurans in chemical structure with a planar molecular conformation that promotes toxicity. As such, PHCZs are termed nitrogenated dioxins and are considered as novel persistent organic pollutants. The sources of PHCZs found in the environment remain unknown and have been debated. The objective of this work was to gain insights into the origin of PHCZs found in natural waters. Ponar grab and core sediment samples were collected from the Great Lakes of North America, including Lakes Michigan, Superior, Huron, Erie and Ontario. The samples were analyzed and characterized for PHCZs using gas chromatography coupled with single- or triple-quadrupole mass spectrometry. The total accumulation of 26 PHCZs in the sediment is >3,000 tonnes, which exceeds those of known anthropogenic organic pollutant groups by orders of magnitude. Spatial and temporal patterns differ significantly among PHCZ congeners and among lakes. Based on their spatial and temporal trends as well as principle component analyses, both natural and anthropogenic sources are present. In particular, the majority of PHCZs found in the sediment of Lake Michigan is believed to have formed naturally. A number of "emerging" PHCZs deserve further monitoring as their deposition to the sediment has been increasing in recent decades. Lower substituted PHCZs may form from in situ dehalogenation of those with more halogens. Anthropogenic sources appear to exist, particularly for the emerging and some light molecular mass congeners.

23 A Chronological Record of Organophosphate Ester Deposition in Sediment

A.O. De Silva, T.E. Peart, C. Spencer, Environment and Climate Change Canada; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; P.A. Fair, NOAA National Ocean Service

Organophosphate esters (OPEs) are used as flame retardants and plasticizers in a variety of products. OPEs have been measured in surface sediments, however, their temporal trends , inferred from dated sediment cores, have not previously been determined. In this study, OPEs were determined in surface sediments from depositional zones of Lake Ontario and from Charleston Harbor area from South Carolina. Twelve of 22 OPEs were detected with >60% frequency in Charleston harbor sediments with tris (2-chloroisopropyl) phosphate (TCPP; 12 ng/g dry wt), tris(n-butyl) phosphate (TnBP; 13 ng/g dw) and ethylhexyl-diphenyl phosphate (EHDPP; 8.7 ng/g dw) predominating. TCPP and TnBP also represented a major proportion of total OPEs in surface sediments from a core collected from the urban influenced western basin of Lake Ontario but were less prominent in more remote central lake site. Analysis of dated cores from the two Lake Ontario sites showed exponential increases in depositional fluxes of 6 OPEs, including TCPP and TnBP, starting post-2000, possibly due to their growing use related to the phase out of polybrominated diphenyl ethers. Other OPEs had parabolic deposition profiles in the central basin suggesting maximum deposition in the 1990s. This is also the first chronological depositional analysis of OPEs in sediment cores in the Great Lakes and suggests emissions to aquatic environments are increasing.

24 Transcript, protein, and metabolite responses in rainbow trout (Oncorhynchus. mykiss) exposed to TBBPA-DBPE

D. Simmons, Univ of Waterloo / Biology; J. Sherry, Environment and Climate Change Canada / Water Science Technology Directorate; B. Chandramouli, J. Cosgrove, SGS AXYS

The Chemical Management Plan (CMP) has identified Tetrabromobisphenol A bis(2,3-dibromopropyl ether) (TBBPA-DBPE) as a replacement flame retardant with the potential to enter the Canadian aquatic environment. There is concern that TBBPA-DBPE might also pose a risk of disrupting the endocrine systems of exposed organisms. The present experiment was designed to assess the sub-lethal effect(s) of TBBPA-DBPE in juvenile rainbow trout in order to identify potential sub-lethal mechanistic pathways. The fish were exposed to waterborne TBBPA-DBPE in a flow-through design. TBBPA-DBPE was delivered to the tanks by peristaltic pumps to maintain consistent concentrations. Nominal exposure concentrations were: 0 µM ; 0.001-; 0.01-; 0.032-; and 0.1-µM. There were three separate exposures; one for 2 days, another for 10 days, and the last for 21 days. Eight fish were housed per tank, with three replicate tanks per exposure concentration for a grand total of 225 fish. We performed analysis of liver transcripts from fish exposed for 21 days, as well as shotgun analysis of plasma proteins and targeted analysis of plasma metabolites on fish from all exposures. We shall present a synthesis of the data from our multi-omics approach to gain insights onto the potential mode of action of TBBPA-DBPE in fish.

Environmental Chemistry

25 Two dimensional 1H and 13C-NMR characterization of atmospheric size segregated organic aerosols

M. Chalbot, Univ of Alabama at Birmingham / Environmental Health Sciences; S. Siddiqui, Univ of Arkansas for Medical Sciences; I. Kavouras, Univ of Alabama at Birmingham

Atmospheric aerosol is a complex mixture of primary and secondary particles originating from anthropogenic and biogenic sources. Organic aerosols (OA) constitute from 50 up to 80% of atmospheric aerosol and play a very important role in the global climate acting as cloud condensation nuclei, atmosphere's oxidative burden and human health. Despite its significance, only 20% of OA is chemically characterized. In a recent review paper (Environmental Pollution, 2014,191, 232-249), we, for the first time, synthesized and critically evaluated the findings of NMR studies on OA, identified knowledge gaps and areas of research. These key issues included: optimization of sampling and analysis protocols, structural characterization of aqueous OA / humic-like substances and source apportionment. Proton and Carbon-NMR spectroscopy is an emerging method used to characterize environmental exposures to specific types of organic compounds. We applied 1D ^{1}H and 2D mononuclear ^{1}H-^{1}H, and heteronuclear ^{1}H-^{13}C NMR to determine the chemical composition of the water-soluble fraction of size segregated organic aerosol collected with a 5-stage (plus backup) cascade impactor at the following size intervals: < 0.49, 0.49-0.96, 0.96-1.5, 1.5-3.0, 3.0-7.2 and 7.2-30 µm. In this paper we discuss the functional group composition and source markers content of size-segregated aerosols, and the size distribution of biogenic and anthropogenic organic markers. Characteristic signals attributed to humic substances, carbohydrates, polyols, aromatic and aliphatic carboxylic acids were found with different contributions for each size fractions. Differences in the nature and contribution of sources, including soil, traffic exhausts and biomass burning, and in atmospheric processes during the same season were also revealed by functional group characterization.

26 Analysis of air monitoring data of cyclic volatile methylsiloxanes

S. Xu, Dow Corning Corporation / Health and Environmental Sciences; N.A. Warner, NILU – Norwegian Inst for Air Research / Environmental Chemistry; J.A. Durham, Dow Corning Corp. / Health and Environmental Sciences; D. McNett, Dow Corning Corporation

Due to their heavy use, cyclic volatile methylsiloxanes (cVMS) are under increased regulatory and scientific scrutiny. In last few years, the fate, transport and distribution of these compounds have been studied both by multimedia environmental fate modeling and also by the environmental monitoring. The objective of this project was to compare the air monitoring data of cVMS with their model predictions and to identify the critical data gaps in our understanding of the major environmental processes regulating the transport and distribution of cVMS in the global atmosphere. The published modeling assessments included both simple steady state simulations and time variable analysis at the global scales using both hypothetical and realistic release scenarios. The air environmental monitoring data are from Northern American and European including sites heavily impacted by human activities and the remote Arctic locations. The temporal and spatial patterns of cVMS concentrations in air were generally in a good agreement with the modeling predictions. However, the spatial gradient of air concentration of all three cVMS were much steeper than the spatial gradients predicted by the models. The biggest inconsistency with the model predictions was the spatial trends in the concentration ratios of various cVMS (e.g. D5/D6) measured at different locations. Further analysis suggested that the above discrepancy between the field data and model predictions could be attributed mainly to the possibility of the additional degradation mechanism in air that has not been recognized and incorporated in any of the current modeling assessments.

27 Use of Cholic Acid as a Surrogate Internal Standard for Steroid Hormone Quantitation in the Whale Blubber Matrix

M. Hayden, Texas Tech Univ/TIEHH / Environmental Toxicology; R. Bhawal, J. Escobedo, C. Harmon, Texas Tech Univ / Center for BioTechnology Genomics; D. Klein, Texas Tech / Environmental Toxicology; S. San-Francisco, M. Zabet-Moghaddam, Texas Tech Univ / Center for BioTechnology Genomics; C. Godard-Codding, Texas Tech Univ / Dept of Environmental Toxicology The Inst of Environmental and Human Health

The International Whaling Commission Scientific Committee has stressed the critical need for studies on reproductive status of the western gray whale (Eschrichtius robustus) population, which it currently designates as critically endangered. Biopsy samples from western gray whales off Sakhalin Island have been collected in collaboration with Russian scientists since 2011. These samples provide precious material amenable to hormone, genetic or stable isotope analyses as previously reported (Gendron et al. 2015, Bickham et al. 2015, Bickham et al. 2013). Yet, with the current ELISA methodology to quantitate steroid hormones from the blubber matrix, limitations include challenges associated with the small amount of biopsy tissue available and cross-reactivity within the assay. Here, we report on a development of the quantitation of progesterone, testosterone, and cortisol via LC-MS/MS analysis in gray whale blubber. Samples from stranded eastern gray whales collected in 1997-2011 were homogenized, extracted for steroids, filtered, evaporated, and dissolved in 50 µL of a 60:40 solution of LC-MS grade water:acetonitrile with 0.1% formic acid. Samples were spiked with a surrogate internal standard of 5 nM cholic acid for the purposes of quantitation, diluted 1:10, and 1 ul was injected onto a C18 reversed-phase column. A 300 nL/min flow rate was used in the chromatography with nanospray ionization into the Thermo LTQ XL linear ion trap mass spectrometer. Preliminary method development include 1) steroid hormone detection from a 50 mg ww blubber sample and 2) cholic acid validation as a viable internal standard for quantitation. Standard curves for cortisol, testosterone, and progesterone quantitation were generated using cholic acid as a surrogate internal standard with the following concentrations: 0.05 nM, 0.1 nM, 0.5 nM, 1 nM, 5 nM, and 10 nM. Cholic acid concentration was held constant at 5 nM and concentrations were reported as peak area ratios. The use of surrogate internal standards is very useful (Kunze et.al 2015), and cholic acid was chosen due to its steroidal structure and lack of measurable accumulation in the blubber samples tested. The small sample mass (50 mg) required for this new methodology for blubber steroid hormone analysis is compatible with biopsy collection in western gray whales and allows for concomitant genetic and stable isotope analyses. Methodology optimization to increase the number of detectable steroid hormones is underway.

28 The dissipation and transport of the glyphosate additive polyoxyethylene tallow amine (POEA)

D. Tush, M.M. Maksimowicz, M. Meyer, USGS / Organic Geochemistry Research Laboratory

The surfactant POEA is an ingredient in many glyphosate formulations--the most widely applied agricultural herbicide in the world. POEA is toxic to many aquatic organisms and is often the primary factor of the toxicity of glyphosate formulations. The fate of POEA applied to agricultural fields and the potential transport of POEA into aquatic systems are generally unexplored research topics. A multiyear study of an active row crop field in Indiana documented that POEA, glyphosate, and a degradation product of glyphosate (AMPA, aminomethylphosphonic acid) persist from year to year with some dissipation from the top 15 cm of the field but little migration into deeper soil. The detection of POEA, glyphosate, and AMPA in stream bed sediments from agricultural and urban watersheds in Georgia, Hawaii, Iowa, Mississippi, North Carolina, and South Carolina indicate the dissipation of these compounds from the application site leads to their transport into nearby surface waters. This is the first study to simultaneously analyze a primary formulation surfactant, the active ingredient, and the major degradate of glyphosate formulations in agricultural soils and corresponding stream bed sediments.

30 Separation and analysis of single walled carbon nanotubes in estuarine sediments using density gradient ultracentrifugation with NIRF and ICP-MS

K. Liu, Duke Univ / Chemistry; M.D. Montaño, Duke Univ / Civil and Environmental Engineering; D. Plata, Yale Univ / Chemical Environmental Engineering; L. Ferguson, Duke Univ / Dept of Civil and Environmental Engineering

Sensitive and reliable quantification and characterization methods are needed to facilitate the ecological risk assessment of carbon nanotubes, including single-walled carbon nanotubes (SWCNT) in the aquatic environment. These analyses are particularly challenging because of the association of SWCNT with particulates (e.g. sediments) and the resulting complexity of samples. Near infrared fluorescence spectroscopy (NIRF) has been used to make sensitive measurements of SWCNT in marine sediments, but this technique is not sensitive to all SWCNT types. Metal catalysts are widely used in synthetic production of SWCNTs, leading to total metal content ranging from 5 - 30%. Therefore, by monitoring the metal types and metal:metal ratio along with monitoring elemental carboncontent, SWCNTs can, in principle be quantified in environmental samples using ICP-MS. Background metals from sediment present challenges to such analyses, however. Thus, we have applied density gradient ultracentrifuge (DGU) to isolate and separate SWCNT in sediment extracts prior to both NIRF and ICP-MS analysis. Several types of SWCNTs (arc discharge, CoMoCat, and HiPCO) were spiked and subsequently extracted from estuarine sediments. SWCNTs were separated into different bands after DGU, primarily into two distinct horizons (one showed near infrared fluorescence, while the other did not). Two techniques,near-infrared spectroscopy (NIRF) and ICP-MS, were applied for quantitation of SWCNTs in these bands. Results indicate excellent separation of SWCNT from interferences in sediments.We have also discovered an apparent disconnect between the metal catalyst particles and SWCNT during density gradient ultracentrifuge separation. It is clear that the SWCNT (within the NIRF band) is not physically associated with metal catalyst. This result was confirmed using single-particle ICP-MS. Although DGU separation seems to be an outstanding method for isolating SWCNT from aquatic sediment for analysis, ourcurrent findings indicate that metal fingerprints derived from residual catalyst may not be a good tracer for SWCNT occurrence and fate in marine sediments, as the associated metal catalyst particles in SWCNT preparations might be transported in different ways relative to the SWCNT.

31 Determining the Dissolution Rate of Nanomaterials in the Aquatic Environment by Ultra-Centrifugation

J. Coleman, US Army Engineer Research and Development Center; N. Hartmann, DTU Technical Univ of Denmark / Dept of Chemistry and Biology; L. Thornton, Univ of North Texas / Biology; K.L. Willett, Univ of Mississippi / Pharmacology; J.A. Steevens, USGS / Environmental Laboratory

The environmental fate and toxicity of nanomaterials are highly influenced by their dissolution kinetics (rate of solubility) and equilibrium solubility (amount of dissolved material). Solubility is material-dependent, but not as such an inherent property. In addition to the material properties, dissolution also depends on the water chemistry of the surrounding media (e.g. ionic strength, ligands, pH, organic matter and temperature). For other nanomaterials, the following parameters will also influence solubility: particle size, state of aggregation and particle coating. It is important to understand nanomaterial dissolution to be able to predict their fate and behavior in the environment. Also, information on particle dissolution is important in the interpretation of toxicological test results. The authors are currently leading the development of

Organization of Economic Cooperation and Development (OECD) standard guidance for determining the dissolution rate of metal nanoparticles. Here we propose a screening study testing up to 3 concentrations of nanomaterials and 3 pH levels for 24 hr in 5 mM sodium bicarbonate water to determine those particles which undergo rapid dissolution such that their ecotoxicity potential is practically indistinguishable from soluble forms. If only partial or no dissolution occurs, a full study is proposed to determine dissolution kinetics and incorporate specific conditions such as media composition, concentration, and pH level lasting up to 28 days. Phase separation methods were tested and we determined that ultra-centrifugation was preferable compared to ultrafiltration and dialysis due to the potential for adsorption to membranes/filtration media and the ability to reduce variability. We have found that polypropylene or high density polyethylene resulted in less adsorption compared to polycarbonate and glass. The results of these studies will be used to develop a draft protocol for dissolution ring tests in the development of a standardized guidance for dissolution rate and ultimately support the environmental hazard classification of metal nanoparticles.

32 Determination of lead in American woodcock (Scolopax minor) feathers and bone with temporal analysis and lead source determination

A.D. French, Texas Tech Univ/TIEHH / Environmental Toxicology; D. Sullins, Kansas State Univ / Division of Biology; W. Conway, Texas Tech Univ / Natural Resource Management; D. Klein, Texas Tech / Environmental Toxicology

Lead (Pb) concentrations are known to exceed biologically relevant thresholds in American woodcock (Scolopax minor). This may be contributing to their negative population trend. Woodcock are susceptible to Pb accumulation through ingesting earthworms, contaminated soil, and Pb shot. Although lead shot was banned for use on waterfowl, it is postulated to be the primary source of elevated Pb in American woodcock. Lead determination was performed using primary feathers (P2), secondary feathers (S14) and wing bones from juvenile woodcock. This allowed for a temporal study because the three sample types provide information on natal origins, migration routes and lifetime Pb accumulation, respectively. All samples were analyzed for total Pb concentration by using an inductively couple plasma – mass spectrometer. Isotope ratios of $^{206/207}$Pb and $^{208/207}$Pb were calculated to determine the sources of Pb woodcock are exposed to. Elevated Pb concentrations (> 4 ppm) were found in 19% of the feathers, with 24% having concentrations ≥ 20 ppm. Approximately 60% of the feathers with elevated Pb were P2 feathers, indicating Pb accumulation is slightly greater at woodcock natal origins. Isotope ratios in both the P2 and S14 feathers overlap with ratios from multiple environmental sources including coal emissions, gasoline, zinc smelting, and various types of Pb shot. The data collected confirm that woodcock are exposed to elevated Pb concentrations. While Pb shot is a possible source of Pb in woodcock, further research is needed to accurately determine the source of Pb in birds with elevated Pb concentrations.

Wildlife Ecotoxicology: From Food Chain Exposure to Population Effects

33 Thyroid Pathology in Deer Mice (Peromyscus maniculata) from a Reclaimed Mine Site on the Oil Sands

J. Smits, Univ of Calgary / Dept of Ecosystem and Public Health Faculty of Veterinary Medicine; A.R. Movasseghi, Univ of Saskatchewan / Prairie Diagnostic Service; J. Rodríguez-Estival, UCLM-CSIC / IREC

Free living small mammals are sensitive, useful and available sentinels which can be studied to evaluate ecological and health risks from pollutants. Information from this small mammal-based investigation may provide insights at higher levels in the food web, and have implication ergarding sustainability of local ecosystems. The extraction of bitumen in areas of northeastern Alberta, Canada, has been associated with the release of complex mixtures of metals, metalloids, polycyclic aromatic compounds, and other compounds to the environment. In previous studies of northern rodents during the spring breeding season, we observed that deer mice (Peromyscus maniculata) from a reclaimed mine site had higher renal levels of cobalt (Co), selenium (Se), and thallium (Tl) compared to the deer mice from a reference site in the same region, but beyond the range affected by airborne deposition of most industry related contaminants. This increased exposure to metals plus other unmeasured contaminants was associated with poorer body condition, smaller testis mass, and increased oxidative stress which was determined through vitamin A and glutathione redox status in both the liver and testes. These findings stimulated further investigation into the health effects, specifically histopathological examination and hormone production of the thyroid glands. Information or reports of naturally occurring thyroid disease in wild animals in general, and in small mammals specifically, is extremely limited. We therefore investigated the structure and function of the thyroid glands and thyroid hormone levels of the deer mice captured on reclaimed and reference sites on and near mining areas on the Athabasca oil sands in Alberta. Mice from the reclaimed site had marked thyroidal changes including follicular cell proliferation and decreased colloid in the follicles compared to animals from the reference site. The abnormal follicular hyperplasia was significantly correlated with higher oxidative stress (p=0.02), as was decreased thyroidal colloid production (p=0.05). Thyroid hormones, both thyroxine and triiodothyronine, were higher in animals with greater oxidative stress (p=0.01) indicating increased metabolic demands from the contaminant related oxidative pressures. This work confirms the value of a combination of endocrinological, histologic and oxidative stress biomarkers for providing a sensitive and meaningful biological measure of the cost of contaminant exposure in native small mammals on the oil sands.

34 Influence of PAH exposure and diet on metabolomic responses of double crested cormorants

S. de Solla, P. Thomas, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; V.S. Langlois, S.J. Wallace, Royal Military College of Canada / Chemistry and Chemical Engineering; J. Cosgrove, B. Chandramouli, SGS AXYS

Field based studies have the unenviable challenges typical of uncontrolled experiments; confounding factors, difficulty in establishing cause-effect relationships, and causal factors that were not considered during the experimental design. In this study, we investigated the putative differences in metabolomic responses of double crested cormorants from 3 colonies in relation to differences in airborne exposure to polycyclic aromatic hydrocarbons (PAHs), dietary exposure to POPs, and diet. Earlier research indicated that airborne exposure to PAHs increased the incidence of mutations in double-crested cormorants that were breeding in Hamilton Harbour relative to those from a Lake Erie reference site; further, alterations in gene expression in the putative p53 (tumor suppression gene) pathway were observed. We examined the metabolomic responses from cormorant chicks from each colony, using 3 tissues (blood, liver, lung). Over 200 metabolites, including acylcarnitines, amino acids, glycerophospholipids, hexose, sphingolipids, and biogenic amines, fatty acids, and bile acids, were measured by flow injection- or liquid chromatography-tandem mass spectrometry. Although all three tissues easily differentiated the three colonies, the majority of differences observed were between the Lake Erie colony and the other two Hamilton Harbour colonies. Based upon estimates of diet using regurgitates and stable isotopes (C,N), most of the differences in metabolomics responses appear to be due to diet, as opposed to either airborne PAH exposure, or dietary exposure to POPs. Metabolomics are a useful tool in determining responses of wildlife in field studies where there are multiple, sometimes confounding, stressors including contaminant exposure and ecological drivers.

35 Neurotoxic impacts of mercury on Arctic Barnacle goslings, raised in moderately contaminated terrestrial habitats in the Arctic

N. van den Brink, Wageningen Univ / Dept of Toxicology; I.B. Scheiber, Univ of Groningen / Centre for Ecological and Evolutionary Studies Behavioural Ecology and Selforganization; M.E. de Jong, Univ of Groningen / Arctic Centre; A. Arini, McGill Univ; J. Komdeur, Univ of Groningen / Groningen Inst of Evolutionary Life Sciences Behavioural and Physiological Ecology; N. Basu, McGill Univ / Dept of Environmental Health Sciences; H.H. van den Berg, Wageningen Univ / Toxicology Dept; M.J. Loonen, Univ of Groningen / Arctic Center

Although the Arctic is remote, it is contaminated by mercury from different sources. Via long range transport, mercury is transported for from lower latitudes to the Arctic via the atmosphere. Additionally, local human activities may also result in contamination. For instance, mining activities have resulted in elevated levels of mercury in the surroundings of the mining areas. The focus of mercury related research in the Arctic has mainly been on marine ecosystems, which are regarded most at risk. Risks associated with mercury in terrestrial ecosystems have been less studied. In the current presentation we will present a pilot-study in which we herded Barnacle goslings in a contaminated mining site and a control site near Ny-Ålesund, Spitsbergen. Herding the goslings made it possible to perform a controlled field study, quantifying the accumulation of mercury in the goslings. Soil in the mining area contained significant higher concentrations of total mercury than the control site. This was also the case for the vegetation (approx. 2.2 times higher in the mining site than the control site). Each group of goslings grazed approximately 3-4 hours per day in their assigned area. At night and during bad weather conditions they were kept in pens. The goslings that grazed in the mine impacted area showed increased levels of total mercury in the liver in comparison to the control group ($p < 0.05$). Concentrations were relatively low, possibly due to growth dilution due to growing feathers. Nevertheless, dopamine receptor levels in the brains of the goslings were significantly related to the hepatic total mercury concentrations. Furthermore, the behaviour of the goslings from the mine-exposed group was significantly different than from the controls. The exposed goslings showed significantly more jumps during controlled observation periods. This study indicates that, although exposure of organisms to mercury in terrestrial Arctic ecosystems may be relatively low, it still results in neurotoxic effects and even effects on the organisms' behaviour. In case of barnacle goslings this may have grave consequences when e.g. interactions between parents and goslings are affected. This warrants for further studies, integrating mechanistic biochemical ecotoxicological observations with ecological relevant observations in behaviour and other fitness parameters.

36 Assessment of Lead and Pesticide Exposure in the Declining Population of Red-breasted Goose (Branta ruficollis) Wintering in Eastern Europe

R. Mateo, UCLM-CSIC / Instituto de Investigacion en Recursos Cinegeticos; N. Petkov, Bulgarian Society for the Protection of Birds; A. López Antia, J. Rodríguez-Estival, UCLM-CSIC / IREC; A.J. Green, EBD-CSIC / Wetland Ecology

The red-breasted goose Branta ruficollis is a globally threatened species (IUCN Vulnerable) and the only European goose species currently in decline. Working on the wintering grounds on the Black Sea Coast, we address two potential causes of decline of this species for the first time: lead poisoning, and contamination from pesticides. We quantified the densities of spent Pb shot in three wetlands used by the geese in north-east Bulgaria, and analysed the Pb concentration in the faeces of red-breasted geese and the more abundant greater white-fronted geese Anser albifrons, using Al concentration as an indicator of soil ingestion. Pb shot densities in sediments were low, and we found no evidence for Pb shot ingestion in red-breasted geese. On the other hand, we found that the geese were feeding on wheat whose seeds were treated with four fungicides: thiram, tebuconazole, difenoconazole and fludioxonil. Using data on the daily food intake, we estimated the exposure levels of the geese to these fungicides, both by measuring the concentrations remaining on seeds and by estimating the amount used to coat the seeds at the time of sowing. We found that the estimated ingestion rates for both geese species exceeded the recognized hazardous doses for thiram, and to a lesser extent for tebuconazole, which indicates that some pesticides may be playing a previously overlooked role in the decline of red-breasted geese.

37 The catbird is the new chicken: high sensitivity to a dioxin-like compound in a wildlife species

M.L. Eng, Univ of Saskatchewan / Toxicology; C.A. Bishop, Environment and Climate Change Canada / Wildlife Research Divsion Science and Technology Branch; D.E. Crump, S. Jones, Environment and Climate Change Canada; T. Williams, Simon Fraser Univ / Dept of Biological Sciences; K.G. Drouillard, Univ of Windsor / Great Lakes Inst for Environmental Research; J.E. Elliott, Environment and Climate Change Canada / Science Technology Branch

Avian toxic equivalency values used for risk assessments of dioxin-like compound (DLC) contaminated sites are based on chicken toxicity testing; however, to date, no wildlife species in North America has been verified to be as sensitive as the chicken. Recently, the Gray catbird (Dumetella carolinensis), a North American songbird, was predicted to be highly sensitive to DLCs based on genotyping of the aryl hydrocarbon receptor (AHR1) ligand binding domain. The objectives of this study were to test the sensitivity of the Gray catbird to the embryotoxic effects of a dioxin-like PCB (PCB-126), and to compare the induction of hepatic CYP1A4/5 mRNA expression between the catbird and the chicken following PCB-126 exposure. Eggs were collected from the South Okanagan Wildlife Management area in British Columbia, Canada, injected with 0.5 µl/g of the vehicle control (DMSO) or one of four PCB-126 concentrations (0.71, 5.36, 11.42 and 39.98 ng/g egg), and artificially incubated to hatch. We also injected chicken eggs with DMSO, 0.01, 0.1, 0.5, or 1 ng PCB-126/g egg, and incubated until hatch to assess induction of CYP1A4/5 mRNA expression by PCB-126; this had not been previously assessed for chickens. There was a dose-dependent increase in catbird embryo mortality with a calculated LD50 of 1.35 ng PCB-126/g egg (95% CI = 0.34 to 2.54 ng/g), which falls within the range of published LD50 values for the chicken (0.4 to 2.3 ng/g egg). There was significant induction of both CYP1A4 and CYP1A5 mRNA in catbird hatchlings from the 0.71 ng PCB-126/g egg dose group. Similarly, in chickens there was significant induction of CYP1A4 and CYP1A5 starting at 0.5 ng PCB-126/g egg. Catbird CYP1A4 induction was 257-fold at 0.7 ng/g and 486-fold at 5.36 ng/g, and CYP1A5 induction was 55-fold at 0.71 ng/g and 87-fold at 5.36 ng/g. In the chicken at 1ng/g, CYP1A4 induction was 106-fold, and CYP1A5 induction was 52-fold. For both catbirds and chickens, CYP1A4 was much more induced than CYP1A5, which is typical of highly sensitive species. The results of this study demonstrate that the gray catbird is at least as sensitive as the chicken to DLCs, based on both embryotoxicity and CYP1A4/5 mRNA induction. This is the first instance of a North American wildlife species being confirmed to be highly sensitive to DLCs.

38 Continuing Immunological and Reproductive Impairments in Great Lakes Colonial Waterbirds Breeding in Contaminated Sites in Michigan during 2010-16

K. Grasman, D. Bouma, S. Hughes, R. Warners, Calvin College / Dept of Biology; M. Annis, US Fish and Wildlife Service; J. Moore, US Fish and Wildlife Service / Interior; L.L. Williams, US Fish & Wildlife Service

This study assessed effects of contaminants, primarily PCBs and PCDDs, on immune function and reproduction in fish-eating birds in the Saginaw Bay and Raisin River Areas of Concern (AOCs) and Grand Traverse Bay during 2010-16 under the Great Lakes Restoration Initiative-Fish and Wildlife Service AOC program. Saginaw Bay sites included two herring gulls colonies (Confined Disposal Facility (CDF) and Little Charity Island), two Caspian tern colonies (CDF and Charity Reef/L. Charity Island) and one black-crowned night heron colony (CDF). Herring gulls were studied in the River Raisin AOC at the Detroit Edison Monroe Power Plant on the western shore of Lake Erie and in Grand Traverse

Bay on Bellow Island. Reference sites were in the lower St. Mary's River (gulls on Pipe Island Twins and terns on Two Tree Island) and on Chantry Island, Lake Huron (herons). Gull nests were marked during egg-laying, and viability was assessed during late incubation using an embryonic viability detector sensitive to heartbeat and movement. Embryonic nonviability in herring gulls in the Saginaw Bay and River Raisin AOCs (7.0% for the CDF, 7.0% for L. Charity, and 8.7% for Monroe) was higher than at the reference site (3.3%). Infertility was the primary cause of nonviability at the reference site. Both elevated infertility and embryonic mortality contributed to nonviability in AOCs. Two gull chicks at Monroe and one embryo on the CDF had crossed bills, a deformity associated with PCBs and PCDDs. In the Saginaw Bay AOC chick productivity was substantially below reference values in 3/5 years for Caspian terns on the CDF (with complete reproductive failure in 2015), 2/3 years for Caspian terns on Charity Reef and L. Charity Island, 1/6 years for herring gulls on the CDF, and 1/5 years for herring gulls on L. Charity Island. In the River Raisin AOC, productivity was very poor in 3/6 years, with complete reproductive failure during 2010. In herring gull chicks the mean phytohemagglutinin (PHA) skin response for T-cell mediated immunity was suppressed 53-57% at both AOCs and 50% in Grand Traverse Bay. This response was suppressed 46-50% in Caspian terns and 39% in black-crowned night herons in the Saginaw Bay AOC. Mean antibody responses were at least two-fold lower in herring gull chicks at both AOCs and in Grand Traverse Bay. Ongoing immunological and reproductive impairments at these contaminated sites are consistent with the effects of persistent pollutants, such as PCBs and PCDDs.

39 Environmental contaminants associated with bioindicator response in tree swallows nesting in US and Binational Great Lakes Areas of Concern

T.W. Custer, C.M. Custer, K. Aagaard, USGS / Upper Midwest Environmental Sciences Center; R.A. Erickson, USGS – UMESC / Upper Midwest Environmental Sciences Center; P.M. Dummer, USGS / Upper Midwest Environmental Sciences Center; C.W. Matson, Baylor Univ / Environmental Science; E. Bigorgne-Vizade, ANSES / Unit of Chemical Substances Risk Assessment Dept; E. Oziolor, Baylor Univ / Environmental Science; N.K. Karouna-Renier, S.L. Schultz, USGS-Patuxent Wildlife Research Center / Beltsville Lab

From 2010 to 2014 tree swallow (Tachycineta bicolor) nestlings were collected from 69 sites in the Great Lakes basin including multiple sites within 27 Areas of Concern (AOCs) and nine nearby non-AOC sites. Polychlorinated biphenyl (PCB) and polybrominated diphenyl ether (PBDE) concentrations were measured in nestling carcasses and stomach contents. Polycyclic aromatic hydrocarbon (PAH) concentrations were measured in nestling stomach contents and perfluorinated compounds (PFCs) were measured in plasma. EROD activity and oxidative stress (8 measures) were measured in liver tissue. Chromosomal damage (DNA CV) was measured in red blood cells. Significant differences among sites and among AOCs were noted for all of the bioindicators. To identify the relative importance of contaminants to the various bioindicators, redundancy analysis was conducted. A model based on individual nestling values for PCBs, PCB TEQs, PFCs, PFOS and PBDEs (N = 230) indicated that the amount of variability within the bioindicators was significantly explained by PCBs (P=0.003) and PBDEs (P=0.025). Among the bioindicators, as EROD activity increased and the TBARS response decreased, the concentrations of PCBs and PBDEs increased. DNA CV and 7 other measures of oxidative stress were not associated with the contaminants measured. A second model based on dietary site means for alkylated PAHs (aPAHs), parent PAHs (pPAHs), PBDEs, and PCBs (N= 55) was significant. However, none of the contaminants predicted a significant amount of the variability. Concentrations of pPAHs did have the lowest significance value (P = 0.14) among the contaminants measured and sample size may have contributed to the lack of significance. A third model based on individual sibling egg values, which included measures of PBDEs, PCBs, PCB TEQs, dioxins/furans, dioxin/furan TEQs, and selected pesticides (8 total) (N = 220) was significant and indicated that only dioxin/furan TEQs explained a significant (P = 0.02) amount of the variability in the data. As EROD activity increased and the TBARS response decreased, the concentrations of dioxin/furan TEQs increased.

40 Pharmaceutical and personal care product exposure in ospreys in Chesapeake and Delaware Bays: largely a clean bill of health, is this a surprise?

T. Bean, Univ of Maryland, College Park / Environmental Science and Technology; B.A. Rattner, USGS-Patuxent Wildlife Research Ctr / Beltsville Lab; R. Lazarus, USEPA / Office of Pesticide Programs; B.W. Brooks, S.R. Burket, Baylor Univ / Environmental Science; W.W. Bowerman, Univ of Maryland / Dept of Environmental Science and Technology

Concerns over potential exposure and effects of pharmaceuticals and personal care products (PPCPs) in non-target wildlife have grown as a result of population level effects in fish (e.g., synthetic hormones) and Asian vultures (i.e., diclofenac). In Chesapeake (CB) and Delaware Bays (DB), wildlife were adversely affected by some environmental contaminants during the 20th century. The piscivorous osprey (Pandion haliaetus) has been used as a sentinel of estuarine health for decades. Between 2011 and 2015, osprey eggs (n= 65 for CB and 27 for DB) and nestling plasma (n= 69 for CB and 29 for DB) were collected and analyzed by MS for PPCPs. Methoxytriclosan was detected in 17 of 65 CB eggs (0.4-7.4 ng/g egg ww) from CB, but levels of this degradant are orders of magnitude below concentrations associated with triclosan toxicity in higher vertebrates. The antihypertensive diltiazem was detected above method detection limits (MDL) in all plasma samples from CB (0.56-8.63 ng/mL), while 22 other analytes were not. In DB only 2 of 20 analytes were detected above MDL (analgesic acetaminophen in 22 of 29 samples, 1.42-3.95 ng/mL and the NSAID diclofenac, 2 of 29 samples, 2.33, 3.73 ng/mL). Analysis of water samples (analytes detected: CB = 18 of 23, d DB = 7 of 20) and osprey forage fish (CB =8 of 23, DB = 8 of 20) indicated exposure to multiple pharmaceuticals that did not bioaccumulate in ospreys. While it is of interest that we observed greater concentrations ($p< 0.05$) in areas with industry and urbanization, it is unlikely statistical significance extends to ecological risk. In all cases, osprey plasma concentrations were 2-3 orders of magnitude below human therapeutic plasma concentrations (diltiazem = 400 ng/mL, acetaminophen = 5000 ng/mL and diclofenac =500 ng/mL). There was no evidence that exposure to PPCPs correlated with effects at the molecular (oxidative DNA damage) through population levels (productivity adequate to sustain the populations in both estuaries). A literature review of wildlife and PPCPs revealed our negative data are perhaps part of a trend indicating PPCP exposure of wildlife is orders of magnitude below effects levels in mammals. Beyond a few instances of population level effects (fish and Gyps vultures), existing data and read-across approaches suggest that adverse effects in wildlife should only result in exposed species with vastly different metabolic pathways or receptive sensitivities than found in laboratory mammals and humans.

Assessing Risks of Pesticides to Federally Listed (Threatened and Endangered) Species at a National Level – Part 1

41 Process and criteria for efficient assessment of pesticide risk to endangered species

J.M. Giddings, B.D. McGaughey, Compliance Services International

Assessment of pesticide risk to endangered and threatened (listed) species on a national scale is a conceptual and logistical challenge. The assessment process must be able to discriminate degrees of risk efficiently across a large number of listed species so that resources can focus on species for which pesticide use has the greatest likelihood of harming individuals and populations. Because risk can never be entirely precluded, explicit protection goals and objective scientific criteria are a critical foundation for regulatory decisions. The risk criteria should address both the magnitude and probability of potential effects; small effects can be tolerated with greater frequency than large effects. The process used in the recent EPA Biological Evaluations (BEs) of 3 organophosphorus insecticides relied extensively on estimated exposure concentrations (EECs) derived using screening-level exposure models, which were taken at face value with virtually no consideration of the probability of those concentrations occurring within the habitat of any given species. Moreover, the BEs failed to distinguish species at high risk from those at lower risk; instead, they concluded that nearly all listed species (including plants) were at risk from these insecticides and required evaluation by the US Fish and Wildlife Service and National Marine Fisheries Service. The process for assessing risk to listed species can be much more efficient if the first step includes a standard screening-level ecological risk assessment (comparable to the process that has been used for decades to make pesticide registration decisions) to eliminate taxonomic groups of low concern from further investigation. Decisions on risk to individual species should then be made in the context of objective criteria using a weight of evidence analysis that effectively categorizes species according to the level of risk.

42 A Risk Assessment Process for Establishing Negligible Risk Earlier in National-Scale Endangered Species Assessments

M.E. Kern, Waterborne Environmental, Inc. / Ecotoxicology Risk Assessment; N. Snyder, Waterborne Environmental, Inc.; J. Amos, Waterborne Environmental, Incorporated / Geospatial Data Technologies; K.E. Kapo, Waterborne Environmental, Inc.

The stepwise endangered species risk assessment process detailed in the Interim Approach combined with more recent approaches communicated by the Federal Agencies (hereafter referred to as “Agency Methods”) in the draft Organophosphate Biological Opinions has yielded useful insights regarding the utility and practical limitations of these methods for risk assessment screening purposes. Agency Methods, while conservative by design, do not clearly incorporate opportunities to take advantage of readily-available information and simple strategies that can optimize the screening ability of the process while maintaining adequate conservatism desired for listed species protection. When strictly following Agency Methods, the number of listed species and habitats where risk is presumed, and therefore require a jeopardy evaluation, is excessive but the level of species relevance and best use of data lacking. As a result, the effectiveness of a tiered assessment process is greatly reduced. Further, the boundary between approaches and refinements used in Step 1 (“May Affect/No Effect”) and Step 2 (“Likely/Not Likely to Adversely Affect) can become unclear and even irrelevant due to the iterative nature of risk assessment. Regardless of the formal step outlined, there is a practical continuum of refinements and approaches that can be applied to effects and exposure analyses to establish negligible risk earlier in the risk assessment. The framework and decision criteria used within the framework should not be such that “Likely to Adversely Affect” decisions are commonly reached due to arbitrary limitations without fully utilizing available species habitat and biological data, species relevant exposure estimates, and surrogate ecotoxicity data. To that end, a systematic process for efficiently and effectively determining negligible risk for species and their habitats early in an assessment is presented. The approach is based on a set of fundamental “best-practices” developed from experience in conducting listed species assessments.

43 Interim Methods Used in the Biological Evaluations to Estimate Risk to Individuals of Threatened and Endangered Species from the Use of Pesticides

M.A. Panger, USEPA / Office of Pesticide Programs; A. Blankinship, USEPA; T. Hawkes, National Marine Fisheries Service; N. Golden, US Fish & Wildlife Service / Ecological Services

The National Marine Fisheries Service (NMFS), U.S. Department of Agriculture (USDA), U.S. Environmental Protection Agency (USEPA), and U.S. Fish and Wildlife Service (USFWS) have developed interim approaches to determine the potential impact to individuals of threatened and endangered species from the use of pesticides at the national level. In April of 2016 draft Biological Evaluations (BEs) using the interim approach for three pilot chemicals (chlorpyrifos, diazinon, and malathion) were released for public comment. Additionally, a workshop was held in the summer of 2016 to allow for additional input from the public and stakeholders on specific technical issues (e.g., exposure in flowing waterbodies, geospatial and process refinements to the interim method, and weight of evidence). This presentation provides an update on the BEs based on the continuing work of NMFS, USDA, USEPA, USFWS; public comments; and the stakeholder workshop.

44 Assessing Risks to Plants Under the Endangered Species Act Process

S. Pollack, L. Laniawe, US Fish and Wildlife Service; E. Donovan, A. Blankinship, USEPA; D.H. Baldwin, NOAA Fisheries / Northwest Fisheries Science Center

The U.S. Fish and Wildlife Service, National Marine Fisheries Service, and U.S. Environmental Protection Agency have been developing an approach for evaluating risk from pesticides to federally listed threatened and endangered plants and their designated critical habitats. Currently there are approximately 900 threatened and endangered plants and 450 critical habitat areas associated with these plants that encompass a variety of taxonomic groups (flowering plants, lichens, ferns, other allies), life history traits, and habitat types. A unique challenge to developing the methods for this diverse group of organisms has been utilizing existing toxicity data on insecticides, where the mechanism of action in plants is poorly understood, and there are few data available. An additional challenge for these plant reviews was to consider not just direct effects to the plants themselves but also indirect effects from reliance on pollinator or seed dispersal mechanisms which may also be unknown or poorly understood for many species. An overview of the current methods and specific challenges to these assessments such as use of plant toxicity data, assumptions related to overlap of species ranges with pesticide use, and the identification of pollinators, will be discussed.

45 Estimating the proportion of a bird population exposed to a single pesticide

N. Golden, US Fish & Wildlife Service / Ecological Services; K.V. Garber, USEPA / Office of Pesticide Programs Environmental Fate and Effects Division; J. Connolly, USEPA; S. Pollack, A. Raabe, US Fish and Wildlife Service; T. Hooper, NOAA – NMFS

The United States Environmental Protection Agency, in collaboration with the US Fish and Wildlife Service and National Marine Fisheries Service recently drafted national level biological evaluations for endangered and threatened (listed) species potentially exposed to chlorpyrifos, diazinon and malathion. In these draft biological evaluations, it was concluded that these chemicals have the potential to cause mortality or sublethal effects to individuals of most listed species. The risk and confidence in these conclusions are high for listed birds given the high acute toxicity of chlorpyrifos and diazinon to these species, known reproductive effects of malathion, and the likelihood that exposures in treated fields and adjacent areas will be of the magnitude where toxicity is observed for all three pesticides. The draft biological evaluation was conducted to determine if exposure to these chemicals was likely to cause an adverse effect to at least one individual of a listed species over the course of the 15 year action. In order to move to the next phase of the pesticide consultation process, it is necessary to derive an estimate of the number of individuals within the population that are likely to be exposed to the pesticide each year. We examine variable exposure scenarios by considering pesticide use as described on labels as well as potential factors that may impact the spatial extent of use over time, such as rotation of crops, proportion of crop historically treated, and application timing. This range of exposure scenarios is overlaid with biological information for species that influence the geographic and temporal distribution within its range. Information such as preferred habitat types, timing of breeding, migration, and feeding habits of different life stages are incorporated into the analysis to better predict the likely number of listed individuals that could encounter pesticide exposure(s). A case study with the least bell's vireo (Vireo bellii pusillus) and applications of diazinon is presented.

46 Use of population modeling in national Endangered Species Act Consultations with Pesticides

J.A. Spromberg, Earth Resources Technology Inc. Contractor with NOAA Fisheries / Northwest Fisheries Science Center; S.A. Hecht, NOAA / National Marine Fisheries Service; G.E. Noguchi, US Fish and Wildlife Service / Ecological Services; K.V. Garber, USEPA / Office of Pesticide Programs Environmental Fate and Effects Division

A Biological Opinion (BO) is a statutory requirement under the Endangered Species Act (ESA) when a Likely to Adversely Affect determination triggers a consultation by the U.S. Fish and Wildlife Service or the National Marine Fisheries Service (Services) to assess potential impacts on a federally-listed endangered or threatened species. The purpose of a BO is for the Services to determine whether a federally proposed action jeopardizes the continued existence of a listed species or adversely modifies (or destroys) designated critical habitat. Because the focus of the BO is at the population and species scales, population models can be useful in assessing potential outcomes that result from an action. A National Academy of Sciences Panel Report discussed and supported the use of population models as a component of ecological risk assessments in the context of BOs regarding the U.S. Environmental Protection Agency's pesticide registration program. This presentation will describe the role population models may play in pesticide BOs for assessing risks to populations of listed species. We will also discuss population model structures and capabilities, data requirements (representing species biology and life history as well as quantitative links between and pesticide exposures and effects), uncertainties, and limitations of model use. Where applicable, population models can inform specific lines of evidence included in a BO. Such models include those applied in Pacific salmonid BOs on several current-use pesticides as well as others being assessed.

47 Species-specific refined endangered species risk assessment for static aquatic habitats: Part 1, exposure

L. Padilla, Stone Environmental, Inc.; M.F. Winchell, Stone Environmental, Inc. / Environmental Systems Modeling; P. Whatling, FMC Corporation; S. Teed, Intrinsik Environmental Sciences Inc.

The current USEPA approach to static aquatic exposure modeling at Step 2 of their interim process for national endangered species assessments uses simplified assumptions about water body characteristics, the surrounding landscape, and agronomic practices. The USEPA approach considers generalized aquatic habitat dimensions, a homogeneously cropped watershed with 100% cropped area, up to two weather time series, one soil profile, and one pesticide application date pattern per crop group and HUC2. The same predictions of pesticide concentrations derived from these generalized assumptions are assigned to all of the species within a given HUC2 regardless of the location of that species range with respect to different agricultural crops, weather, and soils. The refined exposure modeling approach presented here for malathion focuses on quantitatively accounting for observed variability in environmental and agronomic factors that impact the potential pesticide exposures to endangered species. For each species, probability distributions of application timing, weather, soil and slope conditions, and crop configurations around ponds are sampled to generate on the order of 1000 30-year Pesticide Root Zone Model (PRZM)/Variable Volume Water Model (VVWM) realizations. Each realization is composed of multiple PRZM simulations, with the number of simulations being determined by the cropping pattern complexity around a given pond. The refined approach led to more realistic predictions of pesticide concentrations for a wide range of environmental conditions in unique species ranges. Assuming 100% treated area, concentrations for many species were two to three orders of magnitude lower than suggested by the USEPA Step 2 analysis. Accounting for actual treated area based on eight years of recent malathion use data resulted in more realistic concentrations. This methodology is readily reproducible and extensible to assess aquatic species across the United States. Risk results corresponding to the exposure concentrations generated by the probabilistic approach are the topic of a companion presentation.

48 From Biological Evaluation to Biological Opinion: What to expect next with the National Pesticide Consultations

S.A. Hecht, NOAA / National Marine Fisheries Service; K. Myers, US Fish and Wildlife Service; M.A. Panger, USEPA / Office of Pesticide Programs

Current national pesticide consultations are transitioning from evaluating effects to individuals of threatened and endangered species and individual features of their critical habitats (assessed in Biological Evaluations), to evaluating effects on populations, species, and their critical habitat designations (assessed in Biological Opinions). In both documents, ecological risk assessments are used as the organizing framework to determine whether and to what degree the registration of a pesticide as described by current labels affect listed species and their habitats. In April 2016, draft Biological Evaluations for chlorpyrifos, diazinon, and malathion were released for public comment. Each concluded that hundreds of threatened and endangered species and their critical habitats were "likely to be adversely affected", thus triggering the next step of the Endangered Species Act consultations, a Biological Opinion for each of the pesticides. The Biological Opinions will also consider the adverse effects in the context of the environmental baseline, status of the species and their critical habitats, and cumulative effects to determine whether species would be jeopardized and/or their critical habitats would be adversely modified by registration of each pesticide. Since completing the draft Biological Evaluations, staff from the U.S. Environmental Protection Agency, U.S. Fish and Wildlife Service, and National Oceanic Atmospheric Administration's National Marine Fisheries Service (Agencies) began evaluating risk assessment methodologies for determining whether species would be jeopardized and whether designated critical habitat would be adversely modified. An update on the Agencies' progress will be provided that includes conceptual frameworks, key concepts, methodologies, and weight of evidence approaches.

History and Role of SETAC in the Advancements in Environmental Chemistry and Aquatic Toxicology

49 Fire on the water and other stories: The genesis of the science of ecotoxicology

B.A. Stubblefield, Oregon State Univ / Environmental and Molecular Toxicology; T.J. Norberg-King, USEPA / NHEERL/Mid-Continent Ecology Division

In the 1950's, 1960's, and 1970's, a variety of social, economic, and environmental factors in the US led to public concerns regarding environmental quality and public safety. The need to address questions regarding the environmental effects resulting from man's activities and the development of methods and tools with which to address these questions became important during this period. Responses to these concerns led to a number of activities including: the creation of the EPA and the development and implementation of a variety of environmental regulations (e.g., Clean Water Act, Toxic Substance Control Act, Clean Air Act); the development of training programs at universities for educating toxicologists and environmental chemists; the conduct of a great deal of research in academic, industry and government laboratories aimed at the evaluation of environmental contaminants, development of data to satisfy regulatory requirements, and the derivation of criteria/standards; and actions associated with evaluation and clean-up of contaminated sites. Historical perspectives and driving factors will be discussed as they relate to the current state of the science.

50 SETAC's role in promoting environmental chemistry

D. Mackay, Trent Univ / Chemistry

It may not be fully appreciated that SETAC has played a major role in the evolution of the chemistry of contaminants, especially organic contaminants. That evolution continues today and aspects of this evolution are described from a personal perspective. The American Chemical Society (ACS) sponsored a 1964 report "Cleaning our Environment" the Chemical Basis for Action that documented those issues and made 72 recommendations for scientific action. It did not cite or mention Rachel Carson's earlier "Silent Spring" that had generated considerable hostility from the chemical industry! As clean up progressed and gross examples of pollution were successfully mitigated, concern focused more on lower concentration of contaminants and more subtle toxic effects. Clearly there was a need for closer collaboration between chemists, ecologists and toxicologists but there were limited opportunities for professional scientific dialogue. The formation of SETAC in 1979 prompted by professionals from the chemical industry and wildlife toxicologists changed all that. Especially enlightened were a group from Dow Chemical Co. (notably Gene Kenaga) who realized that there was a need to better understand quantitatively and thus manage chemicals introduced to the environment. Fundamental to the proposed structure of SETAC was required and enlightened and equal involvement of professionals from government, industry (including consultants and National Laboratories) and academics and especially their students. The SETAC recipe has proved highly successful professionally to environmental chemists by providing a common venue for meeting and publishing scientific findings. It has expanded to the Global professional society that we enjoy today. The founders and the volunteers who supported their vision were truly visionary and have had a major impact on and understanding of environmental chemistry and its linkages to toxicology.

51 SETAC's role in promoting environmental chemistry through Quantitative Structure Activity/Property Relationships. A – Correlations

P.H. Howard, SRC, Inc.

As noted by the two previous talks by Don Mackay, SETAC has played a major role in the evolution of the chemistry of contaminants, especially organic contaminants. That evolution continues today. In these two presentations, the major role of SETAC in developing correlations between molecular structure and properties will be reviewed. As noted in a brief review letter to the editor in the 1985 issue of ET&C by Robert Lipnick, researchers first started noticing a correlation between physical properties of a chemical and toxicity in the 1890's: in 1893, Charles Richet found correlation between water sol. and toxicity to fish for 7 organic chemicals; in the late 1890's Overton and Meyer found an increase in oil/water partition correlated to an increasing toxicity in a variety of organisms. By the mid 1960's Corwin Hansch and collaborators proposed QSARs using octanol/water partition coefficient (Kow) using linear free energy relationships (LFERs); the latter approach dates back to the mid 1930's. Right around the formation of SETAC, researchers such as Veith and Konemann were finding correlationships between Kow and fish bioconcentration and toxicity. About the same time, it was apparent to the USEPA that the Toxic Substance Control Act (TSCA) would require assessments of tens of thousands of new and present commercial chemicals that had very little physical/chemical or toxicity information. As noted by Lipnick in his letter to the editor, so many QSAR papers were submitted to the 4th annual meeting of SETAC, that another session had to be added and these sessions continued. Because of the focus of SETAC, QSARs in SETAC focused on physical/chemical properties, environmental fate, and ecological toxicity. Valuable collections of the correlations were published such as one by Gene Kenaga, the first SETAC president, on BCF and soil sorption – Ecotox Environ Safety 4: 26-38, 1980. Another was an extensive book by Warren Lyman and David Rosenblatt with support from U.S. Army – Handbook of chemical property estimation methods 1982, reprinted in 1990. That book reviewed many of the correlations between structure and properties – MP, BP, VP, Henry's Law constant, water solubility, Kow, BCF, soil adsorption, biodegradation, photolysis, hydrolysis, volatilization from water, etc. An update of that book was published in 2000 by a variety of authors with Don Mackay and Bob Boethling. These correlations will be reviewed in chronological order.

52 Water Quality Criteria: The history and development of a regulatory tool to protect aquatic systems

B.A. Stubblefield, Oregon State Univ / Environmental and Molecular Toxicology; R.J. Erickson, USEPA / ORD NHEERL Mid Continent Ecology Division

Central to most regulatory schemes aimed at the control of waterborne contaminants for the protection of aquatic life in fresh and marine waters is the development and enforcement of numerical chemical limits. These values are designed with the intent to be protective of most, or all, organisms in aquatic environments. In the US initial efforts aimed at the development of water quality criteria/standards can be traced initially to the California State Water Quality Control Board in 1952 and later to the 1963 McKee and Wolf reference from that same organization. Subsequently the USEPA, or its predecessor organization, published it's "rainbow" of criteria books starting in 1968 with the "Green Book", followed by the 1973 "Blue Book", the 1976 "Red Book" and finally the 1986 "Gold Book." The procedures used to derive these values have evolved over the years but generally rely on data from acute and chronic laboratory-based toxicity tests developed with a range of representative surrogate species. These data are subsequently evaluated using defined statistical procedures to derive "protective" numerical values. The history of the development of these procedures will be discussed.

53 A Retrospective on the Adoption and Application of Whole Effluent Testing in the US

T.J. Norberg-King, USEPA / NHEERL/Mid-Continent Ecology Division

The Clean Water Act (CWA) establishes the structure for regulating discharges of pollutants into the waters of the United States and regulating quality standards for surface waters. The CWA Act was significantly reorganized and amended in 1972 and gave EPA the authority to implement pollution control programs such as setting wastewater standards for the industry and water quality standards for contaminants in surface waters. However, the approach of applying water-quality criteria to control the release of chemicals into water bodies could not cover all potentially toxic pollutants in an effluent nor did it predict biological effects in the receiving waters. Increased production, use and ultimately, environmental releases of synthetic industrial chemicals and a growing public awareness of environmental issues during this time made the application of aquatic toxicity analyses to discharges a natural step. As the CWA made it unlawful to discharge any pollutant from a point source into navigable waters unless a permit was obtained through the National Pollutant Discharge Elimination System (NPDES) permit program; and in 1984, EPA issued a national policy, Policy for the Development of Water Quality-Based Permit Limitations for Toxic Pollutants, that proposed the use of toxicity data to assess and control the discharge of toxic substances to surface waters. Use of acute toxicity tests for effluents testing became routine as the tests provide a more direct estimate of the safe concentration of effluents in receiving waters. New methods to estimate chronic toxicity were developed for effluent testing and validated in field studies and interlaboratory studies. During this time, EPA introduced new test methods with new species, such as the 3-brood Ceriodaphnia dubia test along with abbreviated early life stage tests for other species (fathead minnow, mysid shrimp, inland silverside, sheepshead minnow and more). In this presentation, I will touch on the highlights of the development of the use of whole effluent toxicity and field validation of the method to support the NPDES program. This presentation will cover the highlights of the method development and application to discharges of the US, along with highlighting the vetting of the science through SETAC which in turn supported environmental management decisions. Disclaimer: This presentation does not necessarily reflect the views or the policies of the USEPA.

54 SETAC as Matchmaker Between Chemists and Toxicologists: Two Personal Examples

D. Mackay, Trent Univ / Chemistry

There was a growing realization in the 1970s that organic contaminants did not respect the convenient boundaries between the traditional physical and regulatory media of air, water, soils and sediments. Images from the Moon landings clearly showed the need to address the whole planetary system of linked media, not just its detailed contaminated parts. The concept of chemical fate in connected "unit worlds" employing the fugacity concept was warmly supported within SETAC, especially by Dow Chemical Co. resulting in the emergence of multimedia fate and transport models that now have the potential to treat chemical behavior at scales ranging from small ponds to regional, continental and even global scales. There is increasing scientific and regulatory acceptance that such models can provide a sound basis for predicting and managing chemical fate, especially when coupled with emerging information technologies for data storage, analysis and open dissemination. Second is a brief review of bioconcentration that was originally a puzzling phenomenon noted by Rachel Carson and others. This proved to be a beautiful example of how SETAC brought together scientists from diverse backgrounds in chemistry, biology and ecology to establish our present understanding of bioaccumulation, biomagnification and trophic magnification in a variety of ecosystems and species.

55 SETAC's role in promoting environ. chem. through Quantitative Structure Activity/Property Relationships. B – Computer assisted calculations

P.H. Howard, SRC, Inc.

Initially in the late 1970's and early 1980's, correlations were made between Kow and BCF, fish toxicity, or fate properties. This required that you have a measured Kow value or do a hand calculation to estimate the value. Examples of some of these early hand calculations will be given. One of the earliest computer programs to estimate a property (in this case, Kow) from the chemical structure was CLOGP from Leo and Hansch at Pomona College. This program would take the chemical structure entered as a Simplified Molecular Input Line Entry System (SMILES) string and the computer would add or subtract the coefficients of the atom or functional group fragments to give the estimate. Different investigators used different chemical descriptors and correlated then to numerous properties. For example, Kier and Hall used molecular connectivity indices (MCIs); Syracuse Research Corp/EPA used hand selection of atom/functional group coefficients while other groups used computer programs to select atom/fragments; many of the programs in the OECD Toolbox use degradation pathway rules; and other researchers use molecular orbital calculations (the latter could take long periods of time until computers got faster). Development of the correlation between the chemical descriptor and the activity/property/degradation values used a variety of statistical approaches (linear and non-linear regression, neural networks, partial least squares, etc. The number of end points that could be estimated grew as papers were presented at the SETAC annual meeting and published in ET&C. A brief listing of these programs and endpoints with a little history of when they were developed and their methodology will be presented – these include Daylight software, CHEMEST, ECOSAR, SPARC, EPISuite,™ ACD, ChemAxon, ChemSpider, and the OECD Toolbox. Future needs for QSARs will be discussed.

56 A Retrospective on the Development and Use of Toxicity Identification Evaluations for Whole Effluent Toxicity (WET) Applications

T.J. Norberg-King, USEPA / NHEERL/Mid-Continent Ecology Division

Whole effluent toxicity (WET) testing is a major component of USEPA's Integrated approach to water-quality–based toxics control and a complement to aquatic-life–chemical-specific criteria and biological assessments. Regulatory authorities have been encouraged to use all of these tools to prevent the discharge of toxic pollutants to protect the nation's waterways. To determine what causes the toxicity observed in the WET test, the EPA-Duluth Laboratory began developing various laboratory methods in the early 1980s. We used the WET test(s) to identify the cause(s) of toxicity in effluents under the complex effluent toxicity testing program and applied developing TIE techniques to effluents tested during field studies and in the laboratory. The general procedures were described in freshwater TIE methods manuals for wastewaters and receiving waters. At the same time, USEPA-ORD established a technology transfer center for the water-quality–based permits, technical assistance, and TIEs at Duluth. During this period, numerous refinements of the methods and new approaches for the TIE methods were developed. Many of the chemicals identified through TIEs were not covered under the chemical-specific limits included in NPDES permits or were not expected to cause toxicity at concentrations present. EPA also developed TIE techniques for marine waters using the freshwater TIE approach as a model yet incorporated guidance on the interaction of seawater with the TIE manipulations. These methods have been applied, and further advanced through numerous applications by industry and consulting laboratories. This presentation will cover the highlights of the method development along with highlighting the vetting of the science through SETAC, which in turn supported environmental management decisions. Disclaimer: This presentation does not necessarily reflect the views or the policies of the USEPA.

Deepwater Horizon Oil Spill – The Discoveries and Outreach

57 Sharing the science behind the spill: The partnership of the Gulf of Mexico Sea Grant programs & the Gulf of Mexico Research Initiative (GoMRI)

E.S. Maung-Douglass, Louisiana Sea Grant – LSU / Louisiana Sea Grant; L. Graham, Mississippi-Alabama Sea Grant Consortium; C. Hale, Texas Sea Grant; S. Sempier, Mississippi-Alabama Sea Grant Consortium; M. Wilson, UF/IFAS Florida Sea Grant Extension

Deepwater Horizon oil spill occurred in 2010 off the coast of Louisiana (USA) and continues to be the largest accidental release of oil on record. While scientists from various sectors (e.g., research initiatives, government, environmental consulting) are making major advances in understanding the implications of the incident, effectively communicating those scientific findings continues to be challenging. Two years ago, the Gulf of Mexico Sea Grant programs partnered with the Gulf of Mexico Research Initiative (GoMRI). The resulting outreach program extends oil spill science to target audiences who could utilize oil spill science in decision-making and/or who depend on the Gulf for their livelihood. These target audiences include, but are not limited to, emergency responders, natural resource managers, elected officials, fishermen, and tourism-dependent businesses. Since 2014, our program has met with more than 1000 people within our target audiences from communities across the Gulf of Mexico. Based on our assessment of their needs, we work collaboratively with scientists from all sectors to help us create scientifically accurate extension publications and informational seminars that are a synthesis of published literature from a wide range of areas (e.g., seafood safety, impacts to aquatic life, fate of oil and dispersants). As our program enters its second phase in Fall 2016, we will share approaches used and lessons learned during Phase I, including the need to connect audiences that have not traditionally worked to improve communication during future spills, and unexpected challenges encountered while working with our target audiences and disseminating the science of the spill. More depth on deliverables, program structure and evaluation, as well a peek at what is to come in Phase II of the program will be shared.

58 Polycyclic aromatic hydrocarbons in white shrimp following the Deepwater Horizon accident: community-based science from southeast Louisiana

J. Wickliffe, Tulane Univ; D. Nguyen, Mary Queen of Vietnam Community Development Corporation; M. Wilson, B. Simon, J. Howard, Tulane Univ; S. Frickel, Brown Univ

The Deepwater Horizon Oil Spill had a profound impact on communities living and working along the US Gulf Coast. One could easily argue that the impacts were felt well beyond the US in myriad ways including research, science, policy, and how those are interconnected. Among those most deeply impacted were our fishing and seafood harvesting communities. Generally speaking, research intensive academic institutions and surrounding seafood-reliant communities do not have "shovel-ready" working relationships. Specifically, those that would allow them to jointly respond to environmental health issues during and immediately following a coastal disaster. This was not the case as we report our research results here. We worked as a team (academic researchers and shrimpers) to develop a plan to address paramount concerns regarding the quality of white shrimp that could or would be harvested in 2010 immediately following the capping of the Macondo well. This was done in a culturally appropriate and transparent manner to produce high quality scientific results (i.e. publishable) and meaningful information to our local seafood-reliant communities. In short, we developed a sampling strategy that addressed community- and fisherfolk-specific concerns and used analytical chemistry to determine the presence and quantity of 81 polycyclic aromatic hydrocarbons (both pyro- and petro-genics) in white shrimp from distinct sites in southeast Louisiana. Very few PAHs were detected in white shrimp collected in November 2010, consistent with the findings of other researchers and health agencies. Survey data regarding consumption behaviors specific to heavy consumers (Vietnamese-American shrimpers and their local community) were used to develop relevant and comprehensive probabilistic risk assessments. No unacceptable health risks were found even among the heaviest consumers with respect to PAHs with known toxicities. Together, the results of this community-based research project were effectively communicated back, including translations into Vietnamese, to this and other communities. In addition, research results have also been published in peer-reviewed scientific journals. While working with communities as part of a research effort requires patience, time, and energy, our work clearly demonstrates that it can produce meaningful results for all stakeholders that are involved.

59 Risk Messaging and Public Perception Among Gulf Coast Residents After the Deepwater Horizon Oil Spill

A.S. Kane, Univ of Florida / Dept of Environmental and Global Health

Developing and delivering meaningful risk communications for vulnerable or impacted communities presents dynamic and often multifaceted challenges for researchers. In response to Gulf coast community concerns regarding safety of inshore-harvested seafood after the DWH oil spill, we conducted analytical toxicology for oil spill-related contamination in fish, shrimp, blue crab and oyster, and discerned seafood consumption rates for Gulf coast residents relative to these same seafood categories. This presentation describes approaches taken to provide risk messaging and hazard communications back to participating communities. Many study participants were seafood workers who depend on ecosystem services for their livelihood, and personal identity relative to their multigenerational culture and heritage fisheries. Loss of ecosystem services to seafood working communities, where regular work and remuneration are essential to support families and businesses, can make community members more vulnerable, i.e., less resilient in coping with adverse events and adapting. A case study approach portrays how outreach materials for these communities was developed and delivered by a team of scientists in concert with community partners. Two primary tenets were considered to develop outreach and hazard communication content for communities that were both affected by the oil spill and suffered declines or collapses in their fishery resources: (1) know your audience, and (2) know your audience. Piloting of outreach materials with community partners and residents provided feedback essential to refocusing and better targeting content to foster clarity and meaningfulness for coastal residents. Community engagement in all phases of the study proved an important component of this community-based research to build trust essential to perceiving scientists as a resource, understanding how background levels of PAHs and DOSS in their seafood were not related to the spill, nor their fishery collapse, and valuing scientists' contributions to the community. Understanding different perspectives between and within communities, relative to environmental issues and perception of risk, is vital to messaging science in support of community resiliency, and contributing to the sustainable health of residents and their coastal environments. Supported, in part, by grant from the National Institute of Environmental Health Science (U19 ES020683).

60 Mining the Traditional Ecological Knowledge of Gulf of Mexico Communities to Help Unravel the Legacy of the Deepwater Horizon Oil Spill

D. Wetzel, Mote Marine Laboratory / ELF; J. Reynolds, Mote Marine Laboratory

The Deepwater Horizon oil spill tragedy happened over six years ago, with long lasting impacts on the affected environment and the people who live there. As is expected after such an environmental disaster, a number of studies have been or are being conducted to assess a range of physical, chemical and biological issues, including but not limited to factors that influenced movement and distribution of the oil, the fate of the spilled oil and dispersant, and the effects of oil and dispersant on exposed habitats and organisms. Studies have also been conducted that have addressed the socio-economic and human health impacts on the residents of the impacted areas. However, this effort, as in most environmental research, has typically occurred in the absence of any community input or even awareness. Granted, the execution of research must be done using principles of proper scientific process, which does not require an engagement of local communities. However, the coastal communities of the Gulf of Mexico are deeply dependent on healthy ecosystems and living resources for their survival and well-being, and whereas they rely less than scientists on written documents or scientific analyses, they possess unusual insights into types, extent and causes of environmental changes. They can be productive and valuable partners in developing research initiatives by providing traditional environmental knowledge (TEK) that non-local scientists will never have. Community based participatory research benefits scientists significantly by providing historic environmental information, which is usually not formally documented, but rather is orally passed down through the generations. Archival of videos and diary notes from community members collected during and after the Deepwater Horizon spill, documenting daily observations of a major spill, are yet untapped resources that can still be used to help understand the environmental impacts from the spill. A partnership between a multidisciplinary group of scientists and communities directly impacted by environmental changes takes considerable time in which to achieve trust, extra communication, and a willingness to explore alternative ways of understanding nature and the natural environment. That effort is worthwhile both scientifically and societally, to better assess and solve environmental problems, manage and regulate natural resources, and promote compelling environmental awareness.

61 Oiled Vision: Understanding Fishes' Visual Response to Oil Spills through Research and Film

E.K. Barnes, Univ of North Texas; D. DiNicola, Univ of Miami RSMAS; J.T. Magnuson, Univ of North Texas / Biology; M. Levin, Univ of North Texas / Dept of Media Arts; J. Stieglitz, Univ of Miami – RSMAS / Division of Marine Biology and Fisheries; M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology; A.P. Roberts, Univ of North Texas / Dept of Biological Sciences Inst of Applied Science

The Deepwater Horizon oil spill resulted in a variety of issues concerning both environmental and human health and consequently had extensive coverage by the press during clean-up efforts. Research on the ramifications of the spill is still being undertaken six years later. This project centers on a charismatic gamefish potentially affected by the spill, mahi-mahi (Coryphaena hippurus). Mahi-mahi are dependent on vision for feeding, schooling, spawning, and predator avoidance, like many other large pelagic sportfish. The immediate effects of oiling on juvenile mahi-mahi vision were the focus of research and the basis for a short film. As humans are a highly visual species, the film is designed to make the mahi dealing with visual impairment and deformities caused by oil exposure, relatable. When the eyesight of another animal is failing, the volume of the loss can be understood by the public because of how dependent humans are on vision. The film covers an aspect of the research following the Deepwater Horizon oil spill in a way that helps viewers understand the effects in a new and engaging way; through the eyes of a fish. This research was made possible by a grant from The Gulf of Mexico Research Initiative.

62 How research in oil and surfactant toxicity helped create a community outreach program in southern Louisiana

C. Green, Louisiana State Univ; J.A. Nyman, Louisiana State Univ / School of Renewable Natural Resources

Large amounts of oil spill and wetland research is virtually unintelligible to non-scientists. We are attempting to help non-scientists understand some of this research. Although no spills are preferred, the public is concerned that many current oil-spill clean-up products are only slightly better than the spill effects alone. The public also express concerns about the overall toxicity of the ecosystems they live and work in. Initially, we planned to share information with non-scientists at fishing rodeos within coastal Louisiana, however, that proved unworkable. We then prepared and posted videos on YouTube and also offered public meetings. Our outreach team conducted a series of informational workshops at libraries in Louisiana and recorded metrics of attendance and participation. These initial meetings provided incomprehensible jargon to small audiences but later meetings have been better suited and to larger audiences. Collaborations with LSU's Coastal Roots program, Louisiana SeaGrant and its network of extension agents, and creating a Facebook page to assist in advertising the YouTube videos and public meetings has increased our ability to interface with the community. The team has also conducted a two-day workshop for high school science teachers intended to help them create curriculum for oil and surfactant related topics within their courses. These workshops are a mixture of demonstrations, relevant classroom experiments, and lectures. Printed materials distributed at events complement our oral presentations and demonstrations. To date we have brochures that detail importance of fish physiology and how surfactants in everyday life and their use. We have created videos to detail how toxicologist determine acute toxicity and have created a brief video to inform people about the use of aquatic organisms in toxicology testing. We continue to be challenged when we try to teach non-scientists information, however, we believe that we have discovered what works and what does not work within our community.

63 Post-settlement conclusions of the Trustee toxicity testing program conducted in support of the Deepwater Horizon Natural Resource Damage Assessment

J.M. Morris, M.O. Krasnec, C. Lay, H. Forth, R. Takeshita, J. Lipton, Abt Associates; M.L. Gielazyn, NOAA / co USEPA Region IV

A settlement resolving civil claims in excess of $20B with BP was finalized in April 2016, six years after the Deepwater Horizon (DWH) disaster. Since 2010, we have designed, implemented and managed the Trustee toxicity testing program for the DWH Natural Resource Damage Assessment. This program included over 600 toxicological bioassays and related chemical characterizations. The objectives of the program were to determine the toxicity of DWH oil, dispersed oil, and dispersant to native and surrogate species in the Gulf of Mexico. To that end, we developed a large study matrix with over 35 species of fish and invertebrates and a variety of lethal and sublethal endpoints. Samples of DWH oil representing four distinct degrees of weathering and one dispersant (COREXIT 9500) were tested through a variety of different exposure routes including water accommodated fractions, surface sheens, direct oil exposure, sediment, and dietary. We also investigated the effects of additional environmental stressors including photo-induced toxicity. The studies were conducted by Abt Associates and NOAA scientists along with over 24 principal investigators from collaborating university, government, and private laboratories. We will discuss our more unique discoveries and how information from this program is being reported to the public through various presentations, data portals, and documents.

64 Sublethal impacts of the Deepwater Horizon oil spill on pelagic top predators from the Gulf of Mexico – communicating science to a broad audience

M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology; D. DiNicola, Univ of Miami RSMAS; J. Stieglitz, Univ of Miami – RSMAS / Division of Marine Biology and Fisheries; Y. Wang, RSMAS Univ of Miami; E. Mager, Univ of North Texas / Dept of Biological Sciences; D. Nelson, R.M. Heuer, Univ of North Texas; D. Crossley, Univ of North Texas / Dept of Biology; L. Schlenker, RSMAS, Univ of Miami / Marine Biology and Ecology; C. Pasparakis, Univ of Miami; P. Perrichon, Univ of North Texas; J.T. Magnuson, Univ of North Texas / Biology; L.E. Sweet, Univ of North Texas / Dept of Biological Sciences; A.P. Roberts, Univ of North Texas / Dept of Biology Inst of Applied Science; D.D. Benetti, Univ of Miami / Dept of Marine Ecosystems and Society

A wide range of sublethal effects have been observed in mahi-mahi following exposure to surface slick oil obtained from the 2010 oil spill in the Gulf of Mexico. These sublethal effects include, but are not limited to, reduced swim performance, impaired ability to avoid oil, impaired visual acuity, reduced stroke volume and cardiac output in adults as well as larvae, increased embryonic metabolic rate and energy depletion. An overview of these effects, many of which are observed after brief exposures (< 24 hours) at low and environmentally relevant PAH concentrations (< 10 µg total PAHs/l) will be presented. While these sublethal effects may impair ecological fitness and long term survival, they are difficult to relay to a broad lay audience due to the complexity of the findings. We employ a range of outreach strategies, including social media, hands-on demonstrations at various events, school visits, and web-based video media to disseminate our findings to the broader public. In addition, we are currently developing and testing a web-based interactive teaching module aimed at grades 4-12 on aerobic swim performance. In this web-based teaching module, students at various levels will be able to use real data to perform simulated experiments. As part of the simulations students will select experimental animals and experimental conditions and be introduced to data analysis and complex physiological considerations. The web-based simulation module is paired with lesson plans to assist teachers in tailoring teaching to their students' grade level and includes an assessment of the knowledge gain obtained by the students after having completed the module. The assessment is paired with detailed demographic data allowing for direct evaluation of impact of this outreach effort. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Data are publicly available through the Gulf of Mexico Research Initiative Information & Data Cooperative (GRIIDC) at https://data.gulfresearchinitiative.org.

Scientific Advances Supporting Aquatic Life Water Quality Criteria Derivation – Part 1

65 An Overview of USEPA's Approach to Revising the 1985 Guidelines for Deriving Aquatic Life Criteria

M. Elias, K. Gallagher, USEPA / Office of Water

The USEPA Office of Water will provide an overview and update of the steps being taken to revise the 1985 Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses (Stephan et al. 1985). The presentation will discuss outcomes of the Invited Expert Meeting on Revising Guidelines for Deriving Numerical National Water Quality Criteria, which occurred in September of 2015 and which represented a first major step in the Guidelines revision process. Development steps that have occurred since that time will be detailed along with the planned process forward. The focus will be on a discussion of the two defining objectives that have been identified for the revision: 1) Developing a larger number of criteria more rapidly for the broader protection of aquatic life, and 2) Refining methods for deriving state-of-the-science criteria through comprehensive analyses. The first objective reflects the recognition that thousands of chemicals enter the environment from anthropogenic activities. Because rigorous testing of all chemicals is infeasible, there is a need to efficiently derive criteria using approaches to estimate safe environmental concentrations with limited empirical data. The second objective reflects that for a smaller group of chemicals, criteria development may be scientifically complex, and deriving robust criteria may require extensive study. This presentation represents an introduction and overview to the broader session, which provides an opportunity to further the discussion with the international scientific community on topics and issues relevant to the development of criteria for the protection of aquatic life.

66 Chemical standard derivation for the protection of aquatic life: A guided world tour

C.E. Schlekat, NiPERA; G. Merrington, A. Peters, wca; D. Leverett, WCA-Environment Ltd

Global regulations striving to protect aquatic ecosystems typically share goals with respect to levels of environmental protection, but fundamental differences exist within the methodologies, data selection decisions, and implementation strategies used by different jurisdictions to achieve regulatory goals. This presentation focuses on approaches used by Australia, Canada, the European Union, and the United States of America to develop chemical-specific standards intended to protect aquatic life. At the highest level, these jurisdictions agree that chemical standards play a role in maintaining biodiversity, preventing ecosystem degradation, and protecting endangered species. However, the ways in which these different jurisdictions implement chemical standards and the degree of regional heterogeneity within a given jurisdiction varies considerably. From the scientific perspective, all approaches share the use of laboratory ecotoxicity data as the basis for determining a chemical standard. The different jurisdictions vary in the consideration of laboratory ecotoxicity data at several levels, including the relative importance of acute and chronic data, appropriate statistical endpoints (e.g., preferences for EC10, EC20, No Observed Effects Concentrations, etc.), the relevance of data from specific taxonomic groups (e.g., unicellular algae), and acceptance of data from native versus non-native species. Most jurisdictions recognize probabilistic approaches like Species Sensitivity Distributions (SSDs), but minimum data requirements allowing the use of SSDs, and the models used in data analysis, show jurisdictional differences. Refined approaches accounting for the derivation of regional- and site-specific chemical standards are increasingly recognized (e.g., bioavailability-based approaches for metals), although the level of sophistication (e.g., hardness-based approaches versus full bioavailability normalization) and approaches for implementation vary. Jurisdictions also depart with approaches used to quantify and manage uncertainty, e.g., consideration of multiple lines of evidence, such as field and mesocosm data; and, the use of assessment/uncertainty factors in criteria determination. A case study comparing current approaches for determining quality standards for nickel will be used to highlight the similarities, differences, and possibilities for harmonization among these different jurisdictions.

67 Could ecological thresholds of toxicological concern (eco-TTCs) be used to support development of ambient water quality criteria?

S.E. Belanger, The Procter & Gamble Company / Environmental Stewardship and Sustainability Organization; M.G. Barron, USEPA / Gulf Ecology Division; T.J. Norberg-King, USEPA / NHEERL/Mid-Continent Ecology Division; M.R. Embry, ILSI Health & Environmental Sciences Institute

The Threshold of Toxicologic Concern (TTC) is an approach used for a decades in human hazard assessment. A TTC establishes an exposure level for a chemical below which no appreciable risk to human health is expected based upon a de minimis value for toxicity identified for many toxicologically similar chemicals. The TTC concept applied in an environmental context (eco-TTC) has been proposed to be a Predicted No-Effect Concentration (PNEC) for ecological communities and establishes a concentration expected to have a de minimis probability that effects would be observed for a given group of compounds. Chemical grouping could be defined by mode of action, functional use, or some other relevant criterion. TTCs and eco-TTCs use a form of statistical distribution analysis highly similar to that of a Species Sensitivity Distribution, except that an eco-TTC is based on distributions of PNECs for groups of compounds rather than distributions of test organism endpoints for a specific chemical. Similarly, chemical tolerance distributions (CTDs) are defined as distributions of response values (LC50's or NOECs) for a specific taxonomic units (e.g., algae, invertebrates, fish, or even specific species) within a chemical group. In this presentation we develop eco-TTCs and CTDs and compare the results to water quality criteria values for existing chemicals using approaches from the US and Canada. Based on these results we provide recommendations for what role eco-TTCs or CTDs could play in developing new ambient water quality criteria for chemicals lacking sufficient data to develop chemical-specific values. Disclaimer: This presentation does not necessarily reflect the views or the policies of the US Environmental Protection Agency.

68 Deriving Water Quality Criteria Using Mode of Action Models: ppLFER Target Lipid Model of PAH and Narcotic Toxicity as an Example

D.M. Di Toro, Univ of Delaware / Civil and Environmental Engineering

The EPA technical quidelines for developing aquatic water quality criteria were a seminal contribution. They provided a clear solution to the problem of incorporating varying species sensitivity (protecting at the 5th percentile most sensitive specie) as well as other important considerations (minimum database, frequency of compliance and duration of exposure). However they are limited to one chemical. The purpose of this paper is to suggest that this problem can be overcome by using models that apply comprehensively to all the chemicals in a single mode of action. The polyparameter target lipid model (ppTLM) is an example of such a model. There are two crucial characteristics that make this model, or, for that matter, any model, practical for criteria development. (1) The model requires a species specific parameter that is chemical independent. For the TLM, it is the critical target lipid body burden – the organism lipid normalized concentration that causes 50% mortality. It has been found to be applicable to all chemicals that have the same toxic mode of action, namely type I and II narcosis. (2) The model requires a chemical specific parameter that is species independent. For the TLM, it is the partition coefficient between the target lipid and water, KLW. It is assumed to apply to all organisms that have the same mode and site of action – namely concentrations in the target lipid that produce the same toxicity at the same molar concentration (mmol/kg lipid). It is estimated using either the octanol-water partition coefficient and chemical class corrections for the original TLM, which applies only Type I narcotics, or a polyparameter linear free energy relationship (ppLFER) that estimates KLW using a Abraham model, which applies to both Type I and Type II (polar narcotics). The ppTLM can be used to derive HC5 concentrations since the species sensitivity distribution is the probability distribution of the critical body burdens. Therefore the ppTLM can serve as a prototype for models of modes of action that share the same characteristics: species sensitivity parameter(s) that apply to all chemicals in the MoA class; and chemical binding parameter(s) that apply to all species being considered. The correct additivity model follows from these characteristics. The criteria for PAHs and other classes of narcotic chemicals will be compared to criteria derived using the single chemical EPA methodology.

69 State-of-Science Approaches to Determine Sensitive Taxa for Water Quality Criteria Derivation

M. Willming, ORISE/USEPA / Gulf Ecology Division; C. LaLone, USEPA / Mid Continent Ecology Division; S. Raimondo, M.G. Barron, USEPA / Gulf Ecology Division

Current Ambient Water Quality Criteria (AWQC) guidelines specify pre-defined taxa diversity requirements, which has limited chemical-specific criteria development in the U.S. to less than 100 chemicals. A priori knowledge of sensitive taxa to toxicologically similar groups of chemicals should facilitate more rapid development of AWQC by focusing data collection on the most sensitive aquatic species or taxonomic groups. Two tools available for determining the sensitivity of taxa include Web-based Interspecies Correlation Estimation (Web-ICE; www3.epa.gov/webice/) and Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS; https://seqapass.epa.gov/seqapass/). Web-ICE estimates acute toxicity to aquatic organisms with limited or no test data based on log-linear regression models of the sensitivity of a surrogate and predicted taxon. Web-ICE generated species sensitivity distributions can then identify sensitive taxa and estimate toxicity values. SeqAPASS determines species similarity in aligned amino acid sequences of specific molecular targets, including functional domains such as the ligand-binding domain of a biomolecule responsible for the toxic action of a chemical. Susceptible taxa are identified based on sequence similarity to a known sensitive query species. Linking these two tools would also allow for determining insensitive taxa or groups of general similarity, so that data collection efforts could be optimized towards those species that would drive criteria derivation. Application of state-of-the-science tools such as SeqAPASS and Web-ICE, along with grouping toxicologically similar chemicals by mode of action or molecular initiating event, should facilitate development of the next generation of AWQC.

70 Application of adverse outcome pathway-based tools to ambient water quality criteria development

D.L. Villeneuve, G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; C. LaLone, USEPA / Mid Continent Ecology Division; D.R. Mount, USEPA / ORD NHEERL Mid-Continent Ecology Division Duluth; J.E. Tietge, USEPA / Office of Research and Development National Health and Environmental Effects Research Laboratory Mid-Continent Ecology Division; D.J. Hoff, USEPA / ORD NHEERL Mid-Continent Ecology Division

Increasing numbers and diversity of chemical contaminants are being detected in ambient surface waters. States, regions, and communities across the US are faced with the issue of understanding which chemicals may warrant concern and at what concentrations. Integrating new scientific data streams and predictive approaches into the process of numeric water aquatic life criteria development offers the potential to develop more criteria, for more chemicals, more rapidly. For example, well established models of non-polar narcosis provide an effective estimate of "baseline" toxicity. Emerging data streams from high throughput, pathway-based, toxicity testing programs provide broad spectrum screening for more specific modes of action that may result in deviations from "baseline" toxicity predictions (i.e., excess toxicity). The adverse outcome pathway (AOP) framework provides a scientifically credible basis for linking specific pathway-perturbations to predicted hazard and facilitates systematic consideration of taxa and life stages likely to be sensitive. Application of this information can facilitate more targeted and hypothesis-driven approaches to the collection of data for use in numeric criteria development. It can also support interim application of appropriate AOP-based prediction models in cases where empirical data are lacking. While these approaches will be subject to error and uncertainty, they offer the ability to provide a scientifically-based preliminary estimate of levels of concern, which can immediately guide priority setting and programs at the state and regional level while criteria are refined through the gradual application of stronger data sets and more tailored and sophisticated modeling. Examples illustrating how these tools can be integrated to aid rapid numeric criteria derivation will be presented. The contents of this abstract neither constitute nor necessarily reflect USEPA policy.

71 Potential Applications of Weight of Evidence Methods to Water Quality Criteria

G.W. Suter, S. Cormier, USEPA / National Center for Environmental Assessment

When more than one piece of evidence is available to address a problem, it may be appropriate to weigh the evidence. Evidence may be weighed to derive quantities or qualities. When multiple estimates are available for the same quantity, the quantitative weighing is termed meta-analysis. Currently, when deriving water quality criteria, multiple test results for a species and multiple tests of species in a genus are combined as geometric means. One might quantitatively weight those values before averaging, as in inverse variance weighting. Qualitative weight of evidence may be used, as with human health benchmarks, to determine what mode of action or route of exposure is applicable (e.g., is it an endocrine disrupter; is dietary exposure significant). When deriving criteria using field data, qualitative weight of evidence may be used to determine whether the exposure-response relationship is causal and whether it is significantly confounded. It may also be used to determine whether a field-derived value for one region is applicable to another. The ultimate application of weight of evidence would be to choose among or combine potential criteria derived by different methods (e.g., conventional toxicity tests, microcosms, mesocosms, field surveys, or models). Finally, weight is the opposite of uncertainty. Therefore, qualitative weighting of a body of evidence, based on consideration of relevance and reliability, can be used as an expression of the confidence in a value or conclusion that goes beyond the scatter that is quantified by statistical uncertainty. The views expressed in this abstract are those of the authors and do not necessarily represent the views or policies of the USEPA.

72 A Retrospective Evaluation of the USEPA's Guidelines for Ambient Water Quality Criteria Development Given What We Now Know

D.K. DeForest, K.E. Croteau, R.C. Santore, A.C. Ryan, J. Toll, Windward Environmental LLC

Many of the USEPA's ambient water quality criteria (AWQC) were initially developed in the 1970s and early 1980s, and the USEPA's current guidance for deriving AWQC was released in 1985. Over the last 30+ years, AWQC for a large number of constituents have been either newly developed or updated. The large increase in toxicity datasets now available for a large number of constituents provides an empirical basis for assessing the 1985 AWQC derivation guidance and whether any aspects of guidance should be considered for modification. We conducted a retrospective evaluation of criteria and toxicity data for representative constituents in different chemical classes to evaluate several questions, such as: (1) Are the minimum data requirements for taxonomic diversity (i.e., the "8-family rule") adequate given what we now know from the much broader empirical toxicity data available? (2) Should the minimum data requirements vary by chemical class given our understanding of mode of action? (3) Should end points beyond survival, growth, development, and reproduction be more explicitly considered in criteria development rather than inconsistently evaluated as "other data"? In this presentation we will provide our current thinking on these and other topics pertinent to the question of whether updates to our 31-year old Guidelines for Deriving Numerical National Water Quality Criteria for the Protection of Aquatic Organisms and Their Uses should be considered based on what we have learned in the intervening years.

Advancing -Omics into Regulatory Frameworks: Case Studies and Perspectives

73 Applying population genomics to environmental regulations

J. Shaw, Indiana Univ / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; L. Turner, Indiana Univ / The School of Public and Environmental Affairs; N. Keith, Indiana Univ – Bloomington / School of Public and Environmental Affairs; C. Jackson, S. Glaholt, Indiana Univ / The School of Public and Environmental Affairs; J. Colbourne, Univ of Birmingham / Biosciences College of Life and Environmental Sciences

Differences in inter-individual response are described by variation in environments and genomes that combine to give rise to phenotypic variation observed in populations. Environmental genomics provides tools for understanding these features that offer links to phenotypes, which are in-line with proposed changes in regulatory toxicology. In this talk we draw from recent environmental genomic case studies to explore how environmental stress contributes to genome variability, influences the fate of genetic variation in populations, and over micro-evolutionary time scales determines the fate of phenotypes. These studies contribute to and make use of maturing genomic tool kits for the killifish, Fundulus heteroclitus, and the water flea, Daphnia pulicaria. Using these animal models we explore how functional variation in gene expression and gene regulatory networks contributes to phenotypic plasticity, and influence homeostasis in response to environmental change, and how environment-induced alterations in the magnitude and distribution of gene copy number (CNV) in natural populations contributes to adaptations to extreme environments. We will discuss the importance of understanding genome variation and the evolutionary forces that shape it in light of environmental regulations.

74 How consistent are we? Inter-laboratory comparison for male fathead minnows exposed to 17α-ethinylestradiol

A. Feswick, Univ of New Brunswick Saint John / Biology; M. Isaacs, Univ of New Brunswick Saint John; A. Biales, USEPA / National Exposure Research Laboratory; R. Flick, USEPA / EMMD / National Exposure Research Laboratory; D.C. Bencic, USEPA / National Exposure Research Laboratory; R. Wang, USEPA / Ecological Exposure Research Division; L.L. Herbert, Univ of Liverpool / Inst of Integrative Biology; K.J. Kroll, C. Lavelle, V. Dang, Univ of Florida / Physiological Sciences; L. Escalon, Us Army Engineer Research & Development Center / Inst for Genomics Biocomputing and Biotechnology; C. Vulpe, Univ of Florida, Gainesville / Physiological Science; G.C. van Aggelen, Environment and Climate Change Canada / Toxicology; N.D. Denslow, Univ of Florida / Physiological Sciences; N. Vinas, Midsouth Regional Chapter / Inst for Genomics Biocomputing and Biotechnology; C.J. Martyniuk, Univ of Florida / Physiological Sciences; K.R. Munkittrick, COSIA

Transcriptomic approaches are widely used to examine effects of aquatic contaminants in both laboratory and field studies. Fundamental questions remain however for defining the limits of the technology and how it may be used in environmental monitoring programs. Uncertainties exist as to how molecular initiating events translate into adverse effects at the population level, as well as how large a magnitude or transcriptome response constitutes an adverse effect (threshold). Also debated are the most appropriate metrics for quantifying an “omics” response (e.g. fold change, intensity, p-value, pathway, or network). If omics technologies are to be established in governmental programs for environmental monitoring and risk assessment, they must adhere to rigorous standardization that ensures reliability and consistency. To investigate this, male fathead minnows (FHM), a widely used aquatic species for toxicity testing, were exposed to 25 ng/L EE2 for 96 h, and six independent laboratories received frozen livers to conduct a transcriptome analysis. Independent laboratories were free to use different processing and analysis packages to analyze the dataset. Data were also analyzed using a common method. Congruence was ~50% across laboratories when it came to identifying differentially expressed targets. This was not surprising given the flexibility in methods used to detect differentially expressed transcripts. The range in the magnitude of response of the transcriptome was variable across laboratories, with some laboratories reporting a smaller dynamic range than others for transcript fold change. However, when transcripts were ranked by fold change across laboratories, there was a strong positive relationship ($R2 = >0.9$, $p< 0.001$). Most important from a regulatory or monitoring standpoint was that, when a core group of estrogen responsive genes were singled out and located in each dataset, all laboratories save few exceptions were consistent in identifying the genes as differentially expressed; the laboratories also showed high congruence in estimating magnitude of response across a range of fold changes. This was true regardless of whether a single unified approach or independent data analyses were used. These transcripts were selected to encompass a range of fold change responses from dramatic (>20-fold) (e.g. vitellogenin, estrogen receptor 1) to more subtle a response (< 1.5 fold) (i.e. BOP1, Block of Proliferation 1). These data suggest that transcripts responsive to a chemical stressor can be consistently identified across laboratories, in designs that allow flexibility in the methods used. The results of this study suggest that omics technologies can be used to advance environmental monitoring efforts under a yet to be developed standardization framework.

75 Industrial perspective on environmental genomics for monitoring biodiversity and key species

D. Lyon, Shell Oil Co. / Shell Health Risk Science Team; G. Whale, Shell Health / Shell Health; S. Blight, A. Minard-Smith, Battelle Memorial Inst; C. Phillips, Texas Tech Univ; J. Bickham, Battelle Memorial Inst

The oil and gas industry uses biodiversity assessments to determine baseline conditions and potential impacts during operations. These assessments are often part of a larger environmental monitoring program and vary according to application, but in general, the environmental monitoring programs are labor- and time-intensive. For example, with offshore drilling operations, benthic sediments are partly characterized by isolating organisms via sieving large grab samples and identifying them. This process is costly, time-consuming, and reliant on the availability of qualified taxonomists. Alternative methods for biodiversity assessments would alleviate some of the cost and time pressures and provide a safety net in the event the traditional analyses are inconclusive. One such alternative method is the analysis of environmental DNA (eDNA), which refers to DNA extracted from environmental samples from organisms that inhabit or shed cells and waste in that. We are currently assessing the potential for eDNA methods to provide equivalent or supplementary information as traditional environmental monitoring methods. The analysis of eDNA permits the detection and identification of eukaryotic and/or prokaryotic organisms without direct observation or capture. Molecular approaches like DNA barcoding and eDNA could potentially be less expensive, safer, and more comprehensive than traditional monitoring methods. Shell is interested in the eDNA approach for biodiversity assessments and for species monitoring, and it has undertaken preliminary research to determine the utility and applicability of eDNA analysis. This presentation will discuss the pilot projects using eDNA for sediment assessment and species monitoring. Based on these analyses, eDNA could be used for supplementing traditional monitoring programs. There are several limitations to this approach, such as the biases introduced by PCR amplification, the reliance on the barcoding database for species identification, and the uncertain provenance and longevity of DNA. The promise and limitations of this approach will be discussed from an industry perspective.

76 Transcriptional (RNA-seq) and metabolic (MS/MS) profiling reveals host-microbiome interactions during adaptation to chronic pesticide exposure

J.B. Brown, Lawrence Berkeley National Laboratory / Molecular Ecosystems Biology; S. Langley, K. Wan, S. Morris, G. Karpen, A. Snijders, J. Mao, Berkeley Lab; M.R. Viant, Univ of Birmingham / School of Biosciences; S. Celniker, Berkeley Lab

Chronic pesticide exposure affects over one hundred million people world wide each year, and costs in excess of $1.2B per year in the United States alone. In metazoans, chemical exposures impact both the host and the microbiome. The host genome encodes several thousand enzymes, while the microbiome, in higher bilaterians, encodes millions, and many chemicals, including collateral dietary pesticides, resist host metabolism and are transformed exclusively by microbes. Hence, health affects of pesticide exposures may be moderated by microbial metabolism. We applied a multi-omics, systems biology approach to map host-microbiome interactions during chronic pesticide exposure in two distant metazoans, the model organisms Mus musculus and Drosophila melanogaster. We studied the widely used herbicides paraquat, atrazine and glyphosate, and observed changes in host gene expression, microbiome community architecture, and the gut metabolome that occur during low (10X DWEL) and high (1/10th LC50) dietary exposures. In both species, all three compounds remodel gut microbiomes (16S and metagenomic profiling). In mouse, impacts on the gut microbiome are dependent on host genetic background: GWAS on microbial abundances reveals that numerous microbiome quantitative trait loci (mbQTLs) are coincident with genes involved in inflammatory bowel diseases and cancer. Some microbial clades are completely extinguished by herbicide exposure, and these are replaced by expansions of microbes with overlapping metabolic strategies. In both species, atrazine disrupts expression programs (RNA-seq) for genes involved in cholesterol and lipid biosynthesis and transport, and metabolomics (MS/MS) analysis reveals that these disruptions affect numerous glycerophosphocholines. Therefore, the impacts of atrazine exposure on some biosynthetic processes are conserved between mouse and fly, across 600 Myr of evolution and in radically different microbial backgrounds. Further, all pesticide exposures resulted in neuromuscular phenotypes detectable through machine learning on open-arena behavioral imaging data. This analysis, though preliminary, already points toward both metabolic and transcriptional markers that could be screened in human and other chordate populations exposed to pesticides.

77 Developmental neurotoxic effects of pesticides, MeHg, and PFHxS combining behavior and cognitive studies with metabolomics and proteomics

P. Leonards, VU Univ, Inst for Environmental Studies / Inst for Environmental Studies IVM; H. Viberg, I. Lee, S. Buratovic, Uppsala Univ; S. Jung, Proteome Sciences; P. Eriksson, Uppsala Univ

Worldwide, serious concern has arisen about the increased incidence of learning and developmental disorders in children. Various recent epidemiological studies have indicated that exposure to low doses of environmental biologically active contaminants during human development can have deleterious effects on cognitive development in childhood. The EU-funded project DENAMIC investigates neurotoxic effects (e.g. learning and developmental disorders) of low-concentration mixtures of pesticides and a number of common environmental pollutants in children. In the current study the aim was to investigate the behaviour and cognitive effects of pesticides, methylmercury, and perfluorohexane sulfonate (PFHxS) exposure in mice and to further study the underlying molecular mechanisms of the observed effects using metabolomics and proteomics. Male mice were exposed to a single dose of pesticides (chlorpyrifos, carbaryl, cypermethrin, endosuldfan), methylmercury or PFHxS at postnatal day 10. Behaviour effects were studied at the adult age of 2 to 4 months. The studies showed that all chemicals can cause developmental neurotoxic effects, even after a single exposure which was given at a vulnerable period of brain development. The cognitive and behaviour tests showed that the early life exposure of the compounds can alter adult spontaneous behavior and cognitive function. Interesting the chemicals had different modes of action causing the same apical endpoint (increased spontaneous behaviour). Targeted and untargeted metabolomics and proteomics studies were carried out in brain tissues of cerebral cortex and hippocampus. Biochemical networks were mapped for each brain tissue using MetaMapp and Cytoscape. Metabolomic and proteomic analysis showed that a limited number of metabolites and proteins were down or upregulated, and that most were regulated in hippocampus. The strongest effect was found for PFHxS. Regulated metabolites and proteins were mostly related to axons/neurons, mitochondria, purine pathway, NADPH/NAPD activity, ATP/ribonucleotide metabolic processes. In general, the results showed that the cholinergic system was affected. A positive correlation was found between the levels of the neurotransmitter acetylcholine and acetylcarnitine in hippocampus; it has been suggested in literature that an increase of acetylcarnitine can give a spontaneous release of acetylcholine. The developmental toxic effects might cause neurological/neurodegenerative disorders/diseases.

78 Metabolomics in the Assessment of the Health of Sentinel Species in the Great Lakes

B. Chandramouli, SGS AXYS; H. Butler, SGS AXYS / Metabolomics; T. Watson-Leung, Ontario Ministry of the Environment / Aquatic Toxicology Unit; S. Kleywegt, Ontario Ministry of the Environment & Climate Change / Standards Development Branch; P.A. Helm, Ontario Ministry of the Environment & Climate Change / Environmental Monitoring and Reporting Branch; S.S. Huang, SGS AXYS / Metabolomics; J. Cosgrove, SGS AXYS

Pollutants enter the Great Lakes in Southern Ontario through a variety of sources including wastewater treatment plants (WWTP) and local industries. A diverse set of contaminants has been detected within this environment including metals, pharmaceuticals, PCBs, PAHs and pesticides. The number and range of such compounds presents a significant challenge in both monitoring the effectiveness of regulatory changes implemented to reduce pollution loads and in assessing biological effects and risks. Transcriptomic, proteomic, and metabolomic measurements of sentinel species that have been exposed to environmental samples from affected sites provide an opportunity to evaluate early biological impacts in a controlled laboratory setting and to correlate these biological effects with measured contaminant levels. Such data can provide valuable insight into prioritizing and refining future contaminant measurement strategies, and can inform regulatory approaches. In this set of studies, rainbow trout and hexagenia sp. were exposed to surface water, effluent, and sediment (hexagenia only) collected at various sites and WWTPs in Lake Erie and Lake Ontario. Exposures were performed in a laboratory setting with each exposure lasting 48 hours. Concentration values of 219 metabolites, including amino acids, biogenic amines, ∑hexose, fatty acids, bile acids, acylcarnitines, sphingomyelins, and glycerophospholipids, were measured in rainbow trout liver and whole hexagenia. In parallel, concentrations of PCBs, PAHs, metals, and a diverse set of environmental contaminants were measured in the exposure media. Univariate and multivariate statistical techniques, such as ANOVA, PCA, and OPLS-DA, were used to identify metabolites varying between the different location/concentration groups and to correlate metabolite changes with available water quality and contaminant concentration data. Preliminary analysis indicates that metabolomic differences can be identified in rainbow trout and hexagenia exposed to control samples compared with those exposed to effluent. Furthermore, the metabolomic effects of effluent from specific sites within Lake Ontario are distinct. Likewise, hexagenia sediment exposures show distinct metabolomic differences after exposure to field samples versus exposure to clean sediment. This work is part of a multiomic study on exposure and effects of industrial and urban inputs in the Great Lakes.

79 Transcriptomic response of Mytilus larvae to simultaneous copper and ocean acidification exposure

M. Hall, A.Y. Gracey, Univ of Southern California / Marine Biology and Biological Oceanography

Future changes in ocean chemistry will have an unclear effect on metal toxicity to marine organisms. In particular, very little is known about the combined effects of ocean acidification and metal exposure at the molecular level. High throughput sequencing technologies will allow us to screen for robust biomarkers of metal toxicity that are effective even as ocean acidification progresses. Our past work has identified transcriptional biomarkers of copper exposure in mussel larvae and adults. This research revealed a set of genes with dose-responsive expression that are indicative of copper exposure and correlate well with morphological abnormality. In the current study we tested the consistency of known copper-responsive transcriptional profiles under simulated ocean acidification, and explored novel biomarkers of co-exposure to copper and ocean acidification. We exposed California mussel (Mytilus californianus) embryos to a range of seven copper concentrations and two CO_2 concentrations (400 ppm and 800 ppm) for 48 hours, the crucial time period of early development. At 48 hours, larval survival and proportion of normal development were determined. 30 larval samples spanning our range of copper and CO_2 concentrations were sequenced on an Illumina HiSeq 4000. Both copper and CO_2 concentrations influenced survival and normal development, and animals slightly benefited from exposure to elevated CO_2 concentrations. The transcriptomes revealed that dose-responsive gene expression profiles were evident at both high and low CO_2 concentrations. While many genes exhibited consistent expression profiles in both CO_2 treatments, a subset of genes responded in a unique way to copper stress under future OA conditions. High throughput expression data like this will be vital to develop appropriate and reliable toxicity assays that will still be effective in coming decades.

80 Characterization of gene regulatory networks that coordinate early adaptive response to environmental stress in Daphnia magna

L. Orsini, Univ of Birmingham; J.B. Brown, Lawrence Berkeley National Laboratory / Molecular Ecosystems Biology; O. Solari, Univ of California Berkeley / Statistics; S. He, D. Li, Univ of Birmingham; R. Podicheti, Indiana Univ Bloomington / Molecular Ecosystems Biology; J. Colbourne, Univ of Birmingham / Biosciences College of Life and Environmental Sciences; L. De Meester, Katholieke Universiteit Leuven / Biology

The modulation of mRNA levels through transcriptional and post-transcriptional regulation is among the earliest cellular responses to changing environmental conditions. We analyzed the immediate-early response of three Daphnia magna genotypes to 12 environmental challenges, including 6 biotic and 6 abiotic stressors, lasting between 4 to 24 hours via a genome-wide transcription profiling (RNA-seq). Each exposure was imposed to mimic ecologically relevant conditions that Daphnia encounters in the natural environment, and hence are within the known adaptive, non-toxic regimes for this organism. We find that most differentially expressed genes are modulated in a genotype-specific manner and in response to only one or a few conditions. However, genes are organized into co-responsive modules, and these are coherently co-expressed across numerous conditions and genetic backgrounds. Transcripts associated with adaptation to genotoxic conditions provide straightforward biomarkers of abiotic perturbations, and the specific cohort of responsive genes provides insight into the mode of action of the toxicant. Remarkably, we find transcriptional signatures of diapause in response to stressors as early as 4 hours, indicating that the decision to generate ephippial eggs is made almost immediately upon the transduction of environmental challenges. Condition-specific transcriptional modules also provide an opportunity to discover genes of previously unknown functions, as they are broadly enriched for poorly conserved or recently evolved genes, and this study constitutes the first evidence of biological rolls for several hundred genes. This survey of stress response in a keystone ecological species provides insight into the gene regulatory networks that coordinate early (< 24h) adaptive response to environmental stress.

Status and Trends of the Landscape-Scale Mercury Problem in South Florida and the Everglades

81 History, Trends and Management Implications of Florida's Mercury Problem

T. Lange, Florida Fish & Wildlife Commission / Fresh Fish Research; D.G. Rumbold, Florida Gulf Coast Univ / Depart of Marine and Ecological Sciences

Mercury (Hg) bioaccumulation in fish and wildlife from the Everglades has been a concern since the mid 1970's when first identified as an issue within Everglades National Park. Concerns expanded during the 1980's as sport fish with Hg concentrations well over 1 mg/kg were found within the Everglades Protection Area (EPA). Elevated Hg concentrations in fish and wildlife are an important endpoint within the Everglades mercury cycle and reflect relatively high rates of atmospheric deposition of inorganic Hg coupled with wetland and coastal ecosystems that efficiently produce methylmercury (MeHg). MeHg, the more toxic form of Hg, Bioaccumulates efficiently in aquatic food webs reaching levels of concern to human and wildlife health. In 1992, an Interagency Mercury Science Program, consisting of federal, state, and private entities, was tasked with informing managers on Everglades restoration strategies to prevent a worsening of the Hg problem. An important component of this program, monitoring of fish and other vertebrate species, revealed significant declines in Hg biomagnification during the late 1990's – early 2000s. Yet concentrations remain at levels exceeding criteria for the protection of human health and within the range of potential effects to fish eating wildlife both within the EPA and downstream estuaries. Moreover, spatial gradients in water quality and biogeochemistry continue to produce "hotspots" where both the production and bioavailability of MeHg favor efficient bioaccumulation. Surveys of Hg in fish and wildlife of south Florida within the past five years have revealed Hg concentrations as high as 3.31 mg/kg in the muscle tissue of a largemouth bass (Micropterus salmoides), 4.5 mg/kg in a blacktip shark (Carcharhinus limbatus), 93.6 mg/kg in feathers of osprey (Pandion haliaetus carolinensis), and 100 mg/kg in fur of a panther (Puma concolor coryi). In 2013, the Florida Department of Environmental Protection developed a state-wide, Total Maximum Daily Load (TMDL) for Hg that called for an 86% reduction of anthropogenic emissions for the protection of human and wildlife health. Currently the primary mitigation strategy in the Everglades is through consumption advisories for fish and wildlife which urge reduced consumption of 13 freshwater species, >69 marine species, and 2 wildlife species. Future management approaches should be sought that incorporate the spatial, temporal, and ecological variability of Hg biogeochemistry.

82 The Contribution of Emissions Sources and Atmospheric Deposition to Mercury in South Florida and the Everglades

K. Vijayaraghavan, G. Yarwood, R. Morris, Ramboll Environ

Atmospheric deposition constitutes a potentially major source of loading of mercury to terrestrial and aquatic ecosystems in South Florida. The three main forms of inorganic atmospheric mercury are emitted in different fractions from various anthropogenic and biogenic sources and have different wet and dry deposition characteristics. The deposition contribution to mercury contamination in the Everglades is due to a combination of mercury emitted from local, regional and other world-wide emission sources. In particular, gaseous elemental mercury undergoes long-range transport and is converted to gaseous oxidized mercury through various mechanisms such as in thunderstorms in Florida. The resulting divalent mercury undergoes rapid deposition over South Florida and gets methylated to organic mercury, thus contributing to the mercury contamination in the Everglades. The paper will summarize our current understanding of the relative contributions of emission sources to mercury deposition in South Florida through an examination of both modeling results and monitoring data for wet and dry deposition.

83 Everglades Human Health Risk Assessment for Mercury

D.M. Axelrad, Florida A&M Univ / Inst of Public Health; C. Jagoe, Florida A&M Univ / School of the Environment; T.R. Lange, Florida Fish and Wildlife Conservation Commission; C.D. Pollman, Aqua Lux Lucis

Human exposure to mercury, a neurotoxicant, is primarily from consuming fish contaminated with methylmercury (MeHg). MeHg which is far more bioaccumulative than is inorganic mercury, is most frequently produced in water bodies from inorganic mercury being converted by naturally-occurring sulfate-reducing bacteria to MeHg; MeHg then concentrates up the aquatic food chain. Mercury is by far the leading cause for fish consumption advisories in the USA and in Florida. Current fish consumption advisories for the Everglades recommend that anglers limit and, in some cases refrain, from consuming 13 freshwater species, several marine and estuarine fish species, pig frogs and alligators. Recreational anglers who eat their catch are a subpopulation potentially at increased risk of mercury exposure. Current fish consumption advisories may not be sufficiently protective for those that consume higher than average amounts of fish and game, including some ethnic groups and subsistence fishers. This issue is particularly relevant in Florida with its widespread, elevated fish mercury levels. Accordingly, there is a need to better quantify their exposure to accurately assess the human health risks. Previous studies done in Florida took place in the 1990s and focused on fisher people in the freshwater Everglades. Yet, in southwest Florida, consumption of marine species by recreational anglers is expected to significantly outweigh consumption of freshwater species over the long term. In this presentation, human health risk assessments for various scenarios for consumption of Everglades fish and wildlife will be discussed. As well, possible explanations for the elevated mercury levels in Florida fish as these relate to options for managing human exposure to MeHg will be presented. Additionally, current State efforts to limit anglers' exposure to MeHg along with possible additional options will be considered.

84 Everglades REMAP 2014: Findings for Mercury and Other Biogeochemically Related Pollutants

P. Kalla, USEPA / Region Laboratory; D. Scheidt, USEPA / Water Protection Division; P. Betts, USEPA / Region Laboratory; P. Lorenzo, Florida International Univ / Southeast Environmental Research Center SERC; G. Liu, Y. Cai, Florida International Univ / Dept of Chemistry Biochemistry and Southeast Environmental Research Center

The Everglades Regional Environmental Monitoring and Assessment Program (REMAP) is a probability-based, multi-media survey that the U.S. Environmental Protection Agency (EPA) has conducted to describe, explain, and predict conditions throughout the public Everglades freshwater flow-way since 1995. The latest survey was in the wet season of 2014, when we sampled 119 locations. In addition to mercury, sulfur and phosphorus have been constituents of concern in REMAP because of their relationship to mercury toxicity and bioaccumulation, among other effects. In 2014 there was half as much methyl mercury in surface water as in the previous complete survey, done in 2005. (2014 median = 0.099 ng/l, 2005 = 0.200). There was also less total mercury in surface water, but not in proportion to the difference in methyl mercury (total mercury median of 1.5 ng/l vs. 2.1). The decline in total mercury probably reflected regional and global declines in atmospheric deposition. The mosquitofish (Gambusia affinis), a forage fish ubiquitous in the Everglades, is used in REMAP to assess mercury levels in consumers. In 2014 there was a little over one-third as much mercury in mosquitofish system-wide compared to 2005 (median of 33 ng/g vs. 87). Mercury bioaccumulation hotspots remained, with 13% of the system above EPA's predator protection level of 77 ng/g. In 2014, 26% of the greater Everglades study area had sulfate concentrations in surface water in the range reported to stimulate mercury methylation (2 – 20 mg/l), contrasting with 37% in 2005. Only 63% of the area had < 1 mg/l, which is the Comprehensive Everglades Restoration Plan goal, and only 18% remained at background level (0.022 mg/l, the REMAP analytical method detection limit). Total phosphorus in soil was unchanged, with the median value being 390 mg/kg. REMAP data show that parts of the Everglades with high phosphorus and sulfur may favor mercury methylation, but that they may also have food webs that are sufficiently degraded by these pollutants so as to inhibit mercury bioaccumulation. The remaining mercury hotspots represent places in the landscape where both processes are enhanced.

85 Contrasting Biogeochemical Conditions at Two Everglades Locations with Historically Elevated Mosquitofish (Gambusia holbrooki) Mercury Concentrations

F. Dierberg, J. Potts, M. Jerauld, T. DeBusk, N. Larson, DB Environmental, Inc

Southern Water Conservation Area (WCA)-2A and northern WCA-3A contain similar ridge and slough marsh communities, characterized by low P concentrations and abundant calcareous periphyton. However, marked biogeochemical differences exist between the two regions, which may affect the active mercury (Hg)/methylmercury (MeHg) cycling processes in each area. Both regions at times have been considered "hot spots", since elevated mercury concentrations have been measured in fish, though with considerable temporal variability. We compared biogeochemical factors (i.e., Hg, MeHg, sulfate (SO_4), iron (Fe), and dissolved organic carbon (DOC) concentrations) between and within monitoring locations in these regions: U3 (WCA-2A) and DB-15 (in NW WCA-3A), where a long record exists of elevated Gambusia Hg. Surface waters (SW) at U3 had higher dissolved (diss) Hg (1.0–2.3 ng/L) and diss MeHg (0.1–1.0 ng/L) than at DB-15 (0.5–2.4 ng/L diss Hg; < 0.6 ng/L diss MeHg). In marked contrast, detritus (floc) MeHg averaged 2.2-6.1 ng/g dry at DB-15 and 0.5-2 ng/g dry at U3, and was related to Gambusia tissue Hg. Typically, SW DOC was higher at U3 (23-57 mg/L) than DB-15 (14-37 mg/L), and was among the strongest explanatory variables for MeHg in water and biotic matrices (e.g., floc, Gambusia) within and between sites. However, the aromaticity of DOC was not correlated with SW Hg or MeHg concentrations at either site. Sulfate was much higher at U3 (15-32 mg/L) than DB-15 (< 1.5 mg/L SO_4). Concomitantly, at U3 porewater (PW) sulfide was elevated (1.6-4.9 mg/L) and oxidation reduction potential (ORP) was depressed (about -100 mV) compared to DB-15 (< 0.2 mg/L and about 0 mV, respectively). However, neither detrital MeHg nor SW dissolved MeHg were correlated to SW sulfate concentration at either site. Diss Fe, especially in PW, was much higher at DB-15 (1-4 mg/L) than U3 (< 0.04 mg/L), but was not correlated with MeHg at either site. The elevated Hg concentrations documented in biotic matrices at both U3 and DB-15 demonstrate that Hg methylation and bioaccumulation can occur under diverse biogeochemical conditions, particularly with respect to sulfate availability. This detailed temporal assessment shows a strong linkage between DOC concentrations and SW Hg and MeHg concentrations within and among sites. In addition, our preliminary data suggest that food web and other ecological differences exist between the two sites, which may contribute to higher biotic Hg concentrations at DB-15.

86 Sulfate in the Everglades – Sources and the effect of source reductions on Gambusia Hg concentrations

C. Pollman, Univ of Florida, Gainesville / Geological Sciences

Elevated concentrations of mercury (Hg) in a broad spectrum of Everglades biota have long been recognized as environmental and public health concerns. While the Hg problem ultimately is driven by atmospheric inputs, its biogeochemical cycling and trophic transfer is governed by a variety of physical, chemical and biological factors. Similar to many aquatic ecosystems, key amongst those factors are dissolved organic carbon (DOC) and sulfate. Sulfate dynamics can play a critical role in Hg cycling because methylation of Hg in freshwater aquatic ecosystems is governed in large part by the activity of sulfate-reducing bacteria that use sulfate as the terminal electron acceptor to metabolize organic matter under anaerobic conditions (Gilmour, 2011). Atmospheric emissions source-receptor modeling indicates that only a small fraction of Hg deposited in the Everglades originates within Florida, and the occurrence of DOC is a ubiquitous and natural feature of the Everglades landscape. Sulfate concentrations however are greatly perturbed relative to pre-anthropogenic levels, and reflect enhanced contributions from atmospheric emissions of SO_2 and land management practices using sulfate as a soil amendment in the EAA draining into the Everglades. Thus – of the three key variables governing Hg cycling in the Everglades – controlling sulfate is perhaps the only viable option for mitigating the Hg problem. This paper has two major components. First, I use solute tracers to identify and quantify the contributions of a third source of sulfate to the Everglades – viz. discharges of connate seawater into major Everglades canals draining the EAA. This source, which relates to the hydrologic alterations and practices actively used within the EAA, is thus an anthropogenic source which must be considered in evaluating sulfate control strategies. For the second component of this paper, I explore the sulfate management question by using a structural equation model to predict the effect of various reductions of sulfate on expected Hg concentrations in Gambusia spp. across the Everglades. This model, which was developed by Pollman (2014), incorporates two critical features that necessarily must be included in any statistical model of Hg cycling – the non-linearity between sulfate and methylation; and mediated inter-variable relationships. Predicted changes in Gambusia Hg will be examined both spatially, and with respect to overall shifts in cumulative distribution.

87 Trends, Hotspots and driving factors of mercury within the Everglades Ecosystem

P. Julian, Florida Dept of Environmental Protection / Office of Ecosystem Projects; B. Gu, South Florida Water Mgmt District / Water Resources; K. Weaver, Florida Dept of Environmental Protection / Water Quality Standards; A.L. Wright, Univ of Florida / Soil and Water Science

Mercury (Hg) methylation and bioaccumulation is a major environmental issue in the Greater Everglades Ecosystem since the late 1970s. Areas of elevation Hg concentrations in fish, soil and water can be found through the Everglades system. These areas have been operationally defined as hotspots however no formal, data driven criteria has been developed to define Hg accumulation hotspots. Biological hotspots can be defined as Hg tissue concentrations above a particular wildlife tissue threshold/criteria. Alternatively, hotspots can statistical be defined using geostatistical methods to delineate hotspot occurrence and extent, however this approach is data intensive. This presentation will discuss general trends and patterns of Hg concentrations observed in biotia, atmospheric wet deposition and surface water within the freshwater Everglades Ecosystem. Also this presentation will discuss biological hotspot identification and biogeochemical cycling of Hg. Since Water Year (May 1 – April 30) 1989 to present, Hg tissue concentrations in Largemouth Bass (Micropterus salmoides L.) has been highly variable with no significant trend apparent from sampling locations across the EPA. Meanwhile, lower trophic level species including sunfish (Lepomis spp.) and mosquitofish (Gambusia spp.) Hg tissue concentrations remain relatively high and variable with several stations experiencing significant increases in sunfish tissue Hg concentration and decreasing trends seen in mosquitofish Hg concentration. Meanwhile, wet deposition of Hg, the primary source of Hg, has remained relatively constant through the period of record. Recent studies have discussed geostatistical identification of soil Hg hotspots within the Everglades ecosystem, nutrient stoichiometric control of biological hotspots and the interaction of sulfur, iron and organic carbon within hotspot and non-hotspot locations. Although the state of Florida has adopted a statewide Hg TMDL, more work is needed to better understand and predict Hg dynamics, especially in the context of water quality conditions within the Everglades ecosystem. However, without a quantum step in our ability to link surface water conditions, microbial dynamics, ambient methyl-Hg and biota Hg levels, there is no way to justify any complimentary ecosystem-wide, parameter specific management strategy to reduce Hg risks.

88 Reduction of Sulfate Loading May Mitigate Methylmercury Production in the Everglades

W. Orem, D.P. Krabbenhoft, G. Aiken, USGS; C. Fitz, EcoLandMod, Inc.

Unnaturally high sulfate loading to the Everglades is one of the key factors controlling methymercury (MeHg) production and bioaccumulation in the ecosystem. Background concentrations of sulfate in surface water of the Everglades are typically very low (0.05 – 1 mg/L) and do not support significant levels of microbial sulfate reduction and mercury methylation. Discharge of canal water containing high levels of sulfate (60-70 mg/L long term average) into the Everglades, however, has elevated sulfate concentrations in at least 60% of the ecosystem. The elevated sulfate levels stimulate sulfate reduction and MeHg production. The sulfate contamination originates from the Everglades Agricultural Area (EAA) from agricultural use of sulfur, organic soil oxidation, and other sources. Modeling, and field and experimental studies suggest that reducing sulfate loading can have dramatic impacts on MeHg production in the ecosystem. A modified version of the Everglades Landscape Model that incorporates sulfate and MeHg production modules has shown that a 37% reduction in sulfate loading to the Everglades dramatically reduces the risk of MeHg production by about 20-50% in large areas of the Water Conservation Areas and Everglades National Park (ENP). Greater reductions of sulfate have even more significant impacts on MeHg risk. Between 1999-2002, an area of the central Everglades, formerly a "hot spot" for MeHg production accumulation in fish and wading birds, saw a reduction in sulfate levels from 10 mg/L to background levels (0.05 mg/L) due to rerouting of water accompanying Everglades restoration. In response to the decrease in sulfate concentrations, MeHg levels in water decreased dramatically from 0.8 to 0.1 ng/L, with accompanying changes in MeHg levels in fish and birds. Experimental studies using lab microcosms and field mesocosms also demonstrate that reducing sulfate loading reduces MeHg production. Approaches to reduce sulfate loading to the ecosystem must be multifaceted, and include: (1) Best management Practices (BMPs) on sulfate use in agriculture in the EAA, (2) approaches for reducing organic soil oxidation in the EAA, (3) reducing intrusion of sulfate-rich groundwater, especially in cracked canal bottoms, (4) modifying stormwater treatment areas for more efficient removal of sulfate, and (5) transporting sulfate-contaminated canal water by sheet flow through marsh areas to sensitive parts of the ecosystem (e.g. ENP).

Soil Contaminants: Fate, Bioavailability, Environmental Toxicology and Risk Assessment – Part 1

89 Assessing the ecotoxicity of constituents in dredged marine sediment contaminated with TPH and heavy metals for its beneficial reuse as soil

K. Kim, M. Kim, Seoul National Univ; H. Chae, Hyundai Engineering & Construction Co., Ltd / Research Development Division; E. Kim, Seoul National Univ; K. Nam, Y. Choi, Seoul National Univ / Dept of Civil and Environmental Engineering

A significant amount of dredged marine sediment is produced worldwide by navigation dredging. The dredged sediment can be reused in many ways such as base materials for construction fill and habitat creation. Prior to the beneficial reuse of the dredged marine sediment in terrestrial environment, any potential negative effects of natural and anthropogenic constituents in the sediment on terrestrial receptors should be evaluated and if needed, the sediment should be treated to minimize the effects. This study considered salinity, TPH and heavy metals as constituents in dredged marine sediment potentially toxic to terrestrial receptors. Each constituent was sequentially removed from a dredged marine sediment sample highly impacted by TPH and heavy metals to determine the significance of each as eco-toxicological parameters. The salinity was removed by washing the sediment with deionized water (2 hr, 180 rpm, 1:5 solid-liquid ratio) and TPH was removed by solvent extraction (20 min, 180rpm, 1:6 soild-liquid ratio) and thermal desportion (300?, 1 hr). Heavy metals were removed by a soil washing procedure (1.5 M H_2SO_4, 1:3 soil liquid ratio). After the treatment, the sediment was analyzed for concentration of salinity, TPH and heavy metals, and heavy metal speciation. A toxicity test using Hordeum vulgare was conducted to assess the effect of each constituent on terrestrial receptors after sequential remediation of the sediment. Based on the toxicity test, the salinity reduction in sediment resulted in significant increase in germination and growth of H.vulgare, but the removal of TPH by solvent extraction did not have a positive effect. The toxicity test using H. vulgare after TPH removal by thermal treatment and heavy metal removal by acid treatment is underway to assess the effect of each treatment. Acknowledgement: This study received substantial support from the Geo-Advanced Innovative Action (GAIA) Project of the Korea Environmental Industry & Technology Institute (KEITI).

90 Screening-level ecological risk assessment for beneficial reuse of dredged marine sediment

M. Kim, K. Kim, Seoul National Univ; Y. Ji, Hyundai Engineering and Construction / Research and Development Division; Y. Choi, K. Nam, Seoul National Univ / Dept of Civil and Environmental Engineering

Researches on beneficial reuse of dredged marine sediment has been developed recently. It is important to estimate the environmental impact of dredged marine sediment on terrestrial ecosystem, however the ecological risk of dredged marine sediment has been rarely assessed. In this study, screening-level ecological risk assessment was conducted in order to beneficially reuse dredged marine sediment as soil. Heavy metals (i.e., Cu, Zn, Cd, Pb, Cr, Ni) which are commonly found in dredged marine sediment were selected as target comtaminants. Toxicological data of heavy metals were collected from ECOTOX of US Environmental Protection Agency (USEPA), Canadian Council of Ministers of the Environment (CCME) and some technical papers. Screening process was conducted in order to verify the quality of toxicological information regarding the statement of experimental conditions, endpoint reported, and the statistical analysis used. Stochastic approach (for Cu, Zn, and Cd) and deterministic approach (for Pb, Cr, and Ni) were both used according to the number of screened toxicological information in order to calculate predicted no effect concentration (PNEC). The PNEC values are suggested as the range with the uncertainty factor from 1 to 5. Calculated PNEC values of Cu, Zn, Cd, Pb, Cr, Ni are 17.8 – 39.7, 45.9 – 102.7, 2.3 – 5.2, 16.7 – 37.5, 12.3 – 27.5, 16.7 – 37.5 mg/kg, respectively. This study derived hazardous quotients of the six heavy metals using PNEC value and site-specific predicted environmental concentration (PEC) of each heavy metal. The hazard quotient (HQ) of Cu, Zn, Cr, Pb and Ni were higher than unity indicating a possibility of ecological risk of the five heavy metals when the dredged marine sediment is applied in terrestrial environment. Accordingly, remediation processes and a higher-level ecological risk assessment would be needed for the recycling of the dredged marine sediment.

91 Human exposure to wastewater-derived pharmaceuticals in fresh produce: Data from a randomized controlled clinical trial

B. Chefetz, The Hebrew Univ of Jerusalem / Soil and Water Sciences; G. Fedorova, Univ of South Bohemia in CB / Laboratory of Environmental Chemistry and Biochemistry; G. Tadmor, The Hebrew Univ of Jerusalem / Soil and Water Sciences; O. Paltiel, The Hebrew Univ of Jerusalem / Braun School of Public Health and Community Medicine Hadassah

Fresh water scarcity has led to increased use of treated wastewater as an alternative source for crop irrigation. Concerns have been raised regarding pharmaceutical exposure via treated wastewater. Our aim was to assess whether carbamazepine, an anticonvulsant drug highly persistent in wastewater, is present in commercially available treated wastewater-irrigated produce, and whether human exposure to carbamazepine occurs via ingestion of this produce. In this study we follow the exposure path: wastewater --> irrigation water --> soil --> crops --> consumers. We recruited 34 volunteers aged 18-63 years (20 women and 14 men) to a single blind crossover trial. Group I (n=22) was randomized to receive treated wastewater-produce followed by fresh water-irrigated produce; Group II (n=12) received fresh water irrigated-produce followed by supermarket-purchased produce. Each exposure period lasted one week. During the trial, subjects filled food frequency questionnaires and provided urine samples. Carbamazepine and metabolite levels were measured in produce and human urine, following development of a novel method to extract and measure metabolites in urine matrix. We assessed the proportion of individuals with urinary levels above the LOD or LOQ and area under the curve over the study period. Treated wastewater-irrigated produce exhibited substantially higher carbamazepine levels than fresh water-irrigated produce. At baseline, urinary carbamazepine was undetectable in 13, between LOD and LOQ in 12, and >LOQ in 9 subjects. Following seven days of consuming treated wastewater irrigated-produce all Group I members exhibited quantifiable levels of carbamazepine, while in Group II the distribution remained unchanged from baseline (between group $P < 0.001$). Area under the curve of carbamazepine excretion was markedly higher in Group I versus II ($P < 0.0001$). Urine levels return to baseline following the exposure periods. This study demonstrates "proof of concept" that human exposure to pharmaceuticals occurs through ingestion of commercially available treated wastewater-irrigated produce, providing data which could guide policy and risk assessments.

92 Composting studies in Estonia

E. Haiba, Tallinn Univ of Technology, Tartu College / Dept of Techology; L. Nei, Tallinn Univ of Technology Tartu College / Dept of Env Protection

This work is addressed to the application of biosolids and especially sewage sludge as a major resource in composting. Safe disposal of sewage sludge is one of the major environmental concerns. A considerable drop in the use of P fertilisers can be followed since early 1990s and due to this fact crop production in Estonia takes place largely at the expense of soil P resources. One of the ways of increasing the fertility of agricultural lands is to use nutrient-rich sewage sludge. Unfortunately, this may cause several undesired consequences due to biological and chemical contaminants present in this matter. The presence of some widely used pharmaceuticals, as ciprofloxacin (CIP), norfloxacin (NOR), ofloxacin (OFL), sulfadimethoxine (SDM) and sulfamethoxazole (SMX), was evident in sewage sludge of the two Estonian largest cities, Tartu and Tallinn. The concentrations of pharmaceuticals decreased significantly after sewage sludge digestion and composting (in most experiments their concentrations decreased by 95% or more during 4 months of composting), but they were still present in detectable amounts. Sewage sludge co-composting experiments with sawdust, peat and straw showed the degradation of FQs and SAs. Additions of sawdust clearly speeded up this process, whereas the mixtures with peat and straw performed lower abilities to decompose pharmaceutical residues. The presence of pharmaceuticals in our study affected the microbial community composition of the compost that resulted in lower microbial activity values and affected fungal-to-bacterial ratios in composts. In the end of the experiment the fungi dominated over bacteria in composts with added pharmaceuticals (60-70%). In compost where pharmaceutical residues were not added bacteria dominated over fungi (65%). Novel methodologies were developed and experiments conducted to study the potential accumulation of fluoroquinolones (FQ) and sulfonamides (SA) by food plants – taken up from the soil fertilized with sewage sludge or its compost. It has been shown that due to the low adsorption of SAs on soil particles they are "free" to migrate into plants. Different behaviour is characteristic to FQs as they are accumulated in sludge. Recent years have also shown certain progress in vermicomposting work, in studies involving microbial activity change during composting, and in using compost in afforestation.

93 Pentachlorophenol, chlorinated dioxins and furans in soil surrounding utility poles on the Kenai National Wildlife Refuge in Alaska

L.A. Verbrugge, US Fish and Wildlife Service / Fisheries and Ecological Services; L. Kahn, J.M. Morton, US Fish and Wildlife Service / Kenai National Wildlife Refuge

A local electric utility company maintains above-ground transmission lines within the Kenai National Wildlife Refuge under U.S. Fish and Wildlife Service-issued right-of-way permits. Most supporting poles have been treated with commercial pentachlorophenol mixtures known to contain trace amounts of chlorinated dioxins and furans. These contaminants can migrate from treated poles to surrounding soils, posing potential risks to human health and ecological receptors. To characterize risk and ensure best management practices for pole replacement and/or removal, we collected surface soil samples near twelve utility poles for measurement of pentachlorophenol, chlorinated dioxin and furan congeners, and selected polycyclic aromatic hydrocarbons. There were six sets of paired poles; each pair consisted of a pole installed in the 1950s and a pole installed within the past twenty years that were located near each other. A representative background sample was collected for each pair. Samples were collected at 0 cm, 25 cm and 50 cm from each pole. Pentachlorophenol, dioxin and furan concentrations in soil were quite high at the base of each pole, and diminished approximately an order of magnitude from 0 cm to 25 cm, and again from 25 cm to 50 cm out from the pole. When expressed in terms of 2,3,7,8-tetrachlorodibenzo-p-dioxin toxicity equivalents, the average soil concentrations were 15.2, 5.17 and 1.52 parts per billion at 0, 25 cm and 50 cm distances from the pole, respectively (dry weight). Pentachlorophenol concentrations were 1800, 160, and 18 parts per million at zero, 25 cm and 50 cm distances from the pole, respectively (dry weight). Contaminant levels near the poles are orders of magnitude above screening levels for risk to both human and ecological receptors, warranting a more comprehensive risk assessment. This issue presents complex challenges for state environmental regulators, public land managers, and utility providers who strive to manage risk and protect human health and the environment, while continuing to provide electricity to Alaskan communities at a reasonable cost.

94 North of 60: Linking Herbicide Persistence to Soil Ecological Risk Along Transmission Right-of-Ways in the Yukon Territory

A. Jimmo, Univ of Saskatchewan / Soil Science; K. Stewart, S. Siciliano, Univ of Saskatchewan / Toxicology Group and Dept of Soil Science

Mechanical techniques, including brushing and mowing, are currently the only control methods used on transmission right-of-ways (ROWs) in the Yukon Territory. Primary issues with mechanical methods include increased density and regrowth of target species. Long-term vegetation control along transmission ROWs in the Yukon Territory may be improved through incorporating different management practices. These practices could integrate mechanical and chemical vegetation management with regional or site-specific techniques, such as ecological manipulation. Specifically, incorporating herbicides into the vegetation management program could improve long-term effectiveness, reduce environmental risk and decrease management costs. Therefore, obtaining a greater understanding of the impact of herbicides on the soil from the perspective of a northern terrestrial ecosystem is key in making informed vegetation management decisions. The persistence and toxicity of Garlon® XRT (triclopyr) and Arsenal® Powerline (imazapyr) in soils was assessed at five ROW locations representative of the main ecoregion types where ROWs occur within the Yukon Territory. Soils from four sites were collected at 1, 30 and 365 days after treatment (DAT) to determine persistence of herbicides for each of three application methods (backpack spraying, cut stump and point injection). Soils from a fifth site were collected as soon as herbicides had dried and at 1, 3, 7, 14, 21, 30 and 60 DAT. Increased sampling intervals were added in order to better determine the half-life of each herbicide in Yukon Territory soils. Herbicide residues are being extracted using traditional methods which vary for each herbicide. Results from the persistence testing will be linked to a species sensitivity distribution (SSD) created by a series of dose response tests, including three soil invertebrates, two non-target plant species and four soil enzymes, in reference soils from each field site. Preliminary results suggest that herbicide residues persist longer in northern regions than in temperate regions, however, these residues are below the protective herbicide concentration, or the concentration that impacts less than 25% of the soil community.

95 Evaluation of the environmental fate and ecotoxicological impact of the pesticide chlorpyrifos in soil for improvement of its risk assessment

V. Storck, INRA Dijon / Agroecology; L. Lucini, Catholic Univ of the Sacred Heart; F. Ferrari, AEIFORIA; E. Papadopoulou, Univ of Thessaly; S. Nikolaki, Univ of Patras / Dept of Environmental and Natural Resources Management; P. Karas, D. Karpouzas, Univ of Thessaly; M. Trevisan, Catholic Univ of the Sacred Heart / Inst of Agricultural and Environmental Chemistry; F. Martin-Laurent, INRA of Dijon / Agroecology

Pesticides protect crops from various pests but can also harm non-target organisms. To minimize risks for the environment and human health, a huge amount of studies are carried out and evaluated during the authorization process of each pesticide. However, the prediction of the environmental fate and ecotoxicological impact of a pesticide remains difficult. Several 100 formerly used pesticides are now banned because unexpected risks emerged decades after their authorization. Risk assessment documents of the organophosphate insecticide chlorpyrifos (CHL) particularly lack information about its degradation and potential transformation products in soil, and its impact on non-target microorganisms supporting soil ecosystem services with impact at the global scale. Within the frame of a large European Marie Curie project, we studied the environmental fate of CHL in a lab-to-field dissipation study by (i) quantifying CHL and its main transformation product 3,5,6-trichloropyridinol (TCP), (ii) screening for known and new transformation products, and (iii) measuring its sorption to soil. Furthermore, the ecotoxicological impact of CHL on the soil bacterial community was estimated by (i) Illumina next-generation sequencing of 16S rDNA amplified from extracted soil DNA, and (ii) monitoring the adaptation of soil microorganisms to repeated CHL exposure by analysis of CHL mineralization. Main results are (i) the identification of known and one new transformation products of CHL, (ii) no effect of CHL on the diversity of the bacterial community in our lab-to-field experiment, (iii) but adaptation to repeated CHL exposure as shown by improved CHL mineralization and by microbial diversity analysis. For further research on CHL biodegradation and as potential candidates for bioremediation, we isolated a CHL-degrading bacterial consortium.

96 So the Soil is Contaminated...Now What?

T. Phillips, exp Services Inc.

The environmental risk assessment process in Ontario has become an exercise in exposure control as opposed to facilitating truly scientific, statistically-based risk analyses, environmentally sound decisions, or smart risk management. Risk-adverse provincial policies, misplaced authority, and the booming condominium industry have driven out science and the opportunity for learned practitioners to make sound judgements, particularly with regards to the management of contaminated soils and protection of ecological health. Moreover, efforts to ensure fully unbiased decision-making have resulted in an onerous administrative process that has nothing to do with environmental protection, but makes claims to that effect. This presentation will outline several "flaws" in the execution of Ontario Record of Site Condition (RSC) Regulation 153/04 from the perspective of how the mandated risk assessment process in Ontario differs from the practice as it is taught by academics, and endorsed by professional toxicologists and the SETAC membership.

Environmental Application of Cell-Based and High-Content Screening Assays for Monitoring Program and Risk Assessment

97 In vitro endocrine activity screening of waste and river waters from the Brussels Region, Belgium using the BG1Luc4E2 CALUX Bioassay

K. Van Langenhove, Vrije Universiteit Brussel / Analytical Environmental GeoChemistry; T. Reyns, Scientific Inst of Public Health Belgium; T. Vandermarken, Vrije Universiteit Brussel / Analytical Environmental GeoChemistry; P. Servais, Université Libre de Bruxelles; M.S. Denison, Univ of California / Dept of Environmental Toxicology; J. Van Loco, Scientific Inst of Public Health Belgium; M. Elskens, Vrije Universiteit Brussel / Analytical Environmental GeoChemistry

Presence of endocrine disrupting or active chemicals in waterways is an ever growing global problem as evidenced by the WFD (2013/39/EU) who prioritized some model estrogenic chemicals into their watch list. Analyzing these substances typically involves separation chromatography coupled to mass detection at high cost per sample. However, performing a first screening of water samples using in vitro assays that detect endocrine selective ligands can help prioritize monitoring sites at lower cost. We therefore studied a highly impacted and urbanized river (Zenne River, Brussels, Belgium) that is composed of up to 50% in WWTP effluent downstream. We collected river water and influent and effluent of 2 major WWTPs (North and South) discharging to the river and a hospital effluent in order to gain more knowledge on their fate upon reaching this urban river. To accomplish this we collected water samples on a monthly basis during 1 year, performed SPE clean-up on the dissolved water phase, and analyzed these extracts using the BG1Luc4E2 in vitro transactivational bioassay to detect endocrine agonist activity. Concentrations of activity (BEQs) are reported as mass E2-equivalent concentrations. One of the most interesting features observed is that activity levels in the river tend to increase along the flow of the river, ranging from 1.34ng E2-eq./L to 3.80ng E2-eq./L at the most downstream site. Effluent levels of the two WWTPs (1.47 and 2.55ng E2-eq./L) displayed similar activity, but are able to drive activity variations depending on the river flow and their relative contribution there to. Influent values of the WWTPs and hospital ranged 1 to 2 orders of magnitude higher and pose real concern when untreated wastewaters are released into the river during combined sewer overflow events, which occur frequently in this water system and urban area. Furthermore, by implementing this monitoring program we obtained (annual averaged) in vitro activity results that surpass the limits proposed by the EU WFD (0.4ng/L for E2 and 0.035ng/L for EE2). Keeping in mind there is no clear-cut extrapolation or correlation between these effect-directed analyses and the chemically based limits, our results indicate this river system is highly impacted with endocrine activity and the responsible agents need characterization.

98 Combining cell-based bioassays, chemical analysis and mixture modelling for water quality monitoring

B. Escher, Helmholtz Centre for Environmental Research GmbH – UFZ / Cell Toxicology; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis; F.D. Leusch, Griffith Univ – Smart Water Research Centre / School of Environment and Smart Water Research Centre; P.A. Neale, Griffith Univ / Smart Water Research Centre; R. Altenburger, Helmholtz Centre for Environmental Research UFZ / Bioanalytical Ecotoxicology

Surface waters and drinking water may be impacted by a wide variety of organic contaminants, including pesticides, pharmaceuticals, industrial compounds and by-products of treatment processes. Cell-based bioassays have been applied for many years to complement chemical analysis for water quality monitoring, but similar to chemical analysis where the selection of target compounds remains a point of discussion, so is the choice of the appropriate biological endpoints and bioassays. Reporter gene assays are popular because they target selected individual nuclear receptors or transcription factors and can be adapted to a well reproducible, high-throughput screening format. The endpoints chosen should be anchored in the framework of the adverse outcome pathways and include several steps of the cellular toxicity pathways, including xenobiotic metabolism, molecular initiating events, adaptive stress responses and cytotoxicity. Here we present a strategy to select appropriate endpoints and apply them to several case studies focusing on the application of these tools for water quality assessment in wastewater, surface water and drinking water. Case studies were drawn from both the European Union project SOLUTIONS, which aims to produce solutions for legacy, present and future chemicals that pose a risk to both ecosystems and human health in European water resources, and from international efforts to harmonise the application of bioanalytical tools for evaluation of water recycling and reuse. Mixture toxicity modelling using the bioanalytical equivalent approach was applied to better link the results of the cell-based bioassays with chemical analysis. The case studies showed that for most endpoints the detected chemicals could only explain a small proportion of the effect, which supports the application of bioanalytical tools complementary to chemical analysis for water quality monitoring.

99 Application of the Attagene FACTORIAL™ assay to characterization of surface waters from a nationwide assessment of streams

B.R. Blackwell, ORISE / National Health and Environmental Effects Research Laboratory; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; P. Bradley, USGS / SAWSC; K. Houck, USEPA / National Center for Computational Toxicology; S. Li, D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory

Bioassays can be used to evaluate the integrated effects of complex mixtures from both known and unidentified contaminants present in environmental samples. However, such bio-monitoring approaches have typically focused only on one or a few pathways (e.g. estrogen receptor, androgen receptor) despite the fact that the chemicals in a mixture may exhibit a range of biological activities. High-throughput screening approaches that can rapidly assess samples for a broad diversity of biological activities offer a means to provide a more comprehensive characterization of complex mixtures. The Attagene Factorial™ platform is a high-throughput, cell based assay utilized by USEPA's ToxCast Program, which provides high-content assessment of over 90 different gene regulatory pathways and all 48 human nuclear receptors (NRs). This assay has previously been used in a preliminary screening of surface water extracts from sites across the Great Lakes. In the current study, surface waters samples from 38 sites were collected, extracted, and screened through the Factorial assay as part of a USGS nationwide stream assessment. All samples were evaluated in a six point, 3-fold dilution series and analyzed using the ToxCast Data Pipeline (TCPL) to generate dose-response curves and corresponding half-maximal activity concentration (AC50) estimates. A total of 27 assay endpoints responded to extracts from one or more sites, with up to 14 assays active for a single extract. The four sites in four different states with the greatest number of active endpoints, ranging from 10 to 14, all were associated with anthropogenic wastewater inputs. Across assay endpoints, pregnane X response element (PXRE), aryl hydrocarbon (Ahr), and estrogen response element (ERE) were the most commonly activated endpoints, at 38, 33, and 25 sites, respectively. The results highlight the applicability of cell based, high-throughput assays, specifically the Attagene Factorial assay, to screening level prioritization of environmental sites or of biological pathways that may be adversely impacted. The contents of this abstract neither constitute, nor necessarily reflect, official USEPA policy.

100 Application of ToxCast to Evaluate Potential Biological Effects from Organic Contaminants in Great Lakes Tributaries

S.R. Corsi, USGS / Water Resources Division; L. De Cicco, USGS / Office of Water Information; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory; B.R. Blackwell, ORISE / National Health and Environmental Effects Research Laboratory; A. Baldwin, USGS / Water Resources Division; D.A. Alvarez, USGS-CERC / Physiology and Biochemistry; A. Schroeder, Univ of Minnesota-Crookston / Math Science and Technology; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; P. Lenaker, USGS / Water Resources Division

With the development of "high throughput" in vitro biological assays, screening-level information on potential adverse biological effects is available for a rapidly increasing number of chemicals. The USEPA ToxCast program has now evaluated several thousand chemicals with more than 800 assays. The original intent of this data was to evaluate potential for human health effects, but it is now being extended to evaluate potential for environmental health effects given that ToxCast is based on evaluation of endpoints that are not necessarily organism dependent. The R software package ToxEval was developed as a screening tool to use ToxCast results for evaluation of potential adverse biological effects from trace organic chemicals in water samples. Using ToxEval, trace organic chemical data from water samples and passive samplers collected at 57 Great Lakes tributaries from 2010-2013 were examined to determine which tributaries had the greatest potential for adverse biological effects, with prioritization of the most influential contaminants. Results are being used as part of the

Great Lakes Restoration Initiative to focus current and future investigations that will help understand likely adverse outcome pathways in organisms, and to formulate possible remediation strategies.

101 Use of cell-based receptor assays to screen for endocrine disrupting chemicals and infer potential toxicity in California waters

A.C. Mehinto, Southern California Coastal Water Research Project / Dept of Toxicology; D. VanDervort, Southern California Coastal Water Research Project; K.J. Kroll, Univ of Florida / Physiological Sciences; S.M. Bay, Southern California Coastal Water Research Project / Toxicology Dept; N.D. Denslow, Univ of Florida / Physiological Sciences; K.A. Maruya, SCCWRP

In vitro cell assays are being considered as bioanalytical screening tools for water quality assessment. Recent studies have shown that they can be used to benchmark water of different qualities, suggesting they can provide valuable information in monitoring programs to identify sites requiring further chemical and toxicity analyses. In this study, commercially available cell assays previously optimized for water quality screening were applied to detect endocrine disrupting chemicals (e.g. estrogens and glucocorticoids) in various aqueous samples from California (USA). Results revealed that secondary treated wastewater effluents had the highest levels of endocrine activity while the majority of freshwater streams analyzed showed little to no bioactivity. To further evaluate the potential of bioscreening cell assays to predict toxicity, a study was conducted to characterize the relationship between in vitro and in vivo responses induced by estrogenic chemicals. Larvae and juveniles of the inland silverside, Menidia beryllina were exposed to two estrogenic chemicals and biological endpoints including growth and gene expression changes were evaluated. Our findings indicate that in vivo effects occur at concentrations higher than in vitro responses, thus highlighting the potential of cell assays as screening tools for both occurrence and adverse effects of chemicals in the environment.

102 The Pro-Inflammatory Properties of Sediment Extracts from a Creosote-Contaminated EPA Superfund Site: Inflammation as a Form of Immunotoxicity

C.D. Rice, Clemson Univ / Biological Sciences; R.A. Silva, Clemson Univ ENTOX / Biological Sciences

The southern branch of the Elizabeth River, near Portsmouth Virginia, USA, is one of the most polluted sub-estuaries in North America, and home to the well-studied Atlantic Wood (AW) EPA superfund site. Prior to closure in 2014, this site was heavily contaminated with creosote, metals, and hydrocarbons. The chemical profile and developmental toxicity of sediment waters, as aqueous extracts, from the AW site has been extensively studied for over 20 years by other labs using Fundulus heteroclitus (Atlantic killifish). Based on decades of experimental research using a variety of mammals and fish, many of the contaminants found at the AW site are predicted to be highly carcinogenic and immunotoxic. Through past collaborations with others, we showed that adult AW killifish collected in situ had severe hepatic lesions, including hepatoblastoma and hepatocellular carcinoma, as well as suppressed circulating antibody responses. We also showed that innate immune functions were higher in AW fish, including elevated expression of COX-2, suggesting a pro-inflammatory environment. To further determine the potential of AW matrices to modulate innate immune function(s), this study used the mouse macrophage cell line RAW264.7 as an in vitro model. This cell line is very well characterized and a common in vitro model system for understanding macrophage-related inflammation profiles in immunotoxicology and immunopharmacology. Compared to reference sediment extracts, filter-sterilized aqueous AW sediment extracts induced inducible-nitric oxide synthase (iNOS) and cyclo-oxygenase-2 (COX-2), as well as nitric oxide and IL-6 secretion, at levels higher than induced by standard lipopolysaccharide (LPS, endotoxin) treatments alone. This enhanced pro-inflammatory property of AW extracts is due, in large part, to high levels of endotoxin(s)s (or similar TLR ligands), as polymyxin-B ameliorates this effect. Finally, using a commercially available limulus lysate assay, we show that bacterial endotoxin levels are significantly higher in AW extracts compared to reference extracts. These data suggest that such high induction of pro-inflammatory activity by contaminated sediment extracts is an expected form of toxicity that should be considered in future environmental immunotoxicology studies.

103 Assessment of Potential Environmental and Health Impact of Coal Ash Spill in Dan River, North Carolina

J. Lan, Northeastern Univ; X. Wen, M. Hu, S. Rahman, S. Kakarla, A. Gu, Northeastern Univ / Dept of Civil and Env Engineering

On Feb 2, 2014, the third-largest coal ash spill of U.S. occurred at Eden, N.C., spewing large amount of coal ash and contaminated water into the Dan River. After the spill, parameters such as TOC and trace elements were monitored by USEPA and Duke Energy, and showed elevated trace elements such as As, Cd, Se and Sr in river water, sediment and soil. The concerns of short and long term impacts of the spill demand investigation of fate and transport of toxic substances released from the ash, as well as the associated toxicity and implied ecological and health risks. This project aims to provide a fast and initial toxicity assessment of Dan River water and sediment with spatial and temporal resolution, using a quantitative toxicogenomics-based in vitro assay platform in both yeast and human cells. Toxicity related to genotoxicity, oxidative stress, chemical stress, protein damage and apoptosis were evaluated using proteomics or transcriptional assays. The toxicity profiles allowed for integrated multivariate statistical tools to reveal temporal and spatial patterns, and the relationship with chemical properties. Surface water and sediment samples from eight sites up- and downstream of the spill at three time points over five months were assessed. Compared to control location upstream of the spill, there seemed to be elevated toxicity in the middle part of the river downstream of the spill, especially for Anglers Park and Milton. Similar trend was also observed for trace elements, with relatively high concentration of As at Anglers Park. Toxicity associated with chemical stress (chemical transport, membrane and cell wall) and general stress (apoptosis, cell signaling and metabolism) were significantly enriched, which was consistent with expected effects of trace elements such as As and Pb. Statistical and correlation analysis, as well as “iceberg” metal mixtures confirmed that that the toxicity detected by yeast library was mainly contributed by the detected trace elements. Dissolved organic matters characterized by TOC and fluorescence spectroscopy seemed to only contribute small portion of the toxicity effects detected in this study. The results suggested potential ecotoxicological implications of trace elements in the coal ash. This study demonstrated the cost-effective toxicogenomics-based in vitro assay platform as an effective toxicity method for timely and informative water quality monitoring, as urgently needed by incidents like N.C. coal ash spill.

104 Quantitative Toxicogenomics Assay Revealed the Impact of Disinfection Technologies On Effluent Toxicity

N. Gou, A. Gu, Northeastern Univ / Dept of Civil and Env Engineering; A. Jia, Univ of Arizona; S.A. Snyder, Univ of Arizona / Chemical and Environmental Engineering

The current water and wastewater treatment effectiveness assessment that focuses on targeted contaminants concentration measurements alone is insufficient because it cannot detect the complex risks resulted from mixtures of many contaminants and transformation products (TPs) in the water. This study applied a novel, fast, and cost-effective quantitative toxicogenomics-based approach for evaluation of the toxicity evolution of wastewater effluents disinfected by different technologies, including chlorination, chloramination, ozonation, UV as well as combination of UV and H_2O_2. The impact on overall toxicity, measured by Microtox test and toxicogenmics assay, varied among different disinfection technologies. The toxicogenomics approach showed consistent yet more sensitive results than Microtox test, therefore resulted less sample enrichment. Moreover, the toxicogenomics assay revealed technology-specific toxicity profiles, indicating distinct nature among disinfection technologies and associated specific mixtures of TPs. Chlorination and ozonation showed the highest toxicity reduction efficiency while chloramination is the worst that actually led to significant increase in the effluent toxicity. Although

UV treatments showed no significantly effects on overall toxicity reduction, the toxicity profiles exhibited unique patterns specific to UV that suggested the presence of DNA-damaging TPs. Combination of UV with H_2O_2 seemed to remove the DNA-damaging substances that generated by UV-treatment alone. To further evaluate the contributions of targeted CECs residues to the overall effluent toxicity, we conducted iceberg experiment that compared the toxicity of artificial mixture of 26 CECs detected in the effluent to those of real effluents. The results showed that for most samples, the targeted CECs in the effluents likely only explain part of the whole water toxicity, indicating that the production of toxic TPs. In addition, it highlights the insufficiency of water quality monitoring based on targeted contaminants concentration measurements alone. In summary, this study demonstrated that toxicogenomics-based assay could not only help to evaluate the impact of technology on overall effluent toxicity, but also reveal potential causal agents and toxicity evolution nature. In company with chemical analysis, this quantitative toxicogenomics approach can help to provide guidance on technology optimization, implementation for effluent risk reduction.

Integrating Life Cycle, Risk and Alternatives Assessment with Exposure Modeling for Chemical Decision-Making

105 Impact of oil spill on a palm oil plantation: a Life Cycle Assessment (LCA) study

A. Onwurah, Univ OF Nigeria, NSUKKA / Environmental Management; A.C. Okoye, Nnamdi Azikiwe Univ, Awka / Dept of Environmental Services

Ecosystems could be wild or managed and in both cases they can serve as sources of food, recreation and even employment. The above then suggests that, ecosystems are prerequisite for health and life. In poor countries, especially in rural areas, the health of rural communities may directly depend on locally productive ecosystems as oil palm plantation by providing sources of some forms of livelihood. An ecosystem could negatively be impacted by pollution as in the case of an oil spill incident that affected Owaza oil palm plantation, Abia State, Nigeria. The Owaza local community's dependent on this plantation (ecosystem) for livelihood is apparent but very fundamental. This paper offers a Life Cycle Assessment (LCA) methodology which hinges on valued ecosystem components (VECs) as suitable indicators for impact assessment of the oil spill incident that affected Owaza oil palm plantation. In this work we considered a goal function of ecosystems which is to maximize the dissipation of ecosystem productivity by maximizing the biological functions of the biotic components of the ecosystem such as communities of plants and animal species found within. These functions include photosynthesis by green plants, biological nitrogen fixation (BNF) by diazotrophic bacteria, and aeration of soil by burrowing activity of earthworms. Crude oil spill impact may decrease ecosystem productivity by decreasing chlorophyll level or inhibiting the sunlight energy-harvesting capacity of chloroplast, reduction in fixed soil nitrogen/nutrient cycling and mortality rate/burrowing activity of earthworms. Within this theoretical framework, an assessment of the impact of crude oil spill in Owaza oil palm plantation was carried out by measuring the capacity of the palm trees (in terms of chlorophyll content) to trap light energy. The technique of measuring solar energy trapping potential of chlorophyll (the palm trees), coupled with impediment on VECs was considered a promising tool. Once operational, it could offer a quick and cheap alternative to evaluate crude oil spill impacts in any terrestrial ecosystem of any size. Integration of the above into an ISO compatible LCA framework may be explored.

106 Joint Uncertainty and Sensitivity Analyses for improved and aligned LCA and RA

S. Cucurachi, Univ of California, Santa Barbara / Bren School of Environmental Science Management; Y. Qin, K. Garner, S. Suh, A.A. Keller, Univ of California Santa Barbara / Bren School of Environmental Science and Management

Several works have signaled the need of integrating the life cycle assessment (LCA) and risk assessment (RA) methodologies, due to several common aspects. In this contribution, we show that a powerful way to reach the integration between LCA and RA is through guaranteeing that the output uncertainty and the input parameters influence on the output uncertainty are carefully studied, and communicated. Even though the topic has been attracting increasing attention of practitioners and experts, there is still a lack of understanding and a limited use of the available statistical tools. In this contribution, we introduce a Monte-Carlo protocol to jointly conduct uncertainty and global sensitivity analyses for both LCA and RA models. We focus on a newly developed multi-media fate and transport model, CLiCC-o. Fate and transport models are at the basis of the impact assessment phase of LCA, but are also directly used to characterize human and ecological safety in RA of chemicals. The output of CLiCC-o can be, in fact, directly compared with risk factors, or, alternatively, connected to an effect and exposure model to calculate characterization factors for LCA impact assessment. We use CLiCC-o as a test case. CLiCC-o has 89 environmental parameters and 12 chemical properties as inputs, and is further defined for 22 compartments (e.g. air, freshwater, marine water) and 6 geographical archetypes (e.g. San Francisco Bay). The outputs of the model are daily concentrations in the 22 compartments and geographies. The model inputs are correlated, the model is highly nonlinear, and highly multiplicative. We show that jointly tackling uncertainty and sensitivity is fundamental to guaranteeing that the modeler has a complete understanding of: (1) the uncertainty of the model outputs (2) the structure of the model and (3) the importance of uncertain model inputs and the interaction among them. The combined use of LCA and RA techniques may further be fostered by such a platform. The protocol helps setting rules and a common shared procedure that puts the uncertainty and sensitivity analyses practice in the field of LCA in line with the practices that are more common in RA community, thus de facto improving the value of the information that the tools provide to decision-makers.

107 What do LCA, Decision Analysis, and Community Resilience have in common? Beyond the Chemical Exposure Models

C. Stahl, USEPA Region III

This presentation will discuss two related topics around the concept of doing multi-criteria environmental assessments that include non-chemical stressors as a step toward nurturing community resilience. These topics are: 1) The importance of distinguishing science from non-science components in LCA and decision analysis, and 2) psychosocial effects as an example of a non-chemical stressor that could be made part of a quantitative assessment. Both of these will be illustrated using a case example, using a first principles-directed approach, the Multi-criteria Integrated Resource Assessment (MIRA). What do we want to assess? How to assess the environmental condition of an area subject to mining or drilling? What are the factors that go into answering these questions and are they all purely scientific? Likely not. Much of what is actually missing isn't science but how we use the science, a subjective but (hopefully) not arbitrary decision. Making this distinction between what is science and what is not increases our capability to seek more appropriate approaches to fill in gaps. Do we run an exposure model, build a new model or tool, conduct an expert elicitation or better understand stakeholder needs and values? As we talk about gap-filling, what are the data for non-chemical stressors, such as psychosocial effects? How can we avoid committing the sin of measuring what we can instead of measuring what is important; and how can we avoid perpetuating this into our decision making? Communities often name psychosocial effects as some of their most important concerns and yet, statutory and regulatory requirements, Agencies, and exposure models do not address them. Aside from the discomfort of considering a non-chemical stressor that is viewed as amorphous, untestable, or subjective, excuses about lack of studies or data are often used to justify excluding these kinds of stressors. However, if we change how we think about indicators, it is possible to think quantitatively about qualitative things. We talk broadly about seeking to achieve resilience. However, achieving resilience is not limited to those parameters that are described by the outputs from chemical exposure models. Resilience isn't just for the hippie tree-huggers. Learn how your technical and scientific knowledge can be part of the solution set.

108 Integrating risk metrics into Life Cycle Assessment using rapid exposure modeling for consumer products: Air freshener case study

S.A. Csiszar, Oak Ridge Inst for Science & Education at USEPA / National Risk Management Research Laboratory; D.E. Meyer, K.L. Dionisio, USEPA / National Exposure Research Laboratory; P. Egeghy, USEPA / Office of Research and Development; K.K. Isaacs, P.S. Price, USEPA / National Exposure Research Laboratory; K.A. Scanlon, AAAS Science & Technology Policy Fellow hosted at USEPA; C. Tan, K. Thomas, D. Vallero, USEPA / National Exposure Research Laboratory; J.C. Bare, USEPA / National Risk Management Research Laboratory

A case study was performed to explore methods to integrate high-throughput risk-based screening into life cycle assessment (LCA) for consumer products. It has been recognized that combining LCA and risk assessment (RA) can lead to more comprehensive assessments. LCA evaluates multiple impacts such as climate change, land use, and human health impacts associated with a product, system, or service. Single chemical human health RA (HHRA) evaluates the probability of adverse response associated with human exposures to a given chemical. One difference between LCA- and RA-based exposure calculations is that in LCA calculations are conducted based on a functional unit of the product being studied and in RA dose estimates are often based on exposure to all sources of a chemical. One interesting application of the combination of LCA and HHRA is the analysis of consumer products, to account for environmental sustainability metrics for a product alongside human health risks associated with exposures to chemicals in the product. Exposures to chemicals associated with consumer products can be substantially larger via indoor and near-person pathways (near-field) compared to exposures resulting from releases to the outdoors. This implies that for many chemical-product combinations there may be a higher probability of risk from near-field chemical sources compared to chemicals released outdoors. Methods to prioritize and screen chemicals for risk are becoming available and are based on high-throughput exposure modeling and screening toxicity data; however these methods have yet to be incorporated into LCA. 1,4-dichlorobenzene (p-DCB) in an air freshener was used as the chemical-product combination in the case study. LCA human health impact scores were calculated for p-DCB based on typical household use of an air freshener. High-throughput risk-based screening was based on use of p-DCB in all relevant product types. Both methods indicated that exposure to p-DCB was dominated by near-field exposure pathways by at least two orders of magnitude. The risk-based screening also suggested that exposure to p-DCB was dominated by consumer product sources other than the air freshener. This case study can be used to inform the methodological integration of LCA with risk-based screening methods and to further investigate how results from risk metrics can be incorporated into the interpretation of LCA results taking into account other environmental impacts.

109 Human health risk evaluation from chemical exposure in an LCA context – ProScale

T. Rydberg, IVL Swedish Environmental Research Inst; E. Lundström Belleza, IVL Swedish Environmental Research Inst / Dept of Applied Environmental Science; J. Lexén, C. Loh Lindholm, IVL Swedish Environmental Research Inst; Q. de Hults, BASF SE / European Construction Competence Center; P. Saling, BASF SE / Sustainability Strategy; P. Coërs, E. Van Miert, Solvay SA; A. Wathelet, Solvay SA / LCA; T. Tiemersma, X. Weinbeck, DSM Engineering Plastics B.V; M. Glöckner, Deutsche Bauchemie e.V.; N. Amann, Wacker Chemie AG; P. Ashford, R. Norriss, Anthesis Group; D. Koelsch, Bayer Technology Services GmbH; C. Karafilidis, Covestro Deutschland AG

Increasingly, various stakeholders require information on eco/toxicity aspects of products beyond regulatory requirements for chemicals, e.g. in the framework of Life Cycle Assessment ("LCA"). There is currently no methodology available which fully satisfies the requirements of the industry and other stakeholders in this context, but requirements are often based on lists for priority substances without evaluating their risk in specific applications. This calls for a performance based indicator that can be used and communicated within LCA's, Environmental Product Declarations ("EPD's") and Product Environmental Footprints ("PEF's"). The work presented here is performed in an ongoing project, ProScale, for developing a method for comparing hazard and exposure potential to chemicals constituents of products in a life cycle perspective. The primary intended use is a performance indicator to be provided as additional information in LCA and particularly in PEF and EPD according to the international standards ISO 14025 and EN15804 alongside other LCA impact categories. The ProScale partners are: BASF, Covestro, Deutsche Bauchemie, DSM, IVL, Kingspan, Solvay. The project runs in its current phase until end of 2016. The method developed aims to be a science-based, transparent, pragmatic and generally applicable methodology for a toxicological exposure assessment of products, and should be characterized by: (i) assess the relevant direct exposure potential along the whole life cycle; (ii) use existing data, e.g. REACH based; (iii) allow comparison in relation to technical performance; and (iv) be relevant for business-to-business and business-to-customer communication.In brief, the method is starting from the product ingredients and combines hazard factors and exposure factors for each substance and life cycle stage. The chosen approach for the hazard factor is based on H-phrases, as these are readily available. An ongoing challenge is to refine this approach through the application of a potency factor based on, e.g., derived no-effect levels (DNEL) or occupational exposure limits (OEL). The chosen approach for the exposure factor is to make use of exposure modelling tools available, such as ECEtocTRA or similar for occupational exposure and ConsExpo for consumer exposure. An ongoing challenge here is to safeguard that different modelling tools used for different exposure give compatible results. Initial results based on case studies will be presented.

110 Elements from hazard, exposure, and life-cycle to inform an integrated approach for assessing alternatives

A.M. Mason, American Chemistry Council / CPTD; B. Howard, American Chemistry Council / Value Chain; R. Ehrlich, American Chemistry Council; S. Arnold, The Dow Chemical Company; T. Kingsbury, TKingsbury LLC

The community working to assess alternative ingredients and products face a variety of challenges to balance sometimes competing goals including 1) reduction of the risk associated with chemical ingredients; 2) rewarding chemicals and products that are designed using the principles of green engineering and chemistry; 3) viewing multiple impacts across the spectrum of life cycle stages, all the while 4) maintaining functional and economic performance. Overall, any alternative chemical or product must perform similarly or better than its predecessor, be measurably safer for the user and the environment, and have an economic profile comparable to the chemical or product it replaces. Full alternative assessments as currently practiced involve a substantial amount of expert resources, data, and time so it is important that there is a screening approach to focus resources on viable candidates. Given the broad spectrum of functional roles chemicals and products play, there is currently no “best” solution that will work in all circumstances. This work suggests a set of concepts and elements useful for a screening-level evaluation that directly responds to the question or problem and provides relevant information to the decision at hand. The goal is to suggest conceptual elements and approaches to relate risks with life cycle environmental impacts and to discuss the challenges and possibilities when working toward a process for integrated decision-making. A series of case studies or examples will be used to illustrate the concepts.

111 Integrating Exposure into Chemical Alternatives Assessment Using a Qualitative Approach

B. Greggs, Soleil Consulting, LLC; S. Arnold, The Dow Chemical Company; T.J. Burns, Novozymes; P. Egeghy, USEPA / Office of Research and Development; P. Fantke, Technical Univ of Denmark / Quantitative Sustainability Assessment Division; B. Gaborek, DuPont; L.G. Heine, Lauren Heine Group LLC; O. Jolliet, Univ of Michigan; C. Lee, ExxonMobil / Dept of Tox Enviro Chemistry; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; K. Plotzke, Dow Corning / Health Environmental Sciences; J.P. Rinkevich, SciVera LLC; N. Sunger, West Chester Univ; J. Tanir, HESI; M. Whittaker, ToxServices LLC

Most alternatives assessments (AA) published to date are largely hazard-based rankings, and as such may not represent a fully informed consideration of the advantages and disadvantages of possible alternatives. With an assessment goal of identifying an alternative chemical that is more sustainable, other attributes beyond hazard are also important, including exposure, risk, life-cycle impacts, performance, cost, and social responsibility. Building on the 2014 recommendations by the U.S. National Academy of Sciences to improve AA decisions by including comparative exposure assessment, the HESI Sustainable Chemical Alternatives Technical Committee, which consists of scientists from academia, industry, government, and NGOs, has developed a qualitative comparative exposure approach. Conducting such a comparison can screen for alternatives that are expected to have a higher human or environmental exposure potential, which could trigger a higher-tiered, more quantitative exposure assessment on the alternatives being considered, minimizing the likelihood of regrettable substitution. This talk will demonstrate an approach for including chemical- and product-related exposure information in a qualitative AA comparison. Starting from existing hazard AAs, a series of three chemical-product application scenarios were examined to test the concept, to understand the effort required, and to determine the value of exposure data in AA decision-making. The group has developed a classification approach for ingredient and product parameters to support comparisons between alternatives as well as methodology to address exposure parameter relevance and data quality. The ingredient parameters include a range of physicochemical properties that can impact routes and magnitude of exposure, while the product parameters include aspects such as exposure pathways, use pattern, frequency/duration of use, chemical concentration in product, and use volume, accessibility, and disposal. Key learnings, challenges, and opportunities for further work will also be presented. The views expressed in this presentation do not necessarily reflect the views or policies of the U.S. Environmental Protection Agency.

112 Hazard and Exposure Assessment Screening in Alternatives Assessment

H. Plugge, 3E Company

Establishing functionally equivalence criteria for a chemical/product of concern is a first step in alternatives assessment. Whether de novo designed or selected from the library of existing chemicals, all alternatives will need to undergo a hazard assessment and exposure assessment screening phase. Different hazard assessment methodologies provide apples and oranges as effects making it very hard to compare overall impacts from different alternatives. The presentation will demonstrate a hybrid scientific data/classification approach to hazard screening /assessment, using a composite scoring system for each individual aspect of health effects. Screening of health effects using this methodology would allow the non-expert to derive a preliminary hazard screening. One of the outcomes of this screening would be the identification of datagaps and data anomalies. A near simultaneous step would be the performance of an exposure screening where preliminary simplified exposure assessment data are derived allowing the calculation of a relative risk screening. Again the units here are consistent in a simplified assessment such as this, allowing easy summation for each alternative. More user input would be required here to allow the establishment of realistic exposure scenarios. Preliminary life cycle considerations can also be reviewed at this stage, although not required under the new TSCA regulations. This risk (= exposure * hazard) screening process only weeds out the really much worse alternatives. In addition significant datagaps will be identified. Hence a feedback cycle with screening is established – as datagaps are filled (using Read Across and QSAR among others) , the screening assessment will become more accurate. The number of alternatives which are about equal (or better) than the initial chemical/product, will hopefully be whittled down to about three. A detailed assessment is then to follow using additional data analytics and data gap filling techniques to derive as complete a database as possible with the available resources.

New and Persistent Contaminants in the Environment from the Reuse of WWTP Effluent Streams

113 Identification of Emerging Contaminants from a Waste Water influenced water body Using High Resolution Accurate Mass LC/MS and Statistical Analysis

T. Anumol, Agilent Technologies Inc.; L. Kennedy, Mansfield Univ; J. Zweigenbaum, Agilent Technologies, Inc

Historically pristine sources of water are under increasing threat of contamination from a plethora of point and non-point discharges. With over 15,000 new chemicals introduced daily it is impractical and economically unfeasible to monitor each one. Non-targeted methods using high resolution accurate mass MS can identify many compounds, but the contents of these discharges are not often available in databases. Determination of what components are significant and focused identification of these compounds are critical, but difficult given the variability of environmental samples from the same sampling points at different times. This work examines LC/HRMS data of two creeks in Pennsylvania that feed into the Susquehanna river which is the drinking water source for millions of Americans in the north east. The creeks are impacted by agricultural runoff, fracking and a wastewater plant discharge and were monitored over 6 months using multivariate statistics to determine compounds that should be monitored. 6 creek samples, a sample of the wastewater effluent discharging into the creek, filed and lab blanks were collected and then analyzed using automated online solid phase extraction and an LC-QTOF/MS. Initial Non-targeted analysis using the accurate mass pseudo-molecular ions and fragments of real LC peaks co-eluting against the custom database gave positive identification including pharmaceuticals, pesticides, personal-care products and others using databases and libraries. A statistical analysis of the samples was performed to find different features in each sample. PCA of the statistically significant compounds showed that the wastewater effluent replicates formed a tight group well separated in the first principle component from all other groups. The creek sample downstream was slightly separated from the final effluent but well separated from the upstream creek samples. All blanks formed a tight group well separated from the others. The PCA analysis demonstrates that the statistical procedures can distinguish compounds found at the different points of collection. The non-targeted database analysis also demonstrates that although compounds of interest can be determined, there are many more compounds that cannot using a limited database and statistical analysis will assist in identifying relevant and ‘emerging’ contaminants to be monitored in the future.

114 Wastewater Recycling in Antarctica – Challenge of Micro-contaminant Assessment by Passive Sampling

M. Allinson, The Univ of Melbourne / School of Chemistry; G. Allinson, RMIT Univ / School of Science; K. Kadokami, The Univ of Kitakyushu; M. Packer, Australian Antarctic Division; S. Gray, Victoria Univ; P. Scales, The Univ of Melbourne

The Australian Antarctic Division (AAD) operates Australia's Davis station in the Antarctic and has decided to install a new advanced water treatment plant (AWTP) in conjunction with a secondary wastewater plant to ensure discharges to the environment meet world's best practice. The AWTP was tested during 2014-16 using water from a municipal wastewater treatment plant in Tasmania to see whether it was capable of producing potable water and a non-toxic brine concentrate that can be discharged with minimal environmental impact. The process requirements of the AWTP are small (~20 kL/day) and although the inputs to the plant are source defined because of the known community size and chemical manifests, without the dilution achieved in large scale WWTPs there is potential for spikes in chemical contaminants. One of the challenges for the AWTP is to adequately meet the risks associated with chemicals (single chemicals and mixtures) in its product water. One option is to use passive sampling. In 2015-16, we deployed Chemcatcher passive samplers in the Feed Water, RO concentrate (environmental discharge) and Final Product Water (recycled water). The passive samplers were deployed for one month, with water sampling on the day of deployment and retrieval the following month when a new passive sampler was deployed. This process was undertaken for consecutive months in the autumn of 2015, and then again for 2 months in the winter of 2016. Each passive sampler replicate contained either an Empore™ SDB-XC or an Empore™ C18FF disk, respectively, covered by a polyethersulphone (PES) or Omnipore rate limiting membrane (to stop the receiving phase becoming saturated too quickly). Two multi-residue chromatographic-mass spectrometric methods and a range of recombinant receptor-reporter gene bioassays were used to screen trace organic chemicals (TrOCs), toxicity and receptor activity of the water and passive sampler extracts. This paper will discuss the potential environmental and human health risks of the chemicals observed in water and passive sampler extracts, and the suitability of passive sampling for monitoring the performance of the AWTP in Antarctica.

115 Interactions between dissolved organic matter, organic pollutants and carbon nanotubes in the environment

M. Engel, The Hebrew Univ of Jerusalem; B. Chefetz, The Hebrew Univ of Jerusalem / Soil and Water Sciences

In recent years, herbicides and pharmaceuticals have been frequently detected in aquatic environmental systems. Their presence poses a major threat and therefore efforts must be invested in expanding our knowledge on the behavior of such pollutants in the aquatic environment and in exploring prospective applications for their removal. Carbon nanotubes (CNTs) have drawn special attention in light of their superior adsorptive capabilities. Furthermore, their increasing use will inevitably lead to their release into environmental systems where they may interact with organic pollutants and dissolved organic matter (DOM). Adsorption of organic compounds by CNTs has been widely examined, but the effects of DOM on adsorption under different solution conditions have been rarely addressed. Hence our main objective was to research the influence of DOM on adsorption of the herbicide atrazine and anticonvulsant drug lamotrigine by CNTs in varying solution conditions and introduction stages of DOM. This study shows that atrazine and lamotrigine compete over the same adsorption sites. However atrazine was a far more effective competitor than lamotrigine, suggesting there are adsorption sites preferentially occupied by atrazine. The presence of DOM greatly suppressed adsorption of both pollutants. For example, in the midst of their adsorption isotherms, adsorption of atrazine decreased by 94%, and that of lamotrigine by 69%, at high concentration of DOM, respectively. This may be attributed to competition or blockage of adsorption sites by DOM. However, decrease in adsorption of lamotrigine may also be allocated to the formation of a stable DOM-lamotrigine complex with lower affinity to the CNTs. Increased stability of lamotrigine (and not atrazine) was demonstrated by its enhanced solubility in DOM solution (solubility of lamotrigine was increased by up to 70% in DOM solution). When the CNTs were first exposed to DOM, adsorption of both pollutants was greatly suppressed. But when the pollutant was given the initial advantage, its' adsorption still decreased after DOM was added to solution. This finding implies there are DOM molecules with higher affinity to the CNTs which can replace the adsorbed pollutant and force its' release back into solution. Our findings will advance the understanding of interactions between organic compounds and CNTs in environmental systems containing DOM and improve the potential employment of CNTs in organic pollutant removal technologies.

116 Occurrence and Mass Balance of Fipronil & its Degradates in Wastewater and Biosolids of Eight Wastewater Treatment Plants in Northern California

A. Sadaria, Arizona State Univ ; S.D. Supowit, Arizona State Univ / Biodesign Center for Environmental Security; R. Sutton, San Francisco Estuary Inst; K. Moran, TDC Environmental, LLC; J. Teerlink, California Dept of Pesticide Regulation; R.U. Halden, Arizona State Univ / Biodesign Center for Environmental Security

Fipronil is a phenylpyrazole insecticide used primarily in urban areas for outdoor and subterranean pest control and pet flea treatment. Recently it has been shown to adversely affect sensitive non-target aquatic invertebrate species at low part-per-trillion concentrations (< 100 ng/L), and also has been identified as a chemical of concern in the global collapse of honeybee colonies. The objectives of this study were to (i) conduct a mass balance assessment during activated sludge treatment; (ii) evaluate the occurrence and fate of fipronil and four of its major degradates during treatment, at eight wastewater treatment plants (WWTPs) of Northern California sampled under low-flow drought conditions. Analytes were determined by liquid chromatography tandem mass spectrometry (LC-MS/MS). Mass balance was conducted at a conventional WWTP located in southwestern U.S. and based on flow-weighted samples collected on five consecutive days. Aqueous phase total fipronil appeared to pass through treatment, as mean daily loads of total fipronil related compounds in aqueous phase of raw sewage versus treated effluent ($p = 0.29$) were virtually unchanged. In the eight studied WWTPs, fipronil and its sulfone and sulfide derivatives were detected with 100% frequency in all influent and effluent samples, with concentrations ranging between 13-88 ng/L, 1-28 ng/L, and 1-5 ng/L, respectively. Fipronil amide, a product of fipronil hydrolysis, was absent in all influent samples but detectable in effluent of seven of the plants at concentrations ranging between 1-4 ng/L, suggesting hydrolysis during biological treatment. When taking into account the mass of fiproles associated with particulate matter, a small fraction of the total fiprole loading (35 ±11%) partitioned into sludge and thus was removed but not degraded during wastewater treatment. Overall, 65 ±11% of the total mass of fipronil related compounds entering the plants remained were discharged in treated effluent to surface waters. Concentrations of fipronil compounds detected in sludge ranged between 0.1-91 μg/kg dry weight. The ratio of sulfone and sulfide degradates to fipronil was higher in biosolids when compared to raw wastewater. Results suggest that none of the treatment processes examined in this work provide significant fiprole degradation, resulting in unwanted insecticide presence in both treated effluent and sludge.

117 Kinetics of carbamazepine uptake, transformation, and metabolism in cucumber plants and its drug-drug interaction with lamotrigine

M. Goldstein, M. Shenker, B. Chefetz, The Hebrew Univ of Jerusalem / Soil and Water Sciences

Carbamazepine is a common drug used for the treatment of seizures in epilepsy patients. Carbamazepine is found at low mg/L levels in many sources of drinking water, and in fresh water and treated wastewater used for crop irrigation. Its nonionic state and log Kow of 2.45 make it easy to cross membranes, and to be translocated in the plant predominantly with the transpiration stream, thus accumulating mostly in the leaves. In past studies, we have demonstrated the uptake, translocation, accumulation and metabolism of carbamazepine in several cropsin different soils irrigated with treated wastewater. A number of carbamazepine metabolites are known to be as pharmacologically active as the parent compound and in some cases may be of toxic nature, thus highlighting the need to follow metabolism of pharmaceutical compounds in plants. In this study a timeline of the uptake and translocation of carbamazepine and the formation of several of its metabolites were established over a time period of 96 hours for cucumber plants grown under hydroponic culture. Drug-drug interaction with lamotrigine, also used in the treatment of epilepsy, was evaluated. A linear increase in carbamazepine concentration in both roots and shoots was found and the rate of uptake was shown to be at a lower rate than water uptake, indicating its permeability is lower than reported in past publications. As well as the parent compound, we were able to identify and quantify several of its metabolites. The main metabolites found were 10,11-epoxide-carbamazepine (which is a reactive and pharmacologically active compound), 10,11-dihydroxy-carbamazepine, 2-hydroxy-carbamazepine and 3-hydroxy-carbamazepine. These are also the main products of carbamazepine metabolism in the human liver. Enhanced root metabolism was identified between 72-96 hours pronounced by an elevated 10,11-epoxide-carbamazepine concentration in the plant sap. In the presence of lamotrigine, lower concentrations of 10,11-epoxide-carbamazepine were found in the plant material, indicating decreased metabolism caused by drug-drug interaction. This data is of great importance for further understanding plant uptake and metabolism of xenobiotics – their formation and accumulation in different plant compartments.

118 Comparison of the relative efficacy of two cost effective sampling approaches for fingerprinting VOC emissions from land-disposed sewage sludge wastes

T. Telkamp, H. Juntunen, L. Leinen, Dakota State Univ / Chemistry / College of Arts and Sciences; R. Honour, The Precautionary Group; R.C. Hale, Virginia Inst of Marine Science / Aquatic Health Sciences; M. Gaylor, Dakota State Univ / Chemistry / College of Arts and Sciences

About 8 million dry tons of sewage sludge is generated annually in the US, with well over half now disposed on agricultural and forested lands as soil amendments known euphemistically as "Biosolids." Though containing beneficial nutrients for plant growth, sludge also contains complex mixtures of volatile organic compounds (VOCs) that generate odoriferous and toxic emissions. Indeed, we have observed first hand the stifling odors, as well as acute toxicity of large-scale sludge disposal to resident macrobiota of the sensitive rainforests of the Puget Sound watershed. Though ecotoxic impacts are a primary concern, it is the repugnant odors that are most obvious to and disconcerting for the public and which have escalated concerns for the safety of this practice. Measuring volatile emissions from sludge in situ is challenging, typically requiring complex and costly apparatus. To address this problem, we hypothesized that simple low-density polyethylene plastic strips could be deployed at sludge disposal sites to characterize associated VOC emissions for minimal cost and sampling effort. To evaluate their potential for this, we conducted a controlled headspace exposure assay to assess the capacity for these simple devices to effectively sample sludge-associated VOCs and provide diagnostic fingerprints thereof. For comparison, we also evaluated the efficacy of simple headspace sampling using gas tight syringes. While both approaches revealed emissions of complex VOC mixtures (e.g. hydrocarbons, halogenated hydrocarbons, phenols, ethers, amines, organosulfides, plasticizers and personal care product constituents, etc.) in the ppb to ppm range, each yielded distinct VOC fingerprints. These findings demonstrate the prospective utility of these very simple sampling approaches to provide low cost/low effort diagnostic fingerprints of VOC emissions from land-disposed sewage sludge.

119 Behavior of polyfluorinated alkyl substances, including PFOS and PFOA, in wastewater systems: Experiences from multiple studies in North America

B. Chandramouli, R.D. Grace, SGS AXYS

Poly- and per- fluorinated alkyl substances (PFAS) including perfluorooctanoate (PFOA) and perfluorooctanesulfonate (PFOS) are ubiquitous in the environment due their persistence, and the widespread historical and continuing use of a variety of fluorinated chemicals in applications ranging from fire fighting, mist suppression, food packaging, stain and water resistance application in clothing, and more. Analytical and regulatory attention has focused primarily on PFOS and PFOA, and more recently, on other per- and polyfluorinated compounds in groundwater and other contamination associated with fluorinated compound manufacture, AFFF sites, and industrial sites. WWTP plants also have significant loadings of PFAS, including a wide variety of more complex polyfluorinated compounds that may transform into perfluorinated carboxylic acids (PFCAs) and perfluorinated sulfonic acids (PFSAs) that can be more persistent in the environment than the precursors. These transformations have been observed in both ambient conditions, and in wastewater treatment plants. Therefore, understanding the fate, transformation and mass balance of PFAS through the wastewater treatment process is critical. Current research indicates an increase in PFCAs and PFSAs through conventional wastewater treatment processes, and potential for formation of PFCAs and PFSAs from a wide variety of chemistries, including fluorotelomer alcohol and sulfonate based products. In this work, PFAS occurrence and behavior from multiple studies in WWTP processes in North America is summarized. All analytical work was carried out using isotope dilution/surrogate standard quantitation LC-MS/MS techniques that provided recovery correction and accounting for matrix effects. This enabled robust cross- compartment and inter-study comparisons, partitioning calculations, mass balance studies and more. The analysis of WWTP components presented specific analyte challenges, primarily matrix suppression, which was identified and compensated for using isotope dilution and other analytical techniques.

120 Comparing the environmental input of emerging contaminants from conventional and alternative WWTPs: a targeted and suspect screening study

A.D. McEachran, North Carolina State Univ / Forestry and Environmental Resources; R. McMahen, USEPA; S. Newton, USEPA / Dept of Applied Environmental Science ITM; M.J. Strynar, USEPA / National Exposure Research Laboratory; D. Shea, North Carolina State Univ; E. Nichols, NC State Univ / Forestry and Environmental Resources

Wastewaters are a well-defined source of emerging contaminants into the environment. Conventional, tertiary wastewater treatment systems do not effectively remove many emerging contaminants, including pharmaceuticals and perfluorinated compounds, resulting in the discharge of chemical contaminants into waterways. Forest-water reuse systems are alternative wastewater treatment systems that infiltrate municipal, industrial, and agricultural wastewater through forest soils via slow-rate irrigation. Forest-water reuse systems provide ecosystem service benefits and are lower cost and energy than conventional treatment systems and have recently been investigated as to their pharmaceutical input. However, to better understand their role as a source of emerging contaminants, these systems need to be directly compared to conventional systems. In this study, both a quantitative, targeted and qualitative, suspect screening approach were utilized at a forest-water reuse system and conventional tertiary wastewater treatment system to better understand how emerging contaminant input from a forest-water reuse system compares to a conventional system. Quantitatively, greater concentrations and total mass flow of pharmaceuticals was exhibited downstream of the conventional treatment system. From a suspect screening standpoint, more confirmed chemicals were present, and at a greater relative abundance, downstream of the conventional system as well. This data shows that forest-water reuse systems can reduce the environmental input of emerging contaminants to a greater degree than conventional systems.

Chemical, Biological and Instrumental Methods for Detecting Harmful Algae and Their Natural Toxins

121 Prevalence of cyanotoxin microcystin-LR in sediments in California's Stream Pollution Trends (SPoT) Program and potential toxicity to invertebrates

K. Siegler, Univ of California – Davis / Environmental Toxicology; E. Stanfield, California State Univ Monterey Bay; B.M. Phillips, B.S. Anderson, Univ of California – Davis / Dept of Environmental Toxicology; J.P. Voorhees, Univ of California Davis / MPSL Environmental Toxicology; L. McCalla, Univ of California Davis; S. Zamudio, Univ of Califorina Davis; R.S. Tjeerdema, Univ of California – Davis / Environmental Toxicology

Cyanobacterial harmful algal blooms (CHABs) are an emerging threat to drinking water resources. Microcystis cyanobacteria can release hepatotoxins which affect diverse taxa. Microcystins are stable cyclic heptapeptides that may persist in the environment for weeks to months in water and sediments. Most monitoring efforts have focused exclusively on water samples. California's Stream Pollution Trends (SPoT) Program monitors 100 base of the watershed sites to assess long term trends in toxicity, contaminants and land use. In collaboration with California State University Monterey Bay, SPoT has identified microcystin-LR presence in sediments monitored statewide using modified extraction methods and quantified using enzyme-linked immunosorbent assay (ELISA). Microcystin-LR was detected in 31% (n = 108) of the samples in 2014 and 13% (n = 96) in 2015. Microcystins were found in sediments from diverse habitat types and land uses. In both years, a subset of sites were analyzed in an inter-laboratory method validation study, using ELISA as well as LC-MS. By evaluating sediments at the base of major watersheds throughout the state, SPoT provides a baseline assessment for microcystin-LR prevalence and occurrence statewide. In order to assess the ecological implications of algal toxins in streambed sediments, studies are underway to determine the potential for chronic toxicity to aquatic invertebrates and bioaccumulation with10 d Microcystis exposures using the midge Chironomus dilutus. In addition, experiments evaluating toxicity of anatoxin-a from Phormidium sp. to the amphipod Hyalella azteca, midge C. dilutus, and cladocera Ceriodaphnia dubia will be presented and discussed.

122 Method Development, Monitoring, and Occurrence of Microcystins in Ambient Water

D. Tettenhorst, USEPA / NERL; J. Allen, A. de la Cruz, J. Shoemaker, USEPA / Office of Research and Development

The occurrence and intensity of cyanobacterial harmful blooms have become increasingly common over the last few decades. Cyanobacteria are a worldwide concern in areas with eutrophic water conditions. Cyanotoxins generated from cyanobacteria are harmful ecologically, cause economic impact, and are a public health threat. The accurate detection of harmful cyanotoxins has become increasingly important in the protection of human and ecological health. The USEPA has taken steps to improve the analytical methodology available for the detection and quantification of cyanotoxins. Specific steps include developing methods for cyanotoxins in drinking and ambient water and providing standardized detection and analysis methods for emerging cyanotoxins of concern. EPA recently developed Method 544 for determination of microcystins (MCs) in drinking water using solid phase extraction (SPE) and liquid chromatography/tandem mass spectrometry (LC/MS/MS). Method 544 has been modified for use in ambient water. A review of these methods will be presented with a summary of the challenges associated with method development and modifications for ambient water analysis. A monitoring study for cyanotoxins was conducted in a local Ohio lake in 2015 and again in the summer of 2016. Total MC (extracellular + intracellular toxin) concentrations for thirteen MC congeners at several sites within the lake were measured. A summary of MC concentrations in water samples will be presented, including congener type and the frequency of detection. A comparison of concentrations measured by LC/MS/MS and enzyme-linked immunosorbent assay (ELISA) will be presented, along with a comparison of data from the 2015 and 2016 sampling seasons. In a separate but related study, water samples will also be collected from various lakes or rivers around the United States with moderate to severe cyanobacteria blooms. Data will be presented from these samples for MC concentration, congener profile, and comparison to ELISA concentration.

123 Comparative measurement of microcystins in diverse surface waters using ADDA-ELISA, LC-MS/MS, and MMPB techniques

T. Sanan, United States Environmental Protection Agency / National Risk Management Research LaboratoryW ater Supply and Water Research Division Treatment Technologies Evaluation Branch; D. Lytle, USEPA / Office of Research and Development

The measurement of microcystins, cyanotoxins associated with cyanobacterial blooms which are increasingly prevalent in inland waters, is complicated by the diversity of congeners which have been observed in the environment. At present, more than 150 microcystin congeners have been identified, and this poses a significant challenge to analytical methods intended to assess human health risks in surface and drinking water systems. The most widely employed analytical method at present is the ADDA-ELISA technique which is potentially sensitive to all microcystins, but it is primarily intended as a semi-quantitative method, and questions have been raised regarding the potential for cross-reactivity and false positives. LC-MS/MS methods targeting specific congeners, such as USEPA Method 544, are intended for use as a secondary confirmation following a positive ELISA response, but these techniques can target only those congeners for which commercial standards are available. Accordingly, they are not suitable for ascertaining the safety of a given water sample, given the potential for omitting unknown microcystin congeners which may be present. An alternative approach involves oxidative transformation of microcystins to a common product, 2-methyl-3-methoxy-4-phenylbutyric acid, or MMPB. Measuring MMPB by LC-MS/MS can potentially provide a metric for the sum of all microcystin congeners present in a sample, subject to the efficiency and overall yield of conversion. The present study discusses the results from the application of the MMPB method, applied in conjunction with ADDA-ELISA and individual congener measurement using LC-MS/MS, to measure microcystins in bloom-impacted surface water samples obtained from multiple sites across the United States. Results of toxin measurements will be compared between sites and analytical techniques, and optimized conditions for the MMPB procedure will be presented.

124 Cyanotoxin occurrence associated with cyanoHAB events on an inland reservoir

J. Allen, J. Shoemaker, USEPA / Office of Research and Development; J. Lu, USEPA ORD Cincinnati; J.W. Santo Domingo, USEPA / Cincinnati; C.T. Nietch, M. Elovitz, USEPA / Water Supply and Water Resources Division; D. Tettenhorst, USEPA / NERL; K. Daniels, USEPA / Water Supply and Water Resources Div; S. Guglielmi, Pegasus Technical Services Inc. / co USEPA Cincinnati; M. Varner, USEPA ORD; T. Neyer, Clermont County, OH

A monitoring approach combining wet chemistry and high frequency (HF) water quality sensors has been employed to improve our understanding of the ecology of an inland reservoir with a history of cyanoHAB events. Lake Harsha is a multi-use reservoir managed by the USACE in southwest OH that has experienced an increase in cyanoHAB frequency and intensity. Nutrient, algal taxa, chlorophyll-a, and physico-chemical data have been collected on the lake since 2010 at three week intervals. Beginning in 2014 in cooperation with Clermont County Drinking Water Division, a high frequency monitoring program was implemented to complement the tri-weekly data and provide DWTP operators time-relevant information regarding source water quality. High frequency data included in vivo fluorescence and physico-chemical parameters and were collected at two locations. These data, coupled with microcystin (MC) analyses demonstrated the utility of HF data for tracking the cyanoHAB status of the reservoir. It was also apparent that MC concentrations were potentially underestimated as MC sampling did not coincide with bloom peaks indicated by the HF data. To better characterize the cyanobacterial population and both intracellular and extracellular MC production, an intensive sampling regime was implemented in 2015 and 2016 including LC-MSMS analysis of select MCs, cylindrospermopsin, and anatoxin-a, MC ELISA quantification, molecular analyses, inhibition assay, nutrients, chlorophyll-a, and total organic carbon. Samples were collected weekly except during the initial bloom in June, when samples were collected daily. This approach allowed for the characterization of the cyanobacterial population dynamic and greatest periods of MC production. Data and observations for the period 2014-2016 will be presented.

125 New fluorometer uses the parameter 'unbound phycocyanin' as an early warning system for cyanobacterial T&O compounds and cyanotoxins

C. Moldaenke, A. Dahlhaus, H. Dahlhaus, bbe Moldaenke GmbH; S. Küppers, B. Santiago-Schübel, Forschungszentrum Jülich GmbH

New type of fluorometer uses the parameter 'free PC' ('unbound phycocyanin') as an early warning system for the appearance of difficult to treat cyanobacterial T&O compounds and cyanotoxins The concept of a new spectral fluorometer is demonstrated. This instrument is designed to estimate the potential risk of the appearance of T&O compounds resp. cyanotoxins from cyanobacteria in raw and drinking water online. Goal of the research was to investigate the correlation between the appearance of Geosmin, 2-MIB and/or other taste and odor (T&O) compounds from cyanobacteria, any cyanotoxins by the detection of the presence of 'free phycocyanin'. 'Free phycocyanin' describes that part of the cyanobacteria marker pigment 'phycocyanin' which is not energetically bound to chlorophyll anymore due to lysis and cellular stress. The disrupted phycocyanin has might still be intracellular in a lysed cell with affected membranes but often has already left the cell (extracellular). This lysis can be caused by senescence, mechanically strongly treated raw water or oxidants resp. disinfectants in drinking water treatment plants. Oxidants and disinfectants will affect the cell walls and the cell lysis starts delayed after a certain period of time. T&O compounds the free PC will leave the cells accordingly at the same time; the free PC can be used as an indicator. The method has proven its potentials in the lab already applying mechanical treatment and oxidants to cyanobacteria cells. The estimation of risk described here depends on the cyanobacteria concentration in raw water, its physiological state and the effects of the treatment steps in the water works.

126 Harmful algal bloom smart device application: using image analysis and machine learning techniques for early classification of harmful algal blooms

M. Waters, Northern Kentucky Univ / Mathematics Statistics; J.M. Lazorchak, J. Allen, USEPA / Office of Research and Development; M. Kannan, Northern Kentucky Univ / Biological Physical Sciences

Reports of toxic cyanobacterial blooms, also known as Harmful Algal Blooms (HABS) have increased drastically in recent years. HABS impact human health from causing mild allergies to liver damage and death. The Ecological Stewardship Institute (ESI) at Northern Kentucky University is developing a smart device application that will permit accurate and quick identification of potential HABS. This new application, titled HAB APP, will be used to assist identification of HABS in recreational and drinking water supplies. Using support vector machine computer learning algorithms, the smart device extracts a color histogram from an image and compares it with a pre-loaded trained model of images for classification. More specifically, the algorithm distinguishes between relatively harmless green and potentially harmful blue-green algae. The algorithm will be extended to classify images taken from cameras situated at a nearby lake and along the Ohio River and will include other classes of algae.

127 Effects of eutrophication in fish from Brazilian water supply reservoir

S. Calado, Univ Federal do Paraná / Ecologia e Conservação; T.P. Leite, Univ Federal do Paraná / Farmacologia; G. Santos, Univ Federal do Paraná / Dept of Genetics; J. Wojciechowski, Univ Federal do Paraná; H. Silva de Assis, UFPR / Pharmacology

Reservoirs are water bodies that are used to power energy, water supply and recreation. These anthropogenic activities have caused several problems and environmental impacts in the aquatic ecosystems, which are associated with the eutrophication. Eutrophication results in algae and cyanobacteria blooms. Iraí Reservoir is used to water supply and is located in southern Brazil. The aim of this study was to monitor the water quality in the Iraí Reservoir, the potential toxic effects and depuration of cyanotoxins on Geophagus brasiliensis. Water samples and fish samples were collected in Iraí Reservoir from September 2015 to May 2016. Water samples were used to qualitative and quantitative analyses of phytoplankton and quantification analyses of cyanotoxins. Fish were divided in two groups. The first one was called "site group", which were euthanized after been sampled. The second group was called "depuration group", which was submitted to depuration experiment for 90 days. This experiment was divided in 7, 15, 30 and 90 days. Blood samples were taken to comet assay and liver and kidney tissues were removed in order to measure effects using biomarkers such as superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), glutathione S-transferase (GST), glutathione reduced (GSH), lipoperoxidation (LPO), metallothionein (MT) and comet assay. Phytoplankton samples showed dominance of Microcystis aeruginosa e Dolichospermum planctonicum, both toxic cyanobacteria. Cyanotoxins quantification is being analyzed. Our results suggested recovery of the antioxidant system and reduction of cellular and DNA damage. GPx and GSH activities increased when lipid damage decreased, indicating a protective effect. Likewise the DNA damage in the blood decreased in 90th day, but the liver damage increased in 15th and 30th day, and it was recovery in 90th day. This result suggested biotransformation in metabolites that can cause damage. Furthermore, in the 30th day the GST activity increased. According to our multifactor and ordination analysis, the depuration starts in 15th day of the experiment and the set of the biomarkers was effective to show the differences among the groups. Therefore, aquatic organisms are exposed to contaminants mixture in Iraí Reservoir and the monitoring of water quality in this area is needed to minimize the risks to the human health and to the aquatic environment.

128 Analysis and Occurrence of Marine Biotoxins in the Catalan Coast of Spain at the Western Mediterranean Sea

D. Barcelo, C. Bosch, J. Sanchis, M. Farre, IDAEA-CSIC / Environmental Chemistry

Marine biotoxins are secondary metabolites synthetized by phytoplankton and bacteria. The toxic properties of these compounds have a negative influence in the growth, reproduction and survival of certain species. Moreover, they can bioaccumulate along the food chain[1]. Therefore, their presence is an issue of concern, especially when harmful algal bloom (HAB) takes place. The objective of this study is to assess the occurrence and distribution of 18 toxins pertaining to 4 groups of marine biotoxins in the coastal waters of Catalonia, Spain. The toxins selected for this study were: Azaspiroacids (azaspiracid-1, AZA1; azaspiracid-2, AZA2; azaspiracid-3, AZA3; azaspiracid-4, AZA4; and azaspiracid-5, AZA5); and related pectenotoxins (pectenotoxin2, PTX2), yessotoxins (yessotoxin, YTX; and homoyessotoxin (hYTX); okadaic acid (OA) and related dinophysistoxins (dinophysistoxin-1, DTX1); domoic acid, DA; saxitoxins (neosaxitoxin, NEO) and related gonyautoxins (gonyautoxin-2, GTX2; gonayutoxin-3, GTX3; gonyautoxin-5, GTX5; decarbamoylgonyautoxin-2, dcGTX2; decarbamoylgonyautoxin-3; dcGTX3; N-sulfocarbamoylgonyautoxin-2, C1; N-sulfocarbamoylgonyautoxin-3, C2); and tetrodotoxin, TTX. Therefore, the first objective was to develop and validate a multiresidue analytical method based on solid phase extraction (SPE) followed by High performance liquid chromatography coupled to high-resolution mass spectrometry (HPLC-HRMS) using a Q-Exactive (Thermo Fisher Scientific) hybrid quadrupole–Orbitrap mass spectrometer with an electrospray ionization source operated in positive and negative modes. The method detection limits were in the range of 0.52 to 0.14 µg/l, exhibiting good reproducibility and linearity. Afterwards, surface seawater samples collected at 20 different locations along the Catalan coast (NE of Spain) were analyzed. In each sampling site, water samples were collected inside and outside marinas. Okadaic acid was the prevalent compound found in 90% of the samples witn concentrations ranging from 2.10 to 1778.10 ng/l. Acknowledgement: This work was supported by the by the European Union through the projects Sea-on-a-chip (FP7-OCEAN-2013-614168) and Bravoo (FP7-OCEAN-2013-614010).

21st Century Approaches for Cross-Species Extrapolation in Toxicity Assessment

129 A Cell-Free Neurochemical Assay to Screen Chemicals across Fish, Birds, and Mammals

N. Basu, McGill Univ / Dept of Environmental Health Sciences; A. Arini, McGill Univ; J. Head, K. Mittal, McGill Univ / Dept of Natural Resource Sciences; P. Dornbos, Michigan State Univ; J. Rutkiewicz, Univ of Michigan; B.M. Armstrong, C.A. Murphy, Michigan State Univ / Fisheries and Wildlife

An estimated 30,000+ commercial chemicals are believed to possess neurotoxic properties. As current animal studies are expensive, time-consuming, and overlook many at-risk organisms, development of new screening methods is required. In vitro, cell free assays have potential as relatively inexpensive, screening mechanisms to flag neurotoxic compounds. The objective of this study was to advance a cell-free, neurochemical-based screening assay platform, and to apply it to study 20 species of birds, fish, and mammals, and screen against ~900 chemicals. In Phase 1 of this project, we screened 80 known environmental chemicals (metals, pesticides, personal care products, flame-retardants) against key receptors and enzymes from the glutamatergic, GABAergic, dopaminergic, and cholinergic neurochemical pathways, and did so in multiple taxa including fish (king mackerel, yellowfin tuna, goldfish, rainbow trout, perch), birds (bald eagle, Japanese quail, chicken, zebra finch), mammals (river otter, mink, pilot whale, common dolphin, narwhal, ringed seal, polar bear), and biomedical species (rat, mouse, human). In Phase 2 of this project we took a sub-set of Phase 1 “hits” and derived concentration-response curves. In Phase 3 of this project, we focused on a subset of species and neurochemical endpoints, and screened the USEPA E1K library of 800 chemicals. In this presentation, in addition to presenting our results we will 1) elaborate on the execution of such cell free assays and discuss ‘pros and cons’ of our screening method; and 2) discuss a strategy by which large volumes of in vitro data outputs may be modeled to predict individual-based adverse outcomes pathways.

130 Cross-species extrapolation of uptake and disposition of organic chemicals in fish using a multi-species physiologically based toxicokinetic model

M. Brinkmann, Univ of Saskatchewan – Toxicology Centre / Dept of Ecosystem Analysis; C. Schlechtriem, Fraunhofer IME Inst for Molecular Biology and Applied Ecology / Bioaccumulation and Animal Metabolism; M. Reininghaus, RWTH Aachen Univ / Biologie; K. Eichbaum, RWTH Aachen Univ / Dept of Ecosystem Analysis; S. Buchinger, Federal Inst of Hydrology / Dept Biochemistry Ecotoxicology; G. Reifferscheid, Federal Inst of Hydrology; H. Hollert, RWTH Aachen Univ / Dept of Ecosystem Analysis; T. Preuss, Bayer CropScience / Environmental Modelling

The potential to bioaccumulate is generally considered an unwanted substance property. Consequently, chemical legislations, such as the European REACH regulation, require the chemical industry to provide bioconcentration data for chemicals that are produced or imported at volumes exceeding 100 tons per annuum, or if there is concern that a substance is persistent, bioaccumulative and toxic. To fill the existing data gap for chemicals below this stipulated volume without the need for additional animal experiments, physiologically based toxicokinetic (PBTK) models can be used to kinetically predict whole-body bioconcentration as well as internal concentrations of neutral organic chemicals in different fish tissues. PBTK models have been developed for many different fish species with promising results. In this study, we developed PBTK models for zebrafish (Danio rerio) and roach (Rutilus rutilus) and combined them with existing models for rainbow trout (Onchorhynchus mykiss), lake trout (Salvelinus namaycush) and fathead minnow (Pimephales promelas). The resulting multi-species model allows for cross-species extrapolation of the bioaccumulation potential of neutral organic compounds. Predictions were compared with experimental data and were accurate for most substances. Our model holds strong potential for the probabilistic risk assessment of a chemical’s bioaccumulation potential with special emphasis on cross-species extrapolation of sensitivity.

131 Applying phylogenetic methods to interspecific toxicity extrapolations

D.B. Buchwalter, NC State Univ / Dept of Biological Science; M.D. Poteat, Oak Ridge National Laboratory / Environmental Sciences Division

The tremendous diversity of chemicals used in commerce coupled with the tremendous biodiversity of life on Earth guarantees that we will always be data deficient with respect to understanding chemical hazards to biota. Recent investment in high-throughput (and reductionist) approaches to understanding toxicity is further diverting limited resources from whole animal toxicity evaluation. Thus, the need for rational methods for interspecific toxicity extrapolation is substantial. The manifestation of toxicity is a complex trait resulting from a combination of subordinate traits related to absorption, distribution, metabolism and excretion (ADME) and target site sensitivity. The analysis of species traits in other disciplines (e.g. evolutionary biology, ecology) has demonstrated that the tendency for related species to share common traits is ubiquitous. The development of statistical approaches based on the phylogenetic relatedness of species allows us to quantify the relationship between phylogeny and traits of interest. In this talk, we present an overview of these phylogenetic approaches and efforts by our group to apply them to subordinate traits related to trace metal absorption and excretion vary across faunal groups. We further examine variation in carbaryl toxicity across faunal groups, demonstrating strong phylogenetic linkages with toxicity. Together, these results show proof-of-concept that phylogenetic approaches can be fruitful in interspecific toxicity extrapolations.

132 Improving toxicity extrapolation using molecular sequence similarity: A case study of pyrethroids and the sodium ion channel

M. Willming, ORISE/USEPA / Gulf Ecology Division; C. LaLone, USEPA / Mid Continent Ecology Division; M.G. Barron, USEPA / Gulf Ecology Division

A significant challenge in ecotoxicology has been determining chemical hazards to species with limited or no toxicity data. Currently, extrapolation tools like USEPA’s Web-based Interspecies Correlation Estimation (Web-ICE; www3.epa.gov/webice) models categorize toxicity estimation between the surrogate and predicted species by broad taxonomic groups. Toxicity predictions between more distantly related taxa have greater uncertainty, thus identifying variations in sensitivity across taxonomic levels may improve extrapolation. Because species sensitivity is a function of phylogenetic relatedness, understanding conservation of a chemical’s molecular target can likely inform cross-species predictions of sensitivity based on whole organism toxicity data. EPA’s Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS; https://seqapass.epa.gov/seqapass/) tool can be used to determine cross-species molecular target similarity by comparing protein sequences to a known susceptible query species. The goal of this work was to explore the relationship between sequence similarity of key functional domains of the voltage-gated sodium channel, derived from SeqAPASS, and curated, mode of action specific, acute toxicity data for pyrethroids to improve correlation based toxicity extrapolation. Sequence similarity was determined at the species, genus, and family level to identify variability in sensitivity at each taxonomic level. These analyses showed that species sensitivity to pyrethroids was correlated with the sodium channel gate and ion transport domains across taxa. These results will be used to improve cross-taxa toxicity extrapolation models and reduce uncertainty in predictions by grouping species with similar molecular target sequences and chemicals with the same molecular initiating event.

133 Comparison of toxicological and transcriptional pathway point of departure responses for five chemicals across five divergent species

E.J. Perkins, L. Burgoon, K.B. Donohue, US Army Engineer Research and Development Center / Environmental Laboratory; N. Vinas, Mississippi State Univ / Environmental Laboratory; N.D. Barker, Bennett Aerospace, Inc.; A.M. Mayo, Badger Technical Services, Inc.; X. Guan, Bennett Aerospace, Inc.; P. Chappell, M.S. Wilbanks, US Army Engineer Research and Development Center / Environmental Laboratory

Many efforts are underway to replace animal testing with in vitro assays or animal test models (e.g. fish embryos, Daphnia magna, Caenorhabditis elegans, or human cell lines). To better understand conservation of toxicological response across divergent species, we exposed C. elegans, Daphnia magna, zebrafish embryos and liver differentiaed human pluripotent stem cells to chemicals known to impact specific targets [flusilazole and hexahydro-1,3,5-trinitro-s-triazine (RDX)], an endocrine disruptor (bisphenol A), and a thyroid disrupter (perfluorooctanesulfonic acid), and a liver and hemoglobin toxicant [2,4,6-trinitrotoluene (TNT)]. In our comparison synchronized stage L3 C. elegans were exposed for 24 hr to a range of chemical concentrations, 48h old D. magna were exposed in aqueous media for 48h, 6 hr post fertilization zebrafish embryos exposed for 96hr, and differentiated liver cells were exposed for 24hrs. Mortality, morphological, and behavioral endpoints were monitored where applicable. We also examined changes in transcriptomes in response to chemical exposure in each species. Using transcriptomic data, we identified dose responsive pathways consistent with modes of action pathways and Adverse Outcome Pathways (AOP) known to be associated with each chemical. We then developed points of departure representing genes in those pathways to compare conservation of genes and pathways to toxicological responses across species. In general, pathway based point of departures occurred at lower concentrations than apical effects in all species. Across species, both pathways and toxicological sensitivity were more highly conserved within phylogenetically close alternative animal models. The data suggests that using transcriptional pathway based approaches can inform applicability and extrapolation of toxicological data from one species to another, thereby supporting better development of animal testing models.

134 Predictivity of the ToxCast ER model to non-mammalian in vivo reproductive endpoints measured in environmentally relevant species

K.A. Connors, Procter & Gamble / Global Product Stewardship; R. Judson, USEPA / Office of Research Development; M. Martin, USEPA / National Center for Computational Toxicology

The USEPA's Endocrine Disruptor Screening Program (EDSP) has been charged with screening thousands of chemicals for their potential to affect the endocrine systems of humans and wildlife. In vitro high throughput screening (HTS) assays have been proposed as a way to prioritize chemicals for EDSP Tier 1 screening. A recently developed computational network model of the estrogen receptor (ER) pathway integrated 18 in vitro HTS ER assays within the ToxCast research program and made bioactivity predictions for 1812 chemicals. This computational model is strongly correlated with the in vivo rodent uterotrophic assay. This analysis was performed on 103 of the 1812 chemicals in the ToxCast ER model due to the availability of curated uterotrophic data. By contrast, the USEPA's ECOTOX knowledgebase contains 235 chemicals with population-level or vitellogenin effects with an overlap of 121 of the 1812 ToxCast ER model chemicals. This additional chemical coverage allows for additional assessment of model performance. However, it is unclear how the in vitro HTS assays, generated in mammalian cell- lines and mammalian receptors, correlate with in vivo effects in environmentally relevant species (e.g. fish). Previous work demonstrated ER model concordance with population-level and vitellogenin effects with sensitivities of 0.76 and 0.80, respectively. It should be noted that there were no entries for vitellogenin or population-level effects on mammalian species within ECOTOX. Given the species diversity within each reproductive category, the analysis was repeated considering each vertebrate group separately. Thus, the ER model had greatest sensitivities in predicting fish>amphibians>>birds for both population-level and vitellogenin effects. Test species was explored as a possible confounding factor. When fish vitellogenin data (48 species, 79 chemicals) was limited to only include standard fish experimental species (4 species, 67 chemicals), sensitivity increased from 0.80 to 0.86. This is likely due to a combination of data availability, experimental design, experimental reproducibility, and potential species variation in response. Given the high sensitivity between particular ecological endpoints and the current ER model, future work will look to incorporate existing ecological endpoint data into the ER model to improve and expand chemical prioritization and testing decisions.

135 In Vitro Activation of AHR2, but not AHR1, is Predictive of In Vivo Sensitivity to Dioxin Across Phylogenetically Diverse Species of Fish

J.A. Doering, Univ of Saskatchewan / Toxicology Centre; S. Wiseman, Univ of Lethbridge / Biology; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

Adverse effects of exposure to dioxin-like compounds (DLCs) in vertebrates are primarily driven by activation of the aryl hydrocarbon receptor (AHR). However, mechanisms for the great differences in sensitivity to these effects among species of fish were unknown. Therefore, this study 1) investigated sensitivities to activation by the model DLC, 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), of AHR1s and AHR2s among seven species of fish known to differ in sensitivity to TCDD by almost 40-fold, and 2) characterized the relationship between in vitro sensitivity to activation of AHRs to TCDD and in vivo sensitivity of embryos to TCDD. All AHR1s and AHR2s were activated in a concentration-dependent manner by exposure to TCDD. There was no significant linear relationship ($R^2 = 0.24$) between EC_{50} of AHR1 and LD_{50} of embryos. However, a highly significant positive linear relationship ($R^2 = 0.96$) was observed between EC_{50}s of AHR2s and LD_{50}s of embryos. The slope and y-intercept for this linear relationship for AHR2 of fishes is not statistically different from the slope and y-intercept for the previously determined significant linear relationship among EC_{50} of AHR1 and LD_{50} of embryos of birds to TCDD. Results of this study suggest that sensitivity to activation of AHR2, but not AHR1, mediates adverse effects of and sensitivity to TCDD among phylogenetically diverse species of fish with a comparable relationship as previously demonstrated for AHR1 of birds. This co-relationship resulted in a single equation for predicting sensitivity to TCDD across distantly related species of oviparous vertebrates from EC_{50}s of AHRs. This mechanism-based biological model has the potential to guide more objective ecological risk assessment of DLCs for species of fish that are not easily studied, including threatened or endangered species.

136 Development of an Adverse Outcome Pathway for Progesterone Receptor Agonism Leading to Reproductive Failure in Fish

M. Overturf, Univ of Louisiana at Monroe / Biology; J.C. Anderson, Univ of Ontario Inst of Technology / Faculty of Science; D.A. Holdway, Univ of Ontario Inst of Tech / Science

Environmental toxicology research involving pharmaceuticals has increased greatly over the last 10-15 years. Several of these compounds have been extensively researched due to their potential impacts to the endocrine system of aquatic organisms. The main focus of endocrine

disruption research has centered on how estrogenic and androgenic compounds interact with the endocrine system to elicit reproductive effects. Synthetic progestins have only recently been investigated in which these compounds display negative reproductive consequences in teleost species. Using a cross-species extrapolation approach, the development of an adverse outcome pathway (AOP) for progesterone receptor agonism and its relationship to reproductive failure in fish can be constructed. The use of progesterone receptor homology and mammalian receptor binding affinities of synthetic progestins aid in the prediction of negative impacts of synthetic progestins in fish. The goal of this presentation is to present both qualitative and quantitative data for the support of the development of an AOP for progesterone receptor agonism as it relates to reproductive impairments in fish.

Assessing Risks of Pesticides to Federally Listed (Threatened and Endangered) Species at a National Level – Part 2

137 Update on Methods Used to Estimate Aquatic Pesticide Exposure to Threatened and Endangered Species

C. Peck, C.M. Rossmeisl, J. Carleton, USEPA; T. Hawkes, National Marine Fisheries Service; R. DeWitt, NOAA; G.E. Noguchi, US Fish and Wildlife Service / Ecological Services

Since 2013, the Environmental Protection Agency (USEPA), the National Marine Fisheries Service (NMFS), the U.S. Fish and Wildlife Service (USFWS), and the U.S. Department of Agriculture (USDA) have been developing methods to evaluate exposure and risk on a national scale to aquatic threatened and endangered species resulting from pesticide applications. The methods were released for public review in April of 2016 with the publication of the draft Biological Evaluations (BEs) for three pilot chemicals (chlorpyrifos, diazinon, and malathion). Public comments were solicited and a stakeholder workshop was held to address some of the more complicated issues presented in the pilot BEs, such as exposure predictions in flowing waterbodies. This presentation will provide an overview of methods developed and updated by the Agencies for assessing aquatic species exposure in advance of the release of the final BEs for the pilot chemicals in December 2016.

138 Characterizing Pesticide Exposure to Threatened and Endangered Species with GIS

R. DeWitt, T. Hooper, NOAA – NMFS; K. Paul, US Fish and Wildlife Service; G.E. Noguchi, US Fish and Wildlife Service / Ecological Services; J. Connolly, S. Lennartz, USEPA

The National Marine Fisheries Service, U.S. Fish and Wildlife Service, and U.S. Environmental Protection Agency (EPA), with input from the U.S. Dept of Agriculture (USDA), are developing a national framework for determining the effects of EPA registered pesticides on species and their critical habitats listed under the U.S. Endangered Species Act (ESA). Here we describe the process used to spatially characterize pesticide exposure to listed species and their designated critical habitats. We generate pesticide use-site footprint layers that represent application sites for agricultural and non-agricultural label uses. The Cropland Data Layer (produced by USDA) was used to produce 11 nationwide agricultural use layers. Additional data sets such as the National Land Cover Database (NLCD) were used to generate the non-agricultural use layers. The use-site layers were then expanded to incorporate the off-site transport of pesticides via runoff, drift, and downstream dilution. The resulting layers were then overlaid with species' range and designated critical habitat to determine where species' co-occur with each use. Knowledge of species life-history and distribution, as well as pesticide application rates, timing and methods are used to characterize species' spatial and temporal exposure within their range. Examples of this GIS-based exposure analysis will be presented by using the smalltooth sawfish (Pristis pectinate), listed as endangered in 2003, as a case study. The abundance of smalltooth sawfish in US waters has decreased dramatically over the past century (currently 5% of historical levels). This presentation will also explore some of the uncertainties inherent in the spatial data associated with species range, depiction of use sites, and pesticide exposure.

139 Refined pesticide exposure modeling for endangered species in flowing water habitats

M.F. Winchell, Stone Environmental, Inc. / Environmental Systems Modeling; N. Pai, L. Padilla, Stone Environmental, Inc.; R. Srinivasan, Texas A&M Univ; P. Havens, Dow AgroSciences LLC; J.M. Giddings, Compliance Services International

In their recent Biological Evaluations for three organophosphate insecticides, the USEPA concluded that improved pesticide exposure modeling approaches are needed for simulating pesticide exposure in flowing water habitat. To address this need, a species-specific, spatially distributed watershed scale exposure modeling approach at the 12-digit hydrologic unit code (HUC12) resolution was applied to evaluate chlorpyrifos exposure to flowing water habitats. Over 80,000 HUC12 watersheds cover the continental United States, including streams and rivers representing the low, medium, and high flow generic habitats proposed by the USEPA and the Services. The modeling approach combined the PRZM5 model, the traditional field scale landscape model used by the EPA, and the Soil and Water Assessment Tool (SWAT) watershed scale water quality model. The PRZM5 model was applied in a distributed manner to represent the variability in landscape and agronomic conditions within each HUC12 watershed. The parameterization of the PRZM5 simulations incorporated best available spatial datasets describing the land use and cropping patterns, soils, and weather. The timing of chlorpyrifos applications was based on regional agronomic practices and varied across watersheds, reflecting differences driven by field conditions, resource availability, and pest pressure. Conservative estimates of the percent of crops treated with chlorpyrifos were also included. The PRZM5 simulations provided surface runoff, erosion, and pesticide fluxes entering each HUC12 stream, while the SWAT model simulated realistic time-varying baseflow contributions to streamflow for each HUC12 watershed, providing a significant improvement to the assumption of constant baseflow. The channel system modules of SWAT simulated the downstream routing of the HUC12-level stream inputs. In-channel pesticide environmental fate processes were accounted for, including water and benthic degradation, equilibrium partitioning, settling and resuspension, and volatilization. The uncertainty in several parameters affecting chlorpyrifos environmental fate, baseflow, and channel routing were addressed by generating an ensemble of model simulations representing the expected range of these parameters. Probability distributions of chlorpyrifos exposures were derived for each species range and habitat type and can be used in combination with probabilistic effects determinations to inform risk characterization for the chemical.

140 Toxicity of Pesticide Mixtures in Midwest Streams

M. Shoda, USGS; W.W. Stone, USGS / Indiana Water Science Center; L. Nowell, USGS / California Water Science Center

In order to understand the vulnerabilities of streams in the Midwest and make decisions about areas that may need more intensive monitoring, an understanding of how pesticide mixtures occur in streams and their influence on biological communities is necessary. The Pesticide Toxicity Index (PTI) is a tool for assessing relative toxicity of pesticide mixtures to fish, benthic invertebrates and cladocera in stream water. It is a robust screening tool that incorporates the ability to assess multiple pesticides at once, which is how organisms encounter pesticides in a natural environment. The Watershed Regressions for Pesticides (WARP) models use multiple linear regression to identify watershed characteristics that are used as explanatory variables to predict concentration statistics for individual pesticides in streams. WARP methodology was used in this case to develop models using data from one hundred sites in the Midwest, sampled in May-August of 2013. The highest calculated PTI was modeled for these sites using watershed variables including toxicity-weighted agricultural use intensity, land use, agricultural management practices, soil properties, precipitation and hydrologic characteristics. A unique model to predict stream PTI was generated for fish, benthic invertebrates and cladocera. Toxicity-weighted use-intensity was an explanatory variable common to each of the models and the only variable that directly represents a pesticide source term. Some of the differences in significant explanatory variables between models as well as the differences in model performance may be related to the different pesticides that contributed the most to the highest calculated PTI values. The models were evaluated with independent data, not limited to the Midwest, and found to perform reasonably well with no clear bias. The WARP-PTI models for fish, benthic invertebrates and cladocera were also used to estimate the probability of exceeding a threshold PTI in Midwest streams. These models provide a low resource way to assess PTI at unmonitored streams in the Midwest and provide insight into how pesticide mixtures in streams influence biological communities.

141 Refining Co-occurrence and Proximity Analyses for Endangered Species Assessments

A.R. Frank, Compliance Services International

The FIFRA Endangered Species Task Force (FESTF) has contributed to the USEPA's endangered species and pesticide assessment process for nearly 20 years. Throughout this time, FESTF's efforts have been focused on aggregating, improving, analyzing, and providing data to the USEPA to inform their assessments. The recent release of USEPA's Draft Biological Evaluations, including national-level endangered species assessments, on the first three organophosphates through the registration review program, illustrated the need for improved and refined processes and methods that can enhance efficiency and accuracy while meeting species protection and agricultural goals. The FESTF has aggregated various data sets that can be used to develop a realistic portrayal of agricultural practices, their relationship to species presence, and the mitigating effect of certain environmental and species characteristics. This presentation will explore ways to refine and improve upon USEPA's Action Area definition, species ranges, and the resulting co-occurrence and proximity analyses.

142 Mitigation of Pesticide Drift from Aerial Applications by Riparian Vegetation

G. Tuttle, Washington State Dept of Agriculture / Natural Resources Assessment Section; G. Bahr, Washington State Dept of Agriculture; M. Bischof, Washington State Dept of Agriculture / Natural Resources Assessment Section; T. Coffey, Washington State Univ / Dept of Mathematics and Statistics; J. Demory, M. Drennan, Washington State Dept of Agriculture; J. Hancock, Washington State Dept of Agriculture / Natural Resources Assessment Section; K. McLain, Washington State Dept of Agriculture; A. Nickelson, Washington State Dept of Agriculture / Directors Office

In 2015, the Washington State Department of Agriculture conducted a targeted monitoring study to assess the effectiveness of riparian vegetation at reducing pesticide loading to streams during aerial applications of the organophosphate insecticide malathion. Applications took place at blueberry fields in Whatcom County, Washington. Two control sites (with no dense woody vegetation) were compared to three vegetated sites (with mature riparian vegetation). Vegetation was characterized by height, width, species diversity, and canopy cover. Site and channel geometry was also measured at each site. Eight total malathion application events were monitored at; four each at control and vegetated sites. Pesticide movement was monitored using depositional samplers at the field edge, the beginning of the riparian vegetation, and the center of the stream. Based on statistical modeling by Washington State University, instream malathion deposition was significantly lower at vegetated sites than control site. The site and vegetation characteristics that most reduced instream malathion deposition were increased distance from field (both to vegetation and to water) and increased canopy angle and canopy cover. This analysis predicted that an additional 26% reduction of instream malathion deposition could be achieved by either increasing the distance between the field and the beginning of the riparian vegetation by an additional 0.6 m or increasing canopy cover by an additional 9%. The benefits that riparian vegetation can have for habitat and water quality are already well known. This evidence that riparian vegetation is also effective at reducing drift into streams from aerial pesticide applications makes installation of more riparian buffer vegetation even more important.

143 Implementing an Integrated Pesticide Use Enforcement System in California

J. Haasbeek, CaliCo Solutions LLC; D. Marciano, California Dept of Pesticide Regulation; J. Gless, California Agricultural Commissioners and Sealers Association

The California Department of Pesticide Regulation (DPR) and the California Agricultural Commissioners and Sealers Association (CACASA) have been working together over the past several years to develop integrated management systems for restricted materials permitting, pesticide use reporting, and compliance and enforcement activity tracking. The most recent addition to the Pesticide Use Enforcement (PUE) program is a mobile inspection application that provides field inspectors with immediate access to data from numerous sources within the pesticide regulatory domain, including permitting, licensing, labeling, use reporting, and enforcement. This presentation will highlight the benefits gained from compiling information from these different programs and discuss the difficulties encountered and solutions found over the course of the project implementation.

144 Testing a "Net Conservation Benefit" Approach for Pesticides Using a Small-Scale Pilot for Listed Threatened and Endangered Species

D. Campbell, Syngenta / Dept of Regulatory Affairs; A. DeLucia, L. Peterson, Syngenta Crop Protection

Enacted in 1973, the Endangered Species Act (ESA) is intended to protect animals and plants determined to be endangered or threatened with extinction. Courts have ruled that pesticide registrations conducted under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) are actions subject to the ESA. The scale and scope of these assessments are daunting and unprecedented; under FIFRA, EPA Office of Pesticide Programs registers (permits) pesticides after review of the extensive scientific data set required by Congress, conducting comprehensive reviews of thousands of environmental and human health studies on more than 1000 active ingredients used in more than 19,000 formulated products that are used across broad geographies. EPA and the Services are currently attempting to chart a workable process for FIFRA consultations under ESA, which has been an overwhelming task given legal, scientific and procedural complexities. An approach is needed that reduces complexity, results in true landscape-level improvements for endangered species habitats and allows for a transparent and predictable approach to FIFRA/ESA consultations. Recent presidential memoranda direct federal agencies to incorporate into their decision-making the beneficial ecological services provided by landscape level conservation, and the use of conservation improvement as a mitigation option. Our goal is to conduct a small-scale pilot to test such a net conservation benefit program in this context. Our approach involves: Concept development through interaction with a wide array of experts on endangered species, habitat improvement programs, ESA and FIFRA law, government, farmers and other pesticide users. Selection of the agricultural pest-control practices, species and geographies of the pilot Development of a regulatory framework for demonstration during the pilot that will relate potential pesticide impacts (after avoidance and minimization measures inherent in FIFRA registrations) with on-the-ground habitat improvement work. Measures of successes and areas for improvement and adjustments to the pilot. The presentation describes the overall pilot approach and presents the status and results achieved as well as plans going forward.

Everglades and Wetlands Science Part 1: Ecology and Contaminants in Ever-Changing Ecosystems

145 Mercury contamination in sharks and the relationships between mercury concentrations in various shark tissues

J. O'Bryhim, Univ of Georgia – Savannah River Ecology Laboratory; D. Adams, Florida Fish & Wildlife Commission / Fish and Wildlife Research Inst; J. Spaet, King Abdullah Univ of Science and Technology / Red Sea Research Center; G.L. Mills, Univ of Georgia / Savannah River Ecology Lab; S.L. Lance, Univ of Georgia / Savannah River Ecology Laboratory

Mercury (Hg) exposure poses a threat to both fish and human health. Sharks are known to bioaccumulate Hg, however, little is known regarding how Hg is distributed between different tissue types (e.g. muscle regions, fins, liver, kidney, other organs). We evaluated total mercury (THg) concentrations from eight muscle regions, four fins, and five organs from two different shark species, bonnethead (Sphyrna tiburo) and silky shark (Carcharhinus falciformis) to determine the relationships of THg concentrations between and within tissue groups. THg concentrations were highest in the eight muscle regions with no significant differences in THg concentrations between the different muscle regions and muscle types (red and white). Significant relationships were found between THg concentrations in dorsal axial muscle tissue and the fin inner core, liver, kidney, spleen and heart for both species as well as the THg concentrations between the dorsal fin trailing margin and the heart for C. falciformis and all other sampled tissue types THg concentrations for S. tiburo. We then tested for THg concentrations in shark, ray, and fish meat (muscle) being sold in two open-air markets in San Jose, Costa Rica. THg concentrations were highest in Sphyrna zygaena (3.50 ± 0.47 ppm wet wt) followed by Carcharinus limbatus (2.50 ± 0.78 ppm wet wt), and were the lowest in the fish labeled "Corvina" (0.06 ± 0.05 ppm wet wt). Using the relationships between muscle and liver tissue we were able to estimate THg concentrations (ppm dry wt.) for the livers of these sharks using the known muscle THg concentrations. S. zygaena, which is listed as "vulnerable" by the IUCN – had the highest estimated THg liver concentrations (up to 4.67ppm dry wt.). The elevated Hg levels in the muscle tissues and internal organs (liver) of this species and the other shark sampled have the potential to negatively impact both the health and conservation status of this species as well as having potentially serious health risks to consumers of these products.

146 Assessment of total mercury burden in the American alligator (Alligator mississippiensis) at Merritt Island National Wildlife Refuge (MINWR), Florida

J. Dorsey, Marine Biomedicine and Environmental Sciences; F. Nilsen, J.A. Bowden, National Inst of Standards and Technology / Environmental Chemical Sciences Division; S.E. Long, National Inst of Standards and Technology / Analytical Chemistry Division; R. Lowers, NASA / Environmental Sciences; L.J. Guillette, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences OBYGYN

Mercury is a ubiquitous environmental contaminant that is transported globally via atmospheric circulation. Mercury is toxic in all forms, but the organic form has the ability to bioaccumulate within the tissues of apex predators to concentrations that can be detrimental to these organism's health and fitness in the environment. While many studies focus on seasonal atmospheric deposition trends, studies regarding the seasonal variation of total mercury concentrations in organismal tissues are limited. By comparing seasonal atmospheric and organismal trends, we can determine how fluctuating concentrations influence seasonal behaviors of large predators. Using a long-term sampled population of American alligators (Alligator mississippiensis), we investigate some lingering questions in regard to mercury accumulation and sampling in wild animals. These questions are, if the mercury concentration in an apex predator varies seasonally; if the seasonal variation demonstrated by the atmospheric deposition of mercury is predictive to what is found in apex predators; if both sexes fluctuate similarly with respect of mercury concentration; and, if altered health status is indicative of a higher mercury concentration. To answer these questions, we monitored a constant population of American alligators located at the Merritt Island National Wildlife Refuge in Titusville, Florida, for their mercury concentrations over 7 years. Taking into account the genders, health status, and recaptured individuals, we used precise analytical measurements, spatial analysis, and multiple comparison statistics to identify any significant trends in the present population. We find that there is a statistically significant difference in mercury concentration seasonally, as well as a statistically significant difference in the mercury concentrations of animals with altered health statuses and that total mercury trends that directly correlate with seasonal wet deposition rates for healthy alligators. We present these findings from a model wild population of apex predators to demonstrate the complexity of opportunistic sampling of wild populations as well as lend insight into the effect of seasonal behaviors on samples collected.

147 Effects of trophic position and wetland hydroperiod on mercury accumulation in amphibian larvae

S.L. Lance, Univ of Georgia / Savannah River Ecology Laboratory; M. Winzeler, A. Coleman, Univ of Georgia; C. Tapia, Nova Southeastern Univ; P. Walkup, Wofford College; D. Scott, Univ of Georgia

Bioaccumulation of mercury (Hg) in aquatic food chains is of global concern for wildlife and human health. Previous studies on freshwater fish have demonstrated that Hg accumulation is higher in fish at higher trophic levels in semi-permanent hydroperiod wetlands. The frequency of wetland drying can be positively correlated with Hg accumulation; however, fish only persist in wetlands with infrequent drying. Amphibians, on the other hand, include species adapted to a full range of wetland hydroperiods. Wetland drying and refilling may occur one or more times a year, infrequently every few years, or never in the case of permanent ponds. It is unknown whether Hg accumulation in amphibians is also correlated with hydroperiod. Our objectives were to determine the effects of both wetland hydroperiod and trophic position on Hg levels in larvae of three amphibian species: mole salamanders (Ambystoma talpoideum), marbled salamanders (A. opacum) and southern leopard frogs (Lithobates sphenocephalus). Southern leopard frogs are herbivorous and breed in short to intermediate hydroperiod wetlands. Both salamander species have carnivorous larvae that switch from zooplankton to larval amphibians and aquatic insects during development. Marbled salamanders specialize in wetlands that hold water for no more than 4 to 7 months while mole salamanders require wetlands to hold water for a minimum of 5 months for larvae to complete development. We collected larvae from 25 wetlands on the United States' Department of Energy Savannah River Site near Aiken, S.C. The wetlands represented a range of hydroperiods assessed by a drying score in a previous study. We used a DMA 80 Hg analyzer to measure mercury in 230 freeze-dried, homogenized samples. Overall, both frogs and salamanders in shorter hydroperiod wetlands accumulated more Hg than their counterparts in longer hydroperiod wetlands. Surprisingly, the herbivorous frogs accumulated more Hg than carnivorous salamanders. Within mole salamanders, young of the year larvae accumulated less than paedomorphic larvae that feed at a higher trophic level. From this study it appears that amphibians inhabiting shorter hydroperiod wetlands may be at a higher risk of experiencing the toxic effects of Hg. In addition, herbivorous tadpoles that graze near the wetland sediments may accumulate more Hg than salamander larvae feeding at higher trophic levels, indicating that feeding ecology as well as trophic position may influence Hg uptake.

148 From egg to fledge: Partitioning effects of mercury exposure on reproduction in Great Egrets (Ardea alba)

I.A. Rodriguez, N.E. Vitale, S. Orzechowski, P. Frederick, Univ of Florida / Wildlife Ecology and Conservation

Reproduction in birds is thought to be one of the most sensitive processes affected by mercury (Hg) exposure. Many mechanisms may be involved, including teratogenesis, endocrine disruption, and effects on parental care. Partitioning these effects of Hg has proved elusive in part because the

effects are difficult to study in the same individuals or nests, and in part because effects may be subtle and difficult to assess in complex natural settings. The Everglades (Florida, USA) has a history of mercury contamination that is both temporally and geographically highly variable, making this a good "laboratory" for understanding effects of Hg on a wide-ranging piscivorous bird. In this study, we used nondestructive micro-sampling of egg albumin to determine Hg concentrations before the embryo developed and subsequently sampled the resultant chicks at later stages using blood and feather tissue through fledging. Samples were taken from the 2nd laid egg (0-5 days) and subsequently from blood (≈ 35-45 days) and feathers (≈ 46-60 days) from the same individual in coastal and inland colonies. We sampled albumin from a total of 102 eggs from seven colonies across the Everglades during 2015. No statistical differences were observed in Hg concentrations between coastal and inland colonies in any sampled matrix, and we found no correlation between Hg concentration in albumin and hatching success. However, colony-averaged nest survival (surviving until fledging) was negatively correlated with Hg concentrations from egg (albumin; GLM; p =0.0016), but not to Hg concentration in blood and feathers of chicks. Further, sampled nests with average Hg concentrations in albumin lower than 0.4 mg/kg had nest survival probabilities of 90-95%; in contrast, sampled nests with average Hg concentrations over 0.75 mg/kg had survival probabilities of 42-57%. This information collectively suggests that egg Hg concentrations are affecting nest success, though not through teratogenesis or hatchability. Instead, we suggest that egg Hg is reflective of parental Hg exposure, and that Hg effects on nest success resulted primarily from deficits in parental behavior.

149 Environmental Contaminants Continue to be a Threat to the Endangered Florida Panther

M. Cunningham, Florida Fish and Wildlife Conservation Commission; J. Mercer, Florida Gulf Coast Univ; D. Onorato, Florida Fish and Wildlife Conservation Commission; D. Jansen, National Park Service; B. Clemons, Florida Fish and Wildlife Conservation Commission; A. Brandon, N/A; D.G. Rumbold, Florida Gulf Coast Univ / Depart of Marine and Ecological Sciences

The Florida panther is a subspecies of puma whose population has been reduced to an isolated remnant population occupying the Everglades and Big Cypress ecosystems of South Florida. Research to investigate the decline of this apex predator identified a number of putative or confirmed morbidity and mortality factors including anthropogenic and intraspecific trauma, inbreeding depression, infectious diseases, and environmental contaminants. Contaminants detected in panthers included mercury (Hg), organochlorines (OC; p,p'-DDE, p,p'-DDT, p,p'-DDD, oxychlordane, dieldrin, heptachlor epoxide, mirex, cis-nonachlor, and trans-nonachlor), polychlorinated biphenyls (PCBs; congeners 18, 66, 118, 153, 105, 138, 187, 128, 180, 170, 195, and 206), and anticoagulant rodenticides (brodifacoum, bromodialone). Concentrations of Hg, OCs, and PCBs were highest in panthers occupying the Everglades ecosystem (ENP), and Hg levels appear to be increasing in some areas. Individual panthers continue to have high Hg burdens, especially in ENP. Although the sample size for ENP is small, concentrations up to 100 ppm have been detected in panthers sampled 2004-2013. Additionally, elevated levels – up to 67 ppm – were detected in southern Big Cypress National Preserve 2008-2013. Restoration of historic water flow and/or shifts in diet may be responsible for this apparent increase. Although white-tailed deer and feral swine are the primary prey species in the northern portion of their range, raccoons comprise an increasingly larger proportion of their diet in the southern portion. This greater dependence on raccoons may result in increased exposure to those contaminants that bioaccumulate through the aquatic food chain. The impacts of these contaminants on panther health and reproduction are unknown. Some panthers with undiagnosed mortalities had elevated Hg, OC, and PCB concentrations at the time of death. More commonly, contaminants likely work additively or synergistically with other stressors to impact panther health and reproduction.

150 Pesticides increase infectious disease by disrupting the microbiome

J.R. Rohr, S. Knutie, C. Wilkinson, Univ of South Florida / Dept of Integrative Biology

Animals are colonized extensively by a community of microbes, which are collectively called the microbiota. Studies suggest that gut bacteria play a role in the development and maintenance of the host immune system, which likely affects their susceptibility to parasites. For example, our previous work demonstrates that an early-life disruption in the microbiota increases parasite susceptibility in frogs. However, we know little about how "real world" environmental stressors, such as chemical contaminants, play a role in these interactions. We tested whether the early-life gut microbiota mediates the effect of contaminants on subsequent parasite susceptibility in Cuban tree frogs (Osteopilus septentrionalis), a species that is common throughout Florida and the Everglades. Tree frog tadpoles were assigned to one of four chemical treatments crossed with either sterile (autoclaved) pond water (to manipulate the microbiota) or non-sterile pond water media (to offer a natural source of microbes). For the chemical treatments, tanks received the fungicide chlorothalonil (1.64 µg/L), the insecticide chlorpyrifos (6.68 µg/L), the insecticide imidacloprid (11.9 µg/L), or acetone solvent control for 7 days. After metamorphosis, frogs were exposed to common parasitic gut nematodes in genus Aplectana. Frogs exposed to sterile pond water had a lower relative abundance and diversity of gut bacteria and, when challenged with worms, they had 5-6 times the prevalence as the pond water controls. All three pesticides had similar effects as sterile pond water, increasing infection prevalence by 5-6 fold relative to the non-polluted, non-sterile pond water controls. Thus, our results suggest that amphibian microbiota mediates the effect of chemical contaminants on subsequent parasite susceptibility. Transcriptomic analyses are underway in an effort to link pesticide-mediated changes to the microbiome to immune gene expression and also changes in immunity to long-term reductions in resistance to infections.

Plastic Debris: From the Continent to the Sea

151 Evaluating Wastewater Effluent as a source of microplastics to the aquatic environment

S. Ziajahromi, Griffith Univ Smart Water Research Centre / Griffith School of Environment; P.A. Neale, Griffith Univ / Smart Water Research Centre; L. Rintoul, Queensland Univ of Technology; F.D. Leusch, Griffith Univ – Smart Water Research Centre / School of Environment and Smart Water Research Centre

In recent years the aquatic environment has been widely affected by microplastics released from various sources and microplastics with a suspected wastewater origin have been detected in marine and freshwater environments in the Europe, US and Australia. However, the amount of microplastics entering the aquatic environment via wastewater effluent discharge remains poorly understood. In this study, we developed a novel sampling device to sample microplastics from wastewater in the size range of ≥500 to 25µm. An efficient sample processing method was also applied to improve the sampling of microplastics in wastewater and to minimize the false detection of microplastics. We quantified and characterized microplastics in the wastewater effluent of three major wastewater treatment plants in Australia with different treatment processes including primary, secondary and advanced (reverse osmosis) treatment. Primary effluent contained on average 1.5 microplastic particles per liter, with lower concentrations of 0.4 and 0.2 particle/L detected in the secondary and advanced treated effluents, respectively. The results also revealed that the dominant particle form were fibers followed by granular particles, which are assumed to originate from textiles and cleansing products. Micro-FTIR confirmed the type of quantified microplastic polymers, which mostly included, PET, and polyethylene This study indicates the importance of wastewater effluent as a source of microplastics to the aquatic environment, particularly given the large daily effluent discharge of the studied wastewater treatment plants.

152 Quantitative and qualitative analysis of microplastics in wastewaters, river and estuarine waters

D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry; G.F. Schirinzi, M. Llorca, IDAEA-CSIC; M. Farre, IDAEA-CSIC / Environmental Chemistry

Plastic residues constitutes an emerging problem for the aquatic environment including river, estuaries and coastal areas. Their presence is not only an aesthetic problem since they also can imply harmful damages for the coastal areas and the socioeconomic activities linked to these regions. Microplastics (MPLs) are defined as small particles of plastic in the millimetre to sub-millimetre size range (< 5 mm) and high densities (e.g., 100 000 items per m3). In addition, MPLs are suspected to be accumulated and potentially they can enter the food chain. However, their potential occurrence and impact have not been well investigated. One of the reasons for this being the lack of quantitative analaytical methods in the environment. On the other hand, while the study of the impact of plastic debris in marine environment has been considered for years, the impact of smallest fractions as MPLs and nanoplastics, have been poorly studied in the aquatic environment in general, and in freshwater ecosystem in particular. In this context, the main objective of this work was to develop a combined analytical approach for the characterization and quantitative analysis of MPLs. Two polymers were selected among the more frequently used in consumer products: high-density polyethylene (HDPE) and polystyrene (PS). In this platform presentation this combined approach using Infra red spectroscopy (IR), comprehensive two-dimensional gas chromatography coupled with Time-of-Flight mass spectrometry (GCxGC-TOF/MS), matrix-assisted laser desorption/ionization coupled to time-of-flight (MALDI-TOF) and liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS) using an Orbitrap instrument will be presented and compared in terms of ionization, sensitivity and qualitative information. Among the different techniques, IR spectroscopy was the less sensitive technique, in particular when it was applied to real samples. Regarding to MALDI-TOF, semi-quantitative measurements were achieved but with limits of quantification (LOQ) higher than mg/L. That means that this could be an excellent technique after an improved extraction and pre-concentration steps or for biota samples that usually have higher concentrations of MPLs. LC-HRMS presented so far the best results in terms of quantitative analysis with instrumental limits of quantification (LOQ), between 10 and 100 ppb. Finally, the combined approach was applied to study the occurrence of MPLs in the Delta Ebro River (NE of Spain). The analysis of real water samples from the Ebro Delta detected the presence of PE in influent and effluent WWTP at concentrations of 3.18 and 0.35 mg/Kg, respectively. In addition, the presence of this MPL has been also confirmed in the emissary of St. Carles de la Ràpita as well as in near drainage channels and in three different points of Bahía del Fangar. As regards to the analysis of non-polar semi-volatile plasticizers, the presence of phthalates has been confirmed in all analysed samples The diferent analytical techniques employed will be presented and discussed as well as the results obtained in different real samples from the Ebro river and delta. This work was financially supported by the Spanish Ministry of Economy and Competitiveness, INTEGRA-COAST project (CGL-2014-56530)

153 Sources, Fate and Microbial Interactions of Microplastic Particles in Urban Rivers

J. Kelly, Loyola Univ Chicago / Biology; T.J. Hoellein, Loyola Univ Chicago; S.A. Mason, The State Univ of New York at Fredonia; A.R. McCormick, M.G. London, Loyola Univ Chicago; J.W. Scott, Illinois Sustainable Technology Center

Microplastic particles (< 5 mm) are an environmental contaminant of emerging concern, as recent studies have documented microplastic in marine habitats worldwide. Microplastic sources include fragmentation of larger plastic items, industrial manufacturing pellets, personal care products, domestic cleansers, and synthetic textiles. Rivers have been suggested as a major source of microplastic to global oceans, but there are few measurements of microplastic concentrations or movement in freshwater ecosystems. Our work has documented high microplastic fluxes in urban rivers in the Chicago metropolitan region, ranging from 15,000 to more than 4 million particles per day, and we have identified wastewater treatment plant effluent as a point source of microplastic. Using a longitudinal survey, we demonstrated that microplastic can be transported long distances in a river (> 2 km) and can accumulate to very high concentrations in urban river sediment (10,000 times higher than water column). We also observed dense bacterial colonization of microplastic in urban rivers, and used high-throughput sequencing of 16S rRNA genes to analyze the taxonomic composition of microplastic-attached bacterial communities. Microplastic-attached bacterial communities were distinct in taxonomic composition from communities in associated natural habitats, e.g. water column, seston and benthos. The taxonomic composition of microplastic-attached bacterial communities supports domestic wastewater as a point source of microplastic, as microplastic supported high abundances of bacterial taxa associated with human gastrointestinal infections. Bacterial taxa linked to plastic decomposition were also abundant on microplastic particles, and shifts in microplastic community composition with distance from the WWTP suggest succession towards a ‘stream-like’ bacterial community and away from a ‘WWTP-like’ bacterial community. These results indicate that microplastic represents a novel habitat for bacterial communities and may play a role in dispersal of bacterial taxa within riverine ecosystems. Furthermore, our work suggests that rivers play a major role in the global microplastic life cycle, but the retention, export, and ecological interactions of microplastic in lotic ecosystems are understudied.

154 Microplastic Ingestion By Shape in Several Species of Fish from Lake Ontario

K. Munno, D. Jackson, Univ of Toronto / Ecology and Evolutionary Biology; P.A. Helm, Ontario Ministry of the Environment & Climate Change / Environmental Monitoring and Reporting Branch; D.G. Poirier, Ontario Ministry of the Environment / Laboratory Services Branch; R. Chong-Kit, S. Bhavsar, S. Petro, Ontario Ministry of the Environment & Climate Change

Microplastics, plastics less than five millimetres in size, come from several sources including industry, consumer products and the breakdown of larger plastics resulting in a number of possible shapes. The anthropic origin of microplastics suggests abundance will increase with increasing proximity to major urban centres. Therefore, Lake Ontario is expected to have relatively high abundance of microplastics. To investigate their prevalence in fish digestive tracts relative to the environment, water samples and fish were collected from three sites in Lake Ontario (Humber Bay, Toronto Harbour and Hamilton Harbour) in 2015. Lab-cultured fish were also exposed to microplastics through diet for a period of 24-48 hours to determine whether ingested microplastics were retained in the digestive tract. Results compare differences in excretion relating to shape. Results indicate that various shapes lead to differences in short-term retention for lab-raised fish. The shapes retained in the highest frequencies differ between species. This suggests that various forms of microplastics may accumulate in the digestive system of several fish species following direct ingestion. Preliminary results from field-collected fish suggest fibres are most prevalent in the digestive tract. These results will be compared to water samples collected from the same locations to determine whether certain shapes are more prevalent in fish digestive tracts relative to the surrounding environment, and which sources may contribute most heavily to the microplastic abundance from these locations. The accumulation and retention of microplastics may cause physical harm and nutritional issues typically associated with macroplastics. Information regarding the most problematic shapes of microplastics and the associated potential sources will aid in informing management decisions and policy development.

155 Manageable sources of microplastics to the "sweetwater seas"

P.A. Helm, Ontario Ministry of the Environment & Climate Change / Environmental Monitoring and Reporting Branch; G. Zimmer, E. Nicholls, Ontario Ministry of Environment and Climate Change; M. Stones, Univ of Guelph

Microplastic particles (MPPs), plastic particles less than 5 mm in size, present in Great Lakes waters (the sweetwater seas) became a widely publicized issue in 2012, at the same time pressures to remove plastic microbeads from personal care products took hold. However, sampling in the Great Lakes has shown that there are other sources of microplastics entering the lakes from the urban landscape that have commercial and manageable origins. For example, in conducting surface water manta trawls in 2014 in water waters adjacent to the city of Toronto, we found that a portion of the up to 6.7 million particles per square kilometer were comprised of plastic in the forms of polystryene foam, and rigid plastic particles resembling shavings, cuttings, and twistings, and were likely generated by mechanical means. In the current study, we will highlight findings of nearshore Lake Ontario surface water manta net sampling in 2015 that aimed to isolate wastewater and riverine (runoff) inputs within the waters of Humber Bay adjacent to Toronto, as well as river and wastewater treatment plant effluent sampling for inputs to the waterfront. The watersheds adjacent to the Humber Bay area of the Toronto waterfront are known to have a relatively high density of plastics businesses. Findings indicate that waste streams from producers of plastic products are entering wastewater treatment plants and stormwater runoff with subsequent discharge to the lake. This suggests that management strategies that improve best practices that control generation and loss of fine plastic by-product particles within commercial enterprises will further reduce plastics found in the lakes, in addition to anticipated changes from microbeads.

156 Plastics and other anthropogenic debris in freshwater birds from Canada

E. Holland, Acadia Univ / Biology; M. Mallory, Acadia Univ; D. Shutler, Acadia Univ / Biology

Plastics in marine environments are a global environmental issue. Plastic ingestion is associated with a variety of deleterious health effects in marine wildlife, and is a focus of much international research and monitoring. However, little research has focused on ramifications of plastic debris for freshwater organisms, despite marine and freshwater environments often having comparable plastic concentrations. We quantified plastic and other anthropogenic debris in 340 individuals of 17 freshwater bird species collected across Canada. We determined that freshwater birds had similar rates (11.2%) of plastic ingestion to many marine bird species. This work established that plastics and other anthropogenic debris are a genuine concern for management of the health of freshwater ecosystems, and provides a baseline for the prevalence of plastic debris ingestion in freshwater birds in Canada.

157 Assessment of Plastic Ingestion and Persistent Organic Pollutant Concentrations in Sea Turtles from the Pelagic Realm of the Pacific Ocean

K.E. Clukey, Univ of Hawaii at Manoa / Natural Resources and Environmental Management; C.A. Lepczyk, Univ of Hawaii and Auburn Univ; G.H. Balazs, NOAA National Marine Fisheries Service / Pacific Islands Fisheries Science Center; T.M. Work, USGS National Wildlife Health Center / Honolulu Field Station; Q. Li, Univ of Hawaii at Manoa; J. Lynch, National Inst of Standards and Technology / Chemical Sciences Division

Plastic debris is a growing concern for many marine organisms due to entanglement, ingestion, and exposure to toxic chemicals. We hypothesized that ingestion of plastic debris is a potential source of exposure of persistent organic pollutants (POPs) to threatened pelagic Pacific sea turtles. We necropsied 38 sea turtles [3 leatherback (Dermochelys coriacea), 3 loggerhead (Caretta caretta), 6 green (Chelonia mydas) and 26 olive ridley (Lepidochelys olivacea)] that were incidentally captured in Hawaiian and American Samoan longline fisheries and quantified the amounts and characteristics of plastics in their gastrointestinal tracts. Ingested plastic was found in 87% (n = 33) of the turtles. Mean mass of ingested plastic in all turtles sampled was 9.68 g with a range of 0.0185 g to 64.2 g amongst turtles that ingested plastic. Juvenile green turtles ingested significantly more plastic than other species. Adipose samples from 25 of the turtles (2 loggerhead, 6 green, 17 olive ridley), were analyzed for 83 polychlorinated biphenyls (PCBs), 20 organochlorine pesticides, 32 brominated flame-retardants and hexabromocyclododecane (HBCD). We analyzed differences among species, sex, and correlations with turtle length and capture locations. Total dichlorodiphenyltrichloroethanes (DDTs) were the predominant POP in both loggerhead (mean = 18.3 ng/g wet mass) and olive ridley (15.8 ng/g wet mass) turtles, and the second highest POP class in green turtles (1.80 ng/g wet mass). Total PCBs were the predominant POP in green turtles (2.71 ng/g wet mass), yet had lower concentrations than olive ridley and loggerhead turtles. Green turtles had the highest concentrations of α-HBCD (1.46 ng/g wet mass). Among olive ridley turtles, few sex differences were seen in POP concentrations. Concentrations of several POPs increased with straight carapace length of olive ridleys, suggesting bioaccumulation through age. A geographic gradient was observed with concentrations of several POPs increasing with distance from the equator. Plastic ingestion is extremely common in sea turtles and effects of toxic chemicals could have detrimental effects on their health and survival. Amounts of ingested plastic were unrelated to POP concentrations, suggesting that sea turtle exposure to POPs is predominately through their natural food chain. Additionally, our data provide important baseline POP concentrations for Pacific sea turtles, as this area has not been extensively monitored.

158 Marine microplastics as potential indicators of the Anthropocene

J.A. Ivar do Sul, Federal Univ of Rio Grande / Oceanographic Insitute; M. Costa, Federal Univ of Pernambuco / Dept of Oceanography; G. Fillmann, FURG Univ Federal do Rio Grande; I. Santos, Southern Cross Univ

Marine microplastic pollution is an emerging class of marine pollution that is receiving exponential attention from the scientific community mainly in the current decade. Most concern is related to their accumulation on pelagic habitats, and their environmental impacts to the marine biota their and, more recently, the potential contamination of humans through food resources. Recent surveys showed that plastics are widespread over marine habitats including oceanic trenches and deep sea sediments. Transport and deposition of microplastics over the ocean floor are very slow but efficient processes similar to marine snow, 'faecal express' route and minerals loading; therefore, deep seas are the ultimate repository of microplastics in marine habitats. Because they are highly persistent (i.e., not easily degradable and not completely biodegradable) and clear long-lived on human time-scale, it is expected that they will persist in deep sea sediments for longer periods (i.e., centuries to millennia), being potentially preserved in geological records. Cold temperatures and the lack of UV radiation within the continental shelf – deep ocean gradient magnify plastics preservation. Since plastics have only been produced in large quantities after the II World War, plastic longevity was only inferred through short-time laboratory experiments. As a result, and even more over future, plastics are being incorporated into sediments creating a completely new plastic-rich sediment that mark and identifies human's activities in measurable stratigraphic layers. Regardless of representing one of the most ubiquitous marine pollution forms, microplastics are also a likely indicators of the Anthropocene, a new Epoch to be established within the Geological Time Scale. A number of signs – all anthropogenic in nature, including plastic – are showing that the Anthropocene is indeed stratigraphically distinct from the Holocene. If this premise is confirmed, plastics will be in future 'technofossils' which are trace fossils produced by humans, remaining in the environment for geological time-scales and not for human time-scales as they have been treated until now.

Scientific Advances Supporting Aquatic Life Water Quality Criteria Derivation – Part 2

159 Bringing More "Eco" Into Ecotoxicological Guidance for the Development of Water Quality Guidelines for Metals/Metalloids

S.N. Luoma, Univ of California, Davis / John Muir Inst of the Environment

Existing USEPA criteria for most metals and metalloids in freshwater and salt water are built from toxicological approaches that were initially developed before 1985 and refined thereafter. New knowledge of aquatic geochemistry as it affects metal toxicity has been a major focus refining these criteria and is increasingly incorporated into at least some of the criteria in order to add flexibility in dealing with site-specific conditions. A robust "parallel literature" also developed over the last thirty years that illustrates biological and ecological shortcomings in the existing criteria. Unlike geochemistry, nearly all of this literature is formally excluded from consideration by the minimum data requirements for developing criteria. Here it is proposed that a systematic assessment is needed to determine whether a more comprehensive consideration of biological and ecological understanding could help better achieve flexibility as well as more efficiently and effectively protect the environment. Freshwater and saltwater criteria for cadmium and copper will be evaluated as an example to demonstrate some guidelines useful in evaluating the compatibility of the existing criteria with the more comprehensive literature. Questions that will be addressed in the evaluation of the criteria include: Was chronic toxicity, relevant to population processes, adequately addressed? If not what are the implications? Is the justification for species sensitivity robust and is it consistent with field knowledge of such sensitivities? Are the criteria credible when compared with dissolved concentrations known from modern geochemical analyses of contaminated and uncontaminated waters? How do the criteria compare to studies that include dietary exposure? Are the guidelines justifiable based upon field observations that meet criteria for appropriate effects analysis? How do they compare to robust field or integrated laboratory-field observations? A comprehensive evaluation following modified guidelines of this sort could identify criteria least compatible with the full literature and thus most in need of reform. Methodologies and models will be discussed that could be used in a new generation of guidelines that better links biology, ecology and ecotoxicology as well as field observations and laboratory assays.

160 The disconnection between the laboratory and field in understanding the effects of metals on aquatic insects prompts the need to modernize WQC

D.B. Buchwalter, NC State Univ / Dept of Biological Science

The distributions of species that populate natural systems are often quite different in composition from the distributions of species that populate toxicity datasets. Particularly noteworthy is the extent to which aquatic insects are under-represented in toxicity datasets relative to their importance in nature and in ecological monitoring programs. Remarkably, data from only 1 insect species is required for the generation of water quality criteria despite the fact that there are over 7,000 known aquatic insect species in North America alone. When aquatic insect data are examined for trace metal toxicity, it would appear that they are generally insensitive to metals. However, aquatic insects are often some of the first species to disappear from metal-contaminated sites. In fact, typical laboratory results would indicate that insects only respond to dissolved metals at concentrations orders of magnitude larger than those found in the most insect-depleted contaminated sites. Even with mounting evidence highlighting the obvious disconnect between laboratory toxicity tests and field observations regarding metal toxicity to aquatic insects, water quality criteria for metals continues to rely primarily on toxicity values derived from short term dissolved-only exposures. In this talk, I will discuss four key reasons why such tests don't provide relevant data for this important faunal group, focusing upon recent advances in our understanding of bioaccumulation and mechanisms of toxicity.

161 Mesocosms: Old techniques can provide new insight on aquatic life criterion development

T.S. Schmidt, USGS / Colorado Water Science Center; C. Mebane, USGS / Water; L.S. Balistrieri, USGS

Aquatic life critera aim to protect 95% of all species in aquatic ecosystems and those terrestrial organisms dependent on organisms originating in aquatic ecosystems. These ecosystems are dominated both in numbers and diversity by aquatic insects, however, the data used to develop aquatic life criterion rarely include aquatic insects. In part this is because crustacean, amphipods, zooplankton, and some diptera are easily cultured in the lab while most aquatic insects have long lives and complex life histories not suitable for aquaria. Further, beaker-scale toxicological evaluations using standard toxicity testing organisms are criticized for their lack of ecological relevance. We suggest that mesocosms are a technology that can bridge these knowledge and credibility gaps. Here we present data from a series of experiments conducted in the Aquatic Experimental Laboratory, a USGS mesocosm facility located in Fort Collins, Colorado. These data suggest that mesocosm experiments of the effect of aqueous contaminants are replicable, can produce concentration-response curves, and allow for the measure of direct and indirect effects. Thus, ecological, and not just toxicological, endpoints can be evaluated in mesocosm tests. Finally, mesocosm data are extrapolated to multiple field datasets showing that this type of information is reliably transferable to the ecosystems. As a result, mesocosm results can produce beaker-scale type response metrics in ecologically relevant exposure scenarios that are more easily transferable to real ecosystems than standard bioassays. As new technologies and techniques are pursued to advance criterion development into the next century, old techniques might be worth revisiting.

162 Field-based Methods for Developing Water Quality Benchmarks for Specific Conductivity

S. Cormier, USEPA / National Center for Environmental Assessment; L. Zheng, TetraTech

Protection and restoration of conditions that support aquatic life requires chemical and physical benchmarks, standards, or criteria to set loading limits and clean up goals. In 2011, the USEPA published a field-based method for developing an annual average chronic benchmark for specific conductivity (SC). Biological and SC data were used to estimate the extirpation concentrations of a mixture of ions dominated by bicarbonate and sulfate anions. SC levels that lead to 95% extirpation of more than one hundred benthic aquatic invertebrate genera were calculated and used to develop an extirpation concentration distribution to identify the SC that leads to extirpation of 5% of genera. The model was validated with independent data sets and met the characteristics of probable causation. Additional analyses have supported and corroborated the method and it is an EPA-approved method for developing water quality benchmarks. However, the method was silent on parameters usually associated with implementation of benchmarks and water quality criteria. Since 2011, additional methods have been developed to calculate a maximum exposure limit to complement the continuous exposure benchmark. Duration and frequency parameters have been evaluated. Methods have been designed for situations where large data sets of biological and chemical data are not available. These field-based methods are becoming a practical option for estimating benchmarks for common pollutants such as major ions. The views expressed in this abstract are those of the authors and do not necessarily represent the views or policies of the USEPA.

163 Integrating mesocosm experiments and field data to develop water quality criteria for contaminants in aquatic ecosystems

W.H. Clements, C. Kotalik, Colorado State Univ / Fish Wildlife and Conservation Biology

The limitations of single species toxicity tests for predicting effects of contaminants on aquatic ecosystems have been well described in the literature. For certain classes of stressors in which direct toxicological effects are unlikely (e.g., nutrients, suspended sediment, deposition of iron colloids) or in which standard test organisms are highly tolerant (total dissolved solids), field-derived exposure-response relationships have been used to establish standards. Mesocosm experiments provide an ecologically realistic alternative to laboratory toxicity tests while controlling for the confounding variables associated with field-based approaches. In addition to providing mechanistic insights into stressor-response relationships, mesocosm experiments can be coupled with field assessments to address important policy issues. I will present results of two large-scale studies in which mesocosm experiments were integrated with field-based approaches to validate current water quality criteria or benchmarks. In the first example we used field data from spatially extensive surveys of over 300 Colorado streams to establish concentration-response relationships between trace metals and macroinvertebrate community structure. These data were supported by a set of 24 stream mesocosm experiments that allowed us to develop community-level EC20 values for metals. In the second example mesocosm experiments were used to validate a field-based benchmark for conductivity and to quantify the effects of major ions on natural aquatic insect assemblages. This benchmark has been criticized because of the potential influence of confounding variables and the difficulty demonstrating a causal relationship between elevated conductivity and benthic macroinvertebrate responses. Results showed considerable variation among endpoints and salts; however, we observed significant conductivity-response relationships for all major ions tested. These findings demonstrate the strength of integrating descriptive, field-based approaches with mesocosm experiments to establish causal relationships and to identify safe concentrations of contaminants in aquatic ecosystems.

164 Beakers, buckets, and brooks: utility of mesocosm-type studies in aquatic life criteria derivation and validation

C. Mebane, USGS / Water

Since 1985, aquatic life criteria in the USA have been derived using a species-sensitivity distribution (SSD), wherein laboratory toxicity test data derived with a single-species exposed to a single-substance are presumed to adequately represent tolerances of natural communities. While the 1985 aquatic life criteria guidelines allow that microcosm or field data could be invoked to lower a SSD-based calculation, the guidelines did not support the direct use of microcosm or field data to derive criteria. However in practice, only once (1987 with selenium) has a national criterion known been changed based on field data, and recent national criteria documents have ignored community or field data altogether. In contrast, mesocosm or field data are required to validate SSD-based predicted no-effect concentrations (PNECs) under the European Union Water Framework Directive (WFD) and may be used to generate data for the Japan Chemical Substances Control Law. This presentation will illustrate examples where field or experimental ecosystem data have or could be used in conjunction with traditional SSDs, including generating individual species sensitivity data with aquatic insects that would be infeasible to develop from standard laboratory testing.

165 Censoring as a Tool for Optimizing Data Usage in Region-Specific Species Sensitivity Distributions for Hypoxia

J. Carrick, TIEHH / Dept of Environmental Toxicology; T. Anderson, South Central Regional Chapter / Dept of Environmental Toxicology The Inst of Environmental and Human Health; J.D. Maul, Syngenta Crop Protection / Dept of Environmental Toxicology The Inst of Environmental and Human Health

Hypoxia has emerged as a significant environmental issue for the Gulf of Mexico aquatic ecosystem. This study used species sensitivity distributions (SSDs) to evaluate hypoxia sensitivity among marine and tidally-influenced fish and invertebrates of Texas. Representative models require a broad, unbiased sample of species sensitivity data as input. Unfortunately, it is often the case that sensitivity data are only available for a small number of species. The low quantity of data for DO sensitivity among Texas species provided an ideal setting in which to explore methods for increasing the amount of available, standardized data (e.g., acute LC50s). One approach to increasing data quantity is to relax standards for data quality. For example, rapid toxicity testing has been adopted as a way of obtaining approximate sensitivity data on a large number of species. Since smaller sample sizes are used in such toxicity tests, they often result in indeterminate LC50s which can only be expressed as censored values (i.e., less-than, greater-than, or interval values). The current study also relaxes the requirements for data quality as a tradeoff for data quantity; however, an alternate source of censored data is explored — that is, censored data implicit in non-standardized data. Conversion of non-standardized point values into standardized censored values was investigated as a method of maximizing the use of available sensitivity information in the construction of parametric SSDs. Application of this approach increased sample size of the fish dataset from 10 species to 14 species, and the invertebrate dataset from 4 species to 5 species. Inclusion of censored data also shifted HC5s (the concentration protective of 95% of species) upward and downward by varying amounts, although the differences were not significant. The implications of the study are twofold. First, the study identifies a potential store of information that can be used to supplement low quantity datasets used to construct SSDs. Second, it identifies information that may be unintentionally ignored. Authors have discouraged the common practice of discarding censored data. This study demonstrates that even in datasets where censored data are apparently absent, censored data may still be ignored because that information is concealed in non-standardized point values. Furthermore, the results of this study may be valuable in establishing protective DO levels and assessing risk in the Gulf of Mexico.

166 Development of Chemical Thresholds for Situations where Good Ecological Status is unlikely to be achieved

A. Peters, G. Merrington, wca; L. Ceriani, wca consulting / Inst for Environment and Sustainability IES; C. Schlekat, NiPERA; P. Whitehouse, Environment Agency / Evidence; F. Van Assche, IZA; C. Cooper, International Zinc Association / Dept of Marine Sciences; J. Denton, RioTinto; A. Boullemant, Rio Tinto / Lergacy Management

In the UK, and also likely in some other parts of the European Union, there are challenges in regard to meeting statutory Environmental Quality Standards (EQS) thresholds which are considered to be consistent with good ecological status. As the EQS is a regulatory bright line – you pass, or you fail, it is difficult to gauge the impact status of the waterbody from a chemical perspective. It is also difficult to show that any improvement measures taken in response to EQS failure actually result in a real improvement, because there are no thresholds for lower levels of protection, i.e. an improvement is only registered if the EQS is met. Therefore, thresholds which reflect lower levels of ecological quality could be useful communication tools when looking to demonstrate improvements towards the EQS in situations where meeting it is aspirational. Three metals Fe, Ni and Zn were selected for this study, and three methods were identified to derive "less-than-good" thresholds for lower levels of protection, and for a possible application as targets for impacted environments – i) the use of a higher potentially affected fraction (PAF), from the Species Sensitivity Distribution (SSD) used for EQS derivation, that is hazardous to e.g. 10, 25% of the ecosystem (HC10, HC25), ii) the derivation of an SSD based on a higher effect level (e.g. EC20 or EC50 for chronic effects, rather than EC10 or NOEC), iii) and lastly, the derivation of thresholds directly from ecological data for a relevant metric (e.g. invertebrate abundance and diversity) where related field data are available, using a quantile regression analysis. Because of lack of data, the second method based on a higher effect levels could not reliably provide any sort of conclusion. Nevertheless, less-than-good thresholds as bioavailable HC10 and HC25 metal concentrations were derived from experimental data, and were compared with bioavailable ecological thresholds estimated using benthic macroinvertebrate metrics. Ecological monitoring data of phytobenthos and macrophytes were also used as supporting information. Overall, preliminary results indicated that the use of a less-than-good threshold such as the hazardous concentration to 10% of all species, instead of the currently adopted 5% threshold, would likely be sufficient to ensure an adequate level of protection to ensure the good status of the ecology of the waterbody, i.e. plants, invertebrates, and fish.

Novel Mechanisms of Nanomaterial Toxicity Through Direct Exposure or Indirect Interactions with Environmental Components – Part 1

167 Long term memory (LTM) formation as a non-invasive endpoint to assess copper oxide nanoparticles toxicity in the snail Lymnaea stagnalis

V. Ricottone, T. Henry, Heriot-Watt Univ / School of Life Sciences; K. Lukowiak, Univ of Calgary / Hotchkiss Brain Inst Faculty of Medicine; T.F. Fernandes, Heriot-Watt Univ / School of Life Sciences

L. stagnalis has been widely used as a model species in the investigation of linkages between neurobiology, behaviour, learning and memory. The ability of animals to learn and remember enables them to adapt to environmental changes, however, if under stress, their ability to learn and long term memory (LTM) formation may be affected. Because memory is dynamic, stress can positively or negatively alter LTM formation. We hypothesized that stress induced by exposure to nanomaterials, can alter LTM formation in L. stagnalis,and therefore the normal behaviour response to the environment would change. To investigate this hypothesis, we applied a novel assessment method to detect the effect of chronic exposure (30 days) to CuO nanoparticles (NPs) on LTM formation using the freshwater snail, L. stagnalis. Two endpoints were assessed: aerial respiration behaviour and LTM following operant conditioning in the presence of CuO NPs. Results show that aerial breathing behaviour is not affected at the exposure concentrations range (0-250 μg L^{-1} Cu) of the CuO NPs investigated. However, LTM tests were carried out only for the samples collected from controls and 50, 100 and 150 μg L^{-1} Cu exposure vessels. Snails exposed at higher concentrations were not responsive to the operant conditioning necessary to perform the LTM test. Data collected from the test performed on the control organisms showed the ability of the snails to learn and form LTM. However, after 30 days of exposure to CuO NPs at a concentration of 150 μg L^{-1} Cu, snails were not able to learn or form memory. Overall, these findings are in accordance with our previous experiments. Chronic exposure to CuO NPs demonstrated that at concentrations higher than 200 μg L^{-1} Cu, snails show both lethal and sublethal effects in terms of changes in weight and significant decreases in fecundity parameters. In conclusion, we propose this novel approach as a sensitive method to evaluate the toxicity of nanomaterials. Indeed, results obtained are comparable with those obtained with more conventional methods, where costs and numbers of animals used are considerable higher. This research project is funded by the European FP7 project SUN “Sustainable Nanotechnologies”.

168 Enhanced toxicity of environmentally transformed ZnO nanoparticles relative to Zn ions in the epibenthic amphipod Hyalella azteca

H.C. Poynton, Univ of Massachusetts, Boston / School for the Environment; J. Unrine, Univ of Kentucky / Plant and Soil Sciences; C. Chen, Univ of Kentucky; K. Major, B. Blalock, Univ Of Massachusetts Boston / School for the Environment; S. Alexander, Univ Of Massachusetts Boston

As ZnO nanoparticles (NPs) make their way into the aquatic environment water chemistry will influence their fate, transport, and extent of their dissolution. Although the fate and transport of ZnO NPs is complex, sedimentation is expected in most surface water environments, which will put benthic organisms, including the amphipod Hyalella azteca, at particular risk. In addition, ZnO NPs undergo a complex set of transformations in the environment, including pH dependent changes in speciation and solubility and transformations into phosphates, sulfides and carbonates. The goal of our research is to determine the relative toxicity and uptake of environmentally transformed ZnO NPs to H. azteca and reveal the chemical and physical factors responsible for the differences in toxicity. H. azteca were exposed to ZnSO4, pristine ZnO NPs, and environmental aged ZnO NPs which resulted in three types of particles: 30 nm ZnO-Zn3(PO4)2 core-shell structures, micron scale hopeite-like phase Zn3(PO4)2*4H2O), and ZnS nano-clusters. Exposure conditions included a synthetic freshwater only, increased salinity (3 ppt), and the presence of sediment, with a final exposure where animals were contained within mesh baskets to prevent burrowing in the sediment. Although characterization of the aged particles has shown decreased dissolution of these particles in freshwater, phosphate-aged ZnO NPs had increased toxicity relative to other particles. Saltwater decreased the toxicity of ZnSO4 and all the ZnO NPs, with the greatest reduction in the phosphate-aged particles. In sediments, all treatments are about an order of magnitude less toxic, but when H. azteca are placed in mesh baskets to prevent burrowing, the toxicity is only reduced 3-5 fold relative to the sediment free exposures. Finally, the sulfide aged particles (ZnS nano-clusters) have the greatest reduction in toxicity in the sediment exposures, suggesting binding and possible sequestration of the particles by the sediments. These results confirm previous studies demonstrating that H. azteca is very sensitive to ZnO NPs and the increased toxicity of ZnO NPs relative to ZnSO4 suggest particle-specific effects or enhanced uptake of Zn from the NPs. Because H. azteca is one of the most sensitive organisms to ZnO NPs, there is an urgent need to understand the processes that govern the differential toxicity of these particles. Ongoing studies will address this need by measuring bioaccumulation and biokinetics.

169 Evaluating the novel mechanisms of toxicity of complex nanomaterials across organisms and the impact of organic matter and media components

R. Klaper, Univ of Wisconsin-Milwaukee / School of Freshwater Sciences; J. Bozich, Univ of Wisconsin, Milwaukee / SFS; J. Crago, Texas Tech Univ/TIEHH / Environmental Toxicology The Inst of Environmental and Human Health TIEHH; B. Curtis, School of Freshwater Sciences Univ of Wisconsin Milwaukee; V. Feng, Augsburg College; I. Gunsolus, Univ of Minnesota; M. Hang, Univ of Wisconsin Madison; R. Hamers, Univ of Wisconsin Madison / Dept of Chemistry; C. Haynes, Univ of Minnesota; E. Melby, Battelle Pacific Northwest Laboratories; N. Niemuth, Univ of Wisconsin – Milwaukee / School of Freshwater Sciences; D. Olson, School of Freshwater Sciences Univ of Wisconsin Milwaukee; G. Orr, Pacific Northwest National Laboratory; C. Murphy, Univ of Illinois Urbana-Champaign; T. Qiu, Univ of Minnesota; X. Zhang, Univ of Illinois at Urbana Champaign

Although a variety of nanomaterials have been evaluated for their potential safety, there are questions as to how to use this information to predict the next generation of materials which may be more complex and different in composition. In order to create nanomaterials that are environmentally benign it will be necessary to understand the fundamental molecular interactions that occur between a variety of nanomaterials as well as a variety of organisms in order to minimize negative adverse outcomes. In the Center for Sustainable Nanotechnology (CSN) we are studying several types of next generation materials including complex metal mixture nanomaterials being developed for batteries (including NMC, LiCo and variations of these with differing ratios of metals), NP-polymer combinations, carbon based materials, and ligand-nanoparticle combinations that vary in their charge (AuNP-PAH, AuNP-MPA). For several of these materials we have found evidence of nanomaterial specific responses that are different than the surface ligands on the materials or the ions that may be released during the exposures. These molecular changes include alterations of metabolic pathways, detoxification, growth and reproduction, as well as cell surface functions that may provide insight on the mechanism as well as location of interaction of the nanoparticle with the cells of the organism. We have also compared these results across multiple model organisms in the CSN that represent pelagic as well as sediment dwelling model species. We find significant differences in toxicity across models that are also associated with variation in molecular responses across organisms. This variation may be in part due to differences in the cellular chemistry across species and associated sensitivies. For example vertebrates are more sensitive to manganese and therefore altering concentrations of this metal in battery materials has significant consequence. However, differences seen across model organisms have also been found to be partly due to the different environmental conditions or experimental conditions for each of these species including the presence of organic matter, differences in ions present, or pH which can lead to different states of the nanomaterial present during exposures. The implications for deriving conclusions about the molecular effects of nanomaterials and safety limits across the environment based on different model species will be discussed.

170 Estimating Graphene Oxide Exposure and Biomarker Response in Aquatic Systems

D.C. Bouchard, USEPA / EMMD; X. Chang, USEPA, NRC Associate; M. Henderson, USEPA / NERL; S. Martin, Oak Ridge Inst for Science Education at USEPA; C.D. Knightes, USEPA / Natl Exposure Research Laboratory; B. Avant, Student Services Contractor; R. Zepp, USEPA / National Exposure Research Laboratory

Anticipated applications and production volumes of graphene family nanomaterials have raised concerns about their potential release into the environment. Graphene oxide (GO) is a promising member of the graphene family due to its aqueous solution-based manufacturing utility and its role as a precursor to the synthesis of other graphene-based nanomaterials. GO structure is similar to that of 2-D graphene sheets, but differs in that its basal plane is populated with hydroxyl and epoxy groups, and its edges with carboxyl groups. Due to its high oxygen content, GO has been shown to be readily dispersible in the water column, leading to concerns about its transport and subsequent toxicity in surface waters. In addition, studies have indicated that GO phototransforms under sunlight irradiation to yield a wide array of products with differing transport and toxicity characteristics. These photoproducts include not only transformed GO nanoparticles but also a solubilized fraction of oxygenated PAHs resulting in the potential for complex exposures that include direct GO exposures as well as indirect exposures to GO photoproducts. In this report, an approach for estimating GO transport, transformation, and biomarker response in surface waters is detailed. GO transport and mass distribution in the water column and in sediments is modeled through application of the Water quality Analysis Simulation Program (WASP8) recently updated to include nanoparticle attachment kinetic parameters. The potential toxic effects of estimated environmental concentrations are then interpreted using two different nanomaterial exposure biomarker protocols utilizing model membrane systems and metabolomics profiling. Model membrane systems include DOPC/DOEPC supported bilayers as well as bilayers derived from fathead minnow (Pimephales promelas) cell membrane extracts. GO interactions with model membrane systems are quantified using quartz crystal microbalance deposition measurements. GO-model membranes interactions are compared with fathead minnow metabolomic profiles to assess the potential ecotoxicity of GO in fresh surface waters.

171 Fish gastrointestinal tracts influence the sorption of organic contaminants to single-walled carbon nanotubes

T. Sabo-Attwood, J.H. Bisesi, T. Ngo, B. Castillo, Univ of Florida / Environmental and Global Health; C. Lavelle, Univ of Florida / Physiological Sciences; S. Robinson, Univ of Florida / Envirionmental and Global Health; H.M. Crosby, Univ of Florida; N.B. Saleh, Univ of Texas / Dept of Civil Architectural and Environmental Engineering; L. Ferguson, Duke Univ / Dept of Civil and Environmental Engineering; N.D. Denslow, Univ of Florida / Physiological Sciences

Increases in production and commercial use of single-walled carbon nanotubes (SWCNTs) may lead to their release into aquatic environments. While SWCNTs have been shown to be fairly inert, they exhibit high sorption affinity for hydrophobic contaminants that may already be present in aquatic environments. It has been hypothesized that these interactions may reduce oral bioavailability however evidence from our laboratory suggests that sorbed contaminants may still be bioavailable. The synthetic estrogen, ethinyl estradiol (EE2) sorbs to SWCNTs with high affinity, but these mixtures still cause binding and activation of estrogen receptors in vitro, indicating that EE2 maintains bioactivity either through desorption or by preserved interaction with receptors. To determine if these results translate to systemic responses in fish with variable GI tracts, largemouth bass and fathead minnows were orally exposed to mixtures of SWCNTs and EE2. Bass contain a low pH stomach whereas minnows lack a stomach and maintain a relatively neutral pH (7.4) throughout the intestine. Forty eight hours following exposure of fish to EE2-SWCNT by gavage, hepatic vitellogenin mRNA expression was measured as a classic biomarker of estrogenic exposures. Results indicate that EE2 fails to remain sorbed to SWCNTs in fish gastrointestinal systems, irrespective of gastrointestinal physiology, as vitellogenin levels were induced by EE2 in the presenc e of the SWCNTs. As we have obserbed that the SWCNTs do not cross the intestinal epthelium, these resulst imply that the EE2 desorbs from the SWCNTs and is absorbed where it can circulate to the liver and iduce vitellogenin expression. A similar observation was noted in a longer term study where bass were fed SWCNTs-EE2 for 12 weeks. Finally, to begin to elucidate the mechanism of desorption of EE2 from SWCNTs in the GI system we examined the ability of several gut proteins (trypsin, chymotrypsin and pepsin) to displace EE2 from SWCNTs using radiolabeled binding assays. In preliminary studies, trypsin seemed to displace EE2 from the SWCNTs more effectively than other proteins, suggesting that such proteins can imapct EE2-SWCNTs in a protein specific manner. Overall, results of this work futher our understanding of interactions of SWCNTs and contamiants already present in our aquatic environments which is essential for determining the potential organism and ecosystem health risks of these materials.

172 Characterization of the key mechanisms influencing bioavailability of PAHs adsorbed to carbon nanotubes in the aquatic environment

E.N. Linard, P. van den Hurk, Clemson Univ / Biological Sciences; S.J. Klaine, Clemson Univ / Clemson Inst of Environmental Toxicology

Concurrent with the high applicability of carbon nanomaterials (CNM) in a variety of fields and the potential use for pollution remediation, there is the inevitable release of CNMs into the environment. Due to CNMs' high adsorption affinity for organic contaminants (OC), there is significant concern that CNMs will act as "contaminant transporters." While adsorption of contaminants from CNMs play a significant role in the ultimate fate of adsorbed compounds, there is little conclusive information characterizing the relationship between adsorption behavior and bioavailability of CNM-adsorbed contaminants. Carbon nanotubes (CNTs) are some of the most commonly used CNMs and though CNTs morphology and adsorbate chemical characteristics are strongly influential of adsorption behavior, it has yet to be established how such factors influence bioavailability of the adsorbed contaminant. The goal of the present research was to characterize the bioavailability of a model class of organic contaminants, polycyclic aromatic hydrocarbons (PAHs), adsorbed to CNTs as a function of adsorption behavior focusing on the influence of CNT morphology and PAH physicochemical characteristics. Adsorption isotherms of a suite of PAHs to CNTs and graphene were established in conjunction with quantifying the bioavailability of the adsorbed PAH to Pimephales promelas (fathead minnow)using bile analysis via fluorescence spectroscopy. Experimental results demonstrated that the presence of CNTs and graphene similarly reduced the bioavailability of adsorbed linear PAHs by ~60%, but only reduced the bioavailability of adsorbed angular PAHs by ~25% and 0%, respectively. This indicates that bioavailability of angular PAHs adsorbed to CNTs is more susceptible to the CNT "surface curvature" effect than linear PAHs. Normalization of adsorption capacity to PAH hydrophobicity and the corresponding bioavailability data further suggest that there may be a size threshold; PAHs beyond a certain size and width will remain more bioavailable than smaller yet less hydrophobic PAHs. While adsorbate hydrophobicity is arguably the most influential characteristic driving adsorption behavior, bioavailability of CNT-adsorbed PAHs, and potentially other planar organic molecules, is strongly influenced by the compounds' molecular configuration and size. This study provides insight into both the potential risk of environmental CNTs and the effectiveness of such materials for pollution remediation.

173 Goldfish (Carassius auratus) immune responses to intravenously injected polymer-coated TiO2 nanoparticles

V.A. Ortega, Univ of Alberta / Dept of Biological Science; D. Boyle, Plymouth Univ; J. Hodgkinson, Univ of Alberta / Biological Sciences; M. Belosevic, Univ of Alberta; J.L. Stafford, G. Goss, Univ of Alberta / Biological Sciences

Evidence of nanoparticle (NP) effects on immune cell function has been demonstrated using in vitro models in previous studies that report both the over-activation of pro-inflammatory responses, and suppression of others. Our group has also demonstrated modified immune effects for both cell lines and isolated primary goldfish neutrophils when exposed in vitro to polymer-coated metal-oxide NPs. However, the translation of these effects to in vivo models has not yet been explored. Despite a lack of information of in vivo immune effects, it has been shown that when NPs enter circulation in fish, the vast majority is deposited into kidney and spleen tissues, which in fish are the major hematopoietic organ and where many innate immune cells reside. Thus, there is an increased opportunity for neutrophils and macrophages in these organs to interact and be affected by tissue-accumulated NPs. In this study we have sampled kidney and spleen tissues and isolated kidney neutrophils and macrophages at 0, 1, 7, 14 and 28 days from mature goldfish (Carassius auratus) injected with either polymer-coated TiO_2 (1 μg/g) or Cortland's saline (control). Preliminary results show significant and long-term deposition of Ti metal in the kidney and spleen, increased kidney and spleen tissue damage, increased responsiveness of kidney neutrophils and changes in the expression of various pro- and anti-inflammatory related genes in TiO_2-injected fish. We also show a differential response in the capacity of TiO_2-exposed fish to clear a known pathogen during a 28-day infection challenge. Results from our study demonstrate that NP exposure can significantly impact a fish's capacity to appropriately activate numerous immune functions during an infection and this may affect their long-term health and viability.

174 Release of polymer additives and plasticizers from polycarbonate- and epoxy-SWCNT nanocomposites

M.D. Montaño, Duke Univ / Civil and Environmental Engineering; R. Lankone, Johns Hopkins Univ; H. Fairbrother, Johns Hopkins Univ / Dept of Chemistry; L. Ferguson, Duke Univ / Dept of Civil and Environmental Engineering

Single-walled carbon nanotubes (SWCNTs) have shown considerable promise as filler materials in polymer composites as a result of their excellent mechanical, thermal, and electrical properties. Upon use and subsequent entry into the environment via waste streams, it will be important to ascertain the potential for both carbon nanotube release; as well as, how SWCNTs influence the release of polymer additives and plasticizers from these composites. In this study, we investigated how incorporation of SWCNTs affects the release of plastic additives such as bisphenol A and nonylphenol from polycarbonate and epoxy SWCNT composites under environmentally relevant scenarios. Polymer coupons of varying SWCNT mass loading were subjected to simulated weathering scenarios (e.g. room temperature, elevated temperature, UV light exposure) in both EPA moderately hard water and TCLP extraction media. Aliquots of leachates in the media were taken every 24 hours over the course of five days and were analyzed by LC-MS/MS for polymer additives, while carbon nanotube quantification was carried out by near infrared fluorescence spectroscopy and single particle ICP-MS. Our findings have demonstrated that although the mass loading of SWCNTs in the polymer plays a minimal role in the release of BPA from PC-SWCNT composites, the extraction media significantly impacts the release of BPA from polycarbonate, with releases of BPA leaching exceeding 100ppb over a 48hr time period. Differences in the leaching behavior in different media is likely due to the susceptibility of polycarbonate to hydrolysis at elevated or depressed values of pH. Additionally, single particle ICP-MS has shown minimal release of the SWCNTs from the polymer matrix. Future research plans to incorporate fluorescent CNTs into the polymer matrix in order to quantify SWCNT release by near infrared fluorescence.

Mercury Fate and Biogeochemistry

175 Elemental Mercury: Its uniqueness makes it beautiful yet deadly

H. Gonzalez Raymat, Florida International Univ; G. Liu, Y. Cai, Florida International Univ / Dept of Chemistry Biochemistry and Southeast Environmental Research Center

Since ancient times, mercury has fascinated humankind because it has a silver color, it is liquid at room temperature, and it dissolves gold. Due to its fascinating and unique properties, mercury has been used throughout the history for different applications such as barometers, thermometers, electrical switches, fluorescent light bulbs, and ballast for submarines. Mercury is a special element because its chemistry is different compared to other elements. Mercury is considered a global pollutant because mercury in its elemental form has an atmospheric residence time in the range of six months to one year allowing it to travel for long distances, it can be bioaccumulated and biomagnified through the food chain, and in elevated concentrations is highly toxic to humans. Its toxic effects were already known in the 19th century where it was related the occupational exposure of mercury with the Mad Hatter Disease. The first case of severe methylmercury poisoning was discovered in Minamata city, in 1956 where people consumed large amounts of fish and shellfish that were contaminated with methylmercury from the wastewater release of the chemical factory Chisso Corporation to the Minamata bay. The health effects that provoked methylmercury in the people of Minamata were damage to the central nervous system including loss of vision, hearing and speech damage, cerebellar ataxia, and equilibrium disturbance among others. The Minamata disaster and other disasters of mercury poisoning led to the creation of the Minamata Convention Treaty in 2013 whose objective is to protect the human health and the environment from anthropogenic emissions and releases of mercury and mercury compounds. The principal objective of this paper is to evaluate several aspects of Hg^0 behavior and fate in the environment to provide a better understanding of the chemical processes taking place. This review is important because Hg^0 is an important species in the Hg biogeochemical cycling and its behavior in the environment is not well understood.

176 Mercury concentrations, exposure modeling, and isotopic source tracking of mercury in the marine-caged fish farms, South China

X. Xu, Univ of Georgia; W. Wang, The Hong Kong Univ of Science and Technology / Biology

Provinces along the coast of South China have experienced an unprecedented growth in its marine-caged fish industry. We sampled commonly eaten species from two cage-cultured fish farms at the Fujian Province. Total mercury (THg), methylmercury (MHg), and stable mercury (Hg) isotopes were analyzed for fish muscle, sediments, and fish feeds. Reported δ^{202}Hg and Δ^{199}Hg values indicated mass dependent/independent fractionations (MDF/MIF). THg concentrations of the 14 species were all lower than the human health screening value (300 ng/g, wet). There were no statistical differences in Hg concentrations between the cage-cultured and wild caught fish, but the %MHg in cage-cultured fish were lower due to their shorter food chains. Assuming a body weight of 60 kg, the human dietary MHg intake associated with red seabream, Japanese seabass, orange spotted grouper, or eightbar grouper exceeded the USEPA's reference dose (0.1 ug/kg-day). The sediment δ^{202}Hg were low (-1.45‰ to -1.23‰) but the Δ^{199}Hg (-0.04‰ to 0.01‰) were nearly zero. Given its small percentage of MHg (< 3%), it is inorganic Hg that presented such low δ^{202}Hg values, suggesting both atmospheric deposition and microbial activities contributed to the negative MDF signatures. The MIF signatures indicated an industrial Hg source to this region. Hg isotopic values in fish muscle were dominated by diet with pellet-fed fish presenting lower δ^{202}Hg and Δ^{199}Hg values than the viscera-fed fish. The log-MHg concentrations and %MHg positively correlated with δ^{202}Hg values, but not Δ^{199}Hg values. This is because MIF did not occur during metabolic processes and only reflected the signatures of their diets, so fish eating similar food maintained similar Δ^{199}Hg values. Marine-caged fish farms are unique ecosystems, with large input of industrial sources, high DOC, weak photochemical reactions, strong microbial activities in the sediments, high density and simple feeding activities. Though most species had low Hg concentrations, the consumption of several carnivorous fish (e.g., grouper) were of concern. Pellets and viscera feeds provided the major source of Hg to the farmed fish. We suggest using fish feeds, such as shrimp, with low Hg concentrations as an alternative food. With the increasing production of caged-fish in China, our results demonstrate the need for a detailed exposure modeling and risk assessment of Hg through consumption of marine-caged fish.

177 Kinetics of mercury accumulation and its short-term effects towards freshwater biofilms

S. Le Faucheur, P. Dranguet, V. Slaveykova, Univ of Geneva / Section of Earth and Environmental Sciences Inst Forel

Freshwater biofilms are communities of microorganisms, which accumulate and transform Hg, notably through its reduction, methylation and demethylation. The present study aimed to get further mechanistic understanding on Hg and biofilm interactions and focused on the biological parameters that control Hg accumulation in biofilms. To that end, two biofilms of different ages were exposed to ~150 pM Hg (precisely measured) for 24 h in light and temperature controlled conditions using microcosms. Hg uptake kinetics of biofilms were examined with the measurements of non-extractable (obtained after a washing step with cysteine; proxy of intracellular) inorganic and methyl-Hg contents as a function of time. Hg short-term effects were also analyzed at the genomic, physiological and community levels. The old biofilm was characterized by a biomass per cm^2 twice higher than the young biofilm. However, no significance difference was found in their percentage of biotic fraction and chlorophyll a content. The young biofilm was characterized by a higher abundance of the merA gene and a lower abundance of the hgcA gene than the old biofilm. Finally, taxonomic analysis revealed a difference at the microorganism community levels, especially for microalgae. Hg uptake was characterized by rapid kinetics, within minutes, for both biofilms. However, the Hg uptake rate constant of the young biofilm was 10 times higher than that of the old biofilm, probably due to the diffusion limitation of Hg towards microorganisms by the larger thickness of the EPS matrix of the old biofilms. As such, Hg accumulation in the young biofilm plateaued after 2 h of Hg exposure whereas a linear increase of Hg accumulation was observed during the 24 h of exposure in the old biofilms. Algal communities were strongly affected by that short Hg exposure with a decrease in the chlorophyll a content and in the percentage of Chlorophyta present in both biofilms. Effects on bacteria communities were visible at the genomic level with an increase of the merA gene and community level with the increase of Cyanobacteria percentage. The present study evidenced the rapid response of biofilms to Hg exposure in term of accumulation and effects and highlights their possible use as bioindicators of exposure and effects of Hg towards aquatic microorganisms in contaminated freshwaters.

178 Trophic magnification of mercury in aquatic food webs: worldwide patterns and drivers

K.A. Kidd, Univ of New Brunswick; L. Campbell, Saint Marys Univ / Dept of Environmental Science; M. Chumchal, Texas Christian Univ; T. Jardine, Univ of Saskatchewan / School of Environment and Sustainability and Toxicology Centre; R. Lavoie, Royal Military College of Canada / Biology

The increase in mercury (Hg) concentrations in aquatic organisms with increasing trophic level (measured using d^{15}N), known as the trophic magnification factor (TMF), averages approximately 8 times for methyl Hg, but ranges from 1 to 64 times across diverse food webs. Based on an analysis of 69 food web studies conducted in the last 20 years (before 2013) in marine and freshwater systems, we previously showed that some of this variation is related to latitude, with Arctic food webs having higher TMFs (~10 times) than those from the tropics (~4 times), possibly due to effects of slow growth in animals from the former food webs. Also, areas with high Hg inputs (via atmospheric deposition) tend to have food webs that exhibit lower trophic magnification of this metal, thus lessening risk from exposure in these otherwise contaminated food webs. Yet most of the variation in TMFs across systems remains unexplained. Here we revisit and add new data to this global dataset to further explore these patterns and drivers. We identified an additional 74 studies completed between 2013 and 2016 for potential inclusion in the database. These include studies on under-represented systems such as hydroelectric reservoirs that are known to lead to high Hg in predatory fishes upon dam construction. Given ongoing Hg emissions, deposition and transformations and the Minamata Convention, understanding Hg behavior in food webs at global scales allows for critical links to be made between system characteristics and top predators in food webs that can be used to identify areas at greatest risk from legacy inputs or those that may respond more quickly to global reductions in Hg emissions.

179 Mercury concentrations in northern pike in the Flin Flon, Manitoba area: spatial and temporal responses to smelter closure

M. Evans, Environment and Climate Change Canada; J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; D.C. Muir, J. Wiklund, J. Keating, A. Gleason, Environment and Climate Change Canada; X. Wang, Environment and Climate Change Canada / Aquatic Contaminants Research Division

The Flin Flon (Manitoba) copper-zinc smelter was a major metal emitter with an estimated 20 tonnes/yr of mercury released to the atmosphere over the late 1970s to early 1980s. Copper (Cu), cadmium (Cd), mercury (Hg) and zinc (Zn) exceeded Canada's CCME probable effects level guidelines for sediments in several lakes within 8 km of the smelter and did not approach baseline until ca. 70 km distant. However, Hg concentrations in northern pike were lowest in lakes closest to the smelter and highest in two of four lakes 75-85 km distant. Low Hg concentrations in pike close to the smelter were attributed to the inhibition of Hg methylation by metals at toxic concentrations. Metal emissions later declined with improvements in plant design; the smelter closed in 2010. Our study, conducted over 2008-2015, is investigating spatial and temporal trends in Hg concentrations in lake food webs and focusses on northern pike. Despite major improvements in smelter operation, Cu, Cd, Hg, and Zn concentrations in lake sediments close to the smelter are 1.4-2.0 times higher than in the early 1980s and concentrations in distant lakes 1.1-2.0 times higher. These increases are attributable to immense metal reserves on the landscape which continue to enter the lakes through re-emission and runoff pathways. Moreover, Hg concentrations have increased in pike in two lakes close to the smelter, i.e., from 0.09±0.06 µg/g to 0.25±0.16 µg/g for Phantom Lake and 0.12±0.07 µg/g to 0.33±0.19 µg/g for Meridian Lake. These increases suggest that Hg methylation rates at the sediment water interface have increased, possibly because metals have become less toxic with chemical weathering (in the lake and watershed). Percent methyl Hg, a measure of Hg methylation rates, was 2-3% in lake water and similar to lakes (2-6%) in the Thompson area where sediments are not contaminated with metals. Hg concentrations in pike in Lake 1, 74 km to the northeast, have increased slightly (0.18±0.07 µg/g in 1982 versus 0.25±0.14 µg/g) and more so at McClurg Lake (0.63±0.37 µg/g versus 1.00±0.53 µg/g); increases may be related to warming trends and changing water chemistry. Pike condition factor was similar in 1982 (0.68±0.13) and 2008-2015 (0.68±0.08) as was age (5-7 years) with no spatial patterns related to smelter distance; this suggests that high metal concentrations in sediments have had little impact on pike growth rates and longevity.

180 Mercury Accumulation in Laurentian Great Lakes Fish: Are Global Mercury Inputs Affecting the Great Lakes Ecosystem?

T.M. Holsen, H. Zhou, C. Zhou, B. Crimmins, Clarkson Univ / Civil and Environmental Engineering

Lake Trout (Salvelinus namaycush) and walleye (Sander vitreus) are collected from two sites within each lake, every other year, and total mercury (HgT) is measured as part of the Great Lakes Fish Monitoring and Surveillance Program (GLFMSP). Previous analyses of Hg concentration trends at these locations were inconsistent, with concentrations at some locations increasing, some decreasing and some not changing. This updated trends analysis indicates that at nearly all sampling locations, HgT concentrations are decreasing with the exceptions of the shallow (nearshore) site in Lake Michigan and the deep (offshore) site in Lake Huron, which showed increasing Hg concentrations. Apparent increasing trends at these two locations are likely the result of older fish present in the size class collected as well as possible localized deposition emanating from nearby industrial centers. These results in conjunction with significant reductions in water column Hg; decreases in Hg(0) concentrations in air over the lakes over the past 7-10 years, and declining trends in Hg wet deposition at most locations near the Great Lakes over the past 10 years suggest that environmental regulations enacted by U.S. and Canada are having positive effects in the Great Lakes ecosystem and that increasing global anthropogenic emissions are not overwhelming regional controls and significantly impacting mercury concentrations in the Great Lakes. Analysis of stable Hg isotope results, which is a new tool in Hg research that can help discern differing Hg sources, pathways and processes will also be presented.

181 Gaseous mercury flux from salt marshes is mediated by solar radiation, temperature, and moisture

T. Sizmur, Univ of Reading / Geography and Environmental Science; G. McArthur, Acadia Univ; D.A. Risk, St Francis Xavier Univ / Earth Sciences; R. Tordon, Environment and Climate Change Canada; N.J. O'Driscoll, Acadia Univ / Dept of Earth and Enviromental Science

Salt marshes are ecologically sensitive ecosystems where mercury methylation and biomagnification can occur. Understanding the mechanisms controlling Gaseous Mercury Flux (GMF) from salt marshes is important to predict the retention of Hg in coastal wetlands and project the impact of environmental change on the global Hg cycle. We monitored GMF from a remote salt marsh over 9 days which included three cloudless days and a 4 mm rainfall event. We observed a cyclical diel relationship between GMF and solar radiation. When measurements at the same irradiance intensity are considered, GMF was greater in the evening when the sediment was warm than in the morning when the sediment was cool. This is evidence to suggest that both solar radiation and sediment temperature directly influence the rate of Hg(II) photoreduction in salt marshes. GMF could be predicted from solar radiation and sediment temperature in datasets collected during cloudless days ($R^2 = 0.99$), and before ($R^2 = 0.97$) and after ($R^2 = 0.95$) the rainfall event but could not account for the lower GMF after the rainfall event (in contrast to greater GMF from soils after rainfall events) that we propose is due to increased photooxidation or decreased photoreduction in chloride-dominated aqueous solutions.

182 Methylmercury entry and accumulation in the food web of a semi-arid river-reservoir system

C. Eagles-Smith, J.J. Willacker, USGS / FRESC; J. Chandler, Idaho Power Company; D.P. Krabbenhoft, USGS; J. Naymick, Idaho Power Company; G. Clark, USGS

Water management can be a major driver of mercury (Hg) bioaccumulation and risk, particularly in semi-arid western environments where available water resources are managed for often competing environmental and societal uses. Reservoirs in particular have been associated with elevated mercury bioaccumulation because of the effects of reservoir management on the biogeochemical factors regulating mercury cycling and bioaccumulation. The Snake River ecosystem is among the most heavily managed rivers in the US. It receives substantial agricultural drainwater and contains a series of reservoirs along its 1700 km extent. As part of a multidisciplinary effort to understand the drivers of mercury cycling and biomagnification along the Snake River we examined temporal and spatial patterns of methylmercury concentrations at the base of the food web (zooplankton and benthic invertebrates), as well as bioaccumulation through the fish community. Preliminary results indicate that fish Hg concentrations were substantially elevated in the reservoirs in comparison to upstream and downstream river segments. In the reservoirs, methylmercury concentrations in zooplankton exceeded those of benthic invertebrates but there was strong temporal variability in zooplankton methylmercury concentrations. Zooplankton concentrations were lowest in early spring (March/April) and midsummer (July/August), and highest in late spring (May/June) and late summer/early fall (September/October). Although relative changes over time in zooplankton methylmercury concentrations were consistent throughout the study area, there was substantial site-to-site variation during any given sampling event, and concentrations varied by up to 3-fold across sites. Sites that were strongly stratified with substantial hypolimnetic development had higher zooplankton methylmercury concentrations than unstratified sites, thus we evaluated zooplankton methylmercury concentrations within discrete depth strata. Zooplankton methylmercury concentrations were substantially higher at depths that were near the thermocline than those from the upper epilimnion. However, diel sampling suggested that vertical zooplankton migration may be transporting methylmercury from lower depths to the upper epilimnion, increasing potential exposure to fish and other higher order consumers. Our preliminary results suggest that seasonally dynamic processes influence methylmercury cycling through the Snake River food web.

Soil Contaminants: Fate, Bioavailability, Environmental Toxicology and Risk Assessment – Part 2

183 The long term effects of trace metals on soil microbial functions: Biological and chemical implications

P. Garvey, Univ of Saskatchewan / Soil Science; S. Siciliano, Univ of Saskatchewan / Toxicology Group and Dept of Soil Science

Soil microbial functions are vital for maintaining soil health. There is a lot of evidence showing that soil microbial functions are affected by trace metal contamination in the short term, but that over time they are restored. The long term effect of trace metals on soil microbial functions are however poorly understood. Much of the available data on adaptation is derived from studies focused on European agricultural soils. This study used North American soils across a range of land-uses to identify differences in the adaptation rate and sensitivity. This study aimed at evaluating the methods used to assess the hazards from trace metals using spiked soils. First soils (n=18) were spiked with zinc (Zn) and copper (Cu),8 doses were applied. Then dose-response curves were determined for soil nitrification and enzyme activity (dehydrogenase; arylsulphatase and acid phosphatase). This showed land-use was a factor ($P < 0.01$) effecting the toxicity of Zn & Cu. Boreal forest soil nitrification rates were the most sensitive end-point to Zn (EC50 = 202 ± 44 mg kg^{-1}) and Cu (EC50 = 197 ± 23 mg kg^{-1}). Across all land-uses and soil types a similar pattern of sensitivity was seen: Potential nitrification>dehydrogenase> arylsulfatase> acid phosphatase. Soils were then monitored to identify adaptation of these microbial functions over 180 days. All soils and measurement end-points showed adaptation to both Zn & Cu. The relative sensitivity of each end-point remained consistent after adaptation had occurred. Secondly this study tested whether adaptation to a server stress (trace metals) affects resistance or resilience to a subsequent mild stress. The resistance, resilience and relative soil stability index (RSSI) of soils were determined for heat (60°C for 24 hrs) and moisture stress, applied as short term secondary stresses. This showed that soils which have adapted to Zn & Cu are not less resilient to additional stresses after adaption, than before recovery. This experiment suggests that metal concentration is not a good indicator of soil microbial health but activity is. Additional the effects of primary and secondary stresses on ecosystem functioning are complex and dependent on the effect of the two stresses. Finally this study assessed metal speciation of the artificially contaminated soils. Metal speciation was determined using k-Edge X-ray absorption spectroscopy. Zinc k-edge EXAFS were measured at the HXMA beamline (06-ID1) of the Canadian Light Source Inc.

184 Bioaccessibility and acute toxicity of bismuth to the earthworm Eisenia andrei

Z. Omouri, INRS-Institut Armand Frappier; M. Fournier, INRS-Institut Armand Frappier / ISMERUQAR; P. Robidoux, AGAT Laboratories, Ltd / Specialty services Division

Bismuth (Bi) is increasingly used to replace lead in several industrial applications including the production of alloys and munitions formulations. However, little information is available on the environmental fate and ecological effects of Bi. The present study describes the 14 days acute toxicity of Bi, added as Bi citrate to a natural sandy soil, to the adult earthworm Eisenia andrei. The total measured Bi concentrations were 298, 399.5, 431, and 469.5 mg Bi/kg dry soil. Data indicates that Bi was toxic to E. andrei, as determined by LC_{50} and LOEC, i.e., 416 and 399.5 mg Bi/kg dry soil, respectively. In the presence of E. andrei for 14 d, the bioaccessible fraction of Bi in soil, as determined in KNO_3 aqueous soil extracts, increased by a factor ranging from 1.6 to 30.0 compared to those measured at t=0. Moreover, the increase in soil Bi bioaccessibility was accompanied by a rise in pH and with a increase in mortality of E. andrei. For example, when Bi bioaccessibility increased from 0.262 to 7.516 mg Bi/kg dry soil, the mortality rate increased from 0 to 79 %. We assume that there were at least two routes by which E. andrei enhanced Bi bioaccessibility; one route was guided by the mobility and the biochemical (mucus and bacteria) interactions of E. andrei with soil constituents, and the other route was marked by the death of earthworms and the release of the accumulated Bi from the carcass.

185 Heavy Metals Contamination at the Agbogbloshie Electronic Waste (E-waste) Site in Ghana – Risks to Ecological and Human Health

A. Santa, McGill Univ / Natural Resource Sciences; N. Basu, McGill Univ / Dept of Environmental Health Sciences

There is worldwide increase in the discarding of electrical and electronic equipment (e-waste). Studies at e-waste recycling sites, which are mainly situated in low- and middle-income countries, have started to document ecosystem contamination by heavy metals and organic compounds. Despite concerns, the extent and variability of contamination within a site as well as potential environmental and human health risks is still limited. The objective of this study was to evaluate surface soil at the Agbogbloshie e-waste site (Africa's largest e-waste recycling site) in Accra, Ghana for 19 metals. Within Agbogbloshie, we sampled sites in which e-waste was sorted (n=7), dismantled (n=6), and burned (n=9), as well as in nearby community areas (n=2) and surrounding points (n=26). The soil metal data were analyzed by calculating the enrichment factor (EF) and geoaccumulation index (Igeo) for assessing metal contamination, and the Hazard Quotient (HQ) as a measure of health risk. EF values between 0.5 and 1.5 indicates that the metal is from natural processes or crustal material, while higher values indicate that the metal is from external sources. In average high EF (132-3) was found in all the sampling sites for Cu > Ag > Pb > Cd > Zn > As. The highest EF factors were found in the dismantling areas (EF 362-4) followed by the areas associated with e-waste sorting (EF 318-4) and burning (EF 160-16). For the community sites EF values ranged between 2 and 3. While EF indicates the source of enrichment, Igeo indicates the level of soil contamination with 0 being uncontaminated and > 6 extremely contaminated. The samples from the dismantling and sorting sites had the highest levels of contamination for Cu > Ag > Pb > Cd > Zn As > Se (Igeo 8-2), followed by the burning sites (Igeo 3-7). Soils in the community site were moderated contaminated (Igeo ≤1) by Zn > Cu > Pb > Ag. Concentrations of metals also reach the sample sites located outside the recycling area with EF > 10 and Igeo > 3 for Cu > Ag > Pb > Cd > Zn. The HQ values only exceed the unity for Pb and Cu in the sorting and dismantling site. The Hazard Index (HI =) presented values above 1 for the 3 sites inside the e-waste. Based on EF, Igeo, and HQ, Cu and Pb are the chemicals of greatest concern for environmental and human health, principally in the recycling areas.

186 Does Lead toxicity to the soil microbial community decrease ecosystem service quality?

F. Awuah, Univ of Saskatchewan / Toxicology Centre; B.A. Hale, Univ of Guelph / School of Environmental Sciences; S. Siciliano, Univ of Saskatchewan / Toxicology Group and Dept of Soil Science

The soil biotic community provides several benefits to people. These benefits are termed Ecosystem Services and include food or water provision, and nutrient cycling. The soil microbial community forms an integral part of these processes. Lead exposure, among other metals, inhibits the activity and function of microbial communities which could potentially reduce their ecosystem service performance. Preliminary experiments have shown that lead inhibits the activity of β-D glucosidase and ammonia monooxyenase enzymes. Further studies are being undertaken to understand how this enzyme inhibition affects the xenobiotic degradation potential, climate regulation ability and the organic matter decomposition rate of metal (Pb) stressed microbial communities. To achieve this, 100 soils have been collected from Alberta, Manitoba, Saskatchewan and Yukon. Each of these soils will be spiked with a dose of lead nanoparticles that inhibits at least 50% of β-D glucosidase activity (EC_{50}). Elymus lanceolatus will be grown in the soils for two weeks per Environment Canada's protocol to determine the metal's secondary effects on forage. Forage quality will be determined by a measure of crude protein and biomass. The effects of lead on the climate regulatory role of the microbial communities will be determined by measuring CO_2, CH_4, N_2O using an FTIR. The lead contaminated soils will be re-spiked with glyphosate and the degradation rate will be determined by a measure of mineralized $^{13}CO_2$. The relationship between quantified sub lethal effects of lead on microbial activity and function, and ecosystem service quality will be established at the end of the project.

187 Revisiting the Avian Eco-SSL for Lead: Recommendations for Revision

B.E. Sample, Ecological Risk, Inc; N. Beyer, USGS / Patuxent Wildlife Research Center; M.S. Johnson, US Army Public Health Center / Toxicology; R. Wentsel, Exponent Inc

The avian Eco-SSL for Pb is very low and within background for most of the US. Site-specific risk-based remedial goals for Pb are frequently many times greater. The extremely low nature of avian Pb Eco-SSL limits its utility for screening purposes. Sensitivity analysis indicates that TRVs play an inordinate role in defining Eco-SSLs. The avian TRV used for the Pb Eco-SSL is based on reduced egg production in Japanese quail. Additional analyses shows egg production in Japanese quail to be very sensitive to Pb, displaying effects at doses lower than other species. The Japanese quail TRV may bias the avian Eco-SSL low. Avian toxicity data supporting the Eco-SSL were re-evaluated. Only studies that reported both NOAELs and LOAELs for reproduction, growth, and/or survival were considered. Dose-response data and supporting information were extracted from each study as concentrations and as dose. Response data were recorded as reported by authors and control normalized. Dose-response relationships were developed for dietary concentrations and doses for reproductive, growth, and mortality effect endpoints. Effect levels (10%, 20%, and 50%) were extracted from dose-response analyses. Data were extracted from 8 studies representing 3 Pb forms and 4 species. Data were sufficient to fit curves for egg production (quail, chicken), growth (quail, chicken), and survival (kestrel). Reproduction was most sensitive and survival least with growth intermediate. Japanese quail were more sensitive than chickens, displaying greater variability. In addition, quail data were not always consistent. Limited data for turtle doves and kestrel suggests lower sensitivity. Chicken data appear less variable. Concentrations toxic to chickens were consistent with levels causing physiological effects in other birds. EC_{10} and EC_{20} thresholds for chickens were 3.6 and 7.8 mg/kg/d. Current NOAEL based on quail (1.63 mg/kg/d) approximates quail ED_{20} (1.2 mg/kg/d). Pb Eco-SSL was recalculated based on ED_{10} and ED_{20} and with and without a bioavailability adjustment. Revised avian Pb Eco-SSLs ranged from 29 to 140 mg/kg. Recommendations: 1) Mine the data in the Eco-SSL reports; 2) Extract dose-response data/investigate relationships for other analytes; 3) Re-calculate Eco-SSLs based on dose-response analyses.

188 Effects of chemicals on soil organisms in the field: available methods and ecological background

J. Roembke, ECT Oekotoxikologie GmbH

According to European regulations, the effects of chemicals on soil organisms are studied almost exclusively in the laboratory, i.e. in single-species-tests under well-standardized but highly artificial conditions. In case a risk cannot be excluded, higher-tier tests, i.e. field studies or monitoring approaches could be required but in reality only the earthworm field test (ISO 1999) was regularly performed as part of the risk assessment of pesticides (PPP). According to recent discussions within the European Food and Safety Authority (EFSA) and the European Medicines Agency (EMA), the number of more complex field studies may increase in the foreseeable future, for two reasons. In the case of the PPPs, new regulation (EI 1107/2009) requires the protection of biodiversity – a task which has been interpreted by EFSA as the protection of ecosystem services provided by organism communities. In the case of VMP appropriate risk mitigation measures (RMM) have to be identified for those parasiticides which are classified as being persistent (P), bioaccumulative (B) or toxic (T) in the environment. One possibility in such cases would be a post-authorization monitoring. It is difficult to assess the outcome of monitoring approaches, i.e. to decide whether the protection goals are fulfilled or not (in this case whether the functions and services provided by soil organism are provided or not). Data gained at monitoring sites (e.g. the species composition of an earthworm community) has to be compared with reference data (or Normal Operating Range (NOR)). Such NORs have to be defined beforehand at ecologically comparable but non-impacted sites. In other words, the composition and functions of (temperate) soil organism communities or at least their most relevant groups have to be known. In this presentation soil organism communities of temperate regions will briefly be described, including criteria how to identify the most relevant organism groups and their functions (most prominently: organic matter decomposition). Potentially useful methods and endpoints for measuring them are presented, including sampling and identification techniques. Special emphasis will be given on the validation and standardization of these complex methods. Finally, different ways of presenting and evaluating the outcome of monitoring activities will be presented, using examples from European sites.

189 Soil invertebrate avoidance behavoir from a hydraulic lubricating oil

A. Gainer, Univ of Saskatchewan – Toxicology Centre / Soil Science, Toxicology; S. Siciliano, Univ of Saskatchewan / Toxicology Group and Dept of Soil Science

Avoidance tests are a rapid toxicity test type in soil toxicology to assess the influence of contaminants on organisms behaviors. Behavioral studies are currently lacking in ecotoxicology risk assessment and can easily be incorporated into the common risk assessment tool, the species sensitivity distribution curve. Soil invertebtrate with chemosensing abilities avoid nonvolatile, volatile and semi volatile contaminants. Semi volatile contaminants like petroleum hydrocarbons interfere with chemosensing and alter the distribution and behavior of soil invertebrates populations. Development of guidelines considering ecologically relevant endpoints are important to maintaining ecological functioning of soil invertebrate communities following contamination events. The EC50 values for avoidance tests for numerous soil invertebrates were compared to the EC50 value for reproduction. Soil remediation guideline derived from a SSD was determined with and without inclusion of avoidance tests to assess how these tests influence the resulting guidelines.

190 Effect of select perfluorinated compounds on hatching success of, and accumulation in, the house cricket (Acheta domesticus)

J. Mauricio, S. Lasee, Texas Tech Univ / Dept of Environmental Toxicology / The Inst of Environmental and Human Health TIEHH; S. Subbiah, A. Karnjanapiboonwong, J. Kasumba, D. Wang, Texas Tech Univ / The Inst of Environmental and Human Health; T. Anderson, South Central Regional Chapter / Dept of Environmental Toxicology The Inst of Environmental and Human Health

Perfluorinated compounds (PFCs) are persistent organic pollutants. PFCs are used in a variety of industries including aerospace, automotive, manufacturing, electronics, and textiles. Multiple research studies have provided information regarding concentrations of PFCs in human blood, various mammals, and aquatic life. There is a noted lack of studies regarding the potential terrestrial impacts of PFC contamination. In order to fill this gap, the effect of perfluoro-1-butanesulfonate (PFBS), perfluro-n-octanoic acid (PFOA), perfluoro-1-hexansulfonate (PFHxS), perfluoro-n-heptanoic acid (PFHpA), and perfluoro-n-nonanoic acid (PFNA) on adult accumulation and egg hatching success of the house cricket (Acheta domesticus) was studied. Fertilized cricket eggs (n=20/replicate) were exposed to PFCs in lab-grade sand to evaluate a scenario in which PFCs were readily bioavailable. Each treatment concentration (n = 5; from 0 to 70 µg/g) included 4 replicates except for the high dose. Results suggest that these selected PFCs are toxic to cricket eggs at concentrations ≥ 42 µg/g; these toxic effects are manifested as a decrease in hatching success. Select cohorts that successfully hatched were reared and observed to determine gender ratio and PFC body burdens. Initial results show that PFCs are taken up into the egg and subsequently found in reproductive age adults depending on the chemical and the exposure concentration. Initially, there appears to be some differences in the accumulation of PFHxS and PFOA in adults compared to PFBS. Understanding PFC body burdens in adult crickets following egg exposure should aid in predicting the transport of PFCs through terrestrial food webs.

Frequent Fliers: Effects of the Deepwater Horizon Oil Spill to Birds

191 Deepwater Horizon Oil Spill NRDA Avian Toxicity Studies – Introduction

P.L. Tuttle, US Fish and Wildlife Service / Deepwater Horizon NRDAR Field Office; J. Isanhart, Dept of the Interior / Office of Restoration and Damage Assessment; M. Hooper, USGS / Columbia Environmental Research Center; K.A. Trust, US Fish and Wildlife Service / National Wildlife Refuge System Pacific Region; K.A. Healy, US Fish and Wildlife Service / Deepwater Horizon NRDAR Office

On April 20, 2010, the Deepwater Horizon (DWH) drilling rig exploded, caught fire, and eventually sank in the Gulf of Mexico. The explosion and fire killed 11 workers and injured 17 others. For 87 days, oil and gas flowed uncontrolled from BP's Macondo well, creating the largest offshore oil spill in U.S. history. Under the Oil Pollution Act of 1990, Federal, State, and Tribal Natural Resource Trustees are authorized to conduct a Natural Resource Damage Assessment (NRDA) to assess injuries to natural resources and recover damages to restore, replace, rehabilitate, or acquire the equivalent of those resources injured by an oil spill. As part of the DWH NRDA, the Trustees relied on two primary approaches to assess injuries to migratory birds. The first, the Shoreline Deposition Model, used data on the deposition of impaired and dead birds on shorelines along with other data to estimate mortality across the affected area. The second, the Live Oiled Bird Model (LOBM), estimated injury to birds that were oiled, but died later in the spill timeframe. At the most basic level, the LOBM relied on three primary inputs: 1) the numbers of birds in affected areas, 2) the incidence and degree to which birds were oiled, and 3) the fate of oiled birds (i.e., the likelihood a bird would die or suffer other adverse effects). Studies were undertaken to generate LOBM inputs for major bird groups affected by the spill. Abundance and oiling rates were determined by aerial and/or surface-based surveys. Key to understanding oiled bird fate were data on DWH oil-related health effects in field-collected birds. Specifically, the occurrence of hemolytic anemia in birds from oiled areas was clearly important to understanding bird fate. The Trustees therefore undertook four controlled dosing study approaches to help characterize the breadth of toxicological effects occurring concurrently with documented levels of hemolytic anemia to improve oiled bird fate predictions: 1) Oral dose-response studies; 2) External oiling dose-response studies; 3) Metabolic, thermoregulatory, and flight performance effects studies; and 4) Field-based flight effects studies. The following series of presentations describe, in part, the findings of those studies.

192 Overview of Avian Toxicity Studies for the Deepwater Horizon Natural Resource Damage Assessment

S.J. Bursian, Michigan State Univ / Animal Science; D. Cacela, Abt Associates; F.L. Cunningham, USDA/ WS / National Wildlife Research Center Mississippi Field Station; K. Dean, Abt Associates; B. Dorr, USDA / WS / National Wildlife Research Center; C.K. Ellis, USDA National Wildlife Research Center; C.G. Guglielmo, Univ of Western Ontario / Dept of Biology; K.C. Hanson-Dorr, USDA / WS / National Wildlife Research Center; K.E. Harr, Urika Pathology LLC; K.A. Healy, US Fish and Wildlife Service / Deepwater Horizon NRDAR Office; M. Hooper, USGS / Columbia Environmental Research Center; K. Horak, USDA; J. Isanhart, Dept of the Interior / Office of Restoration and Damage Assessment; L.V. Kennedy, Western Univ / Deparment of Biology; J. Link, Michigan State Univ / Dept of Animal Science; I. Maggini, Univ of Western Ontario / Dept of Biology; J.K. Moye, C. Perez, Univ of Nevada, Reno / Agriculture Nutrition and Veterinary Sciences; C.A. Pritsos, Univ of Nevada / Agriculture Nutrition and Veterinary Sciences; S.A. Shriner, USDA APHIS WS NWRC; K.A. Trust, US Fish and Wildlife Service / National Wildlife Refuge System Pacific Region; P.L. Tuttle, US Fish and Wildlife Service / Deepwater Horizon NRDAR Field Office

In the wake of the Deepwater Horizon oil spill, federal and state agencies conducted a Natural Resource Damage Assessment (NRDA) under the authority of the Oil Pollution Act of 1990. A component of the NRDA included a series of avian toxicity studies. The goal of these studies was to evaluate the impacts of low to moderate oil exposure and potentially repeated oil exposure that did not result in short-term mortality but might result in physiological impacts that ultimately could affect avian survival and health. Four groups of avian toxicity studies were proposed by experts convened by the Department of the Interior. These studies included oral dosing studies, an external dosing study, metabolic effects studies and field-based flight studies. The objectives of the oral dosing studies were to develop dose-response relationships in multiple species that could be used to predict the toxicity of oil ingested by birds following the spill, investigate endpoints that might be linked directly or indirectly to the occurrence of hemolytic anemia (a finding in oil-exposed wild birds) to provide relevance to field studies and to determine oral doses for the metabolic studies. The objective of the external dosing study was to develop quantitative relationships between external oiling of birds (percent cover, amount, location) and internal dose. The objectives of the metabolic effects studies were to determine the adverse effects of oral dosing on energetics and metabolism including flight performance, thermoregulation, food/energy assimilation and body composition and to measure the effects of feather oiling on flight performance. The objective of the field-based flight studies was to determine if oral and external doses of oil affected performance in homing pigeons trained for long-distance free flights. Results from these studies and their significance in terms of physiological impacts that ultimately could affect avian survival and health are provided in subsequent presentations.

193 Evaluation of blood parameters as a measure of physiological injury to oiled birds from the Deepwater Horizon oil spill

J.A. Fallon, Virginia Tech / Fish and Wildlife Conservation; E. Smith, Virginia Tech / Statistics; W.A. Hopkins, Virginia Polytechnic & State Uni / Dept of Fisheries and Wildlife Sciences

The Deepwater Horizon oil spill released an unprecedented volume of crude oil into the Gulf of Mexico. While avian mortality associated with this and other oil spills has been documented, the sublethal physiological effects of oil exposure on birds with moderate and light oiling is not yet clearly understood. We found that American oystercatchers, black skimmers, brown pelicans, and great egrets captured during the spill with small amounts of visible oil present on their feathers suffered from oxidative injury to erythrocytes, had decreased numbers of circulating erythrocytes, and showed evidence of a regenerative hematological response in the form of increased reticulocytes (i.e., young red blood cells). We found Heinz bodies present almost exclusively in birds from sites impacted with oil during the 2010 spill – a change pathognomonic for oxidative injury. Further, we found that packed cell volume values were 4% to 19% lower in birds with visible oil than birds from reference sites and that there were 27% to 40% more reticulocytes present in birds with visible oil than birds from reference sites. Together these findings provide evidence that modest oil exposure, based on visible oiling of feathers, can cause hemolytic anemia. Furthermore, we found that birds with no visible oiling captured from the area potentially impacted by the spill also had Heinz body formation, increased numbers of reticulocytes, and reduced packed cell volumes when compared to birds from reference sites. This observation suggests that even birds without visible oil suffered physiological injury from the spill, with ingestion of oil or oil-related contaminants during foraging or preening as a likely additional route of exposure. Anemia causes a decrease in oxygen availability to tissues, muscle fatigue, lethargy, decreased energy availability, adverse reproductive impacts, and may have implications for survival and fitness. In addition to the hematological effects we found in birds from areas of potential impact, our results also indicate that visible oiling is a better measure of potential physiological impact than circulating polycyclic aromatic hydrocarbon concentrations in the blood, suggesting that visible oil evaluation should be a key component of damage assessment efforts.

194 Effects of Sub-Acute External Exposure to Deepwater Horizon Oil in the Double-crested Cormorant

B. Dorr, USDA / WS / National Wildlife Research Center; K. Hanson-Dorr, USDA APHIS WS NWRC / Dept of Agriculture; K. Dean, Abt Associates; K.A. Healy, US Fish and Wildlife Service / Deepwater Horizon NRDAR Office; J. Link, Michigan State Univ / Dept of Animal Science; K.E. Harr, Urika Pathology LLC; K. Horak, USDA; D. Cacela, Stratus Consulting – Abt Associates; S.J. Bursian, Michigan State Univ / Animal Science

The Deepwater Horizon (DWH) oil spill presented new challenges in how deep-water drilling affects the environment. Key differences affecting wildlife included that oil dispersed from 70 km offshore and the active spill continued for several months, resulting in potential for repeated sub-acute exposure of wildlife to oil. Previous DWH fieldwork indicated subacute exposure to oil may result in hemolytic anemia as well as the more typical suite of impacts of oil exposure associated with thermoregulation, body condition, and organ injury. We evaluated physiological effects in Double-crested Cormorants (Phalacrocorax auritus) externally exposed (n=13) repeatedly to sub-acute levels (13 g/exposure) of artificially weathered DWH petroleum crude oil compared to control birds (n=12). Hematologic values, thermography, body weight, and internal body temperature data were collected across multiple time points and compared using linear mixed effects regression models with a repeated measures structure. Organ weights and tissue were collected at necropsy. Sub-acute external exposure to oil resulted in hemolytic anemia associated with development of Heinz bodies and reduced packed cell volume. Over the study period, we found that WBC, monocyte, and lymphocyte counts were significantly greater ($p < 0.05$) in oiled birds. At necropsy, we documented gross abnormalities in the hearts of oiled birds. Absolute and relative liver, kidney, and gastrointestinal track weight was greater ($p < 0.05$) in treated cormorants, with evidence of associated oxidative damage to both liver and kidney tissues. Internal body temperatures were stable over the course of the study period for both control and treated cormorants; however, infra-red thermal images of oiled cormorants indicated significantly ($p < 0.05$) greater surface temperatures that resulted in greater heat loss in treated cormorants. We presume increased energetic demand to maintain internal body temperature was compensated through observed increased food consumption in oiled birds. Both oiled and unoiled groups maintained or gained weight during the study period. In this study, repeated exposure to sub-acute levels of DWH oil resulted in multiple negative physiological impacts to cormorants.

195 Using a bioenergetics model to predict increased thermoregulatory costs from oil exposure in Double-crested Cormorants

P. Mathewson, Univ of Wisconsin-Madison / Zoology; K. Hanson-Dorr, USDA APHIS WS NWRC / Dept of Agriculture; W. Porter, Univ of Wisconsin Madison / Zoology; B. Dorr, USDA / WS / National Wildlife Research Center

The adverse effects of oil spills on waterbirds is well documented. One important effect is the reduction of body insulation as feather structure is altered by exposure to oil. At the extreme, this leads to death from hypothermia; however, there are likely sub-lethal effects such as increased thermoregulatory costs that can draw resources away from growth, survival, and reproduction. Here, we present a novel use of a bioenergetics model to predict and quantify such chronic, sub-lethal effects. Niche Mapper™ is a heat-balance model that uses information about an animal's morphology and microenvironment to calculate metabolic rates necessary for the model animal to maintain its body temperature while accounting for heat exchange with the environment. We validated Niche Mapper's performance against the physiological response of captive Double-crested cormorants (Phalacrocorax auritus) externally exposed (n=13) repeatedly to sub-lethal levels (13 g/exposure) of artificially weathered Deepwater Horizon oil compared to control birds (n=12) over a 21-day period. We measured physiological response using thermography, body weight, food consumption, and internal body temperature data. Niche Mapper's cormorant model accurately predicted surface temperatures for unoiled birds and birds in which plumage properties were parameterized for effects of repeated exposure to oil. We then simulated food intake in control and oiled cormorants to compare predicted differences in food requirements to observed food consumption. Actual food consumption after exposure to 3-4 doses of oil was 13.2% more than unoiled birds, compared to the model predicted 11.7%. Birds exposed to 5-7 doses of oil consumed 23.6% more food than unoiled birds compared to a predicted 15.3% increase. Multiple factors may account for lower predicted food consumption by Niche Mapper, particularly at higher exposure levels. Regardless of causation, modeled estimates of increased energetic demand due to oil exposure may be conservative with respect to actual demand. We are currently mapping and will discuss predicted thermoregulatory costs from multiple levels of oil exposure for cormorants across their range in the eastern United States and how annual life history stages (wintering, migration and breeding) may be affected by these increased energetic demands. The ability to predict such sub-lethal effects helps to provide a more complete understanding of the consequences of oil spills for wildlife.

196 Cardiovascular effects of Oral and Dermal Oil Toxicity Testing in Double-Crested Cormorant (Phalacrocorax auritus)

K. Harr, T. Rupp, URIKA LLC; J. Link, Michigan State Univ / Dept of Animal Science; F. Cunningham, National Wildlife Research Centre / Aquaculture; K. Dean, Abt Associates; B. Dorr, USDA / WS / National Wildlife Research Center; D. Cacela, Abt Associates; K. Hanson-Dorr, USDA APHIS WS NWRC / Dept of Agriculture; K. Horak, USDA; A. McFadden, Abt Associates; K. Healy, US Fish and Wildlife Service; S.J. Bursian, Michigan State Univ / Animal Science

At necropsy, double-crested cormorants (DCCO) orally dosed with artificially weathered Deepwater Horizon oil showed signs of cardiopathy and extended clotting time. Methods for assessment of pathophysiologic endpoints and functional imaging of DCCO hearts were developed. In this study mixed-sex DCCOs had oil (test, n=13) or water (control, n=12) applied to the breast and back feathers every 3 days, covering approximating 20% of the body surface. Techniques modified for avian species included echocardiography, activated clotting time, and troponin I analyses, in addition to previously developed light and electron microscopic evaluation of anemia. Activated clotting time of externally oiled cormorants was significantly increased over control cormorants, indicating coagulopathy. Opportunistic fecal cytology comparing treated versus control birds documented hematochezia (external blood loss through the feces) in treated birds only. Echocardiography revealed a significantly increased left ventricular chamber size and therefore decreased myocardial contractility both between treated and control birds and treated birds before and after oil exposure. Echocardiography also revealed significant cardiac arrhythmia, including probable ventricular tachycardia, in treated birds only, which could result in mortality. Troponin analyses revealed a significantly increased plasma concentration in treated birds compared to their pretreatment values. In summary, myocardial dysfunction, cardiac arrhythmia, and probable coagulopathy were documented in oil-treated birds only.

198 Oil and the Long Distance Migrant: Flight Patterns, Behavior, and Body Mass is Altered Following Exposure to Oil from the Deepwater Horizon Oil Spill

C. Perez, J.K. Moye, Univ of Nevada, Reno / Agriculture Nutrition and Veterinary Sciences; D. Cacela, K. Dean, Abt Associates; K. McGlamery, B. Sage, Univ of Nevada Reno / Dept of Agriculture Nutrition and Veterinary Sciences; C.A. Pritsos, Univ of Nevada / Agriculture Nutrition and Veterinary Sciences

The three month long Deepwater Horizon oil spill left thousands of birds dead; however, the fate of thousands of other birds that were affected but did not die as a direct result is unknown. This study used the homing pigeon as a surrogate species for migratory birds to investigate the effects of a single external oiling event on their flight performance. Homing pigeons were equipped with GPS data loggers and released 100 miles from their home loft for a series of baseline and experimental flights. After completion of the baseline flights, MC 252 crude oil was applied to the wing and tail feathers of the birds in the treated group (approximately 20% of their surface area). Repeated experimental flights followed the single application of oil and flight performance parameters were recorded. Data from the GPS loggers showed that lightly-oiled homing pigeons flying repeated 100 mile flights resulted in altered flight paths, increased flight duration and increased flight distance. The oiled birds were also unable to regain body mass between flights to the same extent as the control birds. These data suggest that in addition to taking more time to complete flights, the inability of oiled birds to recover their mass between flights would require more time spent at stopover sites, further slowing migration and causing delayed arrival to destination sites. Delays during migration have been shown to cause reductions in reproductive success and survival. This work was funded in part by the U.S. Department of Interior's Natural Resource Damage Assessment for the Deepwater Horizon/Mississippi Canyon 252 Oil Spill and the Nevada Agricultural Experiment Station.

Arctic Spill Science – Fate, Effects and Response

199 Modeling Oil Transport and Fate in the Beaufort Sea – Evaluation of Implications of Response Alternatives

D.P. French-McCay, M. Gearon, Y. Kim, K. Jayko, T. Isaji, RPS ASA

To address questions and support decision-making related to the potential fate of spilled oil in the Arctic and implications of applying potential response options, RPS ASA has modeled oil transport and fate for hypothetical spills in the Beaufort Sea using the SIMAP modeling system. Seasonal ice cover and movement information, simulated by coupled ice-ocean (hydrodynamic) models and from external remote sensing data sets, were utilized in SIMAP to simulate effects of oil encountering moving sea pack ice and fixed landfast ice, respectively. Oil moved with the ice, or was trapped in landfast ice, when ice cover exceeded 30%. The fate processes spreading, evaporation, volatilization, emulsification, and surface oil entrainment were modified by ice cover exceeding this threshold. Dissolution rates and dissolved aromatic concentrations were affected by the processes regulated by ice interactions. Alternative response options were simulated in summer open water and fall freeze-up conditions: no response and (highly effective) subsea dispersant injection. In the no-response case, surfaced oil became trapped in ice and was transported westward north of the Alaskan coast. Effective subsea dispersant use could eliminate this floating and ice-entrapped oil contamination, dispersing it into deep waters. Comparing the results assuming the two response alternatives, the water volumes affected by dissolved aromatics (>1 ug/l) are similar; however, the dose is about an order of magnitude higher in the dispersed-oil case, albeit much deeper in the water column. In most areas, the densities of biota would be expected to be higher in surface waters, as opposed to in deep waters where the subsea dispersant-treated oil would remain. Thus, while the toxicity of the deep-water contamination from the dispersant-treated case would be expected to be higher than that for the similar-sized affected volume of the no-response case, lower densities of biota at depth as compared to in surface waters, as well as protection of wildlife from oil and volatile emissions at the water surface, in/on ice and along shorelines, suggest that subsea dispersant use would lower the ecological consequences of such a catastrophic spill. However, the distributions and sensitivities of organisms would need to be examined for locations of concern before determining a specific response strategy and plan for a large blowout.

200 Biodegradation of Oil and Corexit 9500A by Arctic Marine Microorganisms

K. McFarlin, Univ of Alaska Fairbanks; M. Perkins, Oregon State Univ; J. Field, Oregon State Univ / Dept of Environmental and Molecular Toxicology; M. Leigh, Univ of Alaska Fairbanks

Understanding the biodegradation of oil and the chemical dispersant, Corexit 9500A, in the Arctic becomes increasingly important in areas influenced by oil exploration. Biodegradation by indigenous microorganisms is thought to be the main process contributing to the removal of oil from the environment, and oil degradation potential has been documented in near-shore Arctic marine environments. Combining degradation rates with molecular microbial analyses can provide further insight into the identity of oil- and Corexit-degrading microbes and how the Arctic marine microbial community responds to oil and Corexit. We conducted incubation experiments with offshore and near-shore surface seawater collected in the Alaskan Arctic to quantify the biodegradation of either whole Alaska North Slope crude oil or the surfactant components of Corexit 9500A. Incubations were conducted at 2°C with minimal nutrient addition and sampled at 0, 5, 10, and 28 days for oil, and 0 and 28 days for Corexit incubations. Petroleum hydrocarbons were quantified using GC/MS and the surfactant components of Corexit 9500A were quantified by LC-MS/MS. Next-generation sequencing of 16S rRNA genes allowed the identification of bacteria that grew in response to either oil or Corexit 9500A. The GeoChip microarray was used to detect and quantify genes for oil biodegradation in mesocosm incubations over time. The indigenous microbial community degraded 30% and 40% of the crude oil within 10 and 28 days, respectively. In Corexit incubations, 77% of dioctyl sodium sulfosuccinate (DOSS) was biodegraded within 28 days. When Arctic seawater was incubated with either oil or Corexit 9500A, some bacterial taxa and oil biodegradation genes increased in their relative abundance, suggesting a potential role in biodegradation. Sulfitobacter, Polaribacter, Oleispira and Colwellia species increased in relative abundance over the course of the incubations in response to both oil and Corexit. Some of these genera were also active in the biodegradation of the Deepwater Horizon oil spill. Future studies are needed to better understand the seasonal and spatial variability of oil and Corexit biodegradation potential in Arctic seawater as well as in ice-covered waters.

201 Biodegradation of crude oil and impact on seawater and sea-ice arctic microbial populations following oil spill treatments in the Arctic

C. Boccadoro, IRIS / Environment; S. Le Floch, Le CEDRE; C. Aeppli, Bigelow Laboratory for Ocean Sciences; A. Krolicka, E. Austerheim, International Research Inst of Stavanger IRIS; F. Chevet, Le CEDRE; S. Ramanand, International Research Inst of Stavanger IRIS; L. Camus, Akvaplanniva AS

The impact of a potential oil spill and response techniques on Arctic communities and the fate of the oil in this environment need to be better understood. The International Association of Oil and Gas Producers (IOGP) initiated the Arctic Response Technologies Joint Industry Program (JIP) and, as a part of an international team, is developing a Net Environmental Benefit Analysis (NEBA) support tool for decision-making and environmental impact assessments related to Arctic spills. The project presented here is part of this undertaking, and focusses on oil biodegradation and sea ice microbial communities. The emphasis is on better understanding the biodegradation process and microbial responses to petroleum, following different response technologies, through in situ-exposure experiments in Svalbard. The persistence and biodegradation of the different oil compounds in the sea ice and seawater were assessed following a simulated oil spill and different treatment scenarios. Total and active microbial populations in the different layers of the sea ice were characterized, their biodegradation capabilities evaluated and specific species and genes were quantified to evaluate the microbial response to oil spills and the inherent ability of indigenous microorganisms to degrade petroleum compounds. These results were combined with the oil chemical profile to (1) evaluate the fate of this oil in Arctic sea ice/water and (2) identify the best course of action to minimize negative impacts on the environment. The impact of spills and of different treatment scenarios (dispersant addition, in-situ burning, no treatment) through the ice layers down to the water column were studied using purpose-build semi-open mesocosm structures to perform realistic exposures in-situ. The characterization and, for some species, gene quantification showed surprisingly high bacterial numbers in pristine and contaminated sea ice. Analyses carried out on ice cores from oil-contaminated as well as subsequently treated sites suggest a change in microbial community structure, with an increase in psychrophilic alkane degraders.

202 Comparison of the Relative Sensitivity of Arctic Species to Oil and Dispersed Oil using Total Petroleum and PAH Measures of Toxicity

W.W. Gardiner, ENVIRON / Port Gamble WA; A.C. Bejarano, Univ of South Carolina / Dept of Environmental Health Sciences; M.G. Barron, USEPA / Gulf Ecology Division; J.Q. Word, Ramboll-ENVIRON / Applied Environmental Sciences

Extended periods of open water have expanded the potential opportunities for petroleum and gas exploration and production in the Arctic, increasing the focus on understanding the potential impacts of released oil on aquatic organisms. In many cases, information regarding the toxicity of physically and chemically dispersed oil to Arctic species is generally limited and has been largely based on total petroleum hydrocarbon (TPH) measures of toxicity. In order to better understand the sensitivity of Arctic species to oil and chemically dispersed oil, the relative sensitivity of Arctic species was determined by their position within empirically derived species sensitivity distributions (SSDs) for a range of petroleum products. SSDs were generated using data for acute toxicity (LC50) derived only from spiked declining oil exposures to minimize between test variation. Toxicity data for 35 marine species were included in this evaluation, with a total of 8 Arctic species and 25 non-Arctic species tested in 26 different oil products. Toxicity data for TPH, naphthalenes, or total PAHs for similar oil product types (e.g., middle distilates, light or medium crudes) were grouped in the SSD analyses. Based on the available toxicity data Arctic species were found to have similar sensitivity as non-Arctic species when based on TPH or PAH measures of toxicity.

203 Transcriptomics identifies novel adverse outcome pathways from crude oil exposure in haddock early life history stages

E. Sorhus, Inst of Marine Research / Reproduction and Developmental Biology; J. Incardona, NOAA Fisheries / Env Fisheries Division; T. Furmanek, Inst of Marine Research; N. Scholz, NOAA Fisheries; S. Meier, Environmental Chemistry; S. Jentoft, Univ of Oslo; R. Edvardsen, Inst of Marine Research

Crude oil spills are a worldwide ocean conservation threat. Fish are particularly vulnerable to the oiling of spawning habitats, and crude oil causes severe abnormalities in embryos and larvae. Full elucidation of adverse outcome pathways (AOPs) stemming from crude oil exposure of fish early life history stages is essential for better risk assessments relating to expansion of oil production intoNortheast Arctic regions such as the Lofoten archipelago in northern Norway. A key step towards this goal is an understanding of the underlying mechanisms for developmental defects arising from crude oil exposure. We have explored the transcriptional basis for four discrete crude oil injury phenotypes in the early life stages of the commercially important, Arctic-spawning species Atlantic haddock (Melanogrammus aeglefinus). These include defects in 1) cardiac form and function, 2) craniofacial development, 3) ion and water regulation, and 4) cholesterol synthesis and homeostasis. First, our findings identified a direct link between disruption of calcium-dependent contractility and cardiomyocyte proliferation though effects of oil exposure on key cardiac signalling molecules and transcription factors. These results thus provide the first clear molecular events linking disruption of excitation-contraction coupling by crude oil to altered cardiac morphology. Second, our data provide molecular insight into a complex pattern of genes involved in craniofacial skeletal and muscle development was consistent with an early effect on muscle development, secondarily disrupting the craniofacial cartilages. Finally, additional phenotypes relating to accumulation of oedema and shifts of body fluid and reduced yolk absorption were clearly linked to genes functioning in ion and water regulation and cholesterol biosynthesis. These latter findings suggest novel adverse outcome pathways resulting from crude oil toxicity in developing marine fish from high northern latitudes, and in particular identify cholesterol biosynthetic enzymes as potential bioindicators of oil-induced injury to fish embryos. Overall, our study clarifies initiating events for the well-established cardiotoxicity AOP, and identifies novel AOPs affecting Arctic-spawning Gadid fish. Future studies should characterize the effects of crude oil exposure on embryolarval osmoregulation and cholesterol synthesis at higher levels of biological organization.

204 An ecosystem-based modeling system for the prediction of potential impacts of petroleum and fisheries activities in the marine environment

J. Carroll, Akvaplan-niva; F. Vikebø, D. Howell, Inst of Marine Research; O. Broch, SINTEF Fisheries and Aquaculture; R. Nepstad, SINTEF Materials and Chemistry / Monitoring and Modelling; S. Augustine, G. Skeie, Akvaplan-niva; R. Bast, J. Juselius, UiT – The Arctic Univ of Norway

Fisheries and petroleum resource development are concomitant in some of the world's most productive continental shelf seas. Much of our understanding of the impacts of oil spills to fisheries and the general health of ecosystems has been acquired from a few major events. It remains a significant challenge to link data on effects of oil on individual organisms, mainly gathered through controlled laboratory experiments, to impacts on the population as a whole. The advanced software tool, SYMBIOSES, was developed to improve assessments of environmental impacts linked to oil spill scenarios, and in particular, effects of oil spills on fish stocks at the population level. The tool simulates the distribution and behavior of different life stages of important commercial fish species and their prey, effects of petroleum components on the eggs and larvae of fish and zooplankton, and multi-year changes in fish populations. It allows for impacts on larval survival to be traced through the population to observe the effect of oil spills on overall fish stocks. As a demonstration of the utility of such modeling tools, we will present simulation results for 38 oil spill scenarios, releasing 18-349 x 10^3 metric tons of oil from a single location on the northern Norwegian continental shelf (75.2N 32.4E). These release amounts are comparable to the 1989 Exxon Valdez oil spill in the Gulf of Alaska and the 1979 IxToc I oil spill in the Gulf of Mexico. We examine survival of early life stages of cod and the resulting impacts on the cod population. We will also demonstrate how SYMBIOSES may be used to assess two different oil spill mitigation strategies: reducing the fishing quota and applying dispersant. This study demonstrates the utility of predictive ecological models to explore and inform on a key impact factor of oil spills which, in turn, lends valuable support to science informed decision-making and stakeholder communication.

205 Estimated Impacts of Hypothetical Oil Spills in the Alaska Beaufort Sea on the Arctic Cod Boreogadus saida

B. Gallaway, LGL Ecological Research Associates

The effects of hypothetical spills of Alaska North Slope crude oil (ANS) on Arctic cod Boreogadus saida in the central shelf area of the Alaska Beaufort were evaluated using acute toxicity data; field studies of Arctic cod larval distribution and abundance; natural mortality estimates for Arctic cod eggs and larvae; an oil spill fate/effects model and a fecundity hindcasting biological model. Planktonic life stages of Arctic cod were considered the most susceptible to oil spill impacts. Multiple scales of spill events (1,000 tons, 10,000 tomns, 100,000 tons) were evaluated for both physically and chemically dispersed oil. The potential effects of accidental spills of dispersant only were also evaluated. A 100,000-ton spill of ANS treated with dispersants resulted in a toxic volume of 266 million m^3 as opposed to a volume of 71 million m^3 for a 100,000 ton spill of ANS not treated with dispersants. Dispersants rapidly transports large quantities of the oil from the surface into the water column. A 100,000-ton spill treated with dispersants resulted in estimated losses of about 2 million Arctic cod larvae remaining from an initial 87 million eggs. This level of egg produciton represents the reproductive output of about 7,300 adult females. The population of Arctic cod age 1+ has been estimated to range between 2 and 4 billion fish. These and other data presented herein suggest that adult Arctic cod (age 3) populations in the Alaska Beaufort number in the 10's to 100's of millions. For the time and place evaluated (mid-shelf Alaska Beaufort Sea, mid-August) even a large spill appeared unlikely to have the potential for major impacts on Arctic cod population.

206 Net Environmental Benefits Analysis Supporting Oil Spill Response in the Arctic

W.W. Gardiner, ENVIRON / Port Gamble WA; M.G. Smit, Shell Global Solutions Int.

Oil spill response in the Arctic is complicated by extreme environmental conditions, the presence of ice, and seasonally variable biological communities. Understanding the environmental consequences of different response strategies is critical to implementing actions that will minimize overall impacts of an oil spill event (either from the oil or response activities). The goals are to direct response decisions towards an optimum path for environmental recovery, and to choose options that promote long-term recovery. In a sensitive region such as the Arctic, these goals can be achieved using net environmental benefits analysis (NEBA) to compare and rank the consequences of different response alternatives and identify the potential long-term impacts of oil spill response options while accounting for changing Arctic conditions. NEBA is a transparent and science-based assessment process capable of incorporating a wide range of ecological and socioeconomic considerations. Weighting functions are used to place emphasis on the impacts to protected species and less resilient habitats. Statistical methods are used to quantify changes in ecological habitat values (e.g. fisheries habitat), social values (e.g. food resources) and economic values (e.g. commercial fish stocks) associated with different response options. This paper will review the use of NEBA in cold water environments to support both oil spill response planning and post-spill cleanup decision-making and discuss the results of recent work to enhance and advance the applicability of NEBA tools for oil spill response planning.

Recent Advances and Trends in Poly- and Perfluoroalkyl Substances Research – Part 1

207 Scratching the Surface of PFASs: An attempt at closing the mass balance using four techniques in select Papers & Textiles

A. Robel, Oregon State Univ / EMT; C.M. Butt, Duke Univ / Nicholas School of the Environment; G.F. Peaslee, Hope College / Chemsitry; H.M. Stapleton, Duke Univ / Nicholas School of the Environment; J. Field, Oregon State Univ / Dept of Environmental and Molecular Toxicology

Per-and Polyfluoroalkyl substances (PFASs) have historically been characterized in numerous environmental matrices, however, only a small fraction of these compounds are included in current methods. This study used the most inclusive PFAS methods developed, and yet indications a number of unknown precursor compounds. Since PFASs' accumulation in blood and organs are due, in part, to exposure to consumer products, a small subset of seventeen papers and textiles were analyzed using four techniques: liquid chromatography tandem mass spectrometry (LC-MS/MS) for 73 individual PFASs, gas chromatography mass spectrometry (GC-MS) for 7 individual PFASs, total oxidizable precursor (TOP) assay, and total fluorine by particle-induced gamma-ray emission (PIGE) spectroscopy. The TOP assay was used to quantify the presence of precursors found in consumer products, but not represented by LC-MS/MS data by quantifying the formation of dead-end products including perfluoroalkyl carboxylates (PFCAs) and sulfonates (PFSAs). The net production of PFCAs/PFSAs that could not be accounted for as forming from identified individual PFASs was used as a measure of additional precursors. Nanomolar quantities of PFASs determined by LC-MS/MS and GC-MS and the TOP assay were compared for papers and textiles. In addition, TOP assay data were compared to the total fluorine content of papers determined by PIGE. Total PFASs measured by LC-MS/MS, GC-MS, and TOP assay accounted for less than 50% of the total PFAS present for the majority of these papers and textiles. To account for the missing mass, the extracted material (for LC-MS/MS) was analyzed through PIGE and showed agreement of total fluorine present in these materials, highlighting the utility of these assays for potentially obtaining mass balance on highly-fluorinated substances on papers and textiles.

208 Current Extraction Methods Significantly Underestimate Mass of Zwitterionic and Cationic Polyfluoroalkyl Precursors in Soil and Sediment

K. Barzen-Hanson, S.E. Davis, Oregon State Univ / Dept of Chemistry; J.A. Field, Oregon State Univ / Dept of Environ Molecular Toxicology

Polyfluoroalkyl precursors, especially those with cationic functional groups, are likely to be sorbed to source zone soils and sediments where aqueous film-forming foams (AFFFs) were routinely used for fire-fighter training. AFFFs, containing per- and polyfluoroalkyl substances including polyfluoroalkyl precursors, were routinely applied at military and civilian sites. In order to characterize the sorption (partitioning) behavior of cationic and zwitterionic precursors, batch sorption experiments were conducted using a commercial AFFF formulation. After analyzing the aqueous, vial, and soil phases, the mass balance could not be closed using the current extraction method for polyfluoroalkyl precursors, which is based on low concentrations (15-20 mM) of ammonium hydroxide or sodium hydroxide in methanol. In order to close the mass balance, more rigorous extraction conditions were employed. The novel extraction method consisted of 0.5 M hydrochloric acid in methanol. With a more concentrated acidic methanolic extraction, mass balance was achieved for the cationic and zwitterionic precursors. The novel soil extraction method may reveal "additional" unreported mass of cationic and zwitterionic precursors in AFFF-impacted sites.

209 Qualitative and quantitative analysis of fluorosurfactants in soil impacted by aqueous film-forming foam after the Lac-Mégantic train derailment

S. Mejia, McGill Univ / Civil Engineering and Applied Mechanics; S. VO DUY, Universite de Montreal / Chemistry; M. Desrosiers, CEAEQ; S. Sauve, Universite de Montreal; J. Liu, McGill Univ / Civil Engineering

Aqueous film forming foams (AFFFs) rely on a mixture of hydrocarbon and fluoroalkyl surfactants (poly- and perfluoroalkyl substances, PFAS) to extinguish hydrocarbon fires by preventing fuel from contacting oxygen. The wide use of AFFFs for accidental fires or firefighting training has resulted in a high number of sites with elevated levels of PFAS. The recognition of the environmental and health impact posed by some PFAS, such as perfluorooctane sulfonate (PFOS), leads to the concern about the potential adverse impact of AFFF release. The town of Lac-Mégantic (Québec, Canada) was the location of a major deployment of AFFFs after the July 2013 train derailment accident. An estimated 33,000 litres of concentrated AFFFs were used to extinguish the fire from the spill of millions of liters of crude oil. Though a significant amount of AFFFs was recovered during the clean-up effort, some PFAS made their way into River Chaudière, the sewer system, and surrounding soil. Due to the proprietary nature of AFFF formulation, there is a lack of information regarding the nature of PFAS in AFFF formulation as well as their environmental fate, behaviours and impact. To fill the knowledge gap, we focused on PFAS identification in soil in the current study. Soil samples were collected days after the firefighting activities as well as two years later around the site of the accident. Soil from a biopile treatment system, where excavated oil-contaminated soils were subject to bioremediation, was sampled in 2015. A solvent extraction method was optimized for 34 PFAS analytes in the presence of hydrocarbons as co-contaminants. Lac-Mégantic soil samples were extracted using the method and analyzed both qualitatively and quantitatively using high resolution and tandem mass spectrometry systems. A suite of approximately 60 compounds was qualitatively detected, suggesting the possibility that the total PFAS contamination is significantly underestimated when only compounds for which standards are available are analyzed. Spatial and temporary profiles of PFAS will be presented along with the levels of co-contaminants, and the implications for future study on the PFAS originated from AFFFs will be discussed.

210 Newly-identified polyfluoroalkyl surfactants in the freshwater fish C. commersonii following AFFF deployment at the Lac-Mégantic railway accident

G. Munoz, Universite de Montreal / Chemistry; M. Desrosiers, CEAEQ; S. VO DUY, Universite de Montreal / Chemistry; P. Labadie, H. Budzinski, CNRS; J. Liu, McGill Univ / Civil Engineering; S. Sauve, Universite de Montreal

On July 6th 2013, an unmanned train derailed downtown Lac-Mégantic (Québec, Canada), causing a spill of nearly 6 million liters of crude oil, destroying large parts of the city center, and claiming the lives of 47 people. In the emergency response to contain the fire, the deployment of aqueous film forming foams (AFFFs) lasted for approximately two days and > 30,000 liters of foam concentrate were applied. At least 4 out of the 7 firefighting formulations contained fluoroalkylated surfactants (PFASs), organofluorine chemicals whose persistence, bioaccumulation potential and adverse effects have been documented in the literature. The present study examines the environmental occurrence of historic and newly-identified PFASs in the benthic fish Catostomus commersonii and sediments collected from the adjacent Lake Mégantic and Chaudière River (downstream from the AFFF-impacted site). 28 target and 90 suspect-target PFASs were therefore investigated using ultra-high performance liquid chromatography polarity-switching electrospray ionization coupled to Orbitrap mass spectrometry. Seven zwitterionic or cationic PFASs were synthesized to provide for model analytes for method validation and semi-quantification purposes. In sediments, zwitterionic PFASs dominated PFAS composition profiles (~94%) while perfluoroalkyl acids (PFAAs) were less prevalent (~3%). Levels of PFAAs remained moderate in fish muscle (e.g., PFOS: 0.36–2.5 ng g^{-1} wet-weight), with little or no significant temporal trend when comparing 2013 or 2014 fish samples with 2011 archived samples. In contrast, fluorotelomer sulfonates peaked in the immediate weeks or months that followed the accident, as did several zwitterionic PFASs such as fluorotelomer sulfonamide betaines (8:2 FTAB, 10:2 FTAB) and fluorotelomer betaines (especially 9:3 FTB, 11:3 FTB, 7:1:2 FTB, 9:1:2 FTB and 11:1:2 FTB). With time, levels of betaine-based PFASs gradually decreased in fish, possibly indicating attenuation by biodegradation of the fluorine-free moiety, supported by the observation of likely FTAB metabolites such as fluorotelomer carboxylates and fluorotelomer sulfonamides. These metabolites may convert to PFAAs in the long-run.

211 Transport of Poly- and Perfluoroalkyl Substances in Groundwater, Cape Cod, MA

A.K. Weber, Harvard Univ; L.B. Barber, USGS / National Research Program; D.R. LeBlanc, USGS / New England Water Science Center; C.D. Vecitis, Harvard Univ / John A Paulson School of Engineering and Applied Sciences

Since the 1950s poly- and perfluoroalkyl substances (PFASs) have been used for many applications owing to their high stability and the combination of their surfactant, hydrophobic, and oleophobic properties. Groundwater PFAS contamination has arisen as a concern because of the widespread current and historical use of PFAS-containing aqueous film-forming foams (AFFFs) for fire suppression. Research is needed on PFAS transport properties in groundwater, as these contaminants pose a unique threat to groundwater quality owing to their persistence, bioaccumulation, ubiquity, and adverse human health effects. A site on Cape Cod, Massachusetts, where fire training activities involving AFFF were conducted from 1970 to 1985 has been investigated to understand the subsurface transport of PFASs. More than 100 groundwater samples were collected along a transect extending 1.1 km downgradient from the fire-training area and analyzed with LC-MS/MS to visualize the subsurface PFAS distribution along the groundwater flow path. Land disposal from 1936 to 1995 of secondary treated wastewater effluent onto infiltration beds located 500 m hydraulically downgradient from the fire training area resulted in a wastewater plume that comingles with the PFAS plume. PFAS transport properties were investigated upgradient of and within the wastewater-contaminated zone by comparing PFAS distributions to wastewater-affected geochemical parameters such as specific conductance, pH, temperature, and concentrations of dissolved organic carbon, dissolved oxygen, and dissolved iron. Perfluoroalkyl acids (PFAAs) with short chain lengths and PFAA precursors exhibit unexpected transport rates in the field when compared to results reported in the literature and laboratory partitioning experiments conducted with sediment cores from the field site. Distinctly different PFAS compositions in shallow groundwater below the vadose zones at the fire training area and wastewater-infiltration beds indicate that these are two compositionally different PFAS sources, suggesting that the PFAS composition in groundwater samples can be used to identify potential sources. This work contributes to the understanding of how PFASs migrate from point sources and identifies some mechanisms that could impact transport.

212 Perfluoroalkyl acid concentrations in historical drinking water samples collected from the Greater Cincinnati Region

S.F. Nakayama, National Inst for Environmental Studies / Centre for Health and Environmental Risk Research; M. Yoshikane, IDEA Consultants, Inc.; K. Dasu, M. Mills, USEPA / National Risk Management Research Laboratory; M. Wright, USEPA / National Center for Environmental Assessment; S. Ehrlich, Univ of Cincinnati / College of Medicine

The Health Outcomes and Measures of the Environment (HOME) Study is an epidemiological study conducted in Greater Cincinnati area (Geraghty, et al., 2008), to examine the effects of low-level exposures to prevalent neurotoxicants in a cohort of 400 children followed from 16 weeks of gestation to 5 years of age. As part of the study, serum and drinking water samples were collected during 2003–2006 from each participant's home. Poly- and perfluoroalkyl substance (PFASs) concentrations were measured in serum samples of 6–8 year-old female participants (Pinney SM, et al. 2014). Elevated concentrations of perfluorooctanoic acid (PFOA) were found in 94% of the participants living in one area compared to the National Health and Nutrition Examination Survey (NHANES) 95th percentile for children 12–19 years (8.4 ng/mL), median 22.0 ng/mL. This was speculated to be derived from an industrial source upriver of the Ohio River through drinking water. Drinking water samples were collected directly from the taps into 500-mL HDPE containers and stored frozen until the time of lead analysis in 2007. The samples were transferred to smaller size tubes and stored again at –20 C until our analysis in 2016. The sample volumes were approximately 10 mL. We used a newly developed on-line solid phase extraction method to analyse PFASs in these drinking water samples. In a pilot scale analysis of 25 samples, median concentrations of PFOA and perfluorooctane-suflonic acid (PFOS) were 10 and 7.6 ng/L, respectively, which were comparable to the previously reported levels such as NHANES. The maximum levels for PFOA and PFOS were 108 and 98.6 ng/L, respectively. Some of the samples exceeded the newly established US Environmental Protection Agency (USEPA) Drinking Water Health Advisories for PFOA and PFOS (70 ng/L combined PFOA and PFOS). The full-scale analysis results for 400 samples will be reported and discussed in detail for the presentation. Disclaimer: The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the USEPA. The findings and conclusions of this article are solely the responsibility of the authors and do not represent the official views of the National Institute for Environmental Studies, Japan.

213 Perfluoroalkyl and polyfluoroalkyl substances associated with aqueous film forming foams in Canadian surface waters

L. D'Agostino, S.A. Mabury, Univ of Toronto / Dept of Chemistry

Dozens of novel perfluoroalkyl and polyfluoroalkyl substances (PFASs) have recently been identified in aqueous film forming foams (AFFFs), but environmental detections of these compounds are limited and they have not been previously detected in surface waters. Surface water samples were collected from rivers and lakes in Southern Ontario and Nunavut, including AFFF-impacted sites, urban rivers, and rural sites. Surface water samples were extracted by mixed-mode weak anion exchange solid

phase extraction in a clean lab and analyzed by UPLC-MS/MS both quantitatively where standards were available and semi-quantitatively for other AFFF components. Detection of AFFF components was confirmed by spiking surface water extracts with AFFF extracts. In terms of electrochemical fluorination products, concentrations of perfluorohexane sulfonate (PFHxS) approach those of perfluorooctane sulfonate (PFOS) in some AFFF-impacted waters, perhaps due to degradation of perfluorohexane sulfonamide (FHxSA)-based surfactants used in AFFFs, which were detected in some samples. FHxSA was detected in all AFFF-impacted and urban surface waters at concentrations from 0.04 to 20 ng/L, which indicates the relevance of PFHxS precursors in surface waters. Pre-PFOS phase out carpet protection products are also a potential source of FHxSA. Fluorotelomer PFASs were also frequently detected in surface waters, including 6:2 fluorotelomer sulfonate (FTSA, up to 3.0 ng/L), 6:2 fluorotelomer sulfonamide alkylbetaine (FTAB, up to 22 ng/L), 6:2 fluorotelomermercaptoalkylamido sulfonate sulfone (FTSAS-SO_2, up to approximately 1 ng/L), 6:2 fluorotelomerthioether hydroxyl ammonium sulfoxide (FTSHA-SO) and fluorotelomer betaines (FTBs). Sampling at multiple sites along the Welland River suggests that FTBs are particularly persistent fluorotelomer compounds. Relatively high concentrations of 6:2 FTAB in three watersheds in the Greater Toronto Area (3.5-18 ng/L) may imply other sources in addition to AFFF. Perfluoroalkyl carboxylate (PFCA) profiles of surface waters were generally dominated by C5 and C6 PFCAs over C7 and C8 PFCAs, which could reflect the switch from 8:2 fluorotelomer to 6:2 fluorotelomer PFASs in various applications.

214 Transport potential of per- and poly-fluoroalkyl surfactants in the presence of soil organic matter

Y. Zhi, J. Liu, McGill Univ / Civil Engineering

Repeated use of Aqueous Film-Forming Foam (AFFF) at fire-fighting training areas has resulted in groundwater pollution by a large number of per- and poly-fluoroalkyl substances (PFASs). Management and remediation of such contaminated sites require an understanding of the transport potential of these emerging pollutants. The mobility of perfluoroalkyl carboxylic acids (PFCAs) and sulfonic acids (PFSAs) is controlled by interactions with organic matter and hydrophobicity effect. For the short-chained acids, electrostatic interaction and steric effect appear to be important. As of today, little is known about the transport potential of other types of zwitterionic, cationic, and anionic PFAS, which due to their chemistry could behave very differently from PFCAs and PFSAs. In this study, interactions between 15 PFASs and model soil organic matter (SOM, Pahokee peat) were examined by a novel dynamic HPLC-based column method. The PFASs under examination include not only PFCAs and PFSAs but also fluorotelomer sulfonates (FTSs) and fluorotelomer betaines (FTBs), which have been detected at high levels in surface and ground water impacted by AFFFs. The PFAS elution profiles in the SOM-packed column were constructed through collecting HPLC eluent with the aid of a fraction collector and quantification by LC-MS/MS. Sorption coefficients normalized by organic carbon content (K_{oc}) were determined based on the retention volumes of the PFASs at three Ca^{2+} concentrations and over environmentally relevant pH range. At 5 mM $CaCl_2$, the observed $\log K_{oc}$ values of PFCAs (perfluoroalkyl carbon chain length, n = 3-8) and PFSAs (n = 4, 6, 8) were in the range of 1.27 – 2.53, which was largely consistent with literature values. The observed $\log K_{oc}$ values of FTSs (n = 4, 6, 8) were 1.32-2.48 and three FTBs were 1.84 – 2.20. Calcium ion has a positive impact on the sorption of anionic PFASs to SOM with $\log K_{oc}$ values increased by ~0.2-0.7 when Ca^{2+} concentration was rising from 0.5 to 50 mM. Moreover, raising pH slightly reduced sorption of all PFASs to the SOM. The $\log K_{oc}$ values were decreased by ~0.22-0.58 with pH increasing from 3.8 to 8. This phenomenon is likely caused by enhanced electrostatic repulsion between the anionic head group of PFASs and more negatively charged organic matter surface at a higher pH. Overall, sorption of these compounds follows a chain-length dependence trend. The results are useful for predicting transport behaviors of PFAS in AFFF-impacted sites.

Environmental Chemistry Perspectives from Around the Globe

215 Why TBT contamination still matters in South America

I.B. Castro, Univ Federal de São Paulo / Instituto do Mar; G. Fillmann, Univ Federal do Rio Grande / Instituto de Oceanografia

Antifouling biocides contamination has been appraised along South American coastal areas during the last decade with most of these studies focused in butyltin (BT) levels and imposex occurrence (a known biomarker of TBT contamination). Due to many national wide use restrictions, and after the Antifouling System Convention (AFS) banning of TBT-based antifouling paints issued by the International Maritime Organization in 2008, environmental levels of TBT as well as imposex incidence begun to decline in many areas worldwide. In South America, TBT levels and effects also decreased in areas under the influence of commercial harbors. However, recent studies have pointed out that impacts related to TBT usage are still evident in sites of Argentina, Brazil, Colombia, Chile, Ecuador, Peru and Venezuela with maritime activities related to smaller vessels (mainly fishing and pleasure boats). In all cases, TBT concentrations detected were sufficiently high to induce environmental effects. Furthermore, recent TBT inputs have frequently been detected in many of these evaluations. This scenario is, at least partially, caused by the absence of local regulations on the use of TBT-based antifouling paints. Within South America, only Brazil and Argentina have some restrictions against TBT and only Brazil and Uruguay are signatories of the AFS convention. Even so, recent inputs have been found in two of these countries. In addition, TBT can be easily purchased by users for mixing to commercial antifouling paints to boost their efficiency. In addition, most antifouling paints marketed in South America do not include information on the active biocide used in their formulation, hindering legislative and oversight actions. Thus, the implementation of pertinent regulations, with special care about their effective application, is crucial to lower the inputs, and consequent impacts, of BTs on South American coastal areas as has happened in Europe and North America.

216 Trace Metal Pollution of Suburban Roadside Surface Soil by Road Dust

M. Fiala, Texas Southern Univ – Dept of Environmental Science and Technology / Dept of Environmental and Interdisciplinary Sciences; H. Hwang, Texas Southern Univ / Environmental Science

Operation of motor vehicles is one of the major sources of environmental contamination, especially in urban environments. In many urban watersheds, tires and brake pads are significant sources of Zn and Cu, respectively. A previous study showed Houston road dust to contain trace metals at elevated concentrations. Houston road dust may be a significant source of trace metals to surrounding soil through atmospheric deposition and stormwater runoff. To better understand the fate and transport of trace metals in road dust, surface soil (2 cm) was collected 1 m from the edge of Highway 6 approaching a traffic signal in Sugarland, Texas at 200, 160, 100, 50, 25, 15, and 5 m from the intersection. Upon arrival at the laboratory, samples were dried, and sieved to fractions of 500 µm–1 mm, 250-500 µm, 125-250 µm, 63-125 µm, and2) are low for Cu (0.05) and Zn (0.003), and moderate for Cd (0.51), Ni (0.48), and Cr (0.53) indicating dissimilar sources. Copper and Zn likely originate from brake and tire wear particles, with deposition and resuspension being strongly influenced by wind and other vehicle-related forces. Significant fractions of Cd, Ni and Cr likely originate from concrete pavement wear. Relative anthropogenic metal input, known as enrichment factors (EF), is calculated using surface soil sample (< 63µm) collected on campus of Texas Southern University containing Cu (20.6 µg/g), Zn (104.9 µg/g), Cr (20.3 µg/g), and Fe (0.7%). Using Fe as the normalizing element, EF for these samples are Cu (1.7), Zn (1.5), and Cr (1.2). Due to limited uncertainty, EF values > 1 indicate moderate anthropogenic input, with surface soil being moderately polluted by Cu, Zn and Cr. Further studies will be completed to determine whether traffic-related trace metals are infiltrating roadside soil, or rather being transported through stormwater.

217 Platinum Group Elements in Bioaccessible Fractions of Street Dust from Toronto, Canada

C.L. Wiseman, Univ of Toronto / Toxicology Centre; J. Niu, P. Rasmussen, Health Canada

Road dust particles capable of resuspension are important contributors of metal contamination to local urban air and water sheds. Road dust has been shown to be enriched with potentially toxic metals such as cadmium (Cd) and lead (Pb). While platinum group elements (PGE), which includes platinum (Pt), palladium (Pd), rhodium (Rh) and iridium (Ir), are known to be accumulating in urban environments, less is known about their concentrations in road dust. This study addresses data gaps on environmental exposures to metals in an urban context, most notably those associated with bioaccessible road dust fractions. In the first study phase, PGE concentrations in coarse and fine fractions of road dust collected in Toronto were characterized to assess spatial variability as a function of road type and traffic volume. Samples were collected in Fall 2015 in cooperation with the City of Toronto, which uses regenerative street sweepers that dry-fractionate dust sweeps into coarse "hopper" (< 2 mm) and fine "dust box" (ca. < 3 microns). PGEs were determined in air-dried, sieved samples using NiS fire-assay-INAA. The results confirm an enrichment of Pd, Pt, Rh and Ir in road dust, attributed to emissions from automotive catalytic converters. Overall, Pd was observed to occur at the highest relative concentrations in road dust, with a City median of 115 µg/kg, followed by Pt (median: 52 µg/kg) and Rh (median: 15 µg/kg) and Ir (median: 0.40 µg/kg), while Os and Ru were below limits of detection. Pd concentrations were the most variable, ranging from a low of 16 µg/kg (local/residential road) to a maximum of 344 µg/kg (municipal expressway). Fine/coarse enrichment ratios for PGE increased from lowest to highest in the following order: Pt(2)=Pd(2)< Rh(3)< Ir(10). The observed two-fold to ten-fold enrichment of PGE in the finer fractions of road dust is of concern, given the greater relevance of the fine fraction to environmental and human health. The preliminary results of this study indicate a need to more closely examine the concentrations of potentially toxic elements associated with fine road dust fractions. Next steps will involve the elemental characterization of sweeps collected in Spring 2016 in the City of Toronto and the application of in vitro methods to assess the chemical bioaccessibility of metals in road dust.

218 Biogeochemical processes occurring in forested mountain catchments deduced from chemical and sulfur isotopic composition of drainage water

A.M. Gonzalez, J.S. Schwartz, Univ of Tennessee / Dept of Civil and Environmental Engineering

Physical catchment features influence the chemical and isotopic composition of their drainage water (streams and seeps). Lower stream orders by definition integrate smaller drainage areas; thus, the biogeochemical processes occurring in forested mountain catchments are reflected most clearly in first-order streams and interflow seeps (i.e., consisting of recent precipitation). In the Great Smoky Mountains National Park (GRSM), grab samples of first-order stream, tributary and seep water were analyzed for a suite of chemical parameters (e.g., pH, acid-neutralizing capacity [ANC], and dissolved ions) and sulfur isotope composition. A wide range of drainage water compositions were identified (low and high sulfate content; low and high pH and ANC), but high sulfate concentrations were not consistently associated with low pH/ANC. Spatial distribution of drainage water with a given composition was 'patchy:' catchments with low pH/ANC drainage water were commonly found adjacent to those with moderate to high pH/ANC drainage water. Drainage water composition resulting from interaction with sulfidic bedrock can appear similar to that resulting from deposition of acid-forming atmospheric sulfur oxides. However, the water composition of streams and seeps sampled in this study was not related to elevation (as expected if atmospheric deposition was the dominant source of sulfur and acidity), or to reductions in deposition of atmospheric sulfate. It did show some relationship to catchment geology, specifically to the extent of exposed sulfidic bedrock. This drainage water composition survey demonstrates the relative importance of catchment geology in driving biogeochemical processes that influence the character of catchment drainage water, and shows how drainage water composition can be used to deduce catchment-specific characteristics.

219 Colloidal-facilitated transport of nitrogen as a function of land-use in a major river basin discharging to the Great Barrier Reef lagoon

J. Judy, CSIRO Land and Water; J. Kirby, CSIRO / Advanced Materials Transformational Capability Platform Land and Water; M. McLaughlin, Univ of Adelaide and CSIRO Land and Water; M. Farrell, CSIRO Agriculture; A. Hawdon, R. Bartley, S. Wilkinson, CSIRO Land and Water; P. Bertsch, Univ of Kentucky / Plant and Soil Sciences

Since European settlement of Australia, sediment and nutrient loads to the Great Barrier Reef (GBR) marine zone have increased dramatically as a result of land-use changes, particularly agricultural intensification. The resulting reduction in water quality has been linked to eutrophication, loss of coastal marine biodiversity and a dramatic reduction in GBR coral cover. Recent research has suggested that up to 87-95% of sediment < 10 µm in diameter exported from the Burdekin River Basin into the GBR lagoon is the result of the erosion of gullies, which are common landscape features in areas used for grazing. Fine sediment can directly reduce coastal water clarity and coral recruitment, while N has the potential to be transported over a much larger area and further reduce water clarity by feeding primary production. The degree to which this subsurface sediment loss is comprised of mobile colloids is unknown, as is the degree to which these colloids may facilitate transport of nitrogen into the GBR lagoon. Here we examine water-dispersible colloids (WDC) collected from areas under sugar cane and compare them to WDC collected from gullies formed in grazing lands. Physical characteristics of WDC were assessed via measurement of particle size/morphology, mineralogy and electrophoretic mobility. Total N concentration associated with the WDC as well as with < 0.45 µm and < 3kDa size fractions were analyzed. As ^{15}N abundance in N from animal waste is distinct from that of N in inorganic fertilizer, the ^{15}N natural abundance in the WDC and in the < 3kDa size fraction were assessed to determine if colloid-associated N can be linked to specific land uses. We anticipate that the results of this research will help refine our understanding of N fluxes into the GBR lagoon and will contribute to the development of improved models and land management practices.

220 Occurrence of brominated and organophosphorus flame retardants in indoor dust in a Brazilian city

J. Cristale, M.R. de Marchi, São Paulo State Univ UNESP / Analytical Chemistry; T.G. Belé, São Paulo State Univ UNESP; S. Lacorte, IDAEA-CSIC / Environmental Chemistry

Indoor dust is indicated as one of the most important human exposure routes to flame retardants (FRs). Most of data about occurrence and levels of FRs in dust are from North American, European and Asian Countries, but scarce data is available for countries that do not have regulatory laws concerning fire safety of materials, as is the case of many South American countries. In this study, eight polybrominated diphenyl ethers (PBDEs), four new brominated flame retardants (NBFRs) and ten organophosphorus flame retardants (OPFRs) were determined in indoor dust from different places in Araraquara-SP (Brazil). A total of 46 samples were collected from homes (houses and apartments), workplaces, primary schools and cars. OPFRs, PBDEs and NBFRs were detected in 100% of the samples. OPFRs were present at the highest concentrations, and the most abundant compounds were TBOEP, TPHP, TDCIPP and TCIPP. The most abundant brominated FRs were BDE-47, BDE-99, BDE-209, BEH-TEBP and DBDPE. It was hypothesized in this study that soil particles blowing into the indoor environment from outdoors could have a significant dilution effect on the FR levels in house dust, but it was not confirmed since no difference in terms of concentration was observed among house and apartment samples. In addition, the FR distribution was also similar among houses and apartments, and were correlated to the presence of electronic equipments, furniture and construction materials present in each sampling site. Primary schools presented FR levels similar/lower than the observed in homes, except for TBOEP, that was about thirty times higher in schools. Workplaces presented the highest FR levels, mainly for brominated FRs, attributed to the presence of several computers and electronic equipments in these places. Most of FRs were detected in car dust samples, and TDCIPP, TPHP, BDE-209, BEH-TEBP and DBDPE were the most abundant compounds. An OPFR increasing tendency associated to a PBDE decreasing was observed for newer vehicles, indicating that international prohibition on PBDEs use is also influencing Brazilian auto industry. In conclusion, FR levels and profiles in this study were similar to the observed in other countries, indicating that although Brazil do not regulates the use of FRs, these compounds are present in the commercialized products, which are diffusive sources of FRs to the surrounding environment, exposing humans to these contaminants.

221 Evaluating Primary Contaminant Pathways to Combined Sewer Systems Discharging to the Lower Duwamish Waterway Superfund Site, Seattle, WA

C. Greyell, D. Williston, R.A. Jack, J.H. Stern, King County / Dept of Natural Resources and Parks

King County conducted a pilot study to examine pathways of contaminant sources to combined sewer basins that discharge to the Lower Duwamish Waterway Superfund site in Seattle, Washington. In combined sewer basins, both sewage (domestic and industrial wastewater) and stormwater are normally routed to wastewater treatment facilities. However, during large storm events, these basins can temporarily route excess sewage and stormwater directly into nearby waterways as combined sewer overflows (CSOs) to prevent sewer backups into homes and streets. Because CSOs can be a pathway of contamination to the waterway, understanding whether contaminants mainly enter the system via sewage or stormwater can help guide source control activities in the combined sewer basins, which supports the Superfund sediment cleanup effort. From 2011 to 2013, aqueous samples were collected with autosamplers from two combined sewer systems along the Lower Duwamish Waterway during both baseflow (sewage only) and stormflow conditions (sewage and stormwater). Samples were analyzed for metals, PAHs, phthalates, PCBs, and dioxin/furans. Flow was also measured to calculate the average flow rate during each sampling period. Average chemical loading rates were then estimated for each flow condition to evaluate the primary pathway (sewage or stormwater) for each contaminant during storm events. Stormwater was identified as the primary pathway for most contaminants in each study basin, despite differences in land-use. The findings of this pilot study can be used by King County to guide basin-wide source tracing efforts in combined basins prior to CSO control.

222 Pharmaceuticals, plasticisers, perfluorinated compounds and illicit drugs in the aquatic environment: What is their fate?

J. Wilkinson, P.S. Hooda, Kingston Univ London / Natural and Built Environments; J. Swinden, J. Barker, S. Barton, Kingston Univ London / Life Sciences Pharmacy Chemistry

Pharmaceuticals, personal care products (PPCPs) and other emerging contaminants (ECs) such as plasticisers, perfluorinated compounds (PFCs) and illicit drug metabolites are known contaminants of the aquatic environment. Most commonly, the study of such compounds is limited to their occurrence dissolved in river, lake or ocean waters. Few studies assess their accumulation in suspended particulate material, sediment, and aquatic organisms. Here, thirteen markers of anthropogenic contamination were selected for the study of their occurrence in the aquatic environment. PPCPs/ECs studied included pharmaceuticals acetaminophen, diclofenac, and ethinylestradiol, plasticisers bisphenol-A, bisphenol-S and 4'-hydroxyacetophenone, perfluorinated compounds (PFCs) perfluorooctanoic acid, perfluorooctanesulfonic acid, perfluorononanoic acid and perfluorobutane sulfonic acid, and illicit drugs/metabolites methamphetamine, amphetamine and benzoylecgonine. Selected contaminants were quantified in river water (n=69), sewage treatment works (STW) effluent (n=22), field/street drainage (n=5), bound to SPM (n=16), river sediment (n=23), bioaccumulation in aquatic plants Callitriche sp. (n=8) and Potamogeton sp. (n=7), amphipod crustacean (Gammarus pulex, n=10) and the aquatic snail (Bithynia tentaculata, n=7). Solid phase extraction followed by an in-house validated method for liquid chromatography-tandem mass spectrometry was used for all analysis. Extractions were carried out using ultrasonic-assisted solvent extraction. Highest levels of pharmaceuticals were recorded in STW effluent and typically did not exceed 1 ug/L while levels of plasticisers and PFCs were generally higher in street runoff (typically not exceeding 2 ug/L). Accumulation was lowest in sediment and highest in Callitriche sp. where levels of target contaminants typically did not exceed 75 ng/g dry sediment and 250 ng/g dry plant respectively. Here we demonstrate that quantification of PPCP/EC occurrence in river water alone is not a sufficient assessment of these contaminants in the aquatic environment. The widespread occurrence of selected contaminants in this study highlights the importance of less well-characterised means of exposure to such contaminants (e.g., sediment and food sources for higher organisms). To the knowledge of the authors, this is one of, if not the most detailed accounting of PPCP/EC fate and distribution in the aquatic environment conducted in the United Kingdom to date.

Alternative Approaches to Animal Testing for Ecotoxicity Assessments – Part 1

223 Quantifying the Benefits of Using Read-Across and In Silico Techniques to Fulfill Hazard Data Requirements for Chemical Categories

K. Stanton, F. Kruszewski, American Cleaning Inst

Substantial benefits are realized through the use of in silico techniques to fill data pags for structurally similar substances. Considerable experience in applying these techniques was gained under two voluntary high production volume chemical (HPVC) programs – the International Council of Chemical Associations' (ICCA) (with the cooperation of the OECD) Cooperative Chemical Assessment Programme and the USEPA's HPV Challenge Program. These programs led to the compilation and publicly availability of baseline sets of health and environmental effects data for thousands of chemicals. The American Cleaning Institute's (ACI) contribution to these national and global efforts included the compliation of these datasets for 261 substances. Due to the structural similarity of the chemicals within the categories, their environmental fate, physical-chemical and toxicological properties are likely to be similar, which was confirmed by examining available data from across the range of substances in a category. This has allowed the utilization of read-across and trend analysis techniques and qualitative structure activity relationship (QSAR) tools to fill data gaps. Quantifying benefits resulting from avoided testing through the use of in silico tools, namely, the associated avoidance of testing costs and sacrifce ofanimals lead to estimates that, for these 261 substances, the use of tens of thousands of test animals and expenditures of millions of dollars were avoided.

224 Balancing the effectiveness and practicality of alternative test endpoints for the fathead minnow fish embryo toxicity test

[illegible], Texas Christian Univ / Biology; [illegible], Texas Christian Univ; [illegible], M.K. Sellin Jeffries, Texas Christian Univ / Dept of Biology

In recent years the fathead minnow fish embryo toxicity (FET) test has been developed and proposed as an alternative to the larval growth and survival (LGS), a whole effluent toxicity test utilized in the United States. The FET test represents a positive step forward with regard to the welfare of fish used in toxicity testing; however, the utility of the FET test is limited due to its reliance on lethal endpoints. Here, we sought to determine whether the inclusion of sublethal metrics could enhance the FET test by improving test sensitivity or by allowing for the prediction of adverse sublethal or chronic effects. FET tests were conducted using three reference toxicants—sodium chloride, ethanol and sodium dodecyl sulfate. Typical FET test endpoints (i.e., coagulation, presence of heart beat, somite formation and tail detachment) were evaluated in addition to three sublethal endpoints – wet weight, the presence of developmental abnormalities and the expression of genes associated with growth, stress and toxicity. Significant reductions in growth were observed in FET tests conducted with NaCl and EtOH, albeit only among embryos exposed to the highest concentration of each chemical. Pericardial edema was the most commonly observed developmental abnormality and was found to respond to each of the chemicals in a dose-dependent manner. Alterations in expression of a few genes related to growth and stress (i.e., igf-1, ghr and hsp70) were also noted; however, such changes were chemical specific and tended to only occur among embryos exposed to chemical concentrations also capable of eliciting significant mortality. An evaluation of each of these endpoints with regard to their practicality for FET test use (i.e., cost, time required and experience required) suggests that growth and edema could serve as potential FET test endpoints, while gene expression may not be as practical given the resources required for its assessment.

225 Alternative Testing Platforms for Screening Ecological Hazards

C. Lehman, Dow Chemical Company / Toxicology and Environmental Research and Consulting

We have developed and validated small scale, screening-level, environmental toxicity assays for fish, daphnia and algae for use in our laboratory. These assays are typically conducted in a well-plate format, and they have reduced cost and animal use over traditional full-scale OECD or OCSPP guideline tests. The fish screening assay utilizes fish embryos in lieu of juvenile or adult fish, thereby reducing the number of animals used for testing, aligning with the 3 Rs of animal testing (refine, reduce, replace). Using the three screens to determine which taxon is the most sensitive may further reduce the need to test fish species altogether. The screens can also be used to develop Predicted No Effect Concentrations for screening-level risk assessments. These small scale screens have business utility as well. Often during product development limited quantities of test material are available, and these screens conducted in well-plates can significantly reduce the amount of test material required for exposures, which reduces cost and waste. Since many products that chemical companies develop are novel chemistries, they are not always within the domain of accepted quantitative structure activity relationships (QSARs) or other predictive models. Thus, these screening level environmental toxicity assays can provide critical toxicity information early in the process of identifying candidate chemistries for further development. Frequently, product registration packages include read-across arguments among chemical categories, which assume the ecotoxicity of a molecule is comparable to other chemicals with similar structures. Strategically filling in gaps or uncertainties in read-across arguments or checking the reliability of QSAR models is also a potential use for these screening assays. Despite the many advantages of these assays, only traditional assays are recognized as reliable in compliance testing. We propose that these high-throughput assays gain regulatory acceptance by outlining their utility, versatility, and potential compliance advantages.

226 Possibilities for Using Fish Embryo Tests in Place of Fish Acute Toxicity – Threshold Approach Strategies for Ecotoxicity Hazard Determination

S.E. Belanger, J.M. Rawlings, The Procter & Gamble Company / Environmental Stewardship and Sustainability

The Threshold Approach is a sensible strategy used by ecotoxicologists to prioritize chemicals for testing using fish as described in OECD Guidance No. 126. Acute testing is initially conducted using algae and Daphnia and the lower of the two values is used to set a limit test on juvenile fish acute toxicity testing (OECD 203 TG). If fish display no mortality, a decision is made that the lower tested value from algae and Daphnia can be used for hazard classification and risk assessment purposes in the absence of a full 96 hr LC50 study on vertebrates. Large savings in animal testing is the result. With the advent of Fish Embryo Tests (OECD 236 TG) we have re-evaluated the Threshold Approach in light of replacing acute fish tests with fish embryo tests. A data base on comparative FET-fish acute toxicity from Belanger et al. (2013) was extended to include algae and Daphnia in order to address the question if similar conclusions on the utility of the Threshold Approach would be expected if full replacement occurred. A total of 166 comparisons of Fish and FET toxicity were compiled (updating Belanger et al. 2013) of which 79 compounds were found to have a full complement of FET, fish, algae, and Daphnia data. An additional 128 compounds had FET, fish and Daphnia data (no algae) and 87 compounds had FET, fish, algae (no Daphnia). In this talk we will review the chemical coverage for each data set and the relative rankings of acute toxicity based on geometric mean and lowest available aquatic toxicity values in order to assist a judgement of the appropriateness of the FET to be used as a replacement for fish in the Threshold Approach Guidance. The expectation, given the FET-fish acute toxicity relationship of Belanger et al. (2013) and Busquet et al. (2014) is that the FET provides equivalent information to that of fish in this process. Recommendations for OECD, based on our findings, will be provided.

227 Mode of Action (MOA) Assignment Classifications for Ecotoxicology: Evaluation of Available Methods

M.R. Embry, ILSI Health & Environmental Sciences Inst (HESI); M.G. Barron, USEPA / Gulf Ecology Division; A. Beasley, Dow / Product Sustainability Consultant Toxicology and Environmental Research Consulting; S.E. Belanger, The Procter & Gamble Co. / Central Product Safety Dept; J. Brill, The Procter & Gamble Co. / Environmental Stewardship and Sustainability; D. DeZwart, DdZ-Ecotox; B. Farr, ILSI Health and Environmental Sciences Inst (HESI); M. Halder, A. Kienzler, European Commission – Joint Research Centre / IHCP EURL ECVAM; T.J. Norberg-King, USEPA / NHEERL / Mid-Continent Ecology Division; H. Sanderson, Aarhus Univ / Environmental Science; R.M. Sternberg, USEPA / Environmental Fate and Effects Division; P. Wilson, SANOFI

There are various structure-based classification schemes to categorize chemicals based on MOA which have been applied for both eco and human toxicology. With increasing calls to assess 1000s of chemicals, some of which have little available information other than structure, understanding how each of these MOA schemes was devised, what information they are based on, and the limitations of each is critical. Several groups are developing low-tier methods to more easily classify or assess chemicals, using approaches such as the ecological threshold of concern (eco-TTC) and chemical-activity. Evaluation of these approaches and determination of their domain of applicability is partly dependent on the MOA classification that is used. The objectives of this study were to evaluate available MOA classification methods using a set of unique chemicals from a large aquatic toxicity dataset, compare the various approaches, and evaluate their utility and limitations in low-tier assessment approaches. The most commonly used MOA classification schemes for ecotoxicology include Verhaar and Russom (included in ASTER), both of which are used to predict acute aquatic toxicity MOA. Verhaar is a QSAR-based system that classifies chemicals into one of 4 classes, with a 5th "other" class, whereas ASTER/Russom includes 8 classifications. Other methodologies include Toxicity Estimation Software Tool (TEST), an application that allows prediction into 5 broad MOAs, with specific MOAs as subcategories. MOAtox is a dataset of MOA assignments for >1200 chemicals that draws from various schemes and assigns 6 broad and 31 specific acute aquatic toxicity MOAs. Other classification systems that can provide insight on a chemicals' MOA include ECOSAR, EPISuite, and the OECD QSAR Toolbox. In this study, >5600 unique CAS numbers were evaluated using the classification and MOA schemes described above. In all of the approaches used, a large percentage (>40%) were classified as narcotics, with very in categories describing more specific mechanisms. However, a large percentage of chemicals were not classified for various reasons. This presentation will provide an overview of available MOA assignment tools, including summarizing their technical basis, comparing consistency in MOA classifications, and assess utility for grouping compounds in large structurally diverse datasets. This presentation does not necessarily reflect the views or the policies of the USEPA or European Commission.

228 Ecological Threshold for Toxicological Concern (eco-TTC) – Assessing the Potential of a New Tool for Environmental Hazard Assessment

A. Beasley, The Dow Chemical Company / TERC; M.G. Barron, USEPA / Gulf Ecology Division; S.E. Belanger, The Procter & Gamble Co. / Central Product Safety Dept; J. Brill, The Procter & Gamble Co. / Environmental Stewardship and Sustainability; D. DeZwart, DdZ-Ecotox; M.R. Embry, B. Farr, ILSI Health and Environmental Sciences Inst (HESI); M. Halder, A. Kienzler, European Commission Joint Research Centre / IHCP EURL ECVAM; T.J. Norberg-King, USEPA / NHEERL / Mid-Continent Ecology Division; H. Sanderson, Aarhus Univ / Environmental Science; R.M. Sternberg, USEPA / Environmental Fate and Effects Division; P.W. Wilson, Sanofi US, Inc. / Health Safety and Environment

The Threshold for Toxicological Concern, or TTC, is well-established for assessing human safety and has been applied for a variety of endpoints including carcinogenicity, teratogenicity, and reproductive toxicity. Recently, we have proposed an extension to the human safety TTC concept for application in environmental situations, termed the ecological TTC or eco-TTC. Eco-TTCs summarize the wealth of ecotoxicological information as Predicted No-Observed Effect Concentrations (PNECs) on diverse chemical substances in the form of statistical (probability) distributions. Eco-TTCs can be developed that allow prediction of untested chemicals based on structural attribute (category), mode of action, or functional use. The approach may be useful for assessing chemicals at early tiers of the risk assessment process, providing hazard perspective on chemicals that lack QSARs, guiding product development discussions, and assisting read across or category justifications. The eco-TTC approach has the potential to reduce the need for vertebrate testing (e.g., fish) in many situations. A database consisting of approximately 110,000 unique ecotoxicological records has been developed based on recent assessments of published data and international chemical management programs. This toxicity data is associated with physical chemistry data and curated taxonomic information for the organisms tested. A process to conclude acute and chronic effects as well as identify the PNEC for exposed ecosystems based on depth and breadth of data have been devised, with the 5th percentile of PNECs for a compound group defined as the ecological TTC. Several mode of action schemes are being assessed to devise a best approach for grouping compounds. Chemicals that are categorized as neutral organics are the most abundant in the dataset, therefore are candidates for an initial in-depth assessment of eco-TTC attributes. Approximately 500 chemicals in the database are included in this analysis at this time with approximately one third having complete acute or chronic data sets (all three taxa). The eco-TTC for non-polar and polar narcotics is explored in depth, with additional categories under development (phenols, esters, reactive compounds, surfactants, pesticides, and pharmaceuticals). Eco-TTCs look to be a promising addition to the toolkit of hazard assessment. This presentation does not necessarily reflect the views or the policies of the USEPA or European Commission.

229 Animal Alternatives for Whole Effluent Toxicity Testing: Perspectives from a Global Workshop

T.J. Norberg-King, USEPA / NHEERL / Mid-Continent Ecology Division; M. Embry, ILSI; S.E. Belanger, The Procter & Gamble Co. / Central Product Safety Dept; T. Braunbeck, Univ of Heidelberg / Centre for Organismal Studies; J.D. Butler, ExxonMobil Biomedical Sciences, Inc / Environmental Toxicology and Chemistry Laboratory; P. Dorn, PB Dorn Associates; B. Farr, ILSI Health and Environmental Sciences Inst (HESI); P.D. Guiney, S C Johnson & Son, Inc / Molecular and Environmental Toxicology Center; J. Hughes, USGS / Columbia Environmental Research Center; M.K. Sellin Jeffries, Texas Christian Univ / Dept of Biology; R. Journel, SANOFI; M. Leonard, L'Oréal Research; J. Oris, Miami Univ / Dept of Biology; K. Ryder, UK Home Office; H. Segner, Univ of Bern / Centre for Fish and Wildlife Health; G.J. Van Der Kraak, Univ of Guelph; P.W. Wilson, Sanofi US, Inc. / Health Safety and Environment; G. Whale, Shell Health

Since the 1940s, effluent toxicity testing has been utilized to varying degrees in many countries to assess potential ecological impacts and assist in determining necessary treatment options for environmental protection. However, it was only in the early 1980's that toxicity based effluent assessments and subsequent discharge controls became globally important, when it was recognized that physical and chemical measurements alone did not protect the environment from potential impacts. Consequently, various strategies using different toxicity tests, whole effluent assessment techniques (incorporating bioaccumulation potential and persistence) plus supporting analytical tools have been developed over 30 years of practice. Numerous workshops and meetings have focused on effluent risk assessment through ASTM, SETAC, OSPAR, UK competent authorities, and EU specific country rules. Concurrent with this drive to improve effluent quality using toxicity tests, interest in reducing animal use has risen. The Health and Environmental Sciences Institute (HESI) organized and facilitated an international workshop in March 2016 to evaluate strategies for concepts, tools, and effluent assessments and update the toolbox of for effluent testing methods. The workshop objectives were to identify opportunities to use a suite of strategies for effluents, and to identify opportunities to reduce the reliance on animal tests and to determine barriers to implementation of new methodologies. As preparation for the workshop, a survey was conducted to assess the use and application of ecotoxicity-based effluent assessments. Preliminary results from this ongoing global survey of effluent assessment strategies were presented in May 2016 at SETAC Europe (Nantes). This talk will focus on the highlights of the workshop, including a review the state of the science, description of the suite of strategies being used for reducing the impact of effluents, discussion on ways to integrate alternative approaches, and identification of opportunities to lessen the reliance on animal testing. Finally, we will give an overview of how various countries approach effluent testing and discuss how these approaches and data generated can integrate into existing risk assessment methodologies. DISCLAIMER: The views, conclusions and recommendations expressed are those of the authors and do not necessarily represent the policies or positions of the European Commission, Canada or USEPA.

230 TSCA Reform: New Options for Animal Testing Alternatives

J. Kneeland, A. Lewis, Gradient

The Frank R. Lautenberg Chemical Safety for the 21st Century Act (Lautenberg Act) will change how chemicals are regulated in the United States. The Lautenberg Act, which reforms the Toxic Substances Control Act (TSCA), requires more careful control and more thorough understanding of hazardous chemicals in the US marketplace. This is consistent with many global regulatory reforms that have already been implemented or are underway. Though many details of the Lautenberg Act and its implementation by the United States Environmental Protection Agency (USEPA) remain to be elucidated, some broad changes to chemical hazard data requirements are expected. In particular, the Act will grant USEPA expanded authority to require companies to obtain additional chemical hazard data. In the backdrop of what are likely to be significantly increased data needs, USEPA is simultaneously stressing that companies should use alternative test methods and tiered testing plans to reduce vertebrate animal testing, if possible. There is a global trend toward increased use of alternative sources of hazard information, including in vitro methods, high-throughput screening, in silico methods such as quantitative structure activity relationships (QSARs), and chemical grouping and read-across approaches. As part of the reforms enacted by the Lautenberg Act, USEPA will be required to develop a strategic plan to encourage the use of these alternative information sources. This presentation will highlight the new possibilities for taking advantage of these approaches, as well as some of the technical challenges that are likely to be encountered during the implementation of the new regulation.

Modeling and Monitoring of Environmental Pesticides Exposure: Regulatory Context and Improvements from Science

231 Plant Uptake – From Scientific Description to Regulatory Implementation

R. Sur, Bayer CropScience AG / Environmental Safety

Plant uptake is a crucial process for a comprehensive leaching assessment of pesticides and their metabolites and a realistic description of plant uptake can be critical for passing the regulatory groundwater exposure assessment. The process of plant uptake is described by parameters like plant uptake factor, transpiration stream concentration factor and root concentration factor. The science behind these parameters, experimental methods of their determination and the consistent and coherent use in leaching models is discussed. Furthermore, an overview on current regulatory guidance, practice, und issues is given. Proposals for use of plant uptake in regulatory leaching assessments should consider appropriate endpoints derived from robust laboratory studies as higher tier option, which provides for a pragmatic approach but protective assessment.

232 Modelling the Fate of Pesticides in European and French Cropping Systems: Integration of Complex Cropping Practices in the Regulatory Risk Assessment

L. Mamy, INRA; A. Boivin, ANSES; S. Lammoglia, INRA; J. Moeys, SLU / CKB, Dept of Soil and Environment; E. Barriuso, INRA

Modelling the fate of pesticides in the environment can help preventing and managing soil and water contamination. In particular, groundwater protection is a key issue for human health and resources sustainability. At the European level, a pesticide shall only be approved if the predicted concentrations in groundwater (PECgw) of the pesticide or of relevant metabolites are below 0.1 µg/L. The PECgw have to be estimated using at least two of four recommended models (MACRO, PELMO, PEARL, PRZM) together with representative European agro-pedo-climatic scenarios available for each crop (FOCUS scenarios). These scenarios assume that the same crop is grown every year. This assumption can be considered as a worst case for PECgw assessment but it does not include crop rotation. The PECgw have to be lower than 0.1 µg/L for at least one of the scenarios for pesticide approval. At the French level, there are two levels of risk assessment for plant protection products (PPP) containing the approved pesticide(s). First, PECgw are estimated from the FOCUS scenarios. The PECgw have to be lower than 0.1 µg/L for all representative scenarios. If not, a refined level of assessment is required. One refinement is based on numerous French agro-pedo-climatic scenarios (FROGS scenarios) coupled with the PEARL model. In contrast to FOCUS scenarios, FROGS scenarios allow to define risk mitigation measures based on specific cropping practices (i.e crop rotation). In order to be as representative as possible of standard agricultural practices, typical crop rotations of 31 French agricultural regions are implemented in FROGS. PPP can only be approved for conditions where PECgw are lower than 0.1 µg/L. However, while these scenarios consider more realistic cropping systems than the FOCUS scenarios, they do not take into account agricultural practices such as cover crops, mulch… In addition, the representation of agricultural practices in the numerical models remains incomplete. Therefore, new tools are needed to consider the variability of cropping systems in risk assessment. Among the most recent developments, the sequential use of a pesticide fate model such as MACRO and a crop model able to simulate the growth of a large range of crops under different agricultural practices (residues management, tillage...) is a promising method to refine risk assessment of pesticides. In the future, it would allow to consider more realistic cropping systems for pesticide regulatory risk assessment.

233 Assessment of available monitoring data and modeled EEC values for an herbicide (linuron) in the US and Canada

G. Hoogeweg, I. Khanijo, Waterborne Environmental, Inc.; K.S. Henry, NovaSource/Tessenderlo Kerley, Inc.; J. Akins, NovaSource Tessenderlo Kerley Inc / Regulatory Affairs; L. Castro, Tessenderlo Kerley, Inc

The purpose of his study was to compile a dataset of monitoring data for an herbicide (linuron) used in North America and to create a geospatial illustration of the water monitoring locations, and to compare these results to the outputs of standard Tier 2 models. Water quality monitoring records were collected for a 25-year period (1986 – 2015). Over 115,000 sample results were obtained for Canada and the US. Monitoring data for the U.S. was available primarily online. Much of the information for Canada was requested from regulatory agencies and other organizations, and, to a lesser degree, available online. Of the 115,000+ records that were collected 89% are associated with the US and 11% of the monitoring data is for Canada. A majority of the data in both the Canada and the US are for surface water (~60%) and for groundwater (~39%), while results for drinking water are less commonly reported (0.02%). About 1% of the monitoring data indicated that the herbicide was detected. In addition to standard percentile assessments, geo-spatial statistics were applied to identify ranges of sampling density for monitoring and to determine if spatial-temporal trends are present in the data. Monitoring data were compared to standard USEPA and PMRA modeling scenarios. The results indicated that no correlation exists between modeled data and observed data for linuron.

234 Insecticides in sediment cores from a rural and a suburban area in South China: A reflection of shift in application patterns

D. Sun, Y. Wei, H. Li, X. Yi, Guangzhou Inst of Geochemistry / Chinese Academy of Sciences; J. You, Jinan Univ / School of Environment

A shift in pesticide application pattern has occurred in recent decades, yet little information is available in the consequence of this shift. To better understand how the shift is reflected in aquatic environment, two sediment cores were collected from a rural (RLY) and suburban (SGZ) river in South China. A variety of legacy organochlorine pesticides and current-use pesticides (CUPs), including organophosphate, pyrethroid and phenylpyrazole insecticides were quantified at distinct increments of the sediment cores. Total insecticide concentrations were in the ranges of 67.6–1671 and 99.2–231 ng/g dry weight in RLY and SGZ with pyrethroids and organochlorines being the dominant components, respectively. In general, the shifting profile of sediment-bound insecticides from legacy organochlorines to CUPs over time followed their historical application pattern, but significant differences were noted between the temporal profiles of the rural and suburban cores in regards to concentrations and composition of insecticides. The observed difference between the suburban and rural cores was synchronous with land use pattern and local economic changes. A steep increased occurrence of CUP in the 1990s was observed in the RLY core, which is consistent with the onset of economic growth in this area. In contrast, the suburban SGZ area has been historically contaminated by legacy OCPs, with fresh input of OCPs in SGZ believed to be caused by soil erosion, caused by land reclamation activities associated with urban expansion. The current study shows the shift in insecticide application pattern from legacy organochlorine to CUPs leading to an elevated CUP occurrence in the environment. It also suggests a stronger need for understanding not only environmental fate and risk, but also how their use pattern and land use changes impact the occurrence of pesticides.

235 Chlorpyrifos in Surface Waters of Central Valley, California: Statistical Analysis of Environmental Monitoring Data

D. Wang, N. Singhasemanon, K. Goh, California Dept of Pesticide Regulation

Pesticides are routinely monitored in surface waters and resultant data are analyzed to assess whether their uses will damage aquatic eco-systems. However, the utility of the monitoring data is limited because of the insufficiency in the temporal and spatial sampling coverage and the inability to detect and quantify trace concentrations. This study developed a novel assessment procedure that addresses those limitations by combining 1) statistical methods capable of extracting information from changing detection limits, 2) statistical resampling techniques that account for uncertainties rooted in the non-detects and insufficient sampling coverage, and 3) multiple lines of evidence that improve confidence in the final conclusion. This procedure was demonstrated by an assessment on chlorpyrifos monitoring data in surface waters of California's Central Valley (2005–2013). We detected a significant downward trend in concentrations, which cannot be observed by commonly-used statistical approaches. We assessed that the aquatic risk was low by using Joint Probability Curve that works with non-detects and can differentiate indicator groups with varying susceptibility and recovering ability. In addition, we showed that the frequency of exceedance over ambient aquatic life water quality criteria was affected by pesticide use, precipitation and irrigation demand in certain periods anteceding the water sampling events.

236 Groundwater Monitoring for regulatory purposes – First steps of a SETAC group to develop a European guidance Document

A. Gimsing, The Danish Environmental Protection Agency / Pesticides and Gentechnology; A. Boivin, ANSES; W. Tüting, German Federal Office of Consumer Protection and Food Safety; J. Agert, Bayer CropScience AG / Environmental Safety; W. Koenig, Federal Environment Agency Germany; J. Kreuger, Swedish Univ of Agricultural Science / Centre for Chemical Pesticides; L. Loiseau, Syngenta; A. Massey, Chemicals Regulation Directorate; B. Miles, BASF SE Agrarzentrum Limburgerhof / Crop Protection Environmental Fate Modelling; A. Newcombe, ARCADIS US Inc; R.L. Jones, Bayer CropScience / Environmental Safety; T. Van der Linden, RIVM / Environmental Quality; A.E. Rosenbom, Geological Survey of Denmark and Greenland / Geochemical

The aim of the SETAC Environmental Monitoring Advisory Group on groundwater (EMAG-GW) is to develop a guidance document on the use of groundwater monitoring data for regulatory purposes in the EU. Preliminary feedback on the following topics will be presented: Utilizing monitoring data in regulatory context: Monitoring data can be used in the regulation of pesticides, but use of such data is not straight forward. Groundwater Monitoring "good practices": The design of a monitoring study and the quality of the data are key to generate valuable monitoring results. The study design should be tailored to the questions that the study is expected to answer. Interpretation of GW monitoring data and how representative is the GW monitoring conducted: How to interpret and use monitoring data in regulation and how to assess the representative nature of monitoring are probably the two main recurrent questions associated with groundwater monitoring. These two questions are raised for both compound specific monitoring studies and for public monitoring programmes which may be available. Recommendations are needed on how results should be used and to define what the monitoring data should represent/cover for both types of monitoring studies/programmes. How can these two types of monitoring complement each other?

237 Pesticide Residues in Yamuna, Hindon and Ghaggar Rivers flowing through Vegetables, Rice and Cotton Cropping Areas

S. Thakur, K. Gulati, Amity Univ / Amity Inst of Environmental Toxicology Safety and Management AIETSM; D. Lal, Ministry of Environment, Forest and Climate Change / Hazardous Wastes Management; P. Jain, Central Pollution Control Board; T. Jindal, Amity Univ / Amity Inst of Environmental Toxicology Safety and Management AIETSM

In India cotton and paddy are the major consumers of crop protection chemicals accounting for 50% and 18% respectively. While vegetables consume about 9% share of the crop protection chemicals. As crops are water intensive, it's the quality of the water that is mostly affected by their cultivation, by runoff chemicals in surface water. Therefore a study was undertaken to analyze the contamination by pesticide in surface water samples in flowing near the farms of vegetable, rice and cotton growing areas along with survey for pesticide use by farmers. Yamuna, Hindon and Ghaggar River streams flowing nearby vegetables, rice and cotton crop growing areas. Samples of rivers (Yamuna, Hindon and Ghaggar) were taken from nearby field crop surface, 2km, 2km bottom and 5km. According to survey pesticide sprayed in vegetables, rice and cotton were Cypermethrin and Malathion, Cypermethrin and Endosulfan, Profenofos and Endosulfan, Ethion and Cypermethrin, Endosulfan, Chlorpyrifos Profenofos and Cypermethrin and Cypermethrin respectively. Yamuna River flowing nearby seasonal vegetable growing area, 45% samples were found contaminated with organochlorine and 25% samples with organophosphorous pesticides above MRL value. All the synthetic pyrethroids analyzed were found below MRL value. Hindon River flowing nearby rice growing area and the variety grown there was 11/21. Samples were found contaminated with 52% by organochlorine pesticides, 25% by organophosphorous pesticides and 12.5% by synthetic pyrethroids above MRL value. Ghaggar River flowing nearby desi cotton growing area and the variety grown there were RG-8, HD-123, 38.6% of surface water samples were found contaminated with organochlorine pesticide, 50% by organophosphorous pesticide and 10.5% by synthetic pyrethroids residues which were above MRL value. The results are alarming and show that either the use of banned pesticides (DDT and Endosulfan) is still continued or they are present in surface water samples as they are very persistent. There is need of proper extension services to educate farmers about the judicious use of new molecules of pesticides along with Integrated Pest Management approach to avoid contamination of water resources.

238 Pesticide residues and degradation in vegetative filter strips for long-term environmental exposure assessments

R. Muñoz-Carpena, Univ of Florida / Agricultural Biological Engineering; A. Ritter, Waterborne Environmental, Inc.; G. Fox, Oklahoma State Univ / Biosystems and Agricultural Engineering; O. Perez-Ovilla, Bayer CropScience / Environmental Safety

Understanding and being able to simulate the fate and transport of pesticides from the application on a field, through a vegetative filter strip (VFS), and finally to adjacent receiving water bodies is critical for conducting environmental risk assessments. Previous research has proposed a modeling approach that links the U.S. Environmental Protection Agency's (EPA's) PRZM/EXAMS higher-tier environmental exposure framework with a well-tested process-based model for VFS (VFSMOD), but it assumed that pesticide mass stored in the VFS was not available for transport in subsequent storm events. The objective of this research was to update the modeling approach to consider four formulations for degradation to accommodate different regulatory environments, and then to determine if residues in the VFS and/or estimated environmental concentration (EECs) differed relative to the degradation formulation. The formulations variably consider temperature and moisture content adjustments as proposed by the European Union and USEPA. Results from three distinct 30-yr USEPA scenarios showed that while the type of degradation equation was important in long-term assessments relative to predicting residues at the beginning of each storm event, the degradation formulation was not important relative to EECs.

Everglades and Wetlands Science Part 2: Cellular, Genetic and Toxicological Outcomes of a Changing Habitat

239 Infectious disease linked to climate and genetic variation in amphibian populations of the southeastern United States

A. Horner, Univ of Central Florida / Biology; E. Hoffman, Univ of Central Florida; A. Savage, Univ of Central Florida / Biology

Infectious disease is a well-known driver of animal declines worldwide. North American amphibians have been impacted by to two major emerging pathogens, the fungus Batrachochytrium dendrobatitis (Bd) and iridoviruses in the genus Ranavirus (Rv). Amphibian populations have responded differently to these disease stressors; some populations have declined precipitously while others persist despite ubiquitous infection.

Environmental factors and host genetics may play important roles in disease dynamics, but few studies incorporate both of these components into their analyses. Our study investigates the effect of environmental and genetic factors on Bd and Rv infection prevalence and severity in a biodiversity hot spot, the southeastern United States. We conducted a retrospective infection study on three amphibian species, using population genetics and quantitativepathogen detection to understand how emerging infectious pathogens have impacted natural populations. By combining genetic factors and environmental variables into a general linear model for species with pathogen infection, we elucidate the relative roles of host genetics and environmental variables on predicting disease impact and spread. We conclude that by incorporating both genetic and environmental factors into conservation plans for amphibians, more effective management strategies can be developed to help protect the Southeast's amphibian biodiversity.

240 Genetic and epigenetic variation in Spartina alterniflora following the Deepwater Horizon oil spill

M. Robertson, Univ of South Florida; A. Schrey, Armstrong State Univ; A. Shayter, Southern Illinois Univ Carbondale; C. Meals, C. Richards, Univ of South Florida

Catastrophic events offer a unique opportunity to study rapid population response to stress in natural settings. Following the Deepwater Horizon oil spill, we simultaneously examined the genetic and epigenetic structure of recovering populations of Spartina alterniflora, a keystone salt marsh grass. In concert with genetic variation, epigenetic mechanisms like DNA methylation may explain the high resilience ofS. alterniflora to oil exposure, and may offer a rapid mechanism of response to severe environmental challenges, like the Deepwater Horizon oil spill. In this study, we quantified genetic and DNA methylation variation using AFLP and MS-AFLP to test the hypothesis that response to oil exposure in S. alterniflora resulted in genetically and epigenetically based population differentiation. We found high genetic and epigenetic variation within and among sites, and found significant genetic differentiation between contaminated and uncontaminated sites. In contrast, we found the majority of the epigenetic variation occurred within sites and found no significant genome-wide epigenetic differentiation in response to oil contamination. However, despite the lack of genome wide patterns in DNA methylation, we found three MS-AFLP loci (14% of polymorphic MS-AFLP loci) that were correlated with oil exposure. Overall, our findings support genetically based response to selection from the oil spill in this system, but also a limited role for epigenetic mechanisms in population differentiation.

241 Using an in vitro organ culture system to assess the estrogenic effects of CWAF exposure on sex determination in the American alligator

C. Williams, College of Charleston; D. Spyropoulos, Medical Univ of South Carolina / Pathology and Laboratory Medicine; L. Guillette, S. Kohno, Medical Univ of South Carolina / Obstetrics and Gynecology

Coastal aquatic ecosystems are often subject to high levels of anthropogenic activity and contamination. Specifically, these areas are increasingly vulnerable to the threat of oil contamination from offshore oil spills or pipeline ruptures. While a growing body of knowledge exists regarding the toxicity of oil, dispersants, and their mixtures, the potential sublethal biological impacts of dispersants and chemically-dispersed oil still merit further investigation. The American alligator, Alligator mississippiensis, is an ideal aquatic sentinel species due to its regional fidelity, long life as a top predator (bioaccumulation), and its environmental sex determination, in which the temperature and/or estrogenic signals of the developing embryo determines its sex. Exposure to estrogen and certain estrogenic compounds in ovo can result in ovarian development at any temperature in the alligator. This study evaluates the effects of CWAF, the chemical enhanced water-accommodated fraction of crude oil with Corexit, on sex determination and differentiation in the alligator by examining patterns of key mRNA abundances involved in the sex determination process including aromatase, anti-Müllerian hormone(AMH), sex determining region Y-box 9(SOX9) and Forkhead box protein L2 (FOXL2). We revealed that CWAF induced estrogenic activity at nearly 50% of the maximum induction of the endogenous ligand 17β-estradiol (E_2) in transactivation assays with alligator estrogen receptors in vitro. To determine the effects of CWAF at the organ level, gonad-adrenal-mesonephric (GAM) organ complexes were isolated from A. mississippiensis embryos one day prior to the beginning of the thermosensitive period for sex determination and cultured at a male-producing temperature for 1-2 weeks with exposure to media controls, CWAF, and three different concentrations of E_2. After two weeks of GAM culture, E_2 and CWAF exposure induced a female-like pattern in several of the genes examined. The results of this study help to establish a framework for assessing targeted effects of contaminants at the receptor and organ levels, and provide important insight into the potential adverse effects of oil and dispersant exposure on reproductive health in aquatic wildlife as well as in humans.

242 Assessing Estrogenic Activity of the Dispersant Corexit 9500 in Two Aquatic Reptiles, the American Alligator and Diamondback Terrapin

N. McNabb, College of Charleston; D. Spyropoulos, Medical Univ of South Carolina / Pathology and Laboratory Medicine; L.J. Guillette, S. Kohno, Medical Univ of South Carolina

During the Deepwater Horizon oil spill, millions of gallons of Corexit 9500 were applied to the surface water and at the wellhead to disperse the oil. This massive release mandates evaluation of the long-term effects of Corexit with a focus on endocrine disruption. Estrogen signals play critical roles in temperature-dependent sex determination (TSD) and gonadal differentiation in some turtles and all crocodilians, in which egg-incubation temperatures determine sex of the embryos during a thermosensitive period (TSP). A single exposure to exogenous estrogen during TSP leads to skewed sex ratios by inducing ovarian development, even at a male-producing temperature. Due to this sensitivity to estrogen, reptiles that exhibit TSD, including the American alligator (Alligator mississippiensis) and diamondback terrapin (Malaclemys terrapin), can be sentinel species to investigate chronic exposure to estrogenic environmental contaminants. Both estrogen receptor isoforms, ESR1 and ESR2, were cloned from the diamondback terrapin and found to be highly homologous to painted turtle, alligator, and chicken ESRs. The cloned ESRs were characterized using nuclear hormone receptor transactivation assays in vitro with 17β-estradiol and Corexit. Additionally, alligator eggs were exposed to Corexit at 0.25, 2.5, and 25 μg/g egg weight prior to TSP to investigate the potential endocrine disruption and estrogenic effects on gonadal development in ovo. Gonadal tissues dissected from alligators at one week old were analyzed using histological methods and quantitative PCR to determine resulting sex ratios and understand the outcome of developmental exposure. While Corext showed potential estrogenic activity in vitro using transactivation assays, no significant effects on sex ratios or testicular mRNA abundance were observed as a result of Corexit exposure, suggesting that Corexit alone does not have strong estrogenic activity in ovo. Further investigations are required to assist in understanding the effects of Corexit exposure on the reproductive health of coastal aquatic reptiles.

243 Exploring the epigenetic and biochemical effects of mercury exposure in Diamondback Terrapins (Malaclemys terrapin)

F. Nilsen, National Inst of Standards and Technology / Environmental Chemical Sciences Division; J. Schwenter, South Carolina Dept of Natural Resources; R.D. Day, NIST / Chemical Sciences Division Hollings Marine Laboratory; B.B. Parrott, Medical Univ of South Carolina; J.A. Bowden, National Inst of Standards and Technology / Environmental Chemical Sciences Group; T.B. Schock, National Inst of Standards and Technology / Analytical Chemistry Division

Mercury is a toxic global pollutant impacting a wide variety of ecosystems across the planet, due to the main route of transmission being atmospheric deposition. Mercury is a potent neurotoxin known to elicit behavioral changes and has been correlated to a myriad of adverse health effects, including congenital heart defects, and reproductive impairment. Sub-lethal, physiological effects of mercury exposure have been difficult to characterize. The Diamondback Terrapin (Malaclemys terrapin) is a long lived, ecologically important mid- to upper trophic level predator in coastal habitats of the Atlantic Ocean, and along the US Gulf Coast. The natural range places this reptilian sentinel in areas historically affected by anthropogenically produced environmental contaminants, including mercury. These qualities make the terrapin an excellent model species for studies of chronic exposure to mercury, as well as a sentinel species for human exposure. In this study, we investigate physiological and epigenetic changes associated with two doses of chronic mercury exposure over a two year time period on an ecologically important reptilian sentinel. Blood samples were analyzed for total mercury content and subsequently analyzed by LC-MS/MS for global DNA methylation patterns and by ^{1}H NMR for metabolomic effects. DNA methylation is a well-studied epigenetic modification that controls gene expression. When DNA methylation patterns are changed as a result of external stimulus, altered gene expression and dysregulation of certain cellular processes can occur. Evaluating DNA methylation changes related to mercury exposure can provide insight into the sub-lethal effects of chronic mercury exposure. Plasma metabolomic profiles were analyzed by multivariate and univariate techniques across doses, gender, and annual time scales. The metabolomics data details the small molecule changes that are taking place as a result of mercury exposure. The combination of these two techniques allows for further elucidation of organism-environment interactions.

244 A means to adapt, a means to disrupt: epigenome-environment dynamics underlying sex determination and reproductive perturbations in the alligator

B. Parrott, Univ of Georgia – Savannah River Ecology Laboratory / Odum School of Ecology; B. Doheny, Medical Univ of South Carolina and Hollings Marine Laboratory / Marine Biomedicine and Environmental Sciences; L.J. Guillette, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences OBYGYN

Unlike traditional models for reproductive health, the American alligator is a long-lived apex predator that undergoes temperature-dependent sex determination (TSD). Further, these animals are oviparous and field collected eggs allow for the investigation of environmental effects on developmental processes. Here, we use the alligator as a model to (1) examine the role of DNA methylation patterning during TSD and (2) investigate how exposures to endocrine-disrupting contaminants (EDCs) during this period may alter the epigenetic landscape in a manner that influences subsequent reproductive function. When compared to their counterparts living in relatively pristine environments, alligators undergoing natural exposures to EDCs display a severely abated ovarian transcriptional response to gonadotropin stimulation. Here, we employ reduced-representation bisulfite sequencing to explore the sexually dimorphic DNA methylome in gonads from embryos exposed to either male- or female-promoting temperatures. We identify numerous temperature-dependent methylated regions within the alligator genome. In addition, we use targeted bisulfite sequencing on the Illumina platform to examine how DNA methylation status of the CYP19A1 promoter, a gene displaying sexually dimorphic expression and DNA methylation patterns, varies in field-collected embryos originating from contaminated environments. We find that the robustness of sexually dimorphic CYP19A1 promoter methylation is reduced in embryos originating from a site contaminated with EDCs. We next probe the consequences of developmentally inappropriate Estrogen Receptor activity on subsequent CYP19A1 expression and find that treatment with a selective ESR1 agonist prior to gonadal differentiation results in down regulation of CYP19A1 in stage 27 ovaries. Results presented here suggest that DNA methylation patterning may play an integral role in mediating the effects of incubation temperature on sex determination and that EDCs may exert their effects by compromising sexually dimorphic epigenetic patterns acquired during development.

A SETAC Pellston Workshop® on Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Substances Data

245 SETAC Pellston WorkshopTM: Environmental hazard and risk assessment approaches for endocrine-active chemicals (EHRA)

A. Leopold, Calidris Environment BV; M. Roberts, Unaffiliated; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; P.D. Guiney, S C Johnson & Son, Inc / Molecular and Environmental Toxicology Center; H. Holbech, Univ of Southern Denmark / Dept of Biology; T. Iguchi, National Inst for Basic Biology / Molecular Environmental Endocrinology; A. Kumar, CSIRO / Center for Environmental Contaminants Research; L.L. Lagadic, Bayer CropScience / Environmental Safety; P. Matthiessen, Unaffiliated; E.M. Mihaich, ER2; J. Odum, Regulatory Science Associates; L.S. Ortego, Bayer CropScience / Environmental Toxicology and Risk Assessment; L. Weltje, BASF SE / Crop Protection Ecotoxicology; J. Wheeler, Dow Agrosciences

Suspected endocrine disrupting substances (EDS) are now being evaluated by several regulatory authorities. A debate is in progress about whether or not EDS can be adequately assessed by following the standard approach involving identification of intrinsic hazards, prediction of exposure and consequent calculation of risk or if hazard alone should be used to decide if chemical registration can be permitted. For this reason the SETAC-Pellston Workshop on Environmental Hazard and Risk Assessment Approaches for Endocrine Active Chemicals (EHRA) was held from the 31st of January to the 5th of Febuary, 2016. It had the following aims: 1) resolving the scientific disagreement about how best to assess the impact of endocrine active substances (EAS); developing guidance to assist regulators and policy makers in their decision making and thereby contribute to speeding up the global progress in controlling these chemicals; 3)identifying areas of uncertainty and knowledge gaps. The approach to the workshop was to identify cross-cutting issues that arose from the six case-studies that were performed ahead of the workshop. Cross-cutting issues emerging from the case-studies covered: improved hazard and risk assessment (Coady et al, in review; Marty et al, in review); whether an EDS can confidently be subjected to environmental risk assessment or whether regulation by hazard is the most appropriate option (Parrott et al, in review); distinguishing between endocrine- versus non-endocrine-specific responses (Mihaich et al, in review). Key questions to be addressed to support endocrine disrupter environmental hazard and risk assessment include: environmental exposure; effects on relevant taxa and life-stages; delayed/multigenerational effects; dose-and concentration-reponse relationships. A proposed decision making scheme developed at the workshop will be presented and discussed. Main conclusions of the workshop will be presented as well as areas of future research.

246 Challenges in Assigning Endocrine Specific Modes of Action: Recommendations for Researchers and Regulators

E.M. Mihaich, ER2; C. Schaefers, Fraunhofer-Institut / Ecotoxicology; D.A. Dreier, Univ of Florida / Physiological Sciences; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre; L.S. Ortego, Bayer CropScience / Environmental Toxicology and Risk Assessment; Y. Kawashima, JAPAn NUS Co., Ltd.; Z. Dang, RIVM / LIEC CNRS UMR; K.R. Solomon, Univ of Guelph / School of Environmental Sciences

As regulatory programs focus on evaluating substances for their endocrine disrupting properties, there is a need for careful study design and data interpretation to distinguish between endocrine versus non-endocrine specific responses. This is particularly important where specific criteria are under development to identify endocrine disrupting properties to enable hazard-based regulation. Irrespective of the regulatory process, most jurisdictions use the WHO IPCS definition of an endocrine disruptor (ED), requiring that a substance is demonstrated to cause a change in endocrine function that consequently leads to an adverse effect in an intact organism. Such a definition is broad, and at its most cautious, might capture many

mechanisms that in general would not specifically be considered ED. For instance, stress is a non-specific, neuro-endocrine response that can lead to adverse outcomes. In addition, non-endocrine toxic mechanisms (e.g. hepatotoxicity, acetylcholinesterase inhibition) may operate secondarily or in parallel to impact the endocrine system and apical endpoints downstream. Furthermore, endocrine responses may be adaptive in nature and designed to maintain homeostasis rather than inducing an irreversible adverse effect. The likelihood of indirect effects is increased in (eco)toxicological studies requiring the use of maximum tolerated dose levels, which must produce some adverse effect. The misidentification of indirect effects as truly ED has serious consequences in terms of triggering animal and resource intensive testing and potentially severe regulatory consequences. A review, based on 6 case study substances, was conducted to evaluate scenarios that could complicate the assessment of whether or not a substance is an endocrine disruptor. In order to achieve this objective, a weight of evidence approach was used to evaluate available data for the case-study substances. In this approach, the weight of evidence was based on biological plausibility, empirical support, and essentiality of key events in adverse outcome pathways. A process is recommended where indicative (endocrine specific and non-endocrine specific) and apical endpoints can be evaluated to investigate whether an endocrine mode of action can be conclusively assigned to the effects observed for a given substance.

247 Uncertainties in biological responses that influence hazard or risk approaches to the regulation of endocrine active substances

J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division; P. Bjerregaard, Univ of Southern Denmark / Biology; K. Brugger, DuPont Crop Protection; L. Gray Jr, USEPA / Office of Research and Development; T. Iguchi, National Inst for Basic Biology / Molecular Environmental Endocrinology; S. Kadlec, Univ of Minnesota – Duluth / Integrated Biosciences; L. Weltje, BASF SE / Crop Protection Ecotoxicology; J. Wheeler, Dow Agrosciences

Endocrine Disrupting Substances (EDSs) may have certain biological effects including delayed effects, multigenerational effects, and non-monotonic dose response relationships (NMDRs) that require careful consideration when determining environmental hazards. The case studies evaluated for the SETAC Pellston Workshop™: Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Chemicals and other key examples from the literature are discussed. EDSs can have specific and profound effects when exposure occurs during sensitive windows of the lifecycle (development, reproductive). This creates the potential for delayed effects where the adverse effect becomes manifest when exposure has ceased, possibly in a different lifestage. This underscores the need for testing in appropriate (sensitive) lifestages and full lifecycle designs that capture adverse effects wherever they occur in the lifecycle. Such tests are available in the tool box and should be employed to derive endpoints that can be considered protective of all life stages. Similarly, the potential for effects to be manifest in subsequent generations (multigenerational effects) has also been raised as a potential issue in the derivation of appropriate endpoints for EDSs. However, the evidence for such effects as a general issue is limited. Indeed this is reflected in the design of new higher tier tests to assess endocrine active substances (EASs) developed by the OECD and US-EPA that move to extended one-generation designs and away from multi-generational studies for fish and mammals. The occurrence of non-monotonic dose or concentration response relationships is also considered a limiting factor for reliable risk assessment of EDSs. Substantial data reviews are underway to inform on their occurrence. However, evidence to date indicates they are more prevalent in in vitro and mechanistic data, not often translating to adverse apical endpoints that would be employed in risk assessment. A proposal of how to evaluate NMDRs in the context of endocrine hazard and risk assessment procedures is presented. If careful consideration of delayed, multigenerational and NMDR effects are made, it is feasible to assess environmental endocrine hazards and derive robust apical endpoints for risk assessment procedures ensuring a high level of environmental protection.

248 Improving environmental assessment of endocrine active substances

K.K. Coady, The Dow Chemical Company / Toxicology Environmental Research and Consulting; R.C. Biever, Smithers Viscient / Dept of Environmental Toxicology; N.D. Denslow, Univ of Florida / Physiological Sciences; M. Gross, WCA Environment; P.D. Guiney, S C Johnson & Son, Inc / Molecular and Environmental Toxicology Center; H. Holbech, Univ of Southern Denmark / Dept of Biology; N.K. Karouna-Renier, USGS Patuxent Wildlife Research Center / Beltsville Lab; I. Katsiadaki, Cefas Weymouth Laboratory / Environment and Animal Health; H.O. Krueger, Wildlife International / Aquatic Plant and Insect Toxicology; S.L. Levine, Monsanto Company / Global Regulatory Sciences; G. Maack, Federal Environment Agency / Ecotoxicological Assessment; M. Williams, CSIRO / Land and Water; J.C. Wolf, Experimental Pathology Labs., Inc.; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory

There has been substantial scientific advancement in the development and implementation of testing, hazard and risk assessment approaches to evaluate potential adverse effects though an endocrine mechanism. In particular, existing test systems and frameworks that have been developed for assessing potential interaction with the estrogen, androgen, and thyroid pathways are relatively comprehensive for identifying and assessing endocrine effects. However, there are now opportunities to retrospectively examine the lessons learned from the recent implementation of these efforts to improve the reliability and relevance of endocrine assessments. Priority areas for improving endocrine screening and testing include: Leveraging information to the extent possible from high through-put screening assays to prioritize and inform testing programs, Using experience with existing assays as a basis for modifying approaches to optimize resource use, Developing additional approaches to address species sensitivity, sensitive life-stages, and critical endpoints to improve the predictive ability to detect an adverse effect at the population level, and Identifying gaps that can be addressed by research to improve testing paradigms. Example ToxCast data sets of endocrine active chemistries will be examined to indicate the utility of high through-put screening to prioritize and inform future testing needs. The example of fathead minnow plasma vitellogenin concentrations across multiple Tier 1 Fish Short Term Reproduction assays will be examined in a post-hoc power analysis to guide future methods development. A summary of the various small fish species used in endocrine screening and testing will be presented to guide species selection based on preliminary chemical information. Finally, research gaps, such as invertebrate endocrine system knowledge, additional endocrine pathways other than estrogen, androgen, and thyroid pathways, and other needed research in the area of endocrine activity will be suggested. Collectively, these recommendations can reduce uncertainty in testing and assessment approaches that evaluate potential adverse effects exerted though an endocrine mechanism.

249 Population-Relevant Endpoints in the Evaluation of Endocrine-active Substances (EAS) for Ecotoxicological Hazard and Risk Assessment

A. Blankinship, USEPA; S. Marty, Dow Chemical Company; J. Chambers, Mississippi State Univ; L.A. Constantine, Pfizer, Inc. / Pharmacokinetics Dynamics and Metabolism; W. Kloas, Liebniz Inst of Freshwater Ecology & Inland Fish.; A. Kumar, CSIRO / Center for Environmental Contaminants Research; L.L. Lagadic, Bayer CropScience / Environmental Safety; J. Meador, NOAA Fisheries / Ecotoxicology and Environmental Fish Health Program; D. Pickford, Syngenta / Inst for the Environment; T. Schwarz, Cefas / Environmental and Animal Health; T.A. Verslycke, Gradient

For ecological risk assessment, endocrine disrupters require the establishment of an endocrine mode of action (MoA) with a plausible linkage to a population-relevant adverse effect. Current ecotoxicolgy test methods mostly incorporate apical endpoints, although, some also include mechanistic endpoints, at the subcellular through organ level, which can help establish an endocrine MoA. However, the link between these endpoints and adverse population-level effects is often unclear. Case studies of endocrine-active substances (EAS) (tributyltin, ethinyl estradiol, perchlorate, trenbolone, propiconazole, and vinclozolin) were used to evaluate the population relevance of toxicity endpoints in various taxa according to the OECD Conceptual Framework for Testing and Assessment of Endocrine Disrupters. For some taxa, such as mollusks, the population relevance of tributyltin-induced gastropod imposex is well established. However, for other taxa, the population relevance of observed effects is not as well understood. Furthermore, potential adaptation and recovery processess also are important to consider when evaluating the adverse effects of EAS exposure on wildlife populations. As our understanding of endocrine perturbations and key event relationships improves, adverse population-level effects will be more easily and accurately predicted. This presentation will focus on examples of potential population relevance from these case study chemicals as well as briefly discuss future needs to better predict population-level effects resulting from EAS exposure.

250 Evaluating the Credibility of Histopathology Data in Environmental Endocrine Toxicity Studies

J.C. Wolf, Experimental Pathology Labs, Inc.; G. Maack, Federal Environment Agency / Ecotoxicological Assessment

Agencies responsible for environmental protection are tasked with developing regulatory guidance that is based on the best available scientific evidence. Histopathology is a common endpoint in toxicologic bioassays; however, because of the subjective nature of this endpoint, and the advanced level of specialized training required for its effective utilization, the reliability of histopathology data can be inconsistent. For the present study, a total of 189 papers that involved investigations of endocrine active substances (EAS) were reviewed for the credibility of their reported histopathology findings. The review process incorporated standardized criteria for article and data selection, and systematic procedures for data evaluation and histopathology credibility (HC) scoring. A major outcome of these efforts was the finding that 54% of the examined papers contained histopathology data that were considered to be either highly credible or credible, whereas such data were deemed to be of equivocal, dubious, or no credibility in 46% of cases. The ultimate goals of this work are to draw attention to reliability issues that can affect the histopathology endpoint, provide recommendations to improve the quality of this endpoint, and suggest an approach for the expeditious and judicious use of histopathology data in weight of evidence determinations required for hazard and/or risk assessment. This exercise was conducted initially as part of a SETAC-Pellston Workshop™ entitled "Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Chemicals (EHRA): Developing Technical Guidance Based on Case Studies to Support Decision Making" that was held in Pensacola, Florida, USA, from January 31st to December 5th, 2016.

Multi-ion Toxicity: Mechanisms and Effects

252 Thoughts on applying existing toxicological understanding to risk assessment for major ions in fresh waters

D.R. Mount, R.J. Erickson, B. Forsman, T.L. Highland, R. Hockett, D.J. Hoff, C.T. Jenson, T.J. Norberg-King, USEPA / NHEERL / Mid-Continent Ecology Division; D.J. Soucek, Illinois Natural History Survey / Illinois Natural History Survey

Recent research in our laboratories and many others have greatly increased understanding of the responses of freshwater organisms to increased concentrations of major geochemical ions (Na, K, Ca, Mg, Cl, SO4, HCO3) in laboratory toxicity tests, stream mesocosms, and in natural streams. The lessons learned to date raise challenges to developing assessment approaches that effectively integrate knowledge from studies of all types. For example, studies of benthic community data from the field suggest that the conductivity associated with changes in those communities varies with the natural background in the study area, but it is not as clear how laboratory toxicity data should be viewed or applied with respect to varying background. Most laboratory toxicity studies involving major ions are conducted using single salts (e.g., NaCl, $MgSO_4$), but most exposures in natural waters involve elevation of multiple ions to varying degrees. As a specific example, how do we interpret toxicity data for $MgSO_4$ alone at low Ca, when in the field elevated Mg usually co-occurs with at least some elevation of Ca as well? And further, how do we balance the practical appeal of guidelines based on single ions (e.g., Cl or SO_4) with our understanding that toxicity is a function of the complete ionic composition of the water?

253 Can major ion uptake kinetics and interactions inform mechanisms of multi-ion toxicity in aquatic insects?

S.A. Scheibener, D. Buchwalter, North Carolina State Univ / Dept of Biological Sciences

Despite a recent surge in interest in freshwater salinization and its consequences to biodiversity, both the scientific and regulatory communities remain relatively uninformed about the mechanisms of multi-ion toxicity. Opinion remains divided as to whether toxicity results from particular individual ionic concentrations, ionic ratios or total salinity/conductivity. Even in the context of evaluating the toxicity of simple salts (e.g. sodium chloride or sodium sulfate), we typically assume toxicity is the result of the anionic concentration, but we don't know that this is 100% accurate. In the face of so many uncertainties, it is important to begin building a fundamental physiological foundation for understanding multi-ion toxicity. In this talk, we will present the results of ongoing studies that examine flux rates of individual ions as a function of their concentration and the interactive effects of other ions in aquatic insects. We show that extreme increases in Mg concentrations are required to out-compete Ca transport. We provide some evidence for an antagonistic effect of potassium, calcium and sulfate on sodium transport. We also compare the kinetics of Na (as NaCl) and SO_4 (as Na_2SO_4) in Neocloeon triangulifer. For both ions, transport rates continue to increase at concentrations beyond those found in the most contaminated freshwaters, suggesting that this species lacks regulatory capacity for controlling uptake rates as concentrations increase. In general, transport rates of these two ions at equimolar concentrations are 2-5 fold high for Na than for SO_4,though both have not been studied under identical ranges. We hope to also present the results of ongoing dual-labeled isotope (^{22}Na and $^{35}SO_4$) experiments that assess the relationship between Na and SO_4 uptake rates under ionic ratio variations.

254 The Mechanistic Toxicity of Multi-Ion Exposures in Pimephales promelas (Fathead Minnow)

K.A. Johnson, Clemson Univ / Inst of Environmental Toxicology; P. van den Hurk, Clemson Univ / Biological Sciences; S.J. Klaine, Clemson Univ / Inst of Environmental Toxicology

Dissolved ions have many important physiological functions within freshwater organisms. Particularly, these ions are necessary for the formation of electrochemical gradients within cells. These gradients produce a delicate balance that controls water homeostasis and further ion movement within the organism. Because the internal ion concentration of freshwater organisms is typically greater than their external environment, it is necessary for them to utilize active transport through a series of pumps and transporters in order to maintain this homeostatic balance. However, due to agricultural irrigation, mining activities, road-salt runoff, and other anthropogenic sources, dissolved ion concentrations in the aquatic environment can become significantly elevated. An increase in dissolved ion levels ultimately leads to an increase in salinity. If the external ion concentration exceeds what is physiologically tolerable for freshwater organisms, then the ionoregulatory function or acid-base balancing capabilities of different organs may become dysfunctional. Seven day static-renewal exposures were conducted with chloride, sulfate, and bicarbonate as variable single ions and in binary mixtures to investigate the underlying mechanisms that lead to ionoregulatory impairment. These mechanisms were evaluated by measuring carbonic anhydrase activity, Na^+/K^+-ATPase activity, and major ion concentrations within individual organs important for ionoregulation, specifically the gill, kidney and intestines. The results of this work provide further insight into the mechanisms of toxicity of ion mixtures to freshwater organisms and serve as a foundation for the development of predictive models to manage water quality.

255 Acute and Chronic Ceriodaphnia Toxicity As a Result of Ion Imbalance and Magnesium Based Hardness

M.S. Bowersox, Tetra Tech, Inc. / Laboratory Dept; P. Siwinski, R. Shaw, P. Spehnkouch, J.M. Diamond, Tetra Tech, Inc.

An effluent from a food and beverage manufacturer caused chronic lethal and sub-lethal toxicity and occasional acute toxicity to Ceriodaphnia dubia. Using recent literature, multiple lines of evidence established that ion imbalance was the cause of observed toxicity. Due to various cleaning procedures in the manufacturing process and the use of magnesium hydroxide in the treatment process, effluent hardness was in excess of 1500 mg/L and a 10:1 ratio of magnesium to calcium was often observed. Correlation analyses implicated increased use of magnesium hydroxide as the cause of toxicity. Using a simulated effluent with various ion characteristics observed in the actual effluent, it was concluded that magnesium was a primary cause of C. dubia acute and chronic toxicity. When non-toxic effluent samples were treated with magnesium hydroxide at concentrations similar to those observed in toxic samples, toxicity effects were observed in the effluent. Reducing the ratio of magnesium to calcium reduced or eliminated effluent toxicity.

256 Comparing responses and dose metrics for mayflies and daphnids exposed to major ion salts

D.J. Soucek, Illinois Natural History Survey; A. Dickinson, Illinois Natural History Survey / Ecology; D.R. Mount, R.J. Erickson, R. Hockett, USEPA / ORD NHEERL Mid-Continent Ecology Division

Field studies have shown that mayflies (Ephemeroptera) tend to be more sensitive than other benthic macroinvertebrates to elevated levels of total dissolved solids in streams. While work with other species has shown that major ion toxicity is dependent on the ionic composition of the water, little is known about how ionic composition influences responses of mayflies to elevated major ions. We tested the toxicity of major ion salts to the mayfly Neocloeon triangulifer using dilution waters in which we manipulated either the concentrations of all background ions, Ca:Mg ratios, or sodium and potassium concentrations. We also conducted acute toxicity tests with D-mannitol and sodium gluconate to investigate potential effects of high osmolarity in the absence of "toxic" cations or anions (D-mannitol) or in the absence of a "toxic" anion (sodium gluconate). Finally, we conducted full-life chronic toxicity tests with two sodium salts. In the case of the sodium salts, expressing LC50s (acute tests) or EC20s (chronic tests) in terms of sodium activity (mM) produced a much narrower range of effect levels than when expressing the same data in terms of the anion activity. Furthermore, exposing mayflies to high osmolarity using D-mannitol resulted in a minor effect on survival, whereas the sodium gluconate test resulted in a sodium activity effect level similar to those produced with inorganic sodium salts. This suggests that sodium, rather than overall osmolarity, was responsible for observed toxicity. Comparing general trends in major ion toxicity for Neocloeon to those observed for Ceriodaphnia dubia revealed similarities in some cases but differences in others. For example, while Na activity appears to be the driver of toxicity to the mayfly in sodium salt tests (NaCl, Na_2SO_4, $NaHCO_3$), for C. dubia, the mechanism of acute toxicity associated with Na salts appears to depend on multiple ions and is closely correlated with osmolarity. While the two species are similar in that it appears the acute toxicity of magnesium and potassium salts may be driven by the cation as well, the species are different in terms of their relative responses to Na, K, and Mg. The acute toxicity of potassium to the mayfly is similar to that of sodium on a mM activity basis, and LC50s for Na and K are ~4-fold greater than those for Mg on a mM activity basis, whereas for C. dubia, K and Mg LC50s are similar, and they are ~4 to 6-fold lower than those for Na on a mM activity basis.

257 The acute and chronic toxicity of major geochemical ions to Hyalella azteca – Ion interactions and interspecies comparisons

R.J. Erickson, D.R. Mount, B. Forsman, T.L. Highland, R. Hockett, D.J. Hoff, C.T. Jenson, T.J. Norberg-King, USEPA / ORD NHEERL Mid-Continent Ecology Division

We have previously reported that the acute and chronic toxicities of major geochemical ions (Na, K, Ca, Mg, Cl, SO4, HCO3) to Ceriodaphnia dubia can involve multiple, independent mechanisms. The toxicities of K, Mg, and Ca salts were best related to the chemical activity of the cation, while the toxicities of Na salts also reflected an influence of other ions and were well correlated with osmolarity. The toxicities of Na and Mg salts were also inversely correlated to Ca and the toxicity of K salts were similarly inversely correlated to Na. However, research by us and others on other freshwater species, including insects, molluscs, and fish, have shown certain inter-species differences regarding these relationships. In this talk, we will report on major geochemical ion toxicity to another crustacean, Hyalella azteca. This species also shows both similarities to and differences from C. dubia. Notable similarities include a high toxicity of K, independent action of Mg and Na salts, and a strong ameliorative effect of Ca on the toxicities of Na and Mg salts. Notable differences included significant variation in the relative toxicities of different salts, and sodium salt toxicity not being correlated with osmolarity but rather suggesting a more specific role of sodium and sulfate. Unlike C. dubia, H. azteca also shows marked differences in the acute:chronic ratios across different salts. This work further emphasizes the need to consider interspecies differences in developing assessment methods for complex ion mixtures. The contents of this abstractneither constitute nor necessarily reflect USEPA policy.

258 Progress in Predicting the Aquatic Toxicity of Mixtures of the Major Ions Using Mechanistically Based Models

C.G. Delos, Great Lakes Environmental Center; R. Bubnyte, HDR inc. / Water Quality Modeling; P.R. Paquin, Hydroqual / Water Quality Modeling; K. Brix, EcoTox / Zoology; D.J. Soucek, Illinois Natural History Survey; K.J. Farley, Manhattan College / Civil and Environmental Engineering; W.J. Adams, Rio Tinto; J. Goodrich-Mahoney, EPRI / Environmental Dept

This exploratory work addresses the aquatic toxicity of mixtures of the seven major ions Ca, Mg, Na, K, Cl, SO_4, and HCO_3. Attempts to develop a water quality criterion for the concentration of any single ion (for example, Cl) and attempts to develop a criterion for the summation of ion concentrations (for example, conductivity or total dissolved solids) are confounded by the influence of the mixture composition on toxicity. Searching for unifying principles for explaining how composition affects toxicity, this work describes further progress in using transepithelial potential (TEP) calculated from Nernst Equation concepts, specifically the Spangler modification of the Goldman, Hodgkin-Katz (GHK) Equation. It also considers whether the Strong Ion Difference approach might have potential for application. Results will be presented for model applications to a few thousand toxicity test treatments from studies of mayfly, daphnids, and fathead minnow. Model strengths and limitations will be described.

259 Predicting the Aquatic Toxicity of Mixtures of the Major Ions: The Need for Speciation

R. Bubnyte, HDR inc. / Water Quality Modeling; W.J. Adams, Rio Tinto; K. Brix, EcoTox / Zoology; C.G. Delos, Great Lakes Environmental Center; K.J. Farley, Manhattan College / Civil and Environmental Engineering; J. Goodrich-Mahoney, EPRI / Environmental Dept; P.R. Paquin, Hydroqual / Water Quality Modeling

The development of water quality criteria for the seven major ions Ca, Mg, Na, K, Cl, SO_4, and HCO_3 has proven to be a challenging endeavor. This is because the toxicity of any individual constituent has been found to be influenced by both the concentrations of the other dissolved solids that are present and by mixture composition as well. One approach that has been used to address multi-ion toxicity (MIT) is to use an integrative measure (e.g., total dissolved solids or conductivity) to quantify the concentration of the overall mixture of major ions present, and to deal with variations in mixture composition on a site-specific basis. Another alternative that has had some success is to use a multi-variate statistical modeling approach. Our efforts have pursued the problem from a different perspective, by computing trans-epithelial potential (TEP) based on the internal and external concentrations of the major ions and model parameters that are evaluated by calibration to toxicity data. The analyses to be presented here will compare results obtained using two alternative approaches that have been used to do this: assuming complete dissociation of the major ions (the simpler approach) versus a more detailed approach that considers chemical speciation. The advantages and disadvantages of these alternative approaches will be discussed. The findings will be illustrated using modeling analyses of MIT toxicity test results for relatively sensitive aquatic invertebrates.

Computational Toxicology: Integrating -Omics and Chemistry to Identify Chemicals of Environmental Concern

260 Integrating chemical monitoring data with high-content and high-throughput effects data to prioritize contaminants and hazards in chemical mixtures

A. Schroeder, Univ of Minnesota-Crookston / Math Science and Technology; D. Martinovic-Weigelt, Univ of St. Thomas; B.R. Blackwell, ORISE / National Health and Environmental Effects Research Laboratory; G.T. Ankley, D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory

Determining ecological risks associated with exposures to complex chemical mixtures in the environment is one of the main challenges of chemical safety assessment and environmental protection. Effects-based monitoring tools that can measure the integrated biological activity of an entire mixture have been proposed as one of the solutions. An important limitation of the effects-based approaches is that they typically do not provide insight into which chemicals are causing the observed biological responses. Current approaches for integrating chemical monitoring with biological effects data will be discussed. More specifically, we will present and critically evaluate two approaches where prior knowledge regarding toxicity of individual contaminants is combined with empirical in situ assessment to predict toxicity of mixtures and prioritize contaminants. The first approach involves development of knowledge assembly models (KAMs; which is specific to the aquatic system of interest) based on chemical monitoring data and publically available chemical-gene interaction data. Follow-up fish transcriptomics studies and reverse causal reasoning approaches are then utilized to prioritize risks and contaminants. The second approach utilizes publically available high-throughput in vitro data to extract benchmark effect concentrations for hundreds of biological targets. From these data, exposure-to-activity ratios are calculated and integrated with empirical in vitro effects assessment to prioritize specific chemicals for further testing and to identify biological effects of interest. The observed or predicted molecular-level effects data generated by these two approaches can be integrated with adverse outcome pathway knowledge to aid extrapolation into regulatory outcomes of concern (e.g., organism- and population-level effects). The contents of this abstract neither constitute nor necessarily represent official USEPA views and policies.

261 A Bayesian network model for predicting aquatic toxicity mode of action using two dimensional theoretical molecular descriptors

J.F. Carriger, T.M. Martin, USEPA; M.G. Barron, USEPA / Gulf Ecology Division

The mode of toxic action (MoA) has been recognized as a key determinant of chemical toxicity but MoA classification systems in aquatic toxicology have been limited. We developed a Bayesian network model to classify MoA using a recently published dataset containing over one thousand chemicals with aquatic toxicity MoA assignments. Two dimensional theoretical chemical descriptors were generated for each chemical using the Toxicity Estimation Software Tool. The model was developed through augmented Markov blanket discovery from the dataset with the MoA broad classifications as a target node. From cross validation, the overall precision for the model was 80.2% with a R^2 of 0.959. The best precision was for the AChEI MoA (93.5%) where 257 chemicals out of 275 were correctly classified. Model precision was poorest for the reactivity MoA (48.5%) where only 48 out of 99 reactive chemicals were correctly classified. Narcosis represented the largest class within the MoA dataset and had a precision and reliability of 80.0%, reflecting the global precision across all of the MoAs. False negatives for narcosis most often fell into electron transport inhibition, neurotoxicity or reactivity MoAs. False negatives for all other MoAs were most often narcosis. A probabilistic sensitivity analysis was undertaken for each MoA to examine the sensitivity to individual and multiple descriptor findings. The results show that the Markov blanket of a structurally complex dataset can simplify analysis and interpretation by identifying a subset of the key chemical descriptors associated with a MoA and provide a network classification model with reasonable prediction accuracy.

262 Computational model for Nrf2-ARE activation in Human HepG2 cells based on whole-molecule chemical properties and mechanistic domains

F. Melnikov, Yale Univ / Forestry and Environmental Studies Center for Green Chemistry and Engineering Molecular Design Research Network; L. Shen, Yale Univ / Center for Green Chemistry and Green Engineering; A. Voutchkova-Kostal, George Washington Univ / Chemistry Dept; J. Kostal, The George Washington Univ; J. Zimmerman, Yale Univ; P. Anastas, Yale Univ / Center for Green Chemistry and Green Engineering

The development of in silico with high sensitivity and specificity is instrumental to the rational design of safer commercial chemicals. Exposure to a variety of commercial chemicals has been associated with reactive oxygen species (ROS) imbalance and oxidative stress (OS), implicated in adverse outcomes such as immune suppression, cancer, neurodegenerative, rheumatoid and cardiovascular diseases. The critical biochemical pathways involved in OS response are largely induced by transcription at antioxidant response element (ARE), which is triggered by covalent modification of the Keap1-Nrf2 complex. Here we present a quantum-mechanical in silico model for ARE induction triggered by adduct formation on the reactive. The model is based on curated in vitro ARE assay data from the EPA's ToxCast/Tox21 initiative, and a data set of > 1000 plasticizers, pesticides, food additives, antimicrobials, and discontinued pharmaceuticals. The likely mechanism for covalent interaction, including acylation, Michael addition, Schiff base formation, and nucleophilic aromatic and aliphatic substitution were identified for each chemical. Classification and Regression Tree (CART) and Support Vector Machine (SVM) models were then developed for each one mechanistic domain using quantum mechanical descriptors and physicochemical properties, calculated taking into account ionization at biological pH. We find that the effectiveness of global parameters at explaining and predicting ARE response depended on structural domain, with several domains showing train and test accuracy > 80% for classification into inactive, weakly active and strongly active chemicals. The work shows the importance of mechanistic considerations in in silico assessments and highlights the opportunities and limitations of global molecular parameters when estimating in vitro biological responses.

263 Integrating multiple levels of information to support Danube risk assessment in SOLUTIONS

P. Antczak, Univ of Liverpool / Inst of Integrative Biology; T.D. Williams, Univ of Birmingham / School of Biosciences; T. Schulze, Helmholtz Centre for Environmental Research – UFZ / EffectDirected Analysis

Environmental monitoring programs, such as the Water Framework Directive in the European Union or the U.S. Clean Water Act (CWA), have accumulated vast amounts of data on contamination and ecology of surface waters within their respective jurisdictions. In parallel, chemical registration processes have resulted in a wealth of chemical property and organism specific single chemical toxicity data. However, it remains a great challenge to link the occurrence of chemical stressors with the observed toxicity in the environment. The SOLUTIONS project was envisaged to address many of these challenges and develop tools and methodologies to support European environmental and water policy decisions [1]. Central to the SOLUTIONS project is the focus on effect based risk assessment using a wide selection of bioassays both in vitro and in-vivo to establish the effects of single chemicals and complex mixtures [2]. A component of this large project is to establish the usability of whole organism transcriptomics data to support bioassay results, hotspot, and emerging pollutant identification. In this presentation we will show the details of the SOLUTIONS project and the application of OMICs to understand the molecular responses of Daphnia magna to chemical stressors in the Danube River Basin. By integrating the various data available in the SOLUTIONS consortium we are able to identify molecular responses directly linking from compound to in vitro bioassay and to broader D. magna molecular responses in an Adverse Outcome Pathway like paradigm. We show that utilizing available toxicological knowledge we can identify some linkages, but that much of the observed response remains unexplained. We show that by approaching this challenge with an unbiased computational methodology we can identify stressors for which little or no toxicological knowledge is available.

264 Computational Predictive Toxicology From Molecular to Geospatial Scales: A Case Study of Inorganic Arsenic

L. Burgoon, US Army Engineer Research and Development Center / Environmental Laboratory

Environmental contamination of drinking water sources with inorganic arsenic may lead to increased health impacts, including cancer, diabetes, and cardiovascular disease. We've used the AOPXplorer as a predictive toxicology tool to enable us to predict potential adverse outcomes, and molecular modes of action for diseases, using transcriptomic and literature information. By coupling these predictions with data from genome-wide association studies (GWAS), single nucleotide polymorphism and population occurrence information, as well as population data from the US Census, we can begin to identify potentially susceptible populations. By combining this information together with water quality information, we are taking a geospatial approach to make predictions about the likelihood of adverse health impacts at the community level. We will also demonstrate how these models help inform decision-making by using a game theory approach to identify the potential impacts of various environmental and policy scenarios.

265 Shifts in microbial community composition and function due to acid mine drainage pollution of Hengshi River (Southeast China)

S. Tang, Univ of Saskatchewan; X. Zhang, Nanjing Univ; M. Wang, Sun yatsen Univ; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; H. Liu, Nanjing Univ; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

Acid mine drainage (AMD) is one of the most environmentally threatening byproducts of the mining industry. Despite its extreme toxicity and acidity, many environments receiving AMD harbor numerous acidophilic and metal-tolerant microorganisms; however, our understanding of the roles of geochemical factors in shaping microbial community structure and the function of microorganisms in natural attenuation of AMD is limited. Located in Southeast China, the Hengshi River is continually contaminated by the Dabaoshan mine, providing an opportunity to explore the effects of AMD-impacted environments on microorganism community composition and function. In this study, twenty-seven sediment samples including five controls were collected from heavily contaminated upstream to lightly polluted downstream sites. Geochemical, and next-generation and high-throughput sequencing analyses were integrated to characterize the spatial distribution and function of microbial communities along the pollution gradient. Geochemical/physicochemical parameters (e.g., pH, conductivity, total organic carbon) of water and sediments significantly differed among samples collected from environments that differed in their extent of contamination with heavy metals (Cd, Cu, Zn, Pb, and As). 16S rRNA sequencing results revealed that bacterial richness and evenness gradually increased along the river with decreasing contaminant levels, which was supported by beta diversity. Most abundant prokaryotic organisms in all samples belonged to the Firmicutes and Proteobacteria phyla. Other phyla, such as Actinobacteria, Acidobacteria, Bacteroidetes, and Nitrospirae that have previously been reported to be characteristic for AMD contaminated environments were also detected in Hengshi samples. At the genus level, Acidocella, Leptospirillum, Thiomonas, and Acidiphilium were significantly dominant in samples from heavily contaminated upstream, compared to the samples from downstream and reference sites. Furthermore, comparative metagenomic analysis indicated that the microbial communities in upstream sites harbored more genes/enzymes for heavy metal detoxification, sulfur oxidationand tolerating low pH, respectively, suggesting diverse metabolic capacities along the pollution gradient of the Hengshi river. Our findings offer an initial insight into the patterns of microbial communities structure and function along the river system contaminated by AMD.

266 Investigating relationships between contaminant and metabolomics profiles in polar bears (Ursus maritimus) from the Hudson Bay Region of Canada

A. Morris, Carleton Univ / Chemistry; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; M. Dyck, Government Of Nunavut / Nunavut Dept of the Environment; B. Chandramouli, J. Cosgrove, SGS AXYS

Polar bears (Ursus maritimus) are the apex predators of the arctic marine food web, and as such are susceptible to the bioaccumulation and biomagnification of a wide range of persistent organic pollutants (POPs) and contaminants of emerging concern from their food sources. Given the wide range of modes of action of the contaminants, determining the effect of mixtures on wildlife has proven to be a challenge for toxicologists. Using metabolomics profiling, changes in hundreds of endogenous metabolites in the tissues of wildlife can be measured in response to many types of stressors, including contaminant exposure. Laboratory experiments have shown significant changes to metabolomic profiles due to contaminant exposure in fish, but few have applied these techniques to field studies. In the present study, tissues were collected from the Southern (SHB) and Western Hudson Bay (WHB) polar bears (n = 41), for the analysis of contaminants (fat and liver) and endogenous metabolites (liver). Approximately 200 contaminants and 218 metabolites (amino acid, biogenic amines, bile acids, fatty acids, and phospholipids) were used to build profiles in the bears, and comparisons were made between males and females from the SHB, and between male bears from the SHB and WHB. Metaboanalyst^{TM} was used to apply partial least squares discriminant analyses (PLS-DA) in conjunction with variable importance projection (VIP) to identify metabolites and contaminants that had a large influence on the separation of the PLS-DA scores. Oxychlordane was the only contaminant identified by the VIP analysis comparing males and females, while the sum of the hexose sugars, 3 polyunsaturated fatty acids (all n-6 fatty acids), 1 monounsaturated fatty acid, 1 saturated fatty acid, and 1 phosphatidylcholine (PC) were also identified. Oxychlordane and all of the metabolites except docosahexaenoic acid were significantly greater in female bears over males. Between the SHB and WHB males, only perfluoro-4-ethylcyclohexane sulfonic acid (PFEtCHxS), and 4 PCs were identified by the VIP analyses. The SHB bears had significantly greater concentrations of PFEtCHxS, and significantly lower concentrations of all of the PCs than the WHB bears. Interesting to note is that male and female metabolomic differences were related to an organochlorine, while the two male populations were differentiated by a perfluorinated surfactant. The potential implications for the health of the polar bears will be discussed.

267 Gradient of evolved resistance to contaminants in Gulf killifish (Fundulus grandis) populations from Galveston Bay, Texas, USA

E. Oziolor, Baylor Univ / Environmental Science; N. Reid, Univ of California Davis; K. Young, Indiana Univ Bloomington; Z. Winfield, Baylor Univ; S.L. Guberman, S. Usenko, Baylor Univ / Dept of Environmental Science; J. Shaw, Indiana Univ / The School of Public and Environmental Affairs and The Center for Genomics and Bioinformatics; A. Whitehead, Univ of California Davis / Environmental Toxicology; C.W. Matson, Baylor Univ / Environmental Science

The Houston Ship Channel (HSC) in Texas includes areas that have historically been found to contain substantial levels of mercury, dioxins, furans, polychlorinated biphenyls (PCBs), and polycyclic aromatic hydrocarbons (PAHs). We collected Fundulus grandis from contaminated areas on the HSC, from sites expected to have intermediate contamination, and from reference sites to establish a total of 12 lab colonies. F1 embryos from HSC populations were up to 1,000x more resistant to PCB126- and 2-5x more resistant to coal tar-induced cardiovascular teratogenesis. We confirmed biparental inheritance and a genetic basis of protection through reciprocal crosses between a reference and contaminated population, and by conducting experiments on F2 embryos for select populations. Similar to patterns observed for Fundulus heteroclitus inhabiting polluted areas along the US Atlantic coast, HSC populations of F. grandis exhibit a reduction of both basal and induced cytochrome P450 1A (CYP1A) activity, suggesting a common mechanism of adaptation. We observe a gradient of adaptation that correlates with the level of pollution at multiple HSC sites. Thus, we sequenced 288 individuals from 7 populations to understand the genetic causes for this resistance. In addition, we look at contaminants in various environmental matrices to be able to understand the chemical drivers of the selective sweeps that we see in F. grandis populations. Such results suggest that the HSC can serve as a “natural laboratory” to study evolutionary processes driven by anthropogenic pollution.

Fate and Effects of Metals: Mechanisms of Toxicity

268 Role of biologically mediated boundary reactions in the bioavailability of cadmium to freshwater phytoplankton

F. Liu, Institut National de la Recherche Scientifique Centre – Eau Terre Environnement; C. Fortin, Univ of Quebec / INRS Eau Terre Environnement; P. Campbell, Université du Québec, INRS / INRS Eau Terre Environnement

Recent studies have suggested that low-molecular-weight (LMW) ligands can enhance metal uptake by marine phytoplankton. We have extended this work to freshwater phytoplankton and have investigated Cd bioavailability in the presence of LMW thiols, with two green algae (Chlamydomonas reinhardtii two strains CPCC11 and CC1690, and Pseudokirchneriella subcapitata) and a cyanobacterium (Anabaena flos-aquae) as our model species. Using nitrilotriacetic acid (NTA) as a metal buffer to hold the free Cd^{2+} concentration constant, we progressively added cysteine to the exposure medium and determined short-term Cd uptake rates; the Cd uptake rates remained constant and were unaffected even when the concentrations of the cysteine-Cd complexes exceeded that of the free Cd^{2+}. Similar results were obtained with green algae grown with different inorganic nitrogen sources (to affect their ability to utilize amino acids) and low zinc concentrations (to affect their ability to take up Cd), and also for other LMW thiols, including penicillamine, mercapto-succinic acid, dithiothreitol and glutathione. These results suggest that the thiol-Cd complexes are not taken up by the algae and that the formation of hypothetical ternary surface complexes with the Cd transporter molecules ‘X’, e.g. cysteine-Cd-X-alga, does not contribute to overall Cd uptake. However, when the experiments were repeated with a fixed free Cd^{2+} concentration, either buffered with NTA or simply complexed with cysteine in the absence of NTA, a significantly higher Cd uptake rate was observed in the presence of cysteine than in the control cultures (where $[Cd^{2+}]$ was buffered by NTA alone). We speculate that the increased Cd bioavailability was due to an enhancement of the free Cd^{2+} concentration in the boundary layer, resulting from chemical oxidation of metal-binding ligands by oxidants released by the algae. Meanwhile, only in the nitrate-acclimated CC1690, a significantly lower Cd uptake rate was observed in the presence of cysteine than in its control (buffered by NTA). This decreased Cd bioavailability may result from a decrease in the free Cd^{2+} concentration in the boundary layer, resulting from de-protonation of metal-binding ligands induced by local pH enhancement as a consequence of algal release of HO^-. The results highlight the importance of biologically-mediated surface processes, in addition to other well-known abiotic processes, in determining metal bioavailability.

269 Toxicity of metal-contaminated sediments from the Upper Columbia River, Washington, to early-life-stage White Sturgeon (Acipenser transmontanus)

H.J. Puglis, R. Calfee, USGS / Columbia Environmental Research Center; E.E. Little, USGS – Biological Resources Division / Columbia Environmental Research Center

The Upper Columbia River (UCR) has been contaminated with metals from effluents resulting from smelter and mining activities. Approximately 10 million metric tons of slag, in addition to liquid effluent, were released from a lead-zinc smelter in Trail, British Columbia from 1947 until 1995, resulting in some UCR sediment metal concentrations being elevated above biological criteria concentrations. In the transboundary reach of the UCR, White Sturgeon population declines have been associated with little to no natural recruitment since the late 1960s. Copper, which is present in significant concentrations in slag, can be mobilized from slag containing sediments and is highly toxic to early life-stage (ELS,1.0 for three of the six sediment treatments tested. Chronic toxic units for copper estimated with a biotic ligand model were also >1.0 in three of the six sediment treatments with both measures of toxic units >1.0 in two of those three treatments. Toxic units >1.0 suggest toxicity may occur. Sturgeon exposed to sediment collected near the city of Northport, WA, which had toxic units >1.0 for both measures, had significant increases in mortality and significant decreases in swimming activity, compared to sturgeon in the control treatment, which were exposed to clean quartz sand. No significant effects were observed in the other sediment treatments. This study sheds light on the relationships between exposure to metals associated with slag and adverse effects on the White Sturgeon population.

270 Subcellular metal partitioning in white suckers exposed to metal-mining effluents: a relevant tool to improve risk assessment for aquatic organisms

N. Urien, INRS-ETE / Centre Eau Terre Environnement; P. Campbell, Université du Québec, INRS / INRS Eau Terre Environnement; L.D. Ramilo, Stantec / Environmental Services; H. Sonnenberg, Stantec Consulting Ltd / Environmental Services; S. Cooper, A. Caron, P. Couture, Université du Québec, INRS / Centre Eau Terre Environnement

Discharges from metal mining operations may lead to metal accumulation and toxicity in exposed aquatic species. Indeed, once metals enter cells, they can bind to sensitive components and cause deleterious effects. Nevertheless, metals can also be detoxified by binding to molecules designed to sequester them and limiting their toxic effects. The objective of this study was to assess the subcellular distribution of metals in white suckers (Catostomus commersoni) exposed to metal-mining effluents, and to relate metal accumulation in specific fractions to toxicity. Mature male and female fish were collected downstream from a metal-mining effluent and in a reference area, and metal partitioning (As, Cd, Cu, Ni, Pb, Se and Zn) among potentially metal-sensitive fractions and detoxified metal fractions in livers and gonads was determined after differential centrifugation and heat-denaturation steps. The liver somatic index (LSI) was significantly lower in exposed fish than in reference fish for males and females, and the gonadosomatic index (GSI) was significantly lower in exposed females. Total hepatic metal concentrations were significantly higher in exposed fish than in reference fish, with Cd, Cu and Se being accumulated the most; no differences between sexes were observed.

However, marked differences in Cu, Se and Zn concentrations between exposed male and female gonads were observed, all being lower in males. Total metal concentrations in female gonads were significantly higher in exposed fish compared to reference fish for Se, Cd and Cu. Subcellular metal fractionation showed that in livers and gonads, 50% of Cd and Cu burdens were found in the heat-stable cytosolic proteins fraction, which includes metallothioneins. In contrast, the largest contributor to the total Se liver and gonad burdens was the potentially metal-sensitive heat-denaturable proteins fraction (livers, 30%; gonads, 50%), and also the mitochondrial fraction in livers (≈ 15%). These results suggest that Cu and Cd were well detoxified and regulated by white suckers, whereas the presence of relatively high Se concentrations in potentially metal-sensitive fractions suggests that exposed fish were subject to stress, likely partly linked to the observed decrease of LSI and GSI. The advantages of subcellular metal partitioning, as a tool to better identify metals of potential concern for risk assessment, will be discussed.

271 Copper toxicity to Florida apple snail (Pomacea paludosa) and development of a Biotic Ligand Model with P. paludosa

T. Hoang, Loyola Univ Chicago / Inst of Environment and Sustainability; G.M. Rand, Florida International Univ / Southeast Environmental Research Center SERC; R.C. Santore, A.C. Ryan, Windward Environmental LLC

The long history use of copper (Cu) in South Florida has resulted in Cu contamination in its ecosystem. Pomacea paludosa is a key species in the South Florida ecosystem and plays an important role as a main food source for many higher trophic organisms, including the snail kite. Our previous studies found that P. paludosa is sensitive to Cu and the toxicity of Cu to P. paludosa is influenced by water quality characteristics. These results revealed that P. paludosa is a good species for the Biotic Ligand Model (BLM). The objective of the present study is to calibrate and validate the US Cu-BLM to P. paludosa in support of development of water quality guidelines for Cu and the South Florida ecosystem, including the Everglades. Copper toxicity tests were conducted with P. paludosa in formulated water that had a wide range of water quality parameters and organism age. The median lethal accumulation concentration (LA50) and the Cu-biotic ligand binding constant for P. paludosa were also determined. Results of the present study were used for calibrating the BLM. In general, the BLM works well with P. paludosa. There was a strong correlation between predicted and measured toxicity. An important note is that organism age plays an important role in sensitivity to Cu. The snail BLM developed in the present study can be used for development of species sensitivity distribution in support of setting site specific water quality criteria for Cu in the South Florida ecosystem.

272 Mechanisms of Selenium-Induced Spinal Deformities in Fish

A. Kupsco, Univ of California – Riverside; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences

Selenium toxicity to oviparous vertebrates is often attributed to selenomethionine (SeMet), which can biomagnify and be passed to offspring through maternal transfer. Although oxidative stress is implicated in SeMet toxicity, knowledge gaps remain in mechanisms of SeMet-induced spinal deformities. In the present study, we use the Japanese medaka (Oryzias latipes) model to investigate the role of oxidative stress, cell death, and the unfolded protein response (UPR) on skeletal gene expression and SeMet toxicity, linking localization of cellular effects to observed abnormalities. Medaka embryos were treated with 2.5µM or 5µM SeMet for 24hr at stage 25 (48 hours post fertilization). Post treatment, embryos were separated into normal, deformed (mild, moderate or severe), or dead categories. Dichlorofluorescein staining demonstrated oxidative stress in tails of embryos with observable spinal malformations. Furthermore, acridine orange staining for apoptosis identified significantly more dead cells in tails of treated embryos. Gene expression studies for the UPR suggest a role for CHOP (c/ebp homologous protein) induced apoptosis in dead and deformed embryos after 5µM SeMet, accompanied by a decrease in PDIA4 (protein disulfide isomerase A4) and no change in Dnajb9 (ER DNA J Domain-Containing Protein 4). This expression was distinct from the UPR induced by well-studied ER stress inducer, tunicamycin, which robustly activated CHOP, PDIA4 and Dnajb9. Finally, SeMet treatment significantly decreased transcripts of skeletal development, Collagen 2a1 mRNA, while increasing Runx2 in dead and deformed embryos, without altering Twist. Results suggest that oxidative stress, the UPR and cell death play key roles in SeMet induced deformities and altered skeletal development factors.

273 Identification of biologic binding of uranium in Danio rerio gonads. Impact on their functionality

Y. Eb-Levadoux, IRSN; S. Mounicou, CNRSUPPA, Laboratoire de Chimie Analytique Bio-Inorganique et Environnement UMR 5254; O. Simon, IRSN; C. Arnaudguilhem, R. Lobinski, CNRSUPPA, Laboratoire de Chimie Analytique Bio-Inorganique et Environnement UMR 5254; S. Frelon, IRSN

Uranium (U) is a radioelement naturally present at trace level ($\mu g.L^{-1}$) in the environment. This level can increase due to geological influences or human activities. Previous waterborne exposures of zebrafish have shown reprotoxic effects after bioaccumulation in the gonads from 20 $\mu gU.L^{-1}$. The objective of this work is to understand this reprotoxicity by studying: i) the U-protein complexes present in gonad (metallomic approach) and ii) the differences in proteome expression between exposed and control groups (proteomic approach). Six groups of adult zebrafishes were studied: waterborne exposed to 0 and 20$\mu g.L^{-1}$ of U for 5 and 20 days, with or without reproduction after 20 days. Bioaccumulation in target organs was performed after exposure. Metallomic approach, i.e. non-denaturing intact uranium-protein complex study, has been developed for our samples. A two-dimensional (pIxMW) fractionation analysis of metals (U, Fe, Cu, Zn and P) was performed using hyphenated separations, i.e. off-gel electrophoresis (OGE) and size exclusion chromatography (SEC) followed by multi-elemental detection (ICP SF MS). Subsequently, identification of potential U protein target was carried out in U-rich OGE fractions by µRPC- ESI FT MS/MS after trypsic digestion. In parallel, phosphorylated protein distribution, as well as vitellogenin amount, were assessed using specific staining or immunodetection after western blot, respectively. Finally, comparison of proteome expression between zebrafish groups was carried out by differential in gel electrophoresis (DiGE). Significant bioaccumulation of U in gonads has been shown with a depuration effect of reproduction event. At the molecular level, whatever the exposure conditions, U mainly coeluted (87±8%) with a 40 kDa-protein of 7-8 pI, also rich in phosphorus. That suggests a strong affinity between U and phosphorylated proteins. In this fraction, potential targets identified included vitellogenin fragments, elongation factors, HSP and SOD. DiGE analysis showed differences between control and U-exposed groups in expression of low molecular weight-proteins that will be further characterized by MS. Cross analysis between both approaches has now to be done to assess if targets are common. Highlighted proteins may be candidates for uranium exposure biomarker and the identification of U ecotoxicity profile. Acknowledgements: Authors acknowledge the NEEDS-Environment program for the funding of TARGETS project supporting this work.

274 Energy cost of metal detoxification strategies in phytoplankton

M. Lavoie, Universite Laval / Biology; J.A. Raven, Univ of Dundee / Division of Plant Science; O. Jones, RMIT Univ; H. Qian, Zhejiang Univ of Technology / College of Environmental Science; M. Levasseur, Laval Univ / Biology

Microalgae use various cellular mechanisms to protect themselves against metal toxicity. However, the efficiency of those mechanisms can be limited since metal detoxification often remains incomplete, even at low, non-growth inhibitory metal concentrations. If the energy cost of metal detoxification is high, there could be a trade-off between the cost of detoxifying these metals in the cell and the energy cost of allowing some of these metals to spillover onto metal-sensitive sites (Strategy 1). Alternatively, if the energy cost allocated to metal detoxification is low, phytoplankton could replace or repair proteins that are bound to inappropriate metals with a modest use of intracellular metal detoxification mechanisms (Strategy 2). To gain further insights on the strategy used for metal detoxification in phytoplankton, we performed an extensive bioenergetics analysis of intracellular metal detoxification mechanisms as well as of the energy cost allocated to the detoxification of metal-induced reactive oxygen species. We considered the synthesis of metal-binding peptides, polyphosphate, metal efflux, metal reduction, enzymatic and non-enzymatic antioxidants in wild-type marine and freshwater eukaryotic phytoplankton based on the biochemical mechanisms of each detoxification strategies and on experimental measurements of detoxifying biomolecules in the literature. The results show that at the onset of metal toxicity to growth, all the intracellular detoxification strategies considered required as little as < 2 % of the total cellular energy available for growth. We conclude that phytoplankton generally use Strategy 2 for intracellular metal detoxification.

275 Stream benthic and algal community responses to metals: an evaluation of endpoint sensitivity using stream mesocosms

C. Kotalik, W.H. Clements, Colorado State Univ / Dept of Fish Wildlife and Conservation Biology; P. Cadmus, Colorado Parks and Wildlife

Larval benthic macroinvertebrate community responses to metals are often used to assess and predict ecological impairment, however, aquatic insect adults and algal community responses have received less attention. We evaluated both structural and functional endpoints by exposing benthic communities to mixtures of Cu and Zn for 14 d using stream mesocosms. We compared two streams in Colorado with past and present EPA superfund designation, the Arkansas River (AR) and the North Fork Clear Creek (NFCC), respectively. Measured responses included the timing and abundance of emerging adults, algal colonization, community metabolism, and benthic community composition. EC50 values, defined as the metal concentration that reduced the response variable by 50%, were estimated for each endpoint. Results show differences in larval and adult responses within the same taxonomic groups, particularly among midges (Chironomidae) and mayflies (Ephemeroptera); however, algal colonization and community metabolism displayed the greatest overall sensitivity to exposure. The relative sensitivity among the endpoints was also different between the two communities, with the AR exhibiting greater tolerance to metals than the NFCC. This result is likely because of differences in their respective exposure histories and community composition. This research highlights the need to comprehensively assess exposure effects beyond larval macroinvertebrate life stages using structural and functional endpoints that differ in sensitivity, while acknowledging context-dependent responses resulting from different stream assemblages.

Use of Freshwater Mollusk Toxicity Data for Improved Conservation of Water and Sediment Quality

276 The influence of glochidial source; including gravid mussel collection site and year on the sensitivity of glochidia to a reference toxicant (NaCl)

P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Unlike, many laboratory-cultured test organisms employed in standardized toxicity tests, the larvae of freshwater mussels (glochidia) are typically obtained from field-collected gravid mussels. While employing naturally-sourced organisms can enhance ecological relevance, wild organisms can potentially introduce additional variability in contaminant response. Because the early life stages of freshwater mussels are among the most contaminant-sensitive aquatic organisms and therefore their responses to waterborne contaminants can influence the derivation of water quality regulations, it is important to understand whether organism source affects toxicity endpoints. This study examined the influence of gravid mussel source, both temporal and spatial differences, on the response of glochidia to a reference toxicant. Acute toxicity tests with sodium chloride and three Lampsilis species were used to determine year-to-year variability in EC50s when mussels were collected from the same sites in Ontario (Canada) for up to eight years. In addition, the influence of gravid mussel collection site on glochidial toxic response was investigating by comparing salt sensitivities of one mussel species (Lampsilis fasciola) collected from different watersheds. Significant differences in a species' EC50 were observed between glochidia obtained from gravid mussels collected from different watersheds. There was less variability in EC50s when gravid mussels were collected from the same location over multiple years. These results illustrate that gravid mussel source can influence the response of glochidia to waterborne contaminants, and that spatial differences (collection site) in organism source had a stronger influence on the toxic response than temporal differences (collection year).

277 Effects of nitrate and an estrogen singly and in combination on freshwater mussel metamorphosis

A. Moore, R.B. Bringolf, Univ of Georgia / Interdisciplinary Toxicology Program

Water quality and contaminants have been identified as critical factors for freshwater mussel populations, many of which are highly imperiled throughout North America and the world. Nutrient pollution, specifically nitrate, is one of the most prevalent causes of water quality degradation globally, with increasing anthropogenic input from suburban and agricultural runoff, municipal wastewater, and industrial waste. Additionally there is mounting evidence that nitrate has endocrine-disrupting effects on aquatic organisms. Nitrate often co-occurs with known endocrine disruptors such as hormones, pointing to the need to understand how these compounds may be interacting to affect wildlife. The potential effects of nitrate and hormones to freshwater mussels are largely unknown, particularly during the parasitic stage of the freshwater mussel lifecycle during which metamorphosis from larvae to juvenile occurs. Therefore, we investigated the effects of nitrate singly and in combination with a model estrogen on freshwater mussel larvae (glochidia) viability, attachment success on host fish, metamorphosis success, and timing of metamorphosis. In the first experiment we exposed Lampsilis siliquoidea glochidia for 24 hours to environmentally relevant nitrate concentrations (0, 50, or 250 mg/L NO_3) alone and in mixture with an environmentally relevant concentration of ethynylestradiol (EE2; 5 ng/L) before inoculation on their primary host, largemouth bass (Micropterus salmoides). In a separate experiment, we exposed largemouth bass to the same series of nitrate and EE2 treatments for 14 days prior to inoculating with unexposed L. siliquoidea glochidia to determine if effects of these compounds on metamorphosis are mediated through the host fish. Nitrate and EE2 exposure altered glochidia attachment, metamorphosis success, timing of metamorphosis and number of juveniles produced and the relative influence of glochidia exposure compared to fish exposure will be discussed, along with a comparison to acute toxicity values for these compounds. Results of these studies are important for improving understanding of the effects of these common contaminants on freshwater mussels at the critical stage of metamorphosis and to better understand the role of water quality in assessing habitat suitability for mussel conservation efforts.

278 Does freshwater mussel propagation method influence juvenile chemical sensitivity?

A. Popp, NC State Univ / Applied Ecology; W.G. Cope, North Carolina State Univ / Dept of Environmental and Molecular Toxicology; M. McGregor, Kentucky Dept of Fish and Wildlife Resources / Center for Mollusk Conservation; L. Koch, US Fish and Wildlife Service; T.J. Kwak, USGS / North Carolina Cooperative Fish and Wildlife Research Unit; T. Augspurger, US Fish and Wildlife Service / Ecological Services; J.F. Levine, North Carolina State Univ / Population Health and Pathobiology

Freshwater mussels of the family Unionidae are ecologically important and globally imperiled, and research is urgently needed to guide their protection and conservation. Identifying and mitigating chemical stressors is an important part of the process, as is assessing mussel-specific sensitivity to pollutants to establish water quality criteria. The newly transformed juvenile life stage has been shown to be sensitive to certain toxicants and is often used in toxicity testing. Thus, there is a need to transform mussel larvae (glochidia) into juveniles within a laboratory setting. Over the past several decades, conservation aquaculture has significantly advanced propagation techniques and long-term growth and maintenance of propagated mussels. Improving standard host-fish (in vivo) infection techniques has contributed to this success, but recently, in vitro culture methods have made it more efficient and cost-effective to raise juvenile mussels in the laboratory. However, ASTM International cautions against using in vitro propagated juveniles in toxicity tests unless their relative chemical sensitivity to in vivo juveniles is described. The objective of this study was to evaluate the relative sensitivity of juvenile mussels produced from both propagation methods to selected chemical toxicants. We conducted 96-hour acute toxicity tests according to the ASTM International guidelines with three species (Lampsilis cardium, L. abrupta, and Utterbackia imbecillis) and six chemicals: chloride, nickel, ammonia, copper, and aquatic herbicides Clearigate and Nautique. We calculated the median lethal concentration (LC50) for each species-chemical combination and compared the LC50s of the in vitro and in vivo juveniles. Statistically significant differences in LC50 between in vitro and in vivo propagated juveniles were observed in 8 of the 17 trials. Six of the eight statistically different tests for a given chemical were within the intra-laboratory variation that has been demonstrated in a recently published study. Moreover, all of these statistical differences were within the variation for inter-laboratory comparisons for a given chemical in the same study, and therefore, indicate that in vitro propagated juvenile mussels may be appropriate for use in ASTM-based toxicity testing. The differences that we observed were likely related to age, developmental stage, or relative condition of the juveniles, as they appeared to become less divergent over time.

279 Sensitivity of the early-life stages of freshwater mollusks to neonicotinoid and butenolide insecticides

R.S. Prosser, Environment and Climate Change Canada / Canada Centre for Inland Waters; E. Holman, Environment and Climate Change Canada / Aquatic Contaminants Research Division; R. Osborne, Univ of Waterloo / Dept of Biology; S.A. Robinson, Environment and Climate Change Canada / Wildlife and Landscape Science Directorate; A.J. Bartlett, Environment and Climate Change Canada / Aquatic Contaminants Research Division; F. Maisonneuve, Environment and Climate Change Canada; S. de Solla, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Neonicotinoid insecticides can be transported from agricultural fields, where they are used as foliar sprays or seed treatments, to surface waters by surface or sub-surface runoff. Few studies have investigated the toxicity of neonicotinoid or the related butenolide insecticides to freshwater mollusk species. The current study examined the effect of neonicotinoid exposure to the early-life stages of the ramshorn snail, Planorbella pilsbryi, and the wavy-rayed lampmussel, Lampsilis fasciola. Juvenile P. pilsbryi were exposed to imidacloprid, clothianidin, or thiamethoxam for 7 or 28 d and mortality, growth, and biomass production were measured. The viability of larval (glochidia) L. fasciola was monitored during a 48 h exposure to six neonicotinoids (imidacloprid, thiamethoxam, clothianidin, acetamiprid, thiacloprid, dinotefuran), or a butenolide (flupyradifurone). The 7-d LC50s of P. pilsbryi for imidacloprid, clothianidin, and thiamethoxam were $\geq$ 4000 µg/L and the 28-d LC50s were $\geq$ 182 µg/L. Growth and biomass production were considerably more sensitive endpoints than mortality with EC50s ranging from 33.2 to 122.0 µg/L. The LC50s for the viability of glochidia were $\geq$ 456 µg/L for all seven insecticides tested. Our data indicate that neonicotinoid and butenolide insecticides pose less of a hazard with respect to mortality of the two species of mollusk compared to the potential hazard to aquatic insects.

280 Toxicity of an Environmentally Relevant Suite of Major Ions and a Trace Element on Juvenile Rainbow (V. iris) and Oyster (E. capsaeformis) Mussels

A.T. Phipps, Virginia Polytechnic & State Uni / Fish and Wildlife Conservation; S. Ciparis, Virginia Tech / Fish and Wildlife Conservation; J.W. Jones, US Fish and Wildlife Service; C.E. Zipper, Virginia Tech / Dept of Crop and Soil Environmental Sciences

The Powell River in Virginia and Tennessee, USA supports diverse freshwater mussel assemblages. Coal mining occurs in the watershed. Throughout the river's extent major ion and trace element concentrations are elevated and mussels have been extirpated or are declining. We conducted a laboratory study to assess the effects of major ions and the trace element nickel (Ni) on growth and survival of juvenile mussels, including one common (Villosa iris) and one endangered (Epioblasma capsaeformis) species. Mussels were exposed to environmentally relevant concentrations of major ions and Ni, to assess the combined toxicity and the potential interaction of Ni with HCO_3(-). Mussels were exposed to diluted pond water alone (control), with Ni only (Ni-control), and with environmentally relevant major ion mixtures with and without Ni for 70 days. The first treatment mimicked low-flow concentrations of Ca(2+), Mg(2+), K(+), HCO(-) and SO_4(2-) in the Powell River at a total ion concentration of 942 mg/L. The second treatment combined the first treatment mixture with an environmentally relevant concentration of Ni (14 µg/L). Mussel survival differed significantly between species, as mean survival was 84.2% for E. capsaeformis and 92.7% for V. iris. There were no significant differences in overall survival between treatments and controls for either species. Total growth showed little variation and was not significantly different between treatments and controls. Results suggest that major ion chronic toxicity alone or in combination with Ni is not the primary source of toxicity for juvenile mussels in the Powell River. The results also suggest that HCO_3(-) does not increase the toxicity of Ni in this system.

281 Chronic sensitivity of freshwater mussels to chemicals with different toxic modes of action

N. Wang, J.L. Kunz, USGS / Columbia Environmental Reserach Center; C.D. Ivey, USGS – CERC / Aquatic Toxicology; D. Cleveland, USGS / Columbia Environmental Research Center; C. Bauer, USEPA / Region V; C. Bauer, USEPA; C. Barnhart, Missouri State Univ / Biology

Native freshwater mussels are among the most imperiled groups of animals, experiencing significant global declines. However, mussels are generally under-represented in toxicity databases. Studies were needed to compile a more comprehensive toxicity database that includes a diversity of mussel species and chemicals to compare the sensitivity of mussels to other freshwater species, and to evaluate the degree to which existing or proposed environmental guidance values and pollutant discharge permit limits are protective of mussels. Over the past 15 years, we have developed, validated, and applied methods to estimate the acute and chronic toxicity of contaminants to freshwater mussels, evaluated the sensitivity of mussels relative to commonly tested fish (e.g., Pimephales promelas and Oncorhynchus mykiss) and invertebrates (Ceriodaphia dubia and Hyalella azteca), and determined the protectiveness of US Environmental Protection Agency (USEPA) 304(a) ambient water quality criteria (WQC) and state water quality standards (WQS) for native mussels. Here we present the results of chronic (28- or 84-day) toxicity tests conducted with juvenile mussels (Lampsilis siliquoidea, L. fasciola, L. abrupta, Villosa iris, and Epioblasma capsaeformis) in water exposures to up to 14 chemicals (chronic nitrate test is ongoing). The chemicals were chosen based on the interest of USEPA or states in developing or updating WQC or WQS and based on different chemical classes and toxic modes of action. Chronic toxicity data from mussels were compared to those from other freshwater species in compiled databases. Mussel species mean chronic values were in the low percentiles (i.e., more sensitive) of species sensitivity distributions (SSDs) for ammonia, chloride, potassium, sulfate, aluminum, chromium (VI), copper, lead, nickel, and zinc, but in the middle and high percentiles of SSDs for cadmium and two organic chemicals (4-nonylphenol and azoxystrobin). Chronic values of some chemicals, including ammonia, chromium (VI), copper, nickel, zinc, chloride, and sulfate, were about equal to or below the chronic WQC or WQS, indicating the WQC or WQS might not protect the mussels tested.

282 Comparing a novel Artificial Mussel and Live freshwater Mussels to Biomonitor Trace Metals

D. Nugegoda, RMIT Univ / School of Applied Sciences; R. Stark, G. Kibria, School of Science RMIT Univ

Mussels are routinely used in biomonitoring trace pollutants in aquatic systems because of their sessile filter feeding lifestyle. In Australian freshwaters only a few species of mussels exist and their population numbers are low. Therefore using live mussels for biomonitoring trace metals in freshwaters is problematic. This study investigated whether a novel artificial mussel (AM) can be used as a suitable replacement for live mussels to monitor trace metals in freshwaters. Both field and laboratory experiments were used to evaluate the efficacy of the AM in comparison with live mussels (LM). Three test sites were chosen in the Goulburn-Murray Water (G-MW) systems Victoria, Australia, comprising river, channel and drain, in conjunction with controlled laboratory experiments at RMIT University. The native freshwater mussel, Velesunio ambiguus was used as the comparative live biomonitor. Both AM and LM were deployed in field trials for three months at the selected locations in the G-MW system. In the laboratory experiments, AM and LM were exposed to varying concentrations (as mixtures) of Cu, Pb and Zn (Cu 20-50 µg/L, Pb 50-200 µg/L, and Zn 100-500 µg/L) over a 28 day period. The live mussels showed preferential uptake of the essential metals Zn and Cu, whereas all trace metals were accumulated without preference by the AM. AM were found to be an effective replacement for native mussels in monitoring the bioavailability of non-essential trace metals in freshwater, however the AM did not reflect the accumulation and hence possibly the bioavailability of essential trace metals by V. ambiguus . Results are reviewed in terms of selective uptake and depuration of essential trace metals by biota when compared with passive samplers including the AM.

283 Imposex of freshwater snail in Eutrophication Lake

L. An, Chinese Research Academy of Environmental Sciences / River and Estuary and Coastal

The earlier studies showed that more than 200 marine gastropods were induced to the occurrence of imposex because they were exposed to environmental concentrations of organic toxins such as tributyltin [1], which was primarily through its interaction with RXR pathway [2]. However, rare attention was focused on other agents or freshwater gastropods. In our present study, the imposex of Parafossarulus striatulus, which is a native freshwater snail in China and distribution widely in lakes and ponds, was found after migration into a eutrophication environment for 3 months. In order to find the potential mechanism of the occurrence of imposex, the snails were exposed to TBT, 9cis- retinoic acid (9cis-RA) and M. aeruginosa under control conditions. After 2 months, as expected, the imposex characteristic was found in females, not only in TBT- (100 ng Sn/L) and 9-cis RA (5 mg/L) groups, but also in M. aeruginosa (>10^8 cell/L)exposure group, which was the dominant species in Taihu. Then, the transcriptome and proteome were performed simultaneously to find the potential inner molecular response mechanism although the shortage of bio-information of gastropod. Interestingly, some key molecular signals were found which could be used to speculate the occurrence of imposex.

Birds as Indicators of Environmental Change: Molecular to Population Effects of Contaminant Exposure and Other Stressors

284 Differential Gene Expression Analysis of Endocrine Effects of In Ovo and Dietary 17β-Trenbolone on Japanese Quail Using RNA-Seq

K. Mittal, McGill Univ / Dept of Natural Resource Sciences; R.S. Cornman, USGS / Fort Collins Science Center; P. Henry, Chesapeake Potomac Regional Chapter; D.T. Sprague, USGS Patuxent Wildlife Research Center; N. Basu, McGill Univ / Dept of Environmental Health Sciences; N.K. Karouna-Renier, USGS Patuxent Wildlife Research Center / Beltsville Lab

Endocrine active substances (EASs) such as 17β-trenbolone (17βT – a synthetic anabolic steroid), have been shown to cause reproductive dysfunction in various aquatic and avian species. Previous studies of Japanese quail (JQ) exposed to 17βT, conducted in our lab using qPCR, found significant changes in the expression of a select group of genes along the hypothalamic-pituitary-gonadal-liver (HPGL) axis. To better understand the broader effects of androgens on birds, we used RNA-Seq to investigate changes in hepatic gene expression in JQ embryos and adults exposed to 17βT. Finding genes that are differentially expressed across treatments is an integral part of characterizing the mechanisms of action of EASs. RNA-Seq is a powerful, high-throughput tool that provides a global interrogation of differential expression of transcripts and their isoforms. Hence, the objective of this study was to identify pathways perturbed in embryonic and adult JQ exposed to 17βT. JQ embryos were exposed in ovo and the JQ adults were exposed in ovo and via dietary uptake post hatch to 17βT (1 and 10 ppm). In total, 1194 genes and 2089 genes were found to be down and up regulated, respectively, in male embryos; 304 and 698 genes were found to be down and up regulated, respectively, in female embryos; 20 and 41 genes were found to be down and up regulated, respectively in adult males; 23 and 40 genes were found to be down and up regulated, respectively in adult females. In female embryos, the peroxisome proliferator-activated receptor (PPAR) signaling pathway was significantly affected by exposure to 17βT. This suggests a disruption of metabolic functions, affecting genes related to cholesterol synthesis. The Gene Ontology (GO) enrichment analysis identified genes grouped under cellular components and biological processes as being significantly over expressed in female and male embryos. However, none of the genes identified in this enrichment analyses were directly related to the steroid pathways. Furthermore, in both sexes, the effects did not translate to the adults, indicating that an inherent regulatory mechanism might be compensating for the exogenous stress caused by trenbolone.

285 A slice of knowledge: Toxicological screening of priority compounds using an avian ex vivo slice culture approach

D.E. Crump, S.P. Jones, Environment and Climate Change Canada

In vitro screening assays have helped transform toxicity testing of priority environmental chemicals and mixtures. Such assays typically utilize primary cell cultures, immortalized cell lines or cell-free methods. The reliance of these assays upon single cell types, genetically similar strains of cells or a lack of cells altogether introduces challenges in terms of extrapolating results to the whole animal. In this study, liver slices were obtained from late-stage chicken and double-crested cormorant embryos (n=6/species) and exposed to graded concentrations of polychlorinated biphenyl (PCB) 126, the organic flame retardant tris methylphenyl phosphate (TMPP), and a complex environmental extract in 24-well culture plates. The technique combines the throughput of a plate-based toxicity assay with the ability to assess inter-individual variability in an intact liver sample. Species-specific ToxChip polymerase chain reaction (PCR) arrays were used to determine hepatic transcriptomic profiles after 24 hours of exposure. Gene expression responses were compared to those in embryonic hepatocytes of the two species exposed to the same chemicals. Certain pathways (e.g. phase I/II metabolism) responded concordantly between hepatocytes and liver slices. Ultimately, this method improves the biological relevance of our toxicogenomics screening program, thereby permitting the prioritization of resources towards compounds presenting the greatest potential risk to wild avian species. However, it will be necessary to compare these findings to whole animal exposure studies to determine the full utility of this ex vivo screening assay.

286 Novel Brominated Polyphenyl Ether Contaminants Competitively Interact with Thyroid Hormones for Recombinant Avian and Mammalian Transthyretin In Vitro

K.L. Hill, Intrinsik / Dept of Biology; W.G. Willmore, Carleton Univ / Dept of Biology; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division

Tetradecabromo-1,4-diphenoxybenzene (TeDB-DiPhOBz) is a highly brominated additive flame retardant (FR) and an alternative FR for 2,2',3,3',4,4',5,5',6,6'-decabromodiphenyl ether (BDE-209). There are several known commercial formulations and products containing TeDB-DiPhOBz, however little information is available on the magnitude and global range of its use. With 14 bromine atoms TeDB-DiPhOBz has low bioavailability, however it can undergo rapid photolytic debromination to e.g. tetrabromo- to heptabromo-DiPhOBz. These photodegradation products have increased bioavailability, and toxicological concern is therefore warranted. Interestingly, methoxylated tetra- to hexa-brominated DiPhOBz have recently been identified for the first time in eggs of herring gull (Larus argentatus), a bioindicator species of the Laurentian Great Lakes. These novel contaminants are thus suspected degradation products of TeDB-DiPhOBz, and metabolism studies using gull microsomes confirm that several methoxy- and hydroxy- polybrominated DiPhOBz compounds are formed in vitro. Virtually no toxicological data exist for this BFR or its potential degradation products, however in vitro chicken hepatocyte and avian PCR assays using photodegradation products of TeDB-DiPhOBz report some alterations in mRNA expression (e.g. CYP1A4 involved in the metabolic pathway). The present study investigates the potential thyroidogenicity of tetrabromo-DiPhOBz along with methoxy- and hydroxy- conjugates, using an in vitro competitive protein binding assay with both recombinant avian and mammalian thyroid hormone transport protein transthyretin. Perturbation of thyroid hormone transport is considered to be one mechanism of action that may affect thyroid function, which is a major toxicological concern with PBDEs and especially hydroxy-BDE metabolite compounds.

287 Responses in thyroid parameters of hatchling American kestrels following embryonic exposure to priority flame retardants

K.J. Fernie, Environment & Climate Change Canada / Ecotoxicology and Wildlife Health; P.F. Henry, USGS / Patuxent Wildlife Research Center; V. Palace, IISD-Experimental Lakes Area; L.E. Peters, Stantec Consulting; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; D. Sprague, USGS Patuxent Wildlife Research Center / Beltsville Lab; T. Bean, Univ of Maryland, College Park / Environmental Science and Technology; B.A. Rattner, N.K. Karouna-Renier, USGS Patuxent Wildlife Research Center / Beltsville Lab

The potential toxicity of priority chemicals is of considerable interest to the Chemicals Management Plan of the Canadian federal government, and the US Environmental Protection Agency. Recent priority chemicals have included 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE; CAS 37853-59-1), and two components of the technical mixture, FireMaster 550®, specifically 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (EHTBB also abbreviated ast TBB; CAS 183658-27-7), and bis(2-ethylhexyl)-2,3,4,5-tetrabromophthalate (TBPH; CAS 26040-51-8). While these flame retardants occur in the environment, including in biota such as birds, their potential effects on birds is largely unknown. Following approved procedures, fertile eggs of captive American kestrels (Falco sparverius) were injected with organic safflower oil (controls) or one of three doses of BTBPE, TBB or TBPH in safflower oil into the aircell on Embryonic Day 5 at concentrations within levels reported in wild bird eggs (10, 50 or 100 ng/g ww). The safflower oil solutions of these 3 individual chemicals (10 and 50 ng/g) were prepared by serial dilutions of the stock 100 ng/g dosing solution, and in sufficient volume for all egg injections. Eggs were artificially incubated until hatching. From each hatchling, blood was collected and organ somatic indices (SI) calculated. Total thyroxine (TT_4) and total triiodothyronine (TT_3) concentrations were analyzed in duplicate in plasma and right thyroid glands. The left thyroid glands were assessed for histological changes, and hepatic tissue analyzed for the outer ring deiodination activity transforming T_4 to T_3 (T_4-ORD). Results suggest that histological changes and activation of the thyroid gland occurred in hatchlings of both sexes, but that responses to the different exposure concentrations and chemicals were not consistent between the sexes. Potential changes in these parameters, as well as hatching success and deformities, in relation to the uptake of these chemicals over the course of embryonic development, will be discussed.

288 Relative potency of polycyclic aromatic hydrocarbons (PAHs) in birds; comparisons among congeners and species

C. Franci, A. Aleksieva, McGill Univ / Natural Resource Sciences; A. Malinova, T. Johnston, McGill Univ; J. Brandenburg, E. Boulanger, J. Head, McGill Univ / Natural Resource Sciences

Polycyclic aromatic hydrocarbons (PAHs) are potent contaminants that are broadly distributed in the environment. Birds have the potential to be exposed to high levels of these chemicals, and yet surprisingly few data describing the relative potency of PAHs are available for avian species. Here, we determine LD50 values for 5 PAHs in birds and explore relative potency and sensitivity among congeners and species. Graded concentrations of each congener were injected into the air cell of unincubated chicken (Gallus gallus) eggs. The eggs were artificially incubated at 37.5°C, and the embryos were monitored throughout development and hatching. All of the PAHs that we tested caused dose-dependent increases in embryomortality, but few other abnormalities (e.g. weight changes, deformities, time to hatching) were observed. Critical windows of developmental sensitivity to were identified between embryonic day 3-9 and 16-22. The rank order potency of DahA > BkF > IdP > BaP > BaA corresponded well with previously published data for fish and mammals, and with in vitro measure of the potency of PAHs in birds. For example, ethoxyresorufin-O-deethylase (EROD) EC50 values from cultured chicken embryo hepatocytes were highly predictive of the LD50 values that we generated ($p < 0.001$, $r^2 = 0.99$). In order to assess differences in sensitivity among species, we also injected Japanese quail (Coturnix japonica) eggs with graded concentrations of BkF, and found that sensitivity in chicken and Japanese quail was approximately equivalent. This contrasts with previous studies that suggest that dioxin-like compounds (a related class of chemicals) are many times less potent in Japanese quail than in chicken (e.g. 40-fold difference in sensitivity to 2,3,7,8-tetrachlorodibenzo-p-dioxin). The data presented here contribute to our developing understanding of mechanisms underlying variability in responses to PAHs among congeners and species.

289 Miniaturized passive air sampler: a novel tool to monitor halogenated flame retardants in wild birds

M. Sorais, UQAM – TOXEN / Biological Sciences; A. Rezaei, R. Izquierdo, Univ of Quebec at Montreal / Dept of Computer Science; J.O. Okeme, Univ of Toronto / Physical and Environmental Sciences; M.L. Diamond, Univ of Toronto / Dept of Earth Sciences; J. Giroux, Univ of Quebec at Montreal / Dept of Biological Sciences; J. Verreault, Université du Québec à Montréal / Dept of Biological Sciences

Atmospheric transport of halogenated flame retardants (HFRs) is now well established. Added in a large range of consumer products to achieve fire safety standards, they ultimately migrate from their commercial substrates to the global atmosphere during their lifespan and beyond. Considering the ubiquitous distribution and potential toxicity of a large array of HFRs, it is crucial to understand their environmental fate and exposure pathways. Previous studies have reported large variations in HFR levels in gulls from the Great Lakes and St. Lawrence River basin. While it is largely accepted that birds are predominantly exposed to HFRs through diet, atmospheric exposure has also been suggested as potential exposure pathway. A recent study from our laboratory suggested that atmospheric exposure might be a determinant exposure pathway for HFRs in ring-billed gulls (Larus delawarensis) from the Montreal area (Canada). However, there is to our knowledge no method allowing the assessment of atmospheric exposure of wild birds to HFRs. The objective of this study was to adapt a passive air sampler (PAS) mounted on free-ranging gulls for monitoring HFR levels in air in both the gas- and particle-phases. Two different adsorbents (polyurethane foam combined to a glass fiber filter versus polydimethylsiloxane) and three exposure periods (one, two, and three weeks) were tested in the field. Results showed that the PAS accumulated all major polybrominated diphenyl ether (PBDE) congeners, hexabromobenzene, Dechlorane 604 Component B, and Dechlorane plus (DP) isomers. Differences in HFR patterns were observed between the two adsorbent types and the three exposure periods. In PAS containing polyurethane foam combined to a glass fiber filter, the contributions of DecaBDE to ΣPBDE were greatest at two weeks of exposure, followed by PentaBDE. DP isomers were the most abundant emerging HFRs determined in these PAS. The larger contributions of DecaBDE and DP were consistent with atmospheric levels reported in the Great Lakes area as well as with tissue levels in ring-billed gulls from Montreal. This novel miniaturized bird-borne PAS thus provided valuable information on the non-dietary exposure of free-ranging birds to ubiquitous HFRs in the environment.

290 Assessing the effects of legacy contaminants on egg and nestling survival of Tree Swallows in Great Lakes Areas of Concern

M. Etterson, USEPA / ORD NHEERL Mid-Continent Ecology Division; C.M. Custer, T.W. Custer, P.M. Dummer, USGS / Upper Midwest Environmental Sciences Center

Great Lakes Areas of Concern (AOCs) are affected by many stressors, some of which are environmental contaminants including PCBs, PBDEs, persistent organochlorine pesticides, dioxins, benzenes, and other chemicals. These toxicants can accumulate in aquatic biota and ultimately transfer to insectivorous birds that use the aquatic areas within AOCs. We used a relatively new multistate survival modeling approach to examine the relationship between avian egg and nestling survival and 11 contaminant concentrations in representative eggs of Tree Swallows (Tachycineta bicolor) using nest boxes placed near reference (n=10) and contaminated sites (n=59) around the Great Lakes. A total of 1,303 nests and 7,752 eggs were included in the modeling effort. Our analyses controlled for other common sources of variation in egg survival, including female age, date within season, year, and both site and AOC. Site, date within year, year, and female age all proved to be important variables in explaining egg survival. Among environmental contaminants, we found few associations between egg and nestling failure and contaminant concentration in representative eggs. Total dioxin furan toxicity equivalents (TDFTEQ) was significantly positively associated with egg failure, but significantly negatively associated with nestling death. Across the full dose response for this contaminant, empirically observed values of TDFTEQ were concentrated at the low end, with only a few values at the higher end of the dose-response. Site, as an explanatory variable, proved much more valuable, as judged by AIC_c, than AOC, suggesting that sites within AOC can vary considerably in stressors and/or response to stressors. Overall, concentrations of the 11 contaminants examined here, appear to be at concentrations low enough to cause few problems for Tree Swallow reproductive success.

291 Differences in mercury exposure of breeding Leach's storm-petrels related to their foraging patterns in the northwest Atlantic Ocean

N.M. Burgess, A. Hedd, Environment & Climate Change Canada / Science and Technology Branch; I.L. Pollet, Dalhousie Univ / Dept of Biology; R.A. Mauck, Kenyon College / Biology Dept; A.W. Diamond, Univ of New Brunswick / Dept of Biology; M.L. Valliant, Environment & Climate Change Canada / Science and Technology Branch

Leach's storm-petrels (Oceanodroma leucorhoa) are small seabirds that breed on coastal islands and make long, multi-day foraging trips during incubation, often beyond the continental shelf. In 2013-15, we attached geolocator tags to adult storm-petrels at seven breeding colonies in Atlantic Canada, to monitor their foraging trips during incubation. When the birds were recaptured 2-4 weeks later, the geolocator data were downloaded and a small blood sample was collected for analysis of total mercury and stable carbon and nitrogen isotope ratios (δ13C and δ15N). Leach's storm-petrels made offshore foraging trips that ranged 260 – 1400 km from their breeding colonies, and foraged over ocean depths ranging 170 – 5700 m. Mean mercury concentrations (± SE) in Leach's storm-petrel blood (n=193) were significantly greater from four colonies around Newfoundland (Baccalieu 1.11 ± 0.05 µg/g, Gull 1.00 ± 0.06 µg/g, Middle Lawn 1.28 ± 0.09 µg/g, and Grand Colombier Islands 1.27 ± 0.05 µg/g) than from three colonies in the Bay of Fundy (Bon Portage 0.65 ± 0.08 µg/g, Kent 0.57 ± 0.04 µg/g, and Machias Seal Islands 0.37 ± 0.06 µg/g). Blood mercury concentrations were positively related to the distance that birds foraged away from their breeding colonies, and to the depth of the ocean over which they foraged. We will discuss the insights provided by data on foraging movements from geolocators and on diet from δ13C and δ15N, for interpreting differences in blood mercury concentrations among and within breeding colonies. We will also assess the toxicological significance of the observed blood mercury concentrations, in light of the declining breeding populations of Leach's storm-petrels at several major colonies in Atlantic Canada. Determining mercury concentrations in the blood of these seabirds, along with their foraging patterns, allows us learn about methylmercury dynamics in offshore ocean foodwebs.

Existing and Emerging Contaminants in Changing Arctic Environments

292 Levels and trends of contaminants in Inuit populations living in northern Canada

M. Curren, Health Canada / Environmental Health Science and Research Bureau Healthy Environments and Consumer Safety Branch; B. Laird, Univ of Waterloo / School of Public Health and Health Systems; M. Lemire, P. Ayotte, Universite Laval / Centre de Recherche du CHU de Québec; L. Chan, Univ of Ottawa / Biology; F. Wania, Univ of Toronto at Scarborough / Physical and Environmental Sciences

The Canadian Northern Contaminants Program (NCP) is concerned with contaminants that reach the Arctic via long-range transport from source areas around the globe. This presentation provides an overview of human biomonitoring data collected over the past decade from the four Inuit regions of northern Canada (Nunavut, Nunavik, Nunatsiavut, and the Inuvialuit Settlement Region). Contaminants of concern in the North include a large number of persistent organic pollutants (POPs) and metals, including mercury. Levels of contaminants are declining in Canadian Inuit populations that have been monitored over time, although chemical concentrations measured in human tissues will vary depending on a person's age and sex and on chemical depuration rates. Moreover, routes of exposure to contaminants vary across the Canadian Arctic. The observation of higher levels of many POPs and metals in Inuit from northern Canada relative to the Canadian general population is likely related to the amount and type of traditional food consumed by Inuit during their lifetimes, in addition to the region where traditional foods are hunted or harvested. On-going biomonitoring by the NCP permits the assessment of spatial and temporal trends for contaminants in people and their environment, and creates opportunities to identify and measure new chemicals in commerce that might be transported to the Arctic. For example, we predict that a small number of compounds included in the third phase of the Canadian Chemicals Management Plan (CMP) may be reasonably persistent in the environment and undergo only very limited metabolism in higher organisms that may be included in the northern traditional diet. NCP human biomonitoring studies, in conjunction with NCP environmental monitoring results for contaminants in other media, have been used to inform the Stockholm Convention for POPs and the Minamata Convention on Mercury and help Canada to meet its obligations under the CMP. NCP assessments on the state of knowledge for contaminants and human health in northern Canada assist in determining whether risk reduction programs nationally and globally are adequate for the protection of health.

293 Organophosphate flame retardants and plasticizers in the Canadian Arctic

L. Jantunen, Environment and Climate Change Canada / Air Quality Processes Research Section; F. Wong, Environment and Climate Change Canada / ITM; A. Burt, Univ of Manitoba; R. Sühring, Fisheries and Aquaculture Science / Coastal Research; G. Stern, Univ of Manitoba; H. Hung, Environment and Climate Change Canada / Air Quality Processes Research Section; M. Pucko, Univ of Manitoba; M. Scheringer, ETH Zurich / Inst for Chemical and Bioengineering; M.L. Diamond, Univ of Toronto / Dept of Earth Sciences

Organophosphate ester (OPEs) flame retardants and plasticizers have received much attention due to their high levels in indoor air and dust and presence in remote locations including the Arctic. The widespread global distribution of OPEs is believed to arrive through various mechanisms including oceanic transport and air transport in the gas phase and on fine particles. Air, water, sediment and zooplankton samples were collected between 2007-2015 as part of ArcticNet and the Northern Contaminants Program in the Canadian Arctic. Samples were mainly taken from on board the CCGS Amundsen but also at Resolute Bay in the lower arctic and Alert in the high arctic. This coordinated sampling helps us understand how OPEs are introduced into the arctic food web. OPEs most frequently detected in the arctic environment were tri-phenyl phosphate (TPhP), tris(2-chloroethyl) phosphate (TCEP), tris(2-chloroisopropyl) phosphate (TCPP), tris(1,3-dichloro-2-propyl) phosphate (TDCPP) and ethyl-hexyl diphenyl phosphate (EHDPP). Levels of OPEs were very high compared to other flame retardants including PBDEs.

294 Perfluoroalkyl Acids in the High Arctic: A Multi-Decadal Depositional Ice Record

H. Pickard, Memorial Univ of Newfoundland; C. Young, Memorial Univ / Dept of Chemistry; J. MacInnis, Memorial Univ; S. Morran, Simon Fraser Univ / Dept of Biological Sciences; A.O. De Silva, Environment and Climate Change Canada; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; M. Sharp, Univ of Alberta; A. Criscitiello, Univ of Calgary

Perfluoroalkyl acids (PFAAs) are persistent, bioaccumulative compounds found ubiquitously within the environment. PFAAs can be formed from atmospheric oxidation of volatile precursors and undergo long-range transport (LRT) through the atmosphere and/or the ocean to remote locations. PFAA deposition is a result of indirect oxidation and direct transport on atmospheric particles. Ice caps preserve a temporal record of this deposition making them useful in studying the atmospheric trends in long-range transport of PFAAs as well as understanding major pollutant sources and production changes over time. A 15 m ice core representing 38 years of deposition (1977-2015) was collected from the Devon Ice Cap in Nunavut and analyzed for PFAAs. Samples were concentrated using solid phase extraction and analyzed using UPLC-MS/MS. The C4-C13 and C18 perfluorocarboxylic acids (PFCAs), C4, C7 and C8 perfluorosulfonic acids (PFSAs), and PFOSA were all detected in the samples. PFCA and PFSA fluxes ranged from 0.162 to 4.44×10^4 ng m^{-2} yr^{1}. All of the PFCA analytes detected in recent years from 2011-2015 show a decrease in flux. This may be due to melting effects or the phase out by the PFOA Stewardship Program. Even-odd pairs of PFCA homologues were observed for the C6-C11 PFCAs with strong correlations, indicating that these compounds are most likely from indirect formation of precursors. The C2-C4 PFCAs have much higher fluxes than the other PFCAs. A number of CFC replacements (HCFCs and HFCs) are additional precursors to these short-chain acids. Data from NOAA for the global mixing ratios of HCFCs and HFCs shows strong correlations with TFA (C2 PFCA). Devon Ice Cap receives pollutants via atmospheric LRT from both North American and Eurasian sources. Air mass back trajectory analyses allow us to determine the fractions of air masses that originate from source regions to the Devon Ice Cap from across the globe. Ion chromatography analyses of marine aerosol tracers further allow us to determine if Devon Ice Cap has received any PFAA contamination from marine aerosols or solely from atmospheric oxidation. Assessments of deposition, homologue profiles, and air mass back trajectories will improve current understandings of LRT of PFAAs to the Devon Ice Cap. This presentation will examine temporal and homologue trends in atmospheric PFAA deposition and compare to known changes in production as well as previous and current ice cap, lake and ocean water measurements.

295 PCB and organochlorine pesticide accumulation and blubber-depth distribution in an Arctic-invading marine mammal predator

S. Pedro, Univ of Connecticut / Natural Resources and the Environment; C. Boba, Univ of Connecticut / Dept of Chemistry; R. Dietz, C. Sonne, Aarhus Univ DMU / Biosciences Dept; A. Rosing-Asvid, Greenland Inst of Natural Resources; A. Provatas, Univ of Connecticut / Center for Environmental Sciences and Engineering; M.A. McKinney, Univ of Connecticut / Natural Resources and the Environment

The spatial and temporal range of killer whales (Orcinus orca) within the Canadian Arctic and Greenland has increased in recent years, coincident with deteriorating Arctic sea-ice conditions. With several Arctic marine mammal species available as potential prey, limited evidence suggests that these invading North Atlantic killer whale populations may be shifting their fish-specialized diet towards one that is richer in marine mammals. Such shifts could lead to higher exposures to biomagnifying contaminants such as polychlorinated biphenyls (PCBs) and organochlorine (OC) pesticides. Killer whales are amongst the most contaminated animals on Earth and face protracted health risks as a consequence of exposure to these contaminants. Virtually all previous killer whale PCB and OC analyses have been performed using the outer blubber layer, obtained through remote biopsy approaches. However, this method may be problematic due to possible heterogeneous distribution of PCBs and OCs within the blubber layers. To address potential health concerns for Arctic-invading killer whales and indigenous Arctic consumers, we measured blubber PCB and OC levels in 10 equal-length blubber sections in 20 individuals harvested in southeast Greenland in 2012-2014. We determined the levels of ∑chlorobenzene, ∑chlordanes, ∑dichlorodiphenyltrichloroethane compounds (∑DDT), ∑endosulfan, ∑mirex, ∑hexachlorocyclohexane and ∑PCB. For individuals analyzed thus far, the highest levels were found for ∑DDT (51.1 ± 3.1 µg g-1 lipid weight) and ∑PCB (44.5 ± 2.7 µg g-1 lipid weight), which far exceeded a 1 part-per-million general threshold level of concern. Levels of ∑PCB and ∑DDT were intermediate between levels reported in fish-feeding killer whales and those that predate marine mammals in earlier studies and other regions. Wet weight contaminant levels varied with blubber depth ($p< 0.05$), but after lipid correction, average contaminant levels were generally similar among layers. Nonetheless, the pattern of PCB and OC levels through the blubber depth appeared to vary among individual killer whales, suggesting that other factors beyond lipophilicity may contribute to PCB and OC concentration variation with blubber depth. On-going analysis of PCB and OC levels in additional individuals will allow for in-depth evaluation of the influence of sex, age class, diet (particularly consumption of Arctic marine mammals relative to fish) on the distribution of these contaminants among blubber layers.

296 Presence and fluxes of legacy POPs and PBDEs in the Western Antarctic Peninsula

M. Khairy, Univ of Rhode Island; E. Markham, Univ of Rhode Island Graduate School of Oceanography; E. Brault, Univ of California Santa Cruz; M.E. Goebel, NOAA / NMFS / SWFSC, Antarctic Ecosystem Research Division; J.L. Luek, Univ of Maryland Baltimore County; R. Lohmann, Univ of Rhode Island / Graduate School of Oceanography; R.M. Dickhut, College of William Mary VIMS

Polybrominated diphenyl ethers (PBDEs) are 'emerged' contaminants that were used as flame-retardants for decades in a wide range of consumer and industrial applications, and are still ubiquitously present in the environment today. Yet little is known about the presence, food web transfer and time trends of PBDEs in the Antarctic. A unique set of >200 biotic samples from the Antarctic was analyzed for PBDEs, including phytoplankton, krill, fish and fur seal milk, spanning several sampling seasons over 14 years. PBDE-47 and -99 were the most dominant congeners determined in all samples, constituting >60% of total PBDEs. In fur seal milk, the higher brominated congeners were becoming more prevalent in later years. A temporal trend was observed for $\sum_{12}$PBDE concentrations in fur seal milk, where concentrations significantly increased ($R^2 = 0.53$, $p < 0.05$) over time (from 2000 to 2014). Trophic magnification factors (TMFs) were calculated for this food web for samples collected in 2010/11; all TMFs were found to be < 1 (range 0.33 – 0.87) indicating biodilution. There is no indication of PBDEs decreasing in Antarctic fur seal milk yet, while numerous studies have reported decreasing trends in the Arctic. This surprising result indicates the need for further research if and when PBDE concentrations in the Antarctic will start declining, too. A comparison between both polar regions suggests a delay of PBDE peak by at least 10 years in the Antarctic. Further insights were gleaned from air and snow samples collected during the austral spring (October – November, 2010) along the western Antarctic Peninsula and analyzed for organochlorine pesticides (OCPs), polychlorinated biphenyls (PCBs) and PBDEs to assess the relative importance of long-range transport versus local primary or secondary emissions. Highest concentrations of PCBs, PBDEs and DDTs were observed in the glacier's snow sample, highlighting the importance of melting glaciers as a possible secondary source of legacy pollutants to the Antarctic. In contrast to other compounds, PBDEs seem to have originated from local sources, possibly the research station itself. Diffusive flux calculations indicated that net deposition is the dominant pathway for PBDEs and chlordanes, whereas re-volatilization from snow (when it melts or metamorphoses) was observed for PCBs and some OCPs.

297 Drivers of Spatial Variability in Fish Mercury Levels in the Dehcho region, NT, Canada

H. Swanson, Univ of Waterloo / Biology; G. Low, Dehcho Aboriginal Aquatic Resources and Oceans Management; B. Branfireun, Univ of Western Ontario / Dept of Biology; M. Low, Dehcho Aboriginal Aquatic Resource and Oceans Management Program; M. Evans, Environment and Climate Change Canada

Leadership and community members in the Dehcho region of the Northwest Territories, Canada, are concerned about levels of mercury ([Hg]) in food fishes. While Lake Whitefish (Coregonus clupeaformis) are generally known to have [Hg] below guidelines, other species, such as Northern Pike (Esox lucius) and Walleye (Sander vitreus), have been the focus of consumption advisories in some lakes. Mercury levels in these species vary widely across lakes within a relatively small geographic area. Previous research has been unable to elucidate the main drivers of among-lake differences in fish [Hg] in this region. From 2013-2015, 8 remote Dehcho lakes were sampled for fish, benthic invertebrates, zooplankton, sediment, and water by a collaborative team that included First Nations and academic researchers. Fish mercury concentrations were related to fish stable isotope ratios, age, size, and growth rates, as well as to a suite of water chemistry and sediment variables. Interim results indicate that size-standardized differences in fish [Hg] among lakes were best explained by concentrations of chlorophyll-a for Walleye (R^2=0.9), and by dissolved organic carbon concentration (R^2=0.6) for Lake Whitefish. For Northern Pike, size-standardized differences in [Hg] were best explained by lake chloride concentrations and age-at-size (R^2=0.93). Intercepts of Hg-del^{15}N relationships for each lake were negatively related to pH, and positively related to concentrations of dissolved methyl mercury in water. These results are discussed in the context of causal mechanisms, consumption advice for northern fishers, and a resulting mercury mitigation strategy initiated by the Dehcho First Nations.

298 Tracing rare earth elements (REEs) in food webs from freshwater, marine and terrestrial ecosystems in the eastern Canadian Arctic

G.A. MacMillan, Universite de Montreal / Dept of Biological Sciences; J. Chételat, Environment and Climate Change Canada / National Wildlife Research Centre; R. Mickpegak, Sakkuq Landholding Corporation Kuujjuaraapik; M. Amyot, Univ of Montreal / Centre for Northern Studies CEN Dept of Biological Sciences

Rare earth elements (REEs) are a group of 17 elements which include the 15 naturally occurring lanthanide metals, as well as scandium (Sc) and yttrium (Y). REEs have critical applications in many high-tech industries, including electronics, medicine, clean-energy, and agriculture. REEs are now also used in eutrophication management systems for freshwaters. Increasing exploitation of these elements has led to a growing scientific interest in REE ecotoxicology, however the scientific literature remains sparse. Field studies examining the bioaccumulation and food web dynamics of REEs are very rare, and none have focused on northern ecosystems which are potentially vulnerable to REEs enrichment from mining activity. Increasing demand for REEs (and decreasing export from China) has led to the recent development of REE mining projects in Northern Canada. The goal of this field-based study was to evaluate the potential for bioaccumulation and trophic transfer of REEs in freshwater, marine, and terrestrial food webs of the eastern Canadian Arctic. Biological samples were collected in 2012, 2014 and 2015 from marine (mussels, common eiders, seals), terrestrial (lichen, moss, hare, ptarmigan, caribou) and freshwater (invertebrates, zooplankton, fish) ecosystems within a restricted geographic radius around Kuujjuarapik-Whapmagoostui (Nunavik, Quebec). Wildlife harvesting and tissue sampling was conducted by local hunters and organized by the Sakkuq Landholding Corporation through a community-based monitoring project. All samples were analyzed for REEs and stable isotope ratios of nitrogen and carbon (Δ15N, Δ13C). Results show both species- and tissue-specific sensitivity to REE bioaccumulation. Lichens, mosses, snowshoe hares, and freshwater and marine invertebrates (freshwater zooplankton, blue mussels and sea urchins) had the highest levels of REE bioaccumulation, while freshwater fish muscles had low concentrations of REEs. All terrestrial and aquatic vertebrates had very low levels of REEs detected in muscle tissues, whereas concentrations in liver tissues were significantly higher for all species. Variation in REE bioaccumulation will be compared to water, sediment and soil concentrations and the potential for biomagnification in the food chain will also be examined.

299 Increasing mercury, cesium and rubidium in Arctic Char in a lake influenced by permafrost disturbance and climate change

D.C. Muir, X. Wang, J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A. Sett, A. Gleason, Environment and Climate Change Canada; A. Cabrerizo, Environment and Climate Change Canada / Aquatic Contaminants Research Division; D. Iqaluk, Resolute Bay; K. Roberts, Queens Univ; S. Lamoureux, Queens Univ / Geography; M. Lafrenière, Queens Univ / Dept of Geography and Planning

Many regions of the Arctic are undergoing climate-related changes, such as increased temperatures, altered precipitation patterns, and permafrost degradation, which have altered fluxes of water, sediment, carbon, nutrients, and mercury (Hg) to freshwater environments. West Lake and East Lake, are adjacent, geologically similar watersheds in the Cape Bounty Arctic Watershed Observatory on Melville Island (Nunavut, Canada), which are currently undergoing climate-driven changes at different rates. The West catchment, experienced numerous active layer detachments during the period 2007-2012, while the East catchment has experienced only minor permafrost disturbances. We hypothesize that these alterations will increase the mobilization of Hg and other elements will result in increasing concentrations of Hg in char in West Lake. To investigate this landlocked Arctic char have been collected for analysis of total Hg (THg) as well as 31 elements annually from 2008 to 2015. THg was determined in char muscle by EPA Method 7473 using a Direct Mercury Analyser and 31 elements were determined by ICP-MS analysis. Stable isotope analysis showed that char (N=100) have significantly more depleted $\delta^{13}C$ in East vs West Lake (mean ± SD; -26.86±1.06 ‰ (N=73) vs -24.98±1.44‰ indicative of greater terrestrial carbon inputs to West Lake. Also $\delta^{15}N$ is significantly lower in West Lake char (10.06±0.81 ‰ vs 10.99±0.70‰) suggesting differences in food sources. The combined results from 2008 to 2015 collections show that the West Lake adult char have significantly higher Hg concentrations (0.159 ± 0.08 µg/g) compared to East Lake (0.097 ± 0.04 µg/g). THg has declined significantly in East Lake (7.2%/y) but has increased slightly in West Lake (~0.5%/y). Cesium and rubidium increased significantly in char from West Lake (5.5 % and 4.1% per y, respectively) while declining or showing no trends in East Lake. Arsenic, cadmium, and zinc were present at similar concentrations in both lakes in almost all years and showed no trends. Results for East Lake are consistent with observations of Hg in landlocked char in 4 other lakes of similar size on Cornwallis Island, where declines of -5.5 to -19%/y have been observed since 2005. None of these lakes have significant permafrost disturbance. The higher concentrations and lack of a decline of Hg in West Lake char are consistent with higher inputs of THg to West Lake resulting from extensive permafrost disturbance in the West watershed.

Recent Advances and Trends in Poly- and Perfluoroalkyl Substances Research – Part 2

300 Determination of AFFF Components Using A Multivariate Analysis following an LC-QToF MS Acquisition

K.J. Rosnack, Waters Corporation / Food Env Business Operations; L. Mullin, Waters Corporation; A. Karmann, MTM Research Centre, Orebro Univ; G. Cleland, Waters Corporation

Aqueous film-forming foams (AFFFs) have been implemented in both military and commercial fire-fighting activities to extinguish flammable liquid fuels. However, uses of these formulations have resulted inadvertently in the release of contaminants into the environment due to migration from the site of application. The various formulations of AFFFs consist of numerous fluorocarbon and hydrocarbon compounds1. Characterizing the unique as well as common components of AFFFs that are currently implemented is the starting point to tracking these constituents through various environmental and biological compartments. In this work, seven AFFF mixtures were analyzed using QTof MS in order to obtain full spectral acquisition from which a multivariate analysis approach could be taken to identify unique components within the mixtures. Data was acquired using alternating high and low collision energy states across the full analytical mass range (data independent), such that product ions were also generated (MSE). Samples were diluted in methanol and chromatographic separation performed using an existing liquid chromatography method for the analysis of perfluorinated compounds. Instrumental performance with regards to mass accuracy (Distinctive grouping from PCA plots could be observed for three AFFFs in both modes, with cluster of five of the seven in ESI+ and four of the seven in ESI-. Pool samples, which contain all ions used in the multivariate analysis, were clustered appropriately towards the middle. Investigation of exact mass/retention time pairs strongly associated with all groupings using molecular formulae calculations and ChemSpider database searching resulted in the identification of multiple sulfate, hydrocarbon and fluorinated compounds. Further interrogation of the markers using trend plots to indicate presence and abundance across all the injections yielded additional identifications that were either unique to specific formulations or in some cases common compounds across multiple AFFFs. For those constituents that had a proposed structure, product ion structures were assigned and used as a means to support a potential identification.

301 A New Method for the Analysis of Thirty Poly and Perfluoroalkyl Substances in Maternal Serum

S. Crispo Smith, California Environmental Protection Agency / Dept of Toxic Substances Control; E. Houtz, ECL California Dept of Toxic Substances Control / Environmental Chemistry Lab; W. Duong, A. Zamora, J. VillaRomero, California Environmental Protection Agency / Dept of Toxic Substances Control Environmental Chemistry Laboratory; N. Wu, R.W. Voss, California Dept of Public Health; M. Petreas, J. Park, California Environmental Protection Agency / Dept of Toxic Substances Control Environmental Chemistry Laboratory

Poly and perfluoroalkyl substances (PFASs) are a large class of anthropogenic and persistent chemicals, some of which bioaccumulate. The National Health and Nutrition Examination Survey (NHANES) and Biomonitoring California have been monitoring twelve PFASs in human serum for over a decade. We have recently extended our list of chemicals to include additional PFASs, with an emphasis on polyfluorinated compounds and short chain replacements to PFOS and PFOA. Currently, we can measure thirty PFAS compounds in human serum. Our compound list includes eight perfluorinated carboxylic acids (PFCAs), four perfluorosulfonic acids (PFSAs), two perfluorinated phosphonic acids (PFPAs), two perfluorinated phosphinic acids (PFPiAs), as well as ten PFCA precursors/intermediates and three PFSA precursors. Our method consists of a manual methanolic extraction of 250µL of serum, clean-up using ENVI-Carb, and compound analysis by liquid chromatography (Nexera UFLC system, Shimadzu) coupled to a triple-quadrupole tandem mass spectrometer (SCIEX QTRAP 5500 MS/MS system). Measured values for National Institute of Standards and Technology Standard Reference Material No. 1958 (NIST SRM) samples were similar to values for the four certified PFASs (recoveries of 72 – 106%, with standard errors ranging from 9 to 11%). For the other compounds that were not certified in the NIST material, in-house QC serum samples at three different spiked-PFAS concentrations were prepared and tested, with compound recoveries ranging from 48% to 132% and standard errors from 7% to 35%. This method is used to analyze samples for Biomonitoring California studies, to determine levels of these PFASs in Californians, and to help establish temporal and spatial trends. We will present preliminary results of PFAS analysis on archived maternal serum samples, collected as part of the State prenatal screening program. Disclaimer: The views expressed herein are those of the authors and do not necessarily reflect those of the California Department of Toxic Substances Control.

302 Monitoring Human Exposure to Poly- and Perfluorinated Alkyl Substances (PFAS) Using Hand Wipes, Silicone Wristbands and House Dust

C.M. Butt, R. Cameron, R. Siebenaler, K. Hoffman, Duke Univ / Nicholas School of the Environment; C.P. Higgins, Colorado School of Mines / Dept of Civil Environmental Engineering; H.M. Stapleton, Duke Univ / Nicholas School of the Environment

Perfluorinated carboxylates (PFCAs) and sulfonates (PFSAs) are globally detected in human tissues but exposure sources are not well understood. Potential sources include diet, drinking water, dermal absorption, air inhalation and dust ingestion. In particular, dust exposure – via hand-to-mouth contact – has not been well quantified. Of concern is direct exposure to PFCAs and PFCAs, but also indirect exposure to precursors such as the fluorotelomer dialkyl phosphates (diPAPs) and fluorotelomer alcohols (FTOHs). PFCAs & PFSAs are widely detected in house dust, but little is known about FTOHs and diPAPs. The aim of this study was to quantify PFCA, PFSA, FTOH and diPAP human exposure in 40 individuals from Durham, NC, via measurement in house dust, hand wipes and silicon wrist bands. Serum samples were analyzed for PFCAs and PFSAs to investigate correlations with exposure levels. A questionnaire was used to assess relationships between behavior and contaminant exposure. House dust was collected using a vacuum and sieved to < 500 µm. Hand wipes were obtained by soaking gauze wipes in isopropyl alcohol and wiping the hands. Participants wore pre-cleaned silicone wrist bands for 5 days, including during showering and sleeping. The 6:2 FTOH was detected in most house dust samples (91%), whereas the 8:2 FTOH was infrequently detected (11%). This is consistent with the reported industry shift from 8:2 to 6:2 telomer-based products. Similarly, the 6:2/6:2 (100%) and 6:2/8:2 diPAP (94%) were frequently detected in dust, whereas the 8:2/8:2 diPAP was infrequently detected (34%). In contrast, PFCAs and PFSAs were infrequently detected in dust. Similar trends were also observed in the hand wipe and wrist band samples. For example, 6:2 and 8:2 FTOH were detected in 100% of the wrist band samples, but 6:2 FTOH was the dominant congener (geometric mean = 190 ng) followed by 8:2 FTOH (14.6 ng). Also, the 6:2/6:2 and 8:2/8:2 diPAP were detected in 100% and 64% of wrist band samples, with 6:2/6:2 diPAP dominating (geo. mean: 3.8 ng) followed by 8:2/8:2 diPAP (1.1 ng). The 6:2 FTOH (r_s=0.59, $p< 0.01$) and 6:2/6:2 diPAP (r_s=0.80, $p< 0.001$) were highly correlated between wrist bands and hand wipes. These trends indicate that wrist bands and hand wipes are suitable measures of recent exposure for FTOHs and diPAPs. Overall, the study results show that direct exposure via hand-to-mouth contact is low from PFCAs and PFSAs, but indirect exposure (FTOHs, diPAPs) may be important.

303 Temporal trends of perfluoroalkyl substances (PFASs) in pilot whales and children from the Faroe Islands

C. Dassuncao, Harvard Univ; R. Bossi, Environmental Science; M. Dam, Environmental Agency; P. Grandjean, X. Hu, Harvard Univ; B. Mikkelsen, The Faroese Museum of Natural History; F. Nielsen, Univ of Southern Denmark; P. Weihe, The Faroese Hospital System / Dept of Occupational Medicine and Public Health; X. Zhang, Harvard Univ / Environmental Health Sciences School of Public Health; E.M. Sunderland, Harvard Univ / School of Engineering and Applied Sciences

Exposure to poly and perfluoroalkyl substances (PFASs) has been associated with adverse impacts on immune health, metabolism and risk of obesity in children. Human exposure to PFASs is thought to be predominantly dietary but the relative contribution from different sources varies substantially across populations. The Faroe Islands are located in the middle of the North Atlantic and the traditional diet of the population includes pilot whale. Here we compare temporal patterns over the last three decades of 17 PFASs in pilot whale muscle to children's sera from the Faroe Islands. We use this analysis to better understand factors affecting the lifetime of these compounds in the marine environment and exposures from marine foods. PFASs in both pilot whale muscle and children's sera from the Faroe Islands have decreased from a maximum ca. 1998-2000 over the past decade but we show that these changes are for markedly different reasons. The drop in pilot whale muscle is driven by a decrease in the precursor, FOSA, whereas declines in children's serum are seen across all compounds. We developed a screening model that shows that the changes of FOSA observed in pilot whales can be explained by dietary ingestion originating from partitioning from the atmosphere. We investigate whether the decline in PFOS observed in children is therefore also driven by a decline in indirect exposure to precursors. To do this we look at trends in PFOS isomer patterns, and the detection frequency of the short-lived precursor FOSA. We found that overtime the percent of branched PFOS has decreased from 49% to 34% and that the frequency of detection of FOSA has declined from 100% in 1993 to 6% in 2012. Taken together this suggests that the observed declines of PFOS in children may be due in large part to decreases in exposure to precursor compounds such as FOSA. To quantify the contribution that pilot whale muscle has to overall PFAS burden in this population we link the pilot whale and human datasets with a PBPK model. We estimate and control for changes in whale consumption with a simple dietary survey and longitudinal MeHg concentrations. The results of this research allow us to make inferences about the shifts in future exposure sources of PFASs for marine food consuming individuals.

304 Toxicity of perfluorinated carboxylic acids to a Zebrafish Liver cell line

S. Guffey, Purdue Univ / Forestry and Natural Resources; C.T. Mahapatra, N.P. Damayanti, J. Serafin, J. Irudayaraj, Purdue Univ; M.S. Sepulveda, Purdue Univ / Dept of Forestry and Natural Resources and School of Health Sciences

Poly- and per-fluoroalkyl substances (PFAS) are used industrially for their stability and resistance to high temperature and chemical degradation, and many environments across the world exhibit low levels of PFAS contamination. However, the commonly used variant perfluorooctanoic acid (PFOA) drew concern as a toxic and persistent organic pollutant. Therefore, it was replaced by shorter carbon chain homologues such as perfluorohexanoic acid (PFHxA) and perfluorobutanoic acid (PFBA). Because few data exist on the toxicity of these substitutes to aquatic organisms, we examined the toxicity of PFOA, PFHxA, and PFBA on a zebrafish liver cell line (ZFL), a model system useful for both biomedical and aquatic environmental studies. Cell viability after 96 h of exposure was lowest for PFOA and PFO-, while PFHxA and PFBA were less toxic. Based on the structural similarity of PFASs to fatty acids, we suspected that these compounds interfere with lipid transport and metabolism. However, we did not detect changes to gene expression of ppar-α,β,γ, fabp3 and crot after 96 h exposure to up to 10 ppm of PFOA, PFHxA, or PFBA. Conversely, we found obvious intracellular lipid droplet accumulation only in PFBA-exposed cells. To examine additional effects on metabolism, we conducted Fluorescence Lifetime Imaging Microscopy using the naturally fluorescent coenzymes NADH and FAD. The fluorescence lifetimes of NADH and FAD and the bound:free ratio of each of these coenzymes decreased in a dose- and carbon length-dependent manner, suggesting disruption of cell metabolism; these data are consistent with an overall decrease in metabolic activity and a partial shift in cellular ATP production from oxidative phosphorylation to anaerobic glycolysis. In conclusion, this in vitro study using ZFL cells revealed that PFASs with shorter carbon chains are less toxic than PFOA, but that exposure to PFHxA or PFBA still affects cell metabolism. Therefore, the application of shorter-chain alternatives is not without risk.

305 Evaluation of PFHx- Pharmacokinetics in Mouse, Rat, Microminipig, Pig, Monkey and Human

S. Gannon, The Chemours Company; M.H. Russell, The Chemours Company / Toxicology and Risk Assessment; R.C. Buck, The Chemours Company / Fluoroproducts

Perfluorohexanoate ($PFHx^-$) elimination kinetics have been determined from published data for multiple mammalian species: mouse, rat, microminipig, pig, monkey and human. For each species, the data was compiled and modeled to identify the kinetic profile of elimination from blood including calculation of elimination rate (hr^{-1}) and elimination half-life (hr). The study shows that $PFHx^-$ elimination kinetics in mammals is consistent with a rapid initial (alpha) phase followed by a slower terminal (beta) phase. Further, the $PFHx^-$ alpha phase elimination has a first-order half-life range of 1-2 hours in mouse, rat, microminipig, pig, monkey and human. The alpha phase elimination in mammals accounts for over 99.7% of the total $PFHx^-$ elimination in mammals. $PFHx^-$ elimination is extensive in the rapid alpha phase and there are no significant pharmacokinetic differences across mammals: mice, rats, monkeys, pigs and humans. The overall conclusion of this kinetic assessment is that $PFHx^-$ does not appear to exhibit significantly different elimination kinetics across a wide range of mammalian species. Details of the assessment for each species will be presented and summarized.

306 Perfluoralkyl Substances at Superfund Sites

L. Gaines, USEPA / OSWER; M.K. Lambert; M.D. Sprenger, USEPA / ERT

Perfluoroalkyl substances (PFAS) have been recognized as emerging contaminants of concern by State and Federal entities for a number of years. Because of the valuable properties of PFAS, they were used in a wide variety of industrial and commercial products. Some of the known uses are coating on surfaces to impart non-stick properties or stain resistance, dust suppression for metal plating, and aqueous firefighting foam (AFFF). As a result, PFAS may have been released into the environment during manufacturing, application, or disposal of wastes and end products. PFAS have been detected in various environmental media including groundwater, soil, and biota at areas associated with their manufacture, use, and disposal. Sites contaminated with PFAS are emerging with high visibility to the public. However, the environmental fate and transport as well as the toxicology of the various PFAS compounds is not completely understood, and analytical challenges still exist. This talk will focus on specific PFAS, media, and site types where PFAS, the challenges site managers have encountered in the field; and additional research that is needed to improve our understanding of PFAS toxicology and analytical methods.

Systems Modeling Approaches for Ecotoxicology to Link Molecular Responses to Ecosystem Effects

308 Linking the Adverse Outcome Pathway to Dynamic Energy Budgets: A conceptual model

C.A. Murphy, Michigan State Univ / Fisheries and Wildlife; R.M. Nisbet, UCSB / Ecology Evolution and Marine Biology; P. Antczak, Univ of Liverpool / Inst of Integrative Biology; A. Gergs, gaiac – Research Inst for Ecosystem Analysis and Assessment / Dept of Environmental Social and Spatial Change; K. Lika, Univ of Crete; T.J. Mathews, Oak Ridge National Laboratory / Environmental Sciences Division; E.B. Muller, Univ of California, Santa Barbara / Marine Science Inst; D.E. Nacci, USEPA / Atlantic Ecology Division; A. Peace, Texas Tech Univ; C.H. Remien, Univ of Idaho / Dept of Mathematics; N. Vinas, Midsouth Regional Chapter / Inst for Genomics Biocomputing and Biotechnology; I.R. Schultz, Battelle Northwest Laboratories / Marine Science Laboratory; K.H. Watanabe, Arizona State Univ West Campus / School of Mathematical and Natural Sciences

Ecological risk assessment quantifies the likelihood of undesirable impacts of chemicals and other stressors at higher levels of biological organization. In practice, the need for methodology that is cost-effective and minimizes the use of vertebrate animals has and will increasingly limit available data to individual organisms and suborganismal processes. Two ecological modeling approaches are being used to connect information at different levels of organization. The first uses quantitative adverse outcome pathway (qAOP) models that link molecular initiating events to key events that are relevant to the physiology and/or behavior of the individual organism. The second uses dynamic energy budget (DEB) models that describe the assimilation of energy by an organism and its allocation to growth, development, maintenance and reproduction at all life stages. qAOPs have clear connections to molecular biology and biochemistry, but typically simulate complicated physiological mechanisms with many parameters and are concerned with toxicological endpoints related to a single process (i.e., growth or reproduction); DEB models have weaker connections with specific sub-organismal processes but simulated mechanisms are simpler and can connect endpoints from multiple physiological processes. As members of a working group at the National Institute for Mathematical and Biological Synthesis (NIMBioS), we are exploring approaches to link the two modeling approaches. First, consistent with a DEBtox approach, we connect internal toxicant concentrations to abstract quantities such as “damage inducing events” that impact measureable physiological responses of organisms. Then, we use qAOP key events to either represent or provide direct measures of damage inducing events that manifest at the level of organs or the entire organism. Finally, by linking the qAOP and DEB approaches and then embedding DEB models into individual-based population and other ecosystem models, we narrow the mismatch between available data and ecological outcomes of concern. Our working group is using two case studies (invertebrate and fish) to demonstrate proof of concept and develop a general framework for future model development, evaluation, and communication that can be applied across different levels of biological organization and ecotoxicological endpoints. We are also partnering with another NIMBioS group that is using ecological models (with DEB modeling) to link individuals to ecosystems services.

309 A systems modeling framework to link organism-level effects of chemical stressors to effects on ecosystem services

C.J. Salice, Towson Univ / Biological Sciences/ Environmental Science; V. Forbes, Univ of Minnesota / Ecology Evolution Behavior

Although protection goals for the ecological risk assessment of chemicals are increasingly being framed in terms of ecosystem service delivery, the type of data collected to assess risk is generally at the level of individual organisms. Currently, extrapolation from what is measured to what we want to protect uses overly simplistic approaches (e.g., hazard or risk quotients) that are not solidly grounded in biology or mathematics. This presentation describes progress and ongoing efforts from a working group funded by the National Institute of Mathematical and Biological Synthesis (NIMBioS) to develop a systems modeling framework to link organismal effects to changes in ecosystem services. The proposed framework quantitatively links physiological energetics, to organism performance, population dynamics, and ecosystem service delivery. The working group is applying the framework to case studies involving trout and daphnids. These species were chosen because they are commonly used in EPA and OECD-approved toxicity tests, are ecologically relevant, and yield a range of ecosystem services. We provide an overview of the specific ecosystem services provided by each species and the modeling tools currently being developed and refined. For trout we are focusing on the services delivered primarily through angling and are using individual-based, bioenergetic models to explore the impacts of 17-alpha-ethinylestradiol on a range of organismal endpoints linked to ecosystem services. Daphnids, alternatively, yield indirect ecosystem services such as water clarity that enhances recreation in lentic systems. Currently, the working group is exploring the use of AQUATOX to link data on effects of chlorpyrifos on daphnids to system-level endpoints including phytoplankton abundance which relate directly to water clarity. Importantly, the efforts reported here are designed to dovetail with an additional, coordinated NIMBioS working group focused on a modeling framework that links suborganismal (metabolic, cellular, and molecular) responses to chemicals to effects that manifest at the organism level. The overarching goal of these collaborative, multidisciplinary groups is a generalizable modeling framework and proof of concept that can be used to relate toxicant responses at levels of organization that are more easily studied (sub-organismal, organismal) to outcomes relevant to society and effective environmental management (ecosystem services).

310 : Role of adverse outcome pathways in developing computational models for regulatory toxicology

G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; C. Wittwehr, European Commision DG Joint Research Centre; H. Aladjov, Bulgarian Academy of Sciences; H. Byrne, Focas Inst; J. de Knecht, RIVM; E. Heinzle, Saarland Univ; G. Klambauer, Johannes Kepler Univ; B. Landesmann, European Commision DG Joint Research Centre; M. Luijten, RIVM; C. Mackay, G. Maxwell, Unilever; M. Meek, Univ of Ottawa; A. Paini, European Commision DG Joint Research Centre; E. Perkins, US Army Corps of Engineers ERDC; T. Sobanksi, European Chemical Agency; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory; K. Waters, Pacific Northwest National Laboratory; M. Whelan, Joint Research Centre – European Commission – Inst for Health and Consumer Protection

Regulatory toxicology for both human health and the environment increasingly is moving from a sole reliance on direct observation of apical toxicity outcomes in whole organism toxicity tests, to predictive approaches in which unacceptable outcomes and risk are inferred from mechanistic data. The adverse outcome pathway (AOP) framework has emerged as a key tool for organizing and communicating knowledge that supports such inference. In this context, AOPs also could support the systematic organization of knowledge to inform and help direct the design and development of predictive computational models to further enhance the utility of mechanistic data for chemical assessment. An international expert workshop exploring this premise was held in September, 2015 in Ispra, Italy. Outcomes from this workshop featured illustrative case studies of AOP-informed model development and application to the assessment of chemicals for skin sensitization in humans and endocrine disruption in fish. The role of problem formulation, not only as a critical phase of risk assessment, but also as guide for both AOP and complementary model development was elaborated. Finally, a proposal for actively engaging the modeling community in AOP-informed computational model development through crowd-sourced competitions was proposed. This presentation will provide an overview of the workshop outcomes relative to a vision for how AOPs can be leveraged to facilitate development of predictive computational models to help support the next generation of chemical safety assessment. . The contents of this abstract neither constitute nor necessarily reflect USEPA, US ACE or European Commission policy.

311 Scaling the effects of multiple stressors from molecular to population levels using Daphnia magna as a model organism

T.J. Mathews, Oak Ridge National Laboratory / Environmental Sciences Division; R.M. Nisbet, UCSB / Ecology Evolution and Marine Biology; N. Vinas, Mississippi State Univ / Environmental Laboratory; C.A. Murphy, Michigan State Univ / Fisheries and Wildlife; P.C. Pickhardt, Lakeland College; A. Peace, Texas Tech Univ / Dept of Mathematics Statistics; A. Gergs, gaiac – Research Inst for Ecosystem Analysis and Assessment / Dept of Environmental Social and Spatial Change; P. Antczak, Univ of Liverpool; L.M. Stevenson, Ecology Evolution and Marine Biology

Understanding the effects of multiple stressors is one of the biggest challenges facing freshwater systems.Although toxicity standards and bioaccumulation models most often consider individual contaminants, most environmental disasters involve complex mixtures of contaminants and other stressors. Because it is impossible to screen for the effects of every possible stressor combination using standard methodology, we are developing a new framework which is not stressor-specific and which will allow for the translation of effects of stressors seen at the subcellular level to larger scale, longer-term impacts at the population and ecosystem level. We employ two quantitative ecological modeling approaches to connect information at different levels of organization. The first uses adverse outcome pathway (AOP) models that link molecular initiating events to key events that are relevant to the physiology and/or behavior of the individual organism. The second uses dynamic energy budget (DEB) models that describe the assimilation of energy by an organism and its allocation to growth, development, maintenance and reproduction at all life stages. Linking the approaches will allow for the screening of thousands of potential stressors on thousands of species, but will require empirical data on a few species to validate models and identify appropriate assays to use for risk assessment methods. In the present study, we used Daphnia magna as a model organism to identify critical data gaps that are needed to link molecular responses to dynamic energy budget processes related to growth, reproduction and reserve dynamics. We exposed individual daphnids to a complex mixture of contaminants found in coal ash, which has recently been the focus of regulatory actions and ecological risk assessments due to environmental spills. Daphnia were were exposed to a gradient of food rations and contaminant concentrations over time. We evaluated gene expression and contaminant body burdens at key life history and molt cycle stages as well as parameters relevant for DEB modeling (weight, length, reproduction, etc) in daphnids exposed to different food and contaminant treatments. These experiments represent a critical first step to bridging the gap between molecular-level responses and larger scale, longer-term impacts at the population and ecosystem level.

312 Linking Adverse Outcome Pathway Analyses to Dynamic Energy Budgets: A Case Study with Endocrine Disruptors and Fish

E.B. Muller, Univ of California, Santa Barbara / Marine Science Inst; K. Lika, Univ of Crete; C.A. Murphy, Michigan State Univ / Fisheries and Wildlife; D.E. Nacci, USEPA / Atlantic Ecology Division; R.M. Nisbet, UCSB / Ecology Evolution and Marine Biology; C.H. Remien, Univ of Idaho / Dept of Mathematics; I.R. Schultz, Pacific Northwest Laboratories / Marine Science Laboratory; K.H. Watanabe, Arizona State Univ West Campus / School of Mathematical and Natural Sciences

Quantitative Adverse Outcome Pathway (qAOP) analyses and Dynamic Energy Budget (DEB) models have complementary strengths. Whereas qAOPs include detail about molecular toxicity mechanisms, DEB models provide quantitative means to project toxic effects observed at the organismal level to impacts expected at the level of populations and beyond. Our overarching goal is to integrate both approaches to improve the predictive power of ecological risk assessment. In this presentation, we show how qAOPs can be embedded within the standard DEB modeling framework. Our examples focus on endocrine disruptors of the reproductive cycle in fishes, notably fathead minnow and various species of salmonids. In a DEB framework, toxicant exposure leads to changes in one or more of the rates at which organisms acquire resources and expend the energy and nutrients therein for maintenance, growth, development and reproduction. Standard DEB considers the workings of hormonal and other forms of regulation in a healthy animal to yield homeostasis, during which the allocation of energy and nutrients to the various budgets are simple functions of animal size and reserve content. In particular, barring severe stress conditions, the partitioning of resources to somatic functions on the one hand and to those supporting reproduction and development on the other is quite simple: the ratio of the two remains constant throughout ontogeny. However, this rule of resource partitioning is too crude for our purposes, as it cannot account for temporal patterns in gonad development during the reproductive cycle of fishes. Moreover, by having control mechanisms implied, standard DEB cannot directly deal with process disturbances due to the toxicant action of endocrine disruptors. Therefore, we have refined DEB theory to include feedback of developmental and reproductive parameters, such as egg mass and liver vitellogenin content, to the allocation of resources to somatic, developmental and/or reproductive processes. This feedback is mediated through hormonal control mechanisms and, thereby, serves as a gateway for linking qAOPs of the impact of endocrine disruptors to DEB.

313 New and emerging statistical machine learning methods for multi-omics data: toward quantitative, molecular ecotoxicology

J.B. Brown, Lawrence Berkeley National Laboratory / Molecular Ecosystems Biology

Epigenetic and metabolomic information in multiple species responding to matched chemical stimulus has the potential to reveal the evolutionary trajectories of adaptive and eco-responsive regulatory networks in metazoans. To date, in both toxicology and pharmacology, and indeed all areas of exposure biology, model organisms have been used as “surrogates” for target species -- if they respond badly we assume the human or ecological response will be qualitatively similar. This does not always appear to be the case – around 20% of presumed carcinogens show no epidemiological evidence of carcinogenicity. We need quantitative models for ecological and human fitness. To bring about the era of quantitative model systems, we require massive collections of well-designed multi-modal omics studies, and computational methods that are able to seamlessly handle heterogeneity in enormously high-dimensional data, even when we have no hint as to the presence or structure of homogeneous processes a priori. The Consortium for Environmental Omics and Toxicology (CEOT) is in the process of taking the first steps toward a phylogenomically informed, quantitative exposure biology, and this progress is rapidly driving new advances in biostatistical machine learning. In this talk, I will discuss new procedures for feature selection and discovery that we are constructing for use in CEOT, the biological insights they have yielded, and their implications for the future of ecotoxicology. I will discuss the

evolutionary trajectories of environmentally responsive genes, the role of the microbiome in mediating the effects of chemical exposures on host fitness, and outline a conceptual framework by which to design and learn from ecotoxicological exposures.

314 Can standard toxicity tests be used to support population level risk assessments for fish

K. Flynn, R.D. Johnson, M. Etterson, USEPA / ORD NHEERL Mid-Continent Ecology Division

Under the Federal Insecticide Fungicide Rodenticide Act (FIFRA), standard toxicity tests are required for fish. Although these studies are focused on individual level effects, they may be used as input parameters to population models in assessing impacts to survival and fecundity. Population modeling in fish is complicated because they exhibit indeterminate growth and other vital rates such as fecundity and survival depend upon size. Because of this, growth estimates are critical for accurate modeling. For assessing mortality from acute exposures, toxicity studies are conducted with standard species (rainbow trout, bluegill) to estimate 96-hour median lethal concentrations (LC50s). For chronic effects, a 30d Early Life Stage (ELS) test is conducted, typically with fathead minnow, in order to identify growth-based no effect levels. In limited cases, full lifecycle test data may be available, to provide information on reproductive effects; however, variability in the fecundity endpoint in some lifecycle tests may be quite large, making interpretation of test results difficult. As an alternative, the Medaka Extended One Generation Reproduction Test (MEOGRT), may offer more power and more consistent estimates of pesticide effects on fecundity. We describe a series of experiments designed to evaluate the ability of standard toxicity tests to adequately provide information on growth, survival and fecundity of medaka (Oryzias latipes) and fathead minnow (Pimephales promelas). We found a strong dependence of fecundity on size, where reductions in fecundity could be induced either through limited ration or chemical stress. Further, medaka exposed to limited ration and chemical stress appeared to allocate differentially to reproduction depending on the amount of energy the animals had available for reproduction. Our results strongly suggest that the recent move towards dynamic energy budget models could provide a unifying underpinning for modeling population-level outcomes from standard FIFRA toxicity tests. However, successful implementation of the approach may require modification of test designs.

315 Quantitative Methods for Linking Adverse Outcome Pathways and Population Models

K. von Stackelberg, NEK Associates LTD / Dept of Environmental Health; S. Graham, Western Washington Univ / Inst of Environmental Toxicology; J.D. Stark, Washington State Univ / Dept of Entomology; W.G. Landis, Western Washington Univ / Inst of Environmental Toxicology

In a complex and changing environment (e.g., in the face of climate change) and with an increasing emphasis on sustainability of coupled human-natural systems, reductionist approaches to environmental management that fail to consider interactions, multiple stressors, and spatial and temporal characteristics of exposures and populations no longer suffice. Chemical risks and effects research has traditionally focused on adverse biological effects of chemical exposure to individuals. A more comprehensive assessment of ecological risk is needed to link chemical effects on individuals to those at increasing levels of biological complexity and to evaluate the spatial and temporal context in which chemical exposures occur. An integrated understanding of species activities (e.g., migration), physical stressors (e.g., habitat, climate, etc.) and biological factors (e.g., trophic interactions) is required to link individual-level exposures to population-, community- and ecosystem-level consequences. Most adverse outcome pathways (AOPs) in the literature are qualitative rather than quantitative – here we demonstrate how existing data and models can be integrated through a Bayesian Relative Risk (BN-RRM) framework that explicitly links molecular initiating events to regulatory outcomes of interest and incorporates the influences of multiple stressors. The flexible approach allows multiple stressors linked to multiple outcomes based on integrating existing data and underlying process models. We provide several examples of ongoing case studies – one for a legacy contaminant with a rich database and existing AOP based on acetylcholinesterase inhibition in fish, and another with a less well understood AOP based on immunotoxic effects of pefluorinated compounds.

Alternative Approaches to Animal Testing for Ecotoxicity Assessments – Part 2

316 Assessment of genotoxicity and carcinogenic cell transformation using a tissue regenerating self-signaling cell line from fish

P. Stahlschmidt-Allner, C. Lerche, B.N. Hölzel, H. Allner, GOBIO GmbH; K. Pfannkuche, Inst for Neurophysiology, Univ of Cologne; B. Allner, GOBIO GmbH

A pluripotent cell line with tissue regenerating capacities has been isolated from the carp brain. The gene expression pattern of this permanent cell culture has been shown to be very similar to embryonic stem cells of vertebrates. A variant derived from this cell line transgenic for H2B-GFP was established (KCB_{GFP}, DSM ACC3285). The stable fluorescence signal related to the nuclear structures of these cells reflects impacts on the integrity of the genome in a self-signaling manner. KCB-GFP cells are perfectly suited for detecting cytogenetic abnormalities, particularly those caused by genotoxic noxa. Especially micronuclei (MNi), the major endpoint in genotoxicity testing, can be visualized and quantified without fixation and nuclear staining. A dose-dependent induction of MNi could be shown for clastogens as well as for aneugens. Cytotoxic exposure concentrations can be identified by apoptotic / necrotic nuclear patterns such as pyknotic or fragmented nuclei. In contrast to mammalian cell lines used in in vitro toxicology, KCB cells are still susceptible to carcinogenic transformation, since they are not immortalized or tumor derived. Changes in the nuclear fluorescence pattern can be monitored in post-exposure follow up-, or continuous exposure cultures. Preliminary results indicate that transformation to cancer cells – in terms of uncontrolled proliferation and/or alterations of nuclear patterns – may be investigated in the same experiment as MNi evaluation. Preliminary results of implantation experiments have shown that KCB-GFP cells integrate into various tissues in most cyprinid species without teratome formation. The application of molecular markers from cancer research, tumor diagnostic and stem cell biology would aid in the recognition of adverse outcome pathways. Transplantation of cells potentially transformed due to exposure to carcinogens would enable evaluation of teratogenicity in vivo, avoiding systemic exposure of animals. Thus, decisions regarding higher tier testing could be supported by a broader spectrum of in vitro endpoints, and animal testing could be limited to the essential minimum according to the 3R principles.

317 The Chemical Exposure Toxicity Space graphical display of exposure times, aqueous concentrations, and chemical activities for aquatic toxicity tests

A. Celsie, Queens Univ; D. Mackay, Trent Univ / Chemistry; J.M. Parnis, Dept of Chemistry; L.S. McCarty, L.S. McCarty Scientific Research & Consulting; J.A. Arnot, ARC Arnot Research & Consulting Inc.; D.E. Powell, Dow Corning Corporation / Environmental Sciences

We introduce a novel graphical Chemical Exposure Toxicity Space (CETS) diagram designed to illustrate plausible test conditions for aquatic toxicity tests for fish. The CETS plot is designed to aid selection of chemical concentrations in water, test durations, and for interpreting test results. The CETS plot depicts the solution to the differential equation describing uptake kinetics of a chemical by a one-compartment fish under dynamic conditions, relating aqueous chemical concentration to time and ultimately to the onset of toxicity. The onset of toxicity is determined either by an assumed lethal concentration (LC50) or by the incipient lethal aqueous concentration deduced from a bioconcentration factor and an estimated critical body residue. The plot includes the maximum test duration which is dependent on the test organism and conditions selected. The exposure time is converted to a dimensionless time quantity, Φ calculated as (1-exp(-(k_2)t). LC50 is plotted against Φ and the resulting curve shows the toxic endpoint at a given water concentration or activity for a given Φ. The solubility and maximum test duration parameters become boundaries of the feasible toxicity test conditions. The CETS plots demonstrate differences in toxicity between chemicals as well as how various factors including hydrophobicity and aqueous solubility of the chemical affect the plausible test duration. Hydrophobic chemicals are shown to have a small range of plausible test conditions. For some chemicals such as super-hydrophobic siloxanes no feasible test zone exists. The plots also suggest that a valuable bioassay approach is to establish a constant exposure concentration in advance using passive dosing techniques and measure time-to-death as was done by van der Heijden et al. (2015).

318 Morphological and metabolic characterization of the rainbow trout intestine grown in vitro with a specific focus on the pyloric

L.M. Langan, A.N. Jha, Plymouth Univ / Biological Sciences; S.F. Owen, AstraZeneca / Safety Health Environment; S.K. Jackson, W.M. Purcell, Plymouth Univ / School of Biomedical Biological Sciences

The present study focuses on the isolation of cells from the pyloric region of the rainbow trout Oncorhynchus mykiss and their successful culture and growth using a modified enzymatic dissociation protocol and a larger cohort of fish (>25cm) than conventionally used in research. While not presented herein, this protocol with small modifications can also be successfully applied to other regions of the intestine in addition to smaller size categories. Epithelial cells extracted using this gentle method do not require external substratum to attach to tissue culture treated plates/flasks, although minimal improvement is observed with coatings of fibronectin or collagen. Cell viability was consistently in the range of 90-97% using the outlined procedure with cells visibly attaching within 3-4 hours of extraction. Epithelial colonies were visible after 48 H post first half media exchange and retain their island like morphology for approximately 5 days before gradually spreading into a flattened formation. Mucolytic cells indicative of active transport pathways stained positively on the extracted and attached cells for neutral (strongly) as would be expected in this size category. Immunohistochemical staining for tight junction proteins such as ZO-1 and E-cadherin revealed extremely similar staining profiles between the native tissue and the in vitro grown cells. Attachment success in transwell insert cups is variable between manufacturers with the conventional cup providing the most consistent adherence and growth. Transepithelial resistance measurements (TEER) indicated a comparable resistance in transwell inserts cups to those reported in the literature for fish intestine, however does not come close to what is reported in the mammalian TEER literature. Interestingly, TEM analysis of cells cultured on inserts show comparable profiles to mammalian models and modifications to this system may be required to improve comparability to native tissue. Finally, metabolic activity was assessed through the EROD assay for CYP1A activity and ECOD assay for CYP3A using appropriate relevant control inducers and inhibitors such as BNF, αNF and Rifamapicin. The maintenance and the propagation of the gut model over an 8 week period provide for in vitro fish studies a preliminary step in the minimization of animals necessary for short term dietary exposure studies in addition to a more comprehensive system to investigate co-culture response with different organs.

319 High Throughput Screening Techniques Once Put on the Shelf, Now Ready for Practicality

S. Hoeppner, Life Science Forensics/Paracel Laboratories

One of the biggest challenges when cleaning up sites has always been the question: “will this actually hurt the animals living here?” Testing is performed according to regulatory criteria, and sometimes at great cost to the end user in instances where the source material is unknown. Performing traditional testing can sometimes be a guessing game and a gamble, if the offending analytes are not readily identifiable. In vitro testing has been employed for decades but has not often been utilized in the past during reclamation and remediation activities. This study’s purpose was to bring some of these in vitro tests out of obscurity and evaluate the potential for synergistic and additive effects to organisms (in a soil matrix) using the same methodologies as the USEPA’s ToxCast program, employing high throughput screening in vitro assays. The main criticism in the past of this type of toxicological testing has traditionally been that it is being performed on discrete analytes, not complex mixtures as they are found in the natural environment, and that it has involved live organism studies that are expensive, take a lot of time, and can only focus on acute toxicity. Now, a new study has been performed and validated to employ a suite of screening protocols employing four essential potential pathways that includes (a) the Tui protein neurotoxicity assay, (b) the Muta-Chromoplate for mutagenicity, (c) OxiSelect™ Oxidative DNA Damage kit and (d) MC7F test performed on human mammary gland tissue from a metastatic cancer site, for endocrine disruptors. This is a peer-reviewed, legally defensible tool for risk assessments and are particularly useful in situations such as oil sands reclamation sites, spill events, and forensic investigations and sites involved with unknown complex mixtures. This method is a cost effective tool that can add a lot more value than simple discrete testing of analytical parameters or traditional toxicology techniques.

320 Behavioural toxicity assessment of silver ions and nanoparticles on zebrafish using a locomotion profiling approach

G. Asmonaite, S. Boyer, Swetox; K. Bresolin de Souza, B. Wassmur, Univ of Gothenburg / Dept of Biological and Environmental Sciences; E.J. Sturve, Univ of Gothenburg

Zebrafish (Danio rerio) is not only a widely used species in the Fish Embryo Toxicity (FET) test but also an emerging model in behavioural ecotoxicology. By using automatic behaviour tracking technology,locomotion of developing zebrafish (ZF) larvae can be accurately recorded and potentially used in anecotoxicological context to detect toxicant-induced behavioural alterations. In this study, we explored if and how quantitative locomotion data can be used for sub-lethal toxicity testing within the FET frame-work. We exposed ZF embryos to silver ions and nanoparticles, which previously have been reported to cause neurodevelopmental toxicity and behavioural retardation in early-life stages of ZF. Exposure to a broad range of silver (Ag+ and AgNPs) concentrations was conducted, and developmental toxicity was assessed using FET criteria. For behavioural toxicity assessment, locomotion of exposed ZF eleutheroembryos (120 hpf) was quantified according to a customised behavioural assay in an automatic video tracking system. A set of repeated episodes of dark/light stimulation were used to artificially stress ZF and evoke photo-motor responses, which were consequently utilized for locomotion profiling. Our locomotion-based behaviour profiling approach consisted of (1) dose-response ranking for multiple and single locomotion variables; (2) quantitative assessment of locomotion structure; and (3) analysis of ZF responsiveness to darkness stimulation. We documented that both silver forms caused adverse effects on development and inhibited hatchability and, most importantly, altered locomotion. High Ag+and AgNPs exposures significantly suppressed locomotion and a clear shift in locomotion towards inactivity was reported. Additionally, we noted that low, environmentally relevant Ag+concentrations may cause subordinate locomotive changes (hyperactivity) in developing fish. Overall, it was concluded that our locomotion-based behaviour-testing scheme can be used jointly with FET and can provide endpoints for sub-lethal toxicity. When combined with multivariate data analysis, this approach facilitated new insights for handling and analysis of data generated by automatized behavioural tracking systems.

321 Capability and capacity of zebrafish embryos (Danio rerio) to biotransform polar chemicals such as clofibric acid, metoprolole and carbamazepine

E.K. Küster, Helmholtz Centre for Environmental Research UFZ / Bioanalytical Ecotoxicology; B. Seiwert, K. Dürkop, Helmholtz Centre for Environmental Research UFZ / Dept of Analytical Chemistry; N. Haase, Helmholtz Centre for Environmental Research UFZ / Dept of Cell Toxicology; S. Brox, T. Reemtsma, Helmholtz Centre for Environmental Research UFZ / Dept of Analytical Chemistry

The zebrafish embryo is a popular test organism in ecotoxicological studies increasingly used in toxicological and pharmacological research. Beside the known sensitivity of the zebrafish embryos to xenobiotics such as pharmaceuticals not much is known about the internal concentration of parent substances and respective transformation products (TPs). Biotransformation within the embryo would affect the toxicological or pharmacological dose via the change of concentration- time and effect profiles of the compounds (toxicokinetics & toxicodynamics). This study focuses on the biotransformation of the pharmaceutical compounds clofibric acid (lipid lowering clofibrate metabolite), metoprolole (ß-blocker) and carbamazepine (antiepileptic drug) by zebrafish embryos at different life-stages up to 96 hours post fertilization. We established a screening method based on LC-high-resolution mass spectrometry using state-of-the-art data evaluation to support ecotoxicological and pharmacological studies. This approach is capable of analysing a multitude of polar compounds (Brox et al. 2014). In the presented work this approach is used for the analysis of the 3 test compounds and their TPs. Identification of the compounds was based on the exact masses, isotopic pattern and the specific fragmentation. Known and previously unknown phase I, phase II TPs and even a possible transport (phase III reaction) could be observed. One of the detected and identified 18 TPs of clofibric acid is especially interesting as this phase I product to our knowledge has never been reported before in other biological or technical systems (Brox et al. 2016). For metoprolole all TPs reported from human studies were also detected in the zebrafish embryos. In addition, quantitative data of the metoprolole tests suggest that the transformation capacity of the zebrafish embryos is limited as the exposure to a high dose of metoprolole did not increase biotransformation product quantity compared to a parallel low dose of the same substance. The carbamazepine analysis did show a very high transformation of carbamazepine into acridine. This result would point to a possible underestimation of carbamazepine uptake by zebrafish embryos if it would be the only substance analysed. The results of this study outline the high potential and capability of zebrafish embryos to biotransform xenobiotica. The similarities and differences to other toxicological test systems will be discussed.

322 Cardiovascular and neurodevelopmental metrics as sublethal endpoints for the fish embryo toxicity test

J. Krzykwa, Texas Christian Univ; M.K. Sellin Jeffries, Texas Christian Univ / Dept of Biology

The United States requires that whole effluent and chemicals be tested for aquatic toxicity using the fathead minnow larval growth and survival (LGS) test. While the LGS test has been effective for determining acute and chronic aquatic toxicity, a fathead minnow fish embryo toxicity (FET) test has been proposed as a more humane alternative because younger organisms are thought to experience less stress during toxicant exposure. Presently, the FET test protocol does not include endpoints that allow for the prediction of non-lethal adverse outcomes or chronic toxicity, which limits its utility relative to other test types. This study investigated the usefulness of sublethal endpoints related to cardiovascular function and development (e.g., heart rate and pericardial area) and neurodevelopment (e.g., eye development and activity levels) and relative expression levels of genes related to growth and development, as additional FET test metrics. FET tests were run with four model toxicants: 3,4 –dichloroaniline, sodium chloride, cadmium chloride, and a water-accommodated fraction of engine oil. Activity levels were evaluated at 24 hours post fertilization (hpf), while eye size, pericardial area, and heart rate were evaluated at 96hpf. Hatched larvae were sampled at the conclusion of the tests (120hpf) for gene expression analysis. Toxicant-induced alterations in these endpoints suggests that sublethal endpoints related to cardiovascular and neurological function and morphology may be useful for estimating predicting non-lethal adverse effects and chronic toxicity. Future studies aimed at linking alterations in these endpoints to longer term adverse impacts are need to fully describe the predictive power of these metrics in whole effluent and chemical toxicity testing.

323 Zebrafish Metabolomics: a Novel Approach for Characterizing Sub-lethal Responses to Xenobiotics

S.S. Huang, SGS AXYS / Metabolomics; J. Benskin, Stockholm Univ / Environmental Science and Analytical Chemistry; B. Chandramouli, SGS AXYS; H. Butler, SGS AXYS / Metabolomics; C.C. Helbing, Univ of Victoria / Dept of Biochemistry Microbiology; J. Cosgrove, SGS AXYS

The introduction of the European Union's Regulation on Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) has placed an increased demand on the use of animals for toxicity testing. At the same time, sensitive and quantitative protocols for characterizing low-dose effects are needed to meet the requirements of 21st century chemical hazard assessment. The high level of conservation of genomic and functional pathways between fish and mammals makes teleost an effective vertebrate model in toxicological testing. Recently the Organization of Economic Cooperation and Development (OECD) recognized the Zebrafish Embryo Toxicity assay (TG236) as an alternative to adult fish toxicity testing. In the present work, we hypothesized that xenobiotics can produce highly specific biochemical fingerprints in organisms exposed at environmentally relevant concentrations. To test this, we measured the metabolomic perturbations in zebrafish (Danio rerio) embryo/larvae following 24-hour exposure to 13 individual chemicals covering a wide range of contaminant classes. Measured metabolites (208 in total) included amino acids, biogenic amines, fatty acids, bile acids, sugars, and lipids. 96 to 120 hours post-fertilization stage, which falls outside of regulatory frameworks dealing with animal experimentations (ex. EU Directive 2010/63/EU), was identified as the most appropriate developmental stage for detecting xenobiotic-induced metabolomic perturbations. Metabolomic fingerprints were largely chemical- and dose-specific and were reproducible in multiple exposures over a 16-month period; importantly, in the absence of morphological response. Furthermore, chemical-specific responses were detected in the presence of a waste water treatment plant effluent. In addition to improving sensitivity for detecting biological responses to low-level xenobiotic exposures, this approach can provide a powerful means of classifying novel contaminants based on the similarity of the metabolomic response to well-characterized substances, while supplementing functional data generated by OECD TG236 with information on molecular phenotype.

Measuring and Estimating Bioavailability: Linking Exposures to Effects for Improved Ecological Risk Assessment

324 Relating in vitro to in vivo: bioavailability an essential element

J. Hermens, Utrecht Univ / Inst for Risk Assessment Sciences; S. Droge, Utrecht Univ; F. Groothuis, N. Kramer, N. Timmer, Utrecht Univ / Inst for Risk Assessment Sciences

In vitro assays are often applied for unraveling toxicological mechanisms of action. This is major strength of these assays and will also lead to a reduction in animal in vivo testing. Such mechanistic studies are mostly qualitative. To extend the use of these assays to hazard characterization and perform quantitative in vitro to in vivo extrapolations (QIVIVE), the dose in the vitro test should be linked to a dose in a whole animal study. The freely dissolved concentration is one example of a dose metric that may link in vitro (cell medium) to in vivo (blood). In order to be successful, one needs accurate information about the dose in the in vitro test.

Nominal concentrations may be appropriate for "simple compounds", but for more hydrophobic or volatile chemicals, information about the actual dose is needed. Exposure modeling is very useful in identifying these more difficult compounds and can also be applied to estimate the actual bioavailable dose. This presentation will focus on the strengths, but also some of the limitations, of the concept of the freely dissolved concentration. Examples from earlier publications as well as new experimental data for cationic surfactants will be presented to identify advantages and potential limitations in estimation and measuring the actual dose and bioavailability in in vitro studies. New data on the dose of a series of benzalkonium chlorides in a cell assay with a fish gill cell line for example show that deviations of measured concentrations from nominal concentrations in the test medium depend, as expected, on the carbon chain length. However, additional factors that influence these deviations are the exposure time as well as the exposure concentration. Earlier studies have also shown that the technique applied to spike a compound in the medium may affect the outcome of the test. Other dosing systems, based on passive dosing from a sink, may circumvent these confounding factors but such dosing systems are available for only specific types of compounds and it is not feasible to apply those techniques in high throughput screening. Also the hypothesis that the freely dissolved concentration represents the bioavailable and active form is not always correct, in particular in non-equilibrium situations, and this will be illustrated with a few examples. More general strengths, limitations and research recommendations of in vitro-in vivo extrapolations will be discussed.

325 Demonstrating the value of applying generic modeling tools for simulating the behavior of organic chemicals in in vitro test systems

J.M. Armitage, Univ of Toronto – Scarborough / Physical and Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting / Dept of Physical Environmental Science, Dept of Pharmacology and Toxicology

A large number of in vitro assays and toxicity tests have been developed over the past few decades to complement in vivo assays and tests and to increase our knowledge about potential modes of toxic action. In vitro toxicity testing has been gaining particular prominence over the past decade due to the increased desire to reduce animal testing and the development of large-scale in vitro testing programs (e.g., ToxCast™). In many cases, dose-response relationships in the test are based on nominal (total) concentrations and there is no confirmation of the actual dose corresponding to the response (or lack of response). Concerns over the use of nominal (total) concentrations rather than measured and/or freely-dissolved concentrations in in vitrotesting have been discussed in the literature. Nevertheless, nominal concentrations are frequently the only metrics reported for in vitro tests, especially for high-throughput screening (HTS) applications where conducting measurements is technically challenging, if not impossible. Various publications have presented modeling approaches for simulating the behavior of organic chemicals in in vitro test systems but in general their use is not widespread. The main objective of this presentation is to demonstrate the value of applying generic modeling tools when designing and interpreting in vitro toxicity testing. Two modeling approaches are discussed, i) equilibrium partitioning and ii) toxicokinetic (dynamic), with model output focused on differences between nominal (total) concentrations and metrics more directly relevant for toxicity (freely-dissolved concentrations and cellular concentrations). Using realistic examples, the model applications illustrate how differences between nominal (total) concentrations and freely-dissolved concentrations are influenced by physical-chemical properties (e.g., hydrophobicity) and test conditions (e.g., cell-free vs. cell-based, presence/absence of serum). The modeling tools can be used i) prior to initiating studies to identify testing scenarios that are more or less problematic and ii) to help interpret in vitro toxicity data reported only using nominal (total) concentrations.

326 Transferring in vivo exposure into in vitro assays using silicone to assess the endocrine activity of POPs accumulated in human breast implants

D. Gilbert, Norwegian Geotechnical Inst / Environmental Technology; P. Mayer, Technical Univ of Denmark / Dept of Environmental Engineering; M. Pedersen, A. Vinggaard, DTU Technical Univ of Denmark / National Food Inst

Persistent organic pollutants (POPs) accumulated in human tissues may pose a risk for human health by interfering with the endocrine system. A new partitioning-controlled dosing approach from silicone was applied in the in vitro H295R steroidogenesis assay to test whether POPs in a mixture composition and at concentrations as found in human silicone implants can interfere with steroidogenesis. Silicone served here as donor of a mixture of POPs while it also acted as sorptive sink for lipophilic hormones produced by the cells. The new dosing method from silicone was compared to conventional solvent-dosing. A mixture of PCBs, PBDEs, HCB and DDT as identified in human silicone breast implants was tested by spiking it into 24-well plate adopted silicone disks. When dosed from silicone, the chemical mixture increased the production of progestagens and androgens in the in vitro assay. However, no changes were observed when co-solvent dosing was applied. Responses were observed in the femtomolar freely dissolved concentration range, which is right in the range of circulating POP levels in humans. The new silicone-based dosing approach allowed (1) linking in vivo exposure levels to in vitro exposure concentrations and (2) linking actual human POP levels to an altered hormone production in a human adrenal cell line in vitro.

327 Free and cellular effect concentrations in high-throughput cell-based bioassays: measurement and models

B. Escher, Helmholtz Centre for Environmental Research GmbH – UFZ / Cell Toxicology; F. Fischer, Helmholtz Centre for Environmental Research UFZ; C. Gaus, The Univ of Queensland / ENTOX; L. Henneberger, Helmholtz Centre for Environmental Research UFZ; J. Hermens, Utrecht Univ / Inst for Risk Assessment Sciences; M.S. Denison, Univ of California / Dept of Environmental Toxicology

In vitro cell-based bioassays could be cost-efficient and ethical alternatives to animal testing in chemical risk assessment. Reasons that prevent in vitro assays from replacing in-vivo tests include difficulties associated with evaluating chemical bioavailability in these systems and ensuring controlled and constant concentrations of chemicals in the cells. In cell assays, bioavailability and biologically effective dose are generally not known and are difficult to quantify due to the small volumes used in these microtiter plate assays. Especially hydrophobic organic chemicals may appear less potent than they really are because their bioavailability is reduced by sorption to protein and lipid components of the growth medium and vials. The cellular concentrations provide a better dose metric for in vitro bioassays and are the point of departure for in vitro to in vivo extrapolations because the effective target concentrations are in principle the same across diverse cell types, and independent whether tested in vivo or in vitro. Here we present a mass balance modeling approach for the assessment of internal exposure in cell-based bioassays that relies on experimentally determined partition coefficients between cells and medium, as well as medium components and water. The partition coefficients in these colloid suspensions were measured with a polymer-desorption method using silicone as third phase. Further model input parameters include the experimentally determined lipid and protein contents of CAFLUX cells and medium. We applied the model to polychlorinated dibenzodioxins in the CAFLUX (Chemically Activated Fluorescent Expression) assay. The CAFLUX uses recombinant mouse hepatoma (H4IIe) cells containing a stably transfected AhR-inducible green florescent protein reporter plasmid. Induction of green fluorescence in these cells occurs in a chemical-, receptor-, dose- and time-specific manner and is a direct measure of the binding/activation of the AhR by chemicals added to the cells. The effect concentrations in this assay were strongly dependent on the medium composition but the modelled cellular concentrations were constant and independent on the medium. After successful experimental validation, the mass balance model was then expanded to ionisable organic chemicals and applied to effect data from the USEPA ToxCast database on the example of GeneBLAzer bioassays, which are reporter gene assays for various hormone receptors and transcription factors.

328 The Aggregate Exposure Pathway (AEP): A conceptual framework for advancing exposure science research and transforming risk assessment

C. Tan, USEPA / National Exposure Research Laboratory; S. Edwards, USEPA / Integrated Systems Toxicology Division; J. Teeguarden, Pacific Northwest Naitonal Lab; P. Egeghy, USEPA / Office of Research and Development; J. Leonard, Oak Ridge Inst for Science Education at USEPA

Recent advances in emerging technologies have enabled new streams of exposure and toxicity data to be generated at higher volumes and speed. These new data offer opportunities to better characterize the intricate interactions among chemical and non-chemical stressors, the environment, and biology in the real world. For example, untargeted analysis of environmental samples can be used to identify mixtures of chemicals commonly found in the same media; and high throughput in vitro assays can be used to identify multiple stressors that are able to interact with the same molecular target to perturb a common biological pathway. However, these opportunities to elucidate the complex relationship between exposures to multiple stressors and multiple human health and ecosystem outcomes can only be realized through more efficient organization of data and knowledge emerging from new technologies and approaches. In toxicological science, the adverse outcome pathway (AOP) framework was conceptualized to organize knowledge of biologically plausible and empirically supported links between perturbations on a biological system at the molecular level and the resulting adverse outcome(s). In exposure science, a similar framework, the aggregate exposure pathway (AEP), is proposed to organize exposure data and predictions. We envision an AEP extending from a stressor's introduction at the source(s), to its fate and transport through environmental media, patterns of external exposure, biokinetic processes, and finally ending at its target site exposure(s). The AEP framework deliberately includes internal dosimetry to allow for integration among AEP, AOP, and dose-response data. In this presentation, the AEP concept will be introduced along with its potential applications, such as identifying primary exposure sources, informing toxicity testing strategies, and improving risk assessment. Disclaimer: Although this work was reviewed by EPA and approved for publication, it may not necessarily reflect official Agency policy.

329 Addressing the challenge of Exposure Science in the 21st Century: A strategy for developing more robust exposure assessment tools

T. Gouin, Unilever / Safety and Environmental Assurance Centre; I. Sorrell, Unilever RD Colworth; B. Nicol, Unilever RD Colworth / Safety and Environmental Assurance Centre SEAC; O. Price, Unilever / Safety and Environmental Assurance Centre SEAC; C. Davies, N. Aptula, C. Barratt, Unilever RD Colworth

Risk assessment is generally divided between human health risk assessment (HRA) and environmental risk assessment (ERA), whereby scientific research, policy decisions, and regulatory instruments for HRA and ERA are addressed by individuals with different sets of expertise and knowledge, oftentimes at different institutes, research organizations, and government agencies. Integration of HRA and ERA, however, could provide substantial benefits, particularly by providing a more efficient framework that addresses emerging challenges and issues that have the potential to impact both the environment and human society. For instance, a continuing challenge in chemical risk assessment, associated with the wide use of chemicals in our modern society, regards the lack of relatively quick, inexpensive, and reliable tools that integrate the various aspects of exposure relative to the intrinsic toxicity that an individual chemical may possess. Recently, a framework for enhancing our mechanistic understanding of the processes that influence exposure to chemicals by individuals and environmental systems, referred to as Aggregate Exposure Pathways (AEPs), has been proposed, and which promises to provide a complementary framework to the development of Adverse Outcome Pathways (AOPs). An important difference between an AEP and an AOP, however, is that while AOPs are non-chemical specific, addressing the specific properties of chemicals is key to quantifying exposure, and therefore AEPs must include chemical-specific information. Here we present the development of various tools aimed at better quantifying exposure for use in risk assessment, and which utilizes cross-domain expertise, from both HRA and ERA, to develop an AEP aligned to the use of chemicals used in personal care products. A major emphasis of the strategy described herein targets the development of tools that both reduce and accurately quantify uncertainty associated with assessing consumer exposure to chemical ingredients used in personal care products.

330 Evaluating the Inhalation Bioavailability of Hydrophobic Organic Contaminants in Dust using Isotope Dilution Method

J. Wang, Univ of California Riverside; A.R. Taylor, J. Gan, Univ of California Riverside / Dept of Environmental Science

In current risk assessment, 100% bioavailability is often assumed when evaluating human exposure to hydrophobic organic contaminants (HOCs) in contaminated land. While this has advantage of being precautionary, it may significantly overestimate the amount of pollutant absorbed by biota, including humans. Therefore, understanding the bioavailability of HOCs is of great significance for adequate risk evaluations. One of the principal sources of human exposure to HOCs is direct inhalation with dust in the air, however, few research has been proposed to investigate the bioavailability of HOCs in dust. In this study, we extended the isotopic dilution theory to the use of stable isotope labeled reference compounds to determine the bioavailability of HOCs in dust. A large set of HOCs (DDTs, PAHs, PCBs, PBDEs) will be investigated using two fluids (Gamble solution and simulated epithelial lung fluid) on different types of dust. Tenax-aided desorption experiment will be used to validate the performance of isotope dilution method, the same dust samples will be subjected to sequential desorption in which Tenax beads are used to recover the desorbed HOCs to facilitate measurement. And also, cellular uptake of HOCs form dust in Human A549 lung epithelial cells will be considered. This novel method is expected to be especially useful for bioavailability measurement and human risk assessment.

331 Improving Mechanistic Models for PCB Bioaccumulation in Fish Using Passive Sampling of Freely Dissolved Concentrations

H. Fadaei Khoei, Univ of Maryland Baltimore County / Civil and Environmental Engineering; A. Watson, SC Dept of Natural Resources / Columbus Center; A. Place, Inst of Marine and Environmental Technology, UMCES / Columbus Center; J.P. Connolly, Anchor QEA, LLC; U. Ghosh, Univ of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering

While empirical results are available in the literature on bioavailability reductions after amendment of PCB-contaminated sediment with a strong sorbent like activated carbon (AC) or biochar, there is a lack of quantitative understanding on how reductions in sediment porewater concentrations and reduced uptake at the base of the food chain impact accumulation in fish. In addition, developing more accurate partitioning models that can predict uptake by pelagic organisms, i.e. algae and zooplankton that serve as food to fish, are key to understanding PCB uptake in fish. With a validated model for bioaccumulation, timely assessments of a remedy progress upon engineering intervention like AC amendment can be performed. This study will present the first robust modeling framework that is able to predict uptake in fish after in-situ remediation that alters bioavailability of pollutants in sediments. Passive sampling measurements are linked to PCB uptake by pelagic and benthic feeding fish, as well as PCB accumulation in algae and zooplankton to provide refined models that will lead to more precise predictions of uptake in the aquatic food chain. PCB exposure to fish was conducted using mummichog (Fundulus heteroclitius) and cory catfish (Corydoras aeneus) in laboratory experiments. Porewater, surface water, and fish tissue concentrations were measured in tanks containing either clean sand, PCB-impacted sediment, or PCB-impacted sediment treated in the field with AC (2.5% d.w.). Benthic blackworms (Lumbriculus variegatus) were exposed to untreated or treated sediments prior to the experiment and were used as food for the fish in the untreated and treated tanks, respectively. AC treatment resulted in 97% reduction in total PCB concentration in porewater and 91% reduction in overlying water. After 90 days of exposure, both fish showed reduced uptake of PCBs in tanks with sediment treated with AC (34 and 74% for cory catfish and mummichog, respectively). Overall, the kinetic model was reasonably accurate in predicting PCB residue in mummichog and led to more accurate predictions than the equilibrium model. For cory catfish the kinetic model over-predicted uptake for most of the congeners and did not improve significantly over the predictions made by the equilibrium model. Ongoing work is focused on the PCB exposure studies using algae and zooplankton and measuring freely dissolved concentration with passive samplers to derive more accurate BCF-K_{OW} correlations.

Advancing Sustainability in SETAC: Implementing the Berlin Declaration

332 Brundtland, The Berlin Declaration, and Beyond

R.J. McCormick, Bureau of Land Management

As we approach the fourth anniversary of the development of SETAC's Berlin Declaration, it is worth reflecting on whence we came, and what the future might hold for us as a society. I will attempt to trace the sustainability history of human society, from pre-history to post-Brundtland, with a focus on the impending, context-enforced, global sustainability paradigm, and thus some implications for the future of our daily resilience endeavours. Humans often carry with them biases of how soil and water and weather organize patterns on a landscape based on where they most recently came from. For example, even after decades of trying to grow olives in Virginia (USA) and failing, social learning did not occur as the immigrants insisted on imposing a world view gained in one region (Europe) on a new world landscape. Open and active learning is a constant challenge that local and global societies will face as the climate continues to change. Unless we approach these novel situations absent the pre-conceived notions and mental filters of how we think our social – ecological systems work, there are likely to be devastating failures. In tying together the principles of the Declaration with resilience and sustainability science, I will present the ecological concepts behind establishing a beachhead on a new landscape (or under a novel climatic regime) that are key to forming a resilient community, rather than just one that is trying to be less unsustainable. Even with some knowledge of the stock and flow of ecosystem services in a place at a time, if your social and cultural knowledge does not know how to exploit those services, ecesis will not occur, and your society will not persist. As noted in early drafts of the Berlin Declaration, dogmatic adherence to social and cultural memes can have unexpected results. The principles in the document offer individuals and society a resilient path to changing mental models and living more sustainably.

333 Sustainability in the face of the Industrialization of Social-Ecological Systems

W. Hauter, Food and Water Watch

The industrialization of social-ecological systems (SES) has allowed for efficiency and in many cases, increased access to basic needs. However, as with everything, do we understand the tradeoffs? Safety, security and accessibility are needed whether we think about food or about energy. Wenonah Hauter, Founder and Director of Food and Water Watch and author of "Foodopoly" and "Frackopoly" will speak on sustainability with a focus on the US food and energy industrialized systems. Wenonah's schedule is such that she is available on Nov 7, 2016 so if it's possible to schedule this session that day, this would work for her as a speaker.

334 Challenges of Sustainability in the Everglades Ecosystem

L. Gunderson, Emory Univ / Dept of Environmental Sciences

Climate change will challenge the adaptive capacity of the Florida Everglades social-ecological system. The Everglades is a subtropical wetland that has been drastically modified over the past century to achieve multiple societal goals: 1) water supply for millions of people, 2) a multi-billion dollar agriculture enterprise, and 3) an international reserve for conservation of biodiversity. Water supply and flood control have largely been successful and, over time, have adapted to seen and unforeseen hydrologic variation. These ecosystem services are sustained by a relatively stable climate. Current agricultural practices are likely unsustainable, as the organic soils that accumulated over thousands of years have been largely oxidized over the past century. For the past two decades, millions of dollars have been spent to recover degraded ecosystem attributes whose resilience was eroded by management efforts. Even with large fiscal resources, recent assessments suggest that the current system is quite limited in it's capacity to experiment and adapt to a changing climate.

335 The Role of Environmental Education in Psychosocial Resilience

C. Stahl, USEPA Region III; B. Duncan, USEPA Region X

In statutory and regulatory contexts, psychosocial effects are not discussed or considered, and yet, when people are asked, these effects are often the most important problem raised. We think of resilience as the capability to "bounce back" when confronted with pollution and disruption. What does resilience mean when applied to communities stressed by anthropogenic activities? One aspect that is oft ignored is psychosocial resilience. What does resilience mean when unwilling stakeholders need to be engaged if the problem is to be addressed? In an experiment conducted during a 2016 global online environmental education course offered by Cornell University, we crowdsourced the 2000+ student participants to ask their ideas about whether and how environmental education could have a role in nurturing psychosocial resilience. Although we initiated the discussion using the mountaintop removal coal mining (MTM) operations as an example of anthropogenic activities having potential psychosocial effects in communities, we asked the global online students to think more broadly to other kinds of activities with similar psychosocial effects. We learned that a current commonly-held conceptual model for environmental education was ill-equipped to help stakeholders and communities address psychosocial resilience and so, an alternative is proposed.

336 Innovations in Resilience – Florida's New Future Legacy

S. Bronson, Florida Earth Foundation

Florida is one of the most diverse states in the US with epic population growth, diminishing natural resources and a conservative political climate. However, there are several dynamic projects and programs that will lead the nation and beyond in innovative efforts to not only retrofit the state for resilience, but create new examples of sustainable systems for both the built and natural environments. Three examples will be discussed of Babcock Ranch, The C-51 project and the Dispersed Water Program that intersect cities and ecological systems in ways that create new paradigms of sustainability.

337 A Required Paradigm Shift to Inform Sustainability

L. Kapustka, LK Consultancy

Increasing numbers of humans and rising expectations for billions to realize improvements in their quality of life are threatening to undermine aspirations for sustainability. These pressures are mounting in ways that appear likely to disrupt stability and predictability of social-ecological systems. For more than two decades, we have known that the traditional approaches of reductionist science are insufficient in terms of understanding and managing outcomes of either community wellbeing or ecological processes that deliver ecosystem services. Reductionist approaches are embedded in a collective mentality of western societies and expressed in laws and policies that attempt to reduce the complexity of societies and ecosystems to linear cause-effect chains. Sustainability Science, which emerged from Systems Ecology and calls for a Post-modern Science, is based on the recognition that societies and ecologies are fundamentally non-linear in their behaviour due in large part to multiple nested feedback loops (some reinforcing or positive; some dampening or negative) that operate on different spatial and temporal scales. There is also the recognition that the welfare of societies is ultimately dependent on reasonably constant flows of ecological goods and services. Despite a general acknowledgement of these aspects of the social-ecological systems, our political system and our science remain anchored in short-term, dramatic responses and demonstrable causal chains to explain effects. Resilience of social-ecological systems is defined by biodiversity/redundancy, connectivity, and slow variables and feedbacks operating in complex adaptive systems. From the societal perspective, managing resilience requires learning and experimentation, broad stakeholder participation, and polycentric governance systems. Rather than a clean causal chain, these systems tend to respond along a number of trajectories (i.e., one-to-many pathways). Moreover, the determinative pressures are more likely to be the slow variables that more often than not are ignored in reductionist approaches as being insignificant. These concepts will be explored by a holistic examination of the capacity of agro-ecosystems to provide sustained flows of multiple ecosystem services. Attention will be drawn to the short-comings of the dominant reductionist approach that focuses primarily on short-term yield.

Lab Data, Hazard, Risk and Regulation of Endocrine Active Chemicals – So What? The Big Picture from Little Pieces

338 Lessons from history – how good are we at predicting the environmental risks of endocrine disrupters?

P. Matthiessen, Unaffiliated

A recent SETAC Pellston Workshop™ 'Environmental hazard and risk assessment approaches for endocrine-active substances – EHRA' came to the unanimous conclusion that providing environmental exposure, effects on relevant taxa/life-stages, delayed effects and dose/concentration-response relationships are adequately characterized, then conducting environmental risk assessment of endocrine disrupting substances (EDSs) is scientifically sound. This was a victory for science and common sense, and united both sides of an increasingly sterile debate about hazard vs risk assessment. However, before we get completely carried away with our own good judgement, it is worth looking at our success rate in predicting and avoiding environmental impacts from EDSs. Some notorious examples which caused and are still causing serious damage, including tributyltin, DDT and some PCBs, entered the market long before environmental evaluations became routine, but we can still ask if modern risk assessment procedures would have detected them (yes and no). Others, such as ethynylestradiol and diclofenac, caused serious impacts which should have been predicted but were not. Yet others, such as the azole fungicides, have been identified as EDSs and may become the subject of bans in certain regions, but there is no field evidence that they are causing harm. The paper will survey this mixed bag of examples and attempt to draw one or two lessons. One conclusion is that, although environmental risk assessment is nowadays a reasonably robust procedure (even for EDSs!), it must go hand in hand with good quality environmental monitoring. This is because no system of chemicals regulation can ever be made perfect without preventing all chemicals from entering the market. Environmental monitoring can and should act as the 'fielder' for catching stray balls. An example of completely unexpected impacts of sewage effluents on the hormonal stress response in fish will be presented as a cautionary tale.

339 Examining the disconnect between laboratory studies of endocrine active compounds and perceived ecological consequences

H.I. Schoenfuss, St. Cloud State Univ / Aquatic Toxicology Laboratory

Laboratory exposure studies of endocrine active compounds, including xenoestrogens and several classes of prescription pharmaceuticals have provided consistent evidence for their adverse effects on exposed organisms. At the same time, field studies have struggled to replicate laboratory findings or have documented effects not observed in the laboratory. This presentation will provide multiple lines of quantitative evidence to argue that the mode-of-action of many endocrine active compounds, coupled with the often overlooked biological complexity of aquatic ecosystems, may explain this disconnect. For example, constant environmental conditions, required in the laboratory to exclude confounding factors, mask the overriding physiological impact of physic-chemical conditions on resident wildlife in field studies. Furthermore, the limitations on within-species and across-species interactions in the laboratory exclude exacerbating circumstances faced by organisms exposed in environmental settings. Finally, fluctuations of mixture composition and concentrations commonly observed in aquatic ecosystems, modulate organismal responses taken for granted in laboratory exposure studies. Although adding complexity, these obstacles to linking laboratory results to field observations should be viewed as an opportunity to expand or understanding of biological complexity rather then a limiting factor in our ability to predict the environmental effects of endocrine active compounds.

340 Social hierarchy modulates biomarker expression in fish exposed to contaminants of emerging concern

J. Ivanova, St Cloud State Univ / Biology; H.I. Schoenfuss, St. Cloud State Univ / Aquatic Toxicology Laboratory; R. Wang, USEPA / Ecological Exposure Research Division

Male fathead minnows (Pimephales promelas) in single-sex exposure groups establish social hierarchy as is evident by the differential expression of secondary sex characteristics (SSCs). SSCs expression is linked to circulating androgens concentrations, which are under the control of hypothalamo-pituitary-gonadal (HPG) axis. We tested the hypothesis that dominant and subordinate males belong to two biologically different subpopulations by pooling ten previously conducted studies in a Meta analysis. All experiments utilized the fish of same age from the same breeding facility and exposed at comparable environmental conditions. The results indicate that control males separated into two distinct subpopulations by SSC score (MANOVA, $p < 0.0001$), and that they also expressed different vitellogenin (VTG) concentrations. Males exposed to both E1 and E2 also formed two subpopulations relative to SSC expression ($p < 0.0001$ and $p < 0.0264$, respectively) but showed higher VTG concentrations when compared to controls. The greatest separation among the subgroups was found in males exposed to mood-altering pharmaceuticals ($p < 0.0001$) while having VTG concentrations comparable to controls. Our results suggest that male population of fathead minnows is heterogeneous. Our results also indicate that social hierarchy influences the fish responses to the contaminants of emerging concern (CECs).

341 Problem Formulation for Hazard Identification of EACs Requires Potency

C. Borgert, Applied Pharmacology & Toxicology, Inc.

Some argue that Hazard Identification (HI) for EAC's should be based on the potential for a chemical to act via an endocrine mode of action (MoA) rather than on the demonstration of adverse effects produced via an endocrine MoA. Thus, cellular or molecular assays would be given prominence in HI for EACs similar to the use of mutagenicity assays in the HI for genotoxicity. But, fundamental differences in these MoAs dictate a different problem formulation step for HI of EACs, where the critical question is not whether a molecular or cellular response is elicited, but with what potency. Vital signaling functions of the endocrine system require it to continuously discriminate the biological information conveyed by potent endogenous hormones from a more concentrated background of structurally similar, endogenous molecules with low hormonal potential. This obligatory ability to discriminate important hormonal signals from background noise is achieved through differential potency and laws of mass action, which together determine receptor occupancy and activation state in target cells. Discrimination based on potency can be theoretically-derived and corroborated by experimentally and clinically observable potency thresholds, without which normal physiological functions would be impossible. Although it has been argued that because the endocrine system is basally activated by endogenous hormones, very small amounts of low-potency chemicals could alter its function, simple receptor occupancy calculations reveal that in contrast, trillions of molecules would be required to change receptor occupancy by any measurable degree. The requirement for a sufficient change in receptor occupancy and cellular activation state, both of which depend on potency and mass action, forms the theoretical basis for potency thresholds derived directly from established principles of endocrine pharmacology. The incorporation of potency thresholds into HI is illustrated here using endogenous estrogens, androgens, and essential fatty acids as examples. The argument that thresholds cannot be proved empirically is mathematically correct, but practically irrelevant for safety assessment. Instead, the relevant question is the dose required to produce a specified level of effect that is deemed to be adverse. Conclusion: Without sufficient potency, there is no hazard, but there is a risk of fictitious endocrine disruption.

342 Missing links in our understanding of estrogenic compounds; chemical quantitation vs. biological assessment – where do we go from here?

N.W. Shappell, USDA-ARS / Biosciences Research Lab

The literature has become replete with reports quantifying estrogenic chemicals in the environment ranging from natural hormones to plasticizers. In addition, laboratories have developed in vitro assays to assess estrogenic activity of both environmental samples and pure chemicals. Information pertaining to the in vivo effects of the chemicals is much less exhaustive and the correlation to in vitro results is often ignored. Estrogenic potency of chemicals can vary significantly depending on the source of transfected estrogen receptor. One lab found trout versus human receptors were 62 fold more sensitive to one compound, while for another compound trout receptors were only 0.04% as responsive as human receptors. The same lab found the in vivo response to a chemical was 1/10,000th as estrogenic as estradiol, while by in vitro assay (transfected estradiol receptors from fish) the chemical was 1/600th as estrogenic. Chemical additivity has been reported from both in vitro and in vivo laboratory exposures, though similar additivity has not been reported for humans “dosed” with multiple estrogenic chemicals. While agriculture and wastewater treatment plants have been implicated as point source contributors of estrogenic contaminants in surface waters, studies of many water bodies have failed to detect these contaminants at biologically relevant concentrations. Further consideration is needed relative to the specific conditions of area of release relative to the impact of various estrogenic agricultural inputs. Surface water release of these compounds in arid regions could result in significant environmental impacts, while posing no problem in less arid regions. Unfortunately, several recent reports have resorted to quantifying estrogen concentration as a sum of all estrogens, ignoring relative estrogenic potential of the specific estrogen. A simple modification of concentration vs. prevalence data would allow for improved risk assessment. The relevance of these findings will be discussed and suggestions for future research directions made.

343 Challenges in ecotoxicology – what does controlled and standardized results mean in a complex and dynamic environment?

T. Brodin, Umeå Univ / Dept of Ecology and Environmental Science; J. Fick, Umeå Univ / Dept of Chemistry

Pharmaceutical residues are found in many aquatic ecosystems all over the world. Groups of pharmaceuticals of particular interest for potential ecological effects are EDC:s (endocrine disruption compounds) and anxiolytic drugs since they are designed to alter human physiology and/or behavior. There is a growing awareness among ecologists that behavioral variation and alterations are important for individual performance, ecosystem function, and species evolution. In ecotoxicology it has been recognised that such behavioral alterations may be caused by contaminants found in natural systems. Recent studies have shown that both EDC:s and anxiolytic drugs can be found present in environmental concentrations high enough to effect behavior of fish. Very little is, however, known about how/if these compounds affect the behavior of other aquatic organisms, or how they interact with natural stressors. In a recent meta-study, comparing studies using behavioral endpoints to studies with acute lethality, development, or reproduction as endpoints, it was concluded that behavioral studies warrant further attention as tools for assessing the effects of environmental contaminants. Information of how/if other key species are affected by exposure is crucial to be able to predict to what extent major ecological effects can be expected. Higher risk for severe ecological impact is predicted if the degree of which species specific effects occurs. That is, if pharmaceutical contamination induce effects that are asymmetric between species or even between life-stages within species. Such asymmetric effects can lead to shifts in species densities and compositions through altered competition and predator-prey interactions. The ecological ramifications of such pharmaceutically induced asymmetric behavioral changes are still unclear, as to date no studies have investigated the issue. Here, I will present empirical evidence for asymmetric behavioral effects of pharmaceutical exposure both within and between trophic levels and discuss potential ecological consequences thereof. I will also illustrate, using novel data, the importance of including natural stressors (e.g. predation risk) for the outcome of ecotoxicological testing of pharmaceutical. Finally I will discuss the problems we face when trying to extrapolate results found in the lab to what will happen in the wild and suggest one possible way of bridging the gap between lab and field.

Assessing Ecological Risk to Inland Environments Due to Increases in Major Ions

344 What we know and don’t know about major ion pollution from 15 years of research in Australia

B.J. Kefford, Univ of Canberra / Inst for Applied Ecology

There has been much concern in Australia about ecological effects of increased salinity, or major ions, from rising saline groundwater which initiated a series of research project starting in about 2000 into the impact of rising salinity on freshwater organisms, community and ecosystems. This research showed certain taxa, e.g. Ephemeroptera (mayflies), are particularly sensitive to salinity rises while others, e.g. macro-Crustaceans, tend to be tolerant. Some, but not all, freshwater taxa actually do somewhat better sub-lethally at slightly elevated salinity. There is, however, a contradiction between the results of field and laboratory studies, in that risk assessment based on single species toxicity tests suggested that no species would be at risk at 1 mS/cm, while at that salinity there is a 50% loss of regional Ephemeroptera, Plecoptera and Trichoptera species richness. Recently attention has shifted to concern about saline effluents from coal mines and gas extracted from coal bed, or coal bed saline effluents. There are many similarities between salinity increases from rising saline groundwater and those from resource extraction but also an important difference. The former saline waters are NaCl dominated and tend to have ionic proportions similar to sea water. In contrast the ionic proportions in waters from coal beds are much more varied with relatively higher proportions of bicarbonates and sulphates occurring. Variations in ionic proportions both change the toxicity and the relative sensitivity of different taxa, producing a considerable challenge. Significant progress may not occur until the physiological mechanisms underlying this variation are understood.

345 Laboratory Evaluations on the Effects of Dissolved Solids on Benthic Macroinvertebrate Communities and Individual Taxa from West Virginia Streams

M.Y. Armstead, M. Wilson, Marshall Univ / Integrated Science and Technology

Much attention has focused on declining macroinvertebrate communities in the Appalachian region as a result of increased dissolved solids from mining activities. Evidence for levels of dissolved solids impairing communities has been primarily based on correlation of large field surveys with landscape disturbance area and water quality from monitoring programs. Field studies specifically evaluating the effects of dissolved solids on native taxa have increased recently, but laboratory confirmation of field surveys is sparse. Hindrances to laboratory confirmation of field surveys include difficulty collecting and handling native taxa, temporal and spatial variability in condition of organisms collected for testing, and difficulty procuring sensitive life stages. Studies on the effects of dissolved solids, measured as specific conductance, on macroinvertebrates from streams in the mining region of West Virginia have been ongoing in our laboratory for 5 years. Evaluations have included: mesocosm studies of field-collected macroinvertebrates exposed to a simulated mine discharge with conductivity ranging from 100 µS/cm to 2400 µS/cm, a multivariate evaluation of the effect of conductivity on individual taxa encountered in the mesocosm studies; and recently, toxicity bioassays with laboratory reared larval mayflies. Results of the multiple projects indicate variable community level effects with initial taxa composition significant in overall test significance despite similarities in community metrics at test initiation. Individual taxa in both Ephemeroptera and Trichoptera orders demonstrate similar sensitivity to increased dissolved solids. Implications of bioassay results from tests utilizing laboratory reared larval mayflies are preliminary as salts are being used to demonstrate fitness of our cultured organisms. However, the relative responses of multiple taxa and comparison of newly hatched and older individuals is informative. Results of the individual projects and trends in our findings will be presented with a discussion of implications for managing current conditions in the mining regions of West Virginia.

346 Individual and community responses in stream mesocosms with different ionic compositions of conductivity and compared to a field-based benchmark

C.T. Nietch, USEPA / Water Supply and Water Resources Division; J.M. Lazorchak, USEPA / Office of Research and Development; D.R. Mount, USEPA / ORD NHEERL Mid-Continent Ecology Division Duluth; W.H. Clements, Colorado State Univ / Dept of Fish Wildlife and Conservation Biology

Several anthropogenic activities cause excess total dissolved solids (TDS) content and its correlate, specific conductivity, in surface waters due to increases in the major geochemical ions (e.g., Na, Ca, Cl, SO_4). However, the relative concentrations of major ions varies with the source, and single-species tests have revealed that ion compositional differences can affect their toxicity. Within the central Appalachian region of the U.S., oil and gas production and surface coal extraction activities are two sources of excess TDS for surface waters; releases from the former are typically dominated by Na, Ca, and Cl, and the latter by Ca, Mg, SO_4, and HCO_3. A stream mesocosm study evaluated the effects of excess TDS from both discharge types against a natural background chemistry by dosing two recipes mimicking each type of excess TDS over a 56d period. Hazard concentrations (HCs) for specific conductivity from EC50 response sensitivity distributions derived from the mesocosm data differed, with HC5 estimates of 792 µS/cm (685 to 933, 95% CI) for the simulated oil and gas produced water excess TDS, and 434 µS/cm (338 to 584, 95% CI) for the recipe simulating streams receiving surface coal mining discharges. While the mesocosm study was originally intended to evaluate TDS limits in NPDES permits, it also serves a dual purpose to evaluate the field based conductivity benchmark of Cormier et al. The benchmark, circa 300 µS/cm, was derived from analyses of benthic samples taken from central Appalachian streams, and was meant to protect communities exposed to ion mixtures comparable to the ionic composition of the surface coal mining recipe dosed to the mesocosms. As the lower 95% confidence interval of the HC5 estimate for the coal mining recipe was 338 µS/cm, these results support the field benchmark as protective for the specific conditions for which it was developed. In keeping with the applicability restrictions imposed by Cormier et al however, the higher HC5 value from the mesocosms exposed to the oil and gas produced water recipe highlights how important it is to keep the context for the benchmark in mind when evaluating risks of discharges with different ionic compositions or for different receiving waters.

347 What Physiological Research on Ion Transport Suggests about the Relationship between Anion Toxicity and Hardness

M. Griffith, NCEA, ORD, USEPA / Office of Research and Development National Center for Environmental Assessment

Bioassay studies have purported to measure the toxicity of anions, such as Cl^- and SO_4^{2-}, in freshwater animals and in several cases have related this toxicity to hardness. However, considering the ion transport physiology of freshwater fish, crustaceans, aquatic insects, and molluscs, attributing the observed toxicity to the anions alone may be questionable, as is the apparent relationship with hardness. Cl^- is known to be transported across apical epithelial membranes of animals from freshwater by a HCO_3^-/Cl^--exchanger, also known as an anion exchanger. Epithelial SO_4^{2-} transporters are not currently known, and SO_4^{2-} is considered relatively impermeant to external epithelial membranes. Hardness is known to decrease the toxicity of divalent metals, because metal ions and Ca^{2+} compete for Ca^{2+} transporters. Consequently, increased Ca^{2+} inhibits metal uptake. In these bioassays, Na^+ salts have generally been used to increase anion concentrations, so Na^+ is increased in addition to the anion but not other ions. In Crustacea, and probably Mollusca, there is mutual competitive inhibition of uptake between Na^+ and Ca^{2+} at an additional transporter, an electrogenic $2Na^+$ or Ca^{2+}/H^+-exchanger, suggesting the observed relationship is associated with Na^+ and hardness. No similar mechanism can explain a hypothesized relationship between hardness and anion toxicity. The views expressed are those of the author and do not necessarily reflect the views or policies of the USEPA.

348 Calcite production is lethal to a model freshwater invertebrate

S. Bogart, S. Woodman, D. Steinkey, Univ of Lethbridge / Biological Sciences; C. Meays, British Columbia Ministry of Environment; G.G. Pyle, Univ of Lethbridge / Biological Sciences

Salinization of freshwaters can, aside from increasing the total ion content in water, result in extensive deposition of calcite in freshwater ecosystems. While extensive calcite deposition occurs naturally in a few aquatic ecosystems, the organisms inhabiting these ecosystems are typically saline tolerant. In this study, we determined whether a model freshwater organism, Daphnia magna, is negatively affected by calcite production or by the components required for calcite production (i.e. high alkalinity and water hardness). Results from a series of 48 hr – 96 hr toxicity experiments revealed that rapid shifts in alkalinity and water hardness were not lethal if no calcite precipitated. However, if water conditions supported calcite precipitation, ≥98 % of D. magna neonates died within 96 hrs of exposure. To determine the potential ecological relevance of our tests, we collected calcite from a mining-affected stream and examined it for the presence of entrapped organisms. Organisms were found embedded in this field collected calcite suggesting that species loss may also be occurring in streams affected by resource extraction where extensive calcite precipitation is induced. Our results support the development of a water hardness + alkalinity guideline for the protection of aquatic life.

349 Salt and Mayflies – chronic exposure and time independence

A. Henderson, Univ of Canberra / Inst of Applied Ecology; G. Kon Kam King, Univ Lyon 1 / Laboratoire de Biométrie et Biologie Evolutive; S. Lehmann, B.J. Kefford, Univ of Canberra / Inst for Applied Ecology

Saline effluent discharges have been a growing concern over the recent years. Suggested safe salinity levels from risk assessments based on species sensitivity distributions (SSDs) suggest no adverse effects at about 1 mS/cm but at this salinity about 50% of the Ephmeeroptera, Plecoptera and Thricoptera (EPT) species are lost in Australia and similar losses occur elsewhere. As shown by Guillaume et al (2015), current SSD methods deriving protection values lack ecological realism and statistical soundness. In particular SSDs are unable to account for time-dependence issues and therefore is unable to truly provide safe protection targets for salinity. Guillaume et al 2015 suggest the use of no effect concentrations (NEC) which are theoretically time independent. But there is a lack of empirical data showing that they are in fact time independently.

Furthermore mortality from salt sensitive EPT species from chronic exposure able to explain the loss of protection at low salinity levels. We conducted experiments with 5 species of EPT collected from a reference site with no salinity exposure and measured mortality over 15- 39 days depending on the species. Results show that NEC values calculated over 96 hours of exposure were very similar to NEC over exposures of weeks, suggesting that the NEC is really time independent. NEC values for EPT were, however, still higher than salinity in which EPT species are lost in nature, suggesting that sub-lethal and/or indirect effects need to be investigated. Such investigations are currently underway.

350 The confounding effects of extremely high salt concentrations in assessing impact of hydraulic fracturing mixtures on rainbow trout

T. Blewett, P. Delompré, A. Weinrauch, Univ of Alberta; G. Goss, Univ of Alberta / Biological Sciences

Hydraulic fracturing involves pumping a mixture of water, fracture proppants, and industrial fluid into deep wells at high pressures to allow for the recovery of tight gas and oil reserves. Flow-back and produced wastewaters (FPW) are extremely high in salinity (up to 330,000 ppt), and also contain elevated concentrations of organic and metal contaminants. From 2005-2013, there were >2500 documented flow-back fluid spills in Alberta alone, and of these, 115 were large spills into either flowing water, freshwater lakes or wetlands. Little data exists on the impact of these complex mixtures on native fish species. Using juvenile rainbow trout, 48 hour acute toxicity tests were conducted to replicate spill effects. Fish were exposed to 7.5% of the total FPW, or salt-matched controls. Gill histology showed significant changes in lamellar width, inter-lamellar cell masses, and changes in cell type with exposure to FPW, similar to effects seen in salt-matched controls. FPW- and salt-matched control exposed fish also showed signs of oxidative stress, with decreased levels of SOD with 50% reduction in the highest exposure tested in the gill and liver, and increased catalase activity in the same tissues. The pattern of measured changes represents a unique signature of impact, suggesting an approach that could be used to track exposures, facilitating an understanding of spill impacts and helping to define a zone of biological influence of the spill. Overall, these data point to significant impacts of salt stress as a confounding factor in understanding the effects of FPW spills. These data will aid in the design of post-spill environmental effects monitoring and risk assessment.

351 Relationship between fish species extirpation and specific conductivity

S. Cormier, USEPA / National Center for Environmental Assessment; M.B. Griffith, USEPA / NCEA Cincinnati; L. Zheng, TetraTech

We investigated the effect of increases in ionic concentration (specific conductivity) on fish species in Central Appalachia. Effect levels were calculated using the extirpation concentration at the 95th centile (XC95) of a weighted cumulative distribution function, a method previously developed using benthic invertebrate genera. As might be predicted mathematically, the genus XC95 values for fish species are higher than those for most of their constituent species. Thus, genus-level effect thresholds may not be predictive of species level effects. However, no fish species, with >25 occurrences had an XC95 less than the benthic invertebrate field-based benchmark in Central Appalachia. Etheostoma baileyi, the emerald darter, had a predicted XC95 value of 322 µS/cm. Thus, a genus level benchmark at the 5th centile of a benthic invertebrate XC95 distribution is protective of most fish species. However, fish are likely to be affected well before extirpation. Access to species level XC95 values and their exposure response models allows evaluation of the effects of increasing ionic concentration on individual species. For example, the probability of observing brook trout, Salvelinus fontinalis, decreases by 10% at 35 µS/cm, by half at 135 µS/cm, and by 95% (extirpated) at 508 µS/cm. Fish species' responses to increasing specific conductivity may be useful for evaluating the effect of salts and may be diagnostic of impairments caused directly or indirectly by ionoregulatory stress. These are the authors views and do not necessarily represent the views or policies of USEPA.

Novel Mechanisms of Nanomaterial Toxicity Through Direct Exposure or Indirect Interactions with Environmental Components – Part 2

352 Roles of Direct and Indirect Light-Induced Transformations of Carbon Nanomaterials in Exposures in Aquatic Systems

R. Zepp, USEPA / National Exposure Research Laboratory; W. Hou, National Cheng Kung Univ / Dept of Environmental Engineering; C. Chen, USEPA / NERL; B. Acrey, USEPA / NERL Athens GA; D.C. Bouchard, USEPA / EMMD; X. Chang, USEPA; M. Henderson, USEPA / NERL; S. Martin, Oak Ridge Inst for Science Education at USEPA; C.D. Knightes, USEPA / Natl Exposure Research Laboratory

Carbon nanomaterials (CNMs) such as fullerenes, carbon nanotubes and graphene-based nanomaterials have a variety of useful characteristics such as extraordinary electron and heat conducting abilities, optical absorption and mechanical properties, and potential applications in transistors and polymer nanocomposites. CNMs often are used in consumer and industrial products as composites with other materials such as polymers. The release of CNMs such as multiwalled carbon nanotubes (MWCNT) from the composites is stimulated by weathering induced by light exposure. Release can be followed by using ICP-MS to measure metal residues that are associated with the nanotubes, by UV-visible techniques or by TEM images of particles that can be leached from the weathered surfaces. In most cases the released CNMs are associated with fragments of the polymer matrix. Little is known about the fate of these unusual CNT-containing fragments but recent studies of microplastic residues in lakes and the ocean suggest that they may accumulate in aquatic organisms. Other studies have shown that rapid sunlight absorption by CNMs such as graphene oxide and carboxylated nanotubes leads to rapid conversions to carbon dioxide and persistent, low-molecular weight photoproducts. Indirect pathways also are available for light-induced transformations of CNMs in natural waters. The indirect pathways are driven by reactive transients such as hydroxyl radicals that are produced by photoreactions of natural organic matter (NOM) and inorganic species such as nitrate, metals and peroxides. The objectives of this presentation are to compare both direct and indirect photochemical pathways for selected CNM transformations driven by sunlight exposure, focusing on structural changes and other factors that influence exposure to the CNMs and their photoproducts in natural waters. We will emphasize carbon nanotubes and graphene oxide in the presentation. Another objective is to define relationships and data that can be used to predictively model effects of CNMs on sunlight-induced photoproduction of reactive transients such as excited triplet states and reactive oxygen species that mediate toxic effects of CNMs and their photoproducts.

353 Predicting Hydroxyl Radical Production from Irradiated Titanium Dioxide Nanoparticles Under Varying Conditions

J. Coral, Clemson Univ / Inst of Environmental Toxicology CUENTOX; C.L. Kitchens, Clemson Univ / Deptartment of Chemical and Biomolecular Engineering; S.J. Klaine, Clemson Univ / Inst of Environmental Toxicology

Organism toxicity to titanium dioxide nanoparticles (TiO_2 NPs) has been quantified as a response to nanoparticle concentration. While this is a satisfactory explanation for most toxicants, TiO_2 nanoparticle toxicity is highly dependent on environmental conditions. TiO_2 NPs produce reactive oxygen species (ROS), primarily hydroxyl radicals, upon exposure to UV light in aqueous solutions. Quantifying hydroxyl radical formation during TiO_2 NP exposure and using that as the independent parameter in dose response relationships may better reflect the toxicological impact. Our previous research has established that TiO_2 NP toxic dose to Daphnia magna decreases by four orders of magnitude, from 1110 mg/L NPs(48h LC_{50}) under cool white fluorescent tubes to 0.202 mg/L NPs(48h LC_{50}) under ultraviolet lights. This increase in toxicity is due to the production of hydroxyl radicals and the subsequent biological interactions of the hydroxyl radical with the organism. The production of hydroxyl radicals can be influenced by multiple environmental factors such as the contribution of NOM to turbidity, radical quenching, particle aggregation, and the intensity of UV light. The goal of this research was to characterize the influence of these external parameters on hydroxyl radical formation. Parameters that were investigated include the following: light intensity and duration, concentration of dissolved organic carbon, and concentration of TiO_2 NPs. Based on measurements from fluorescent spectroscopy, we have built a model that utilizes site-specific water quality and particle specific attributes to better describe the production of hydroxyl radicals generated by TiO_2 NPs. This model will facilitate the development of site-specific water quality criteria for TiO_2 NPs, and is being applied to develop dose-response toxicity curves to D. magna based on hydroxyl concentration.

354 Protein Corona Predicts Biologic Response and Toxicity Mechanisms of Silver Nanoparticles in Fish

J. Gao, Purdue Univ / Forestry and Natural Resources; M.S. Sepulveda, Purdue Univ / Dept of Forestry and Natural Resources and School of Health Sciences

Nanoparticles (NPs) are widely used in daily products, medicine and nanotechnology increasing the likelihood of exposure. Upon exposure, NPs encounter plasma proteins resulting in the formation of a “protein corona” which can modify the biological identity of NPs and affect their distribution and toxicity. In order to better understand the toxic mechanisms of silver nanoparticles (AgNPs) in fish, our research investigated the protein corona from polyvinylpyrrolidone-coated AgNPs (PVP-AgNPs) incubated with fish plasma. Plasma was collected from adult smallmouth bass and incubated with PVP-AgNPs for 1 and 24 h. Nanoparticle tracking analysis (NTA) was used to quantify changes in PVP-AgNP size after incubation. After 1 h of incubation, size increased from 52.6 nm to 57.3 nm and to 56.1 nm in females and males, respectively. After 24 h, PVP-AgNPs continued to increase in size to 60.8 nm and 58.0 nm in females and males, respectively. We then used high-resolution liquid chromatography tandem mass spectrometry (LC-MS/MS) to identify the proteins. We identified proteins associated with the immune system (immunoglobulin and complement proteins), heavy-metal binding proteins, hemoglobin, apolipoproteins, vitellogenin and zona pellucida, the latter two found only in females which could explain the larger size attained in this gender. Interestingly, albumin, an abundant plasma protein, was not found to be part of the corona in these fish. The study of the formation and characterization of protein corona will increase our understanding on the toxic mechanisms of NPs in vivo. This is the first study to examine protein corona in fish plasma.

355 Investigating mitochondrial toxicity of the Metal oxide nanoparticle ZnO

X. Pan, B. Zhang, East Carolina Univ / Biology

Metal oxide nanoparticles (NPs) such as ZnO are frequently used in consumer products such as sunscreen, cosmetics, toothpaste, and textiles. It is well established that various toxic effects caused by nanoparticles are associated with oxidative stress. Thereby we asked if mitochondria is a susceptible target. The model organism Caenorhabditis elegans (C. elegans) provides an excellent in vivo model for this study. Previously, our studies have shown that ZnO NPs induced oxidative stress and increased germ cell apoptosis. In this study we firstly measured the expressions of oxidative stress response and mitochondrial function related genes, including drp-1, fzo-1, eat-3, moma-1, immt-1, chch-3, immt-2, dic-1, ced-9, egl-1, fis-1, fis-2, mff-1, mff-2, act-3, nd4, sod-2, and sod-3. Over 2,000 worms were plated onto each of three ZnO NP treatment groups, including control (614µM, 61.4µM, and 0µM). Worms were exposed for approximately 68 hours at 20°C until worms reached the early adult stage. Then RNAs were extracted and subjected to quantitative RT-PCR analysis. In the 61.4µM treatment, regulation was significantly disrupted ($p< 0.05$) compared to control for moma-1, mff-1, and sod-3. Both moma-1 and sod-3 were down-regulated with fold changes of 0.75 and 0.46, respectively; whereas mff-1 was upregulated by a fold of 1.83. In the 614µM treatment, regulation was significantly altered for eat-3, dic-1, fis-1, fis-2, immt-2, act-3, mff-1, mff-2, sod-2, and sod-3 compared to control. The sod-3 was downregulated by a fold of .30, and all other significant genes were upregulated. Upregulated fold changes were as follows: 4.31 for eat-3, 8.08 for dic-1, 1.85 for fis-1, 1.73 for fis-2, 1.44 for immt-2, 2.55 for act-3, 1.25 for mff-1, 1.83 for mff-2, and 1.93 for sod-3. Based on the gene expression results, several mutant strains were selected for testing their sensitivity to ZnO NP exposure.

356 In vivo exposure to gold nanoparticles alters steroidogenesis gene regulation in the liver irrespective of exposure route in Danio rerio

T. Botha, North-West Univ / School of Biological Science; Y. Ikenaka, S.M. Nakayama, M. Ishizuka, Hokkaido Univ / Graduate School of Veterinary Medicine; V. Wepener, North-West Univ / Unit for Environmental Sciences and Management

Gold nanoparticles (nAu) are being developed for applications as a novel drug delivery system allowing for targeted delivery into cells. The dose concentration of in vitro studies is known however with in vivo exposures the delivered dose is often unknown; therefore a range of concentrations were used to determine possible effects on the steriodogenesis pathway. Adult Danio rerio were exposed to nine concentrations of nAu ranging from 5 mg/l to 45 mg/l for 96 h following standard OECD protocols. Pooled liver samples of each concentration were used for Microarray as well as RT-PCR analysis to determine changes in genes relating to the steriodogenesis. The Cytochrome P450 activity (mM/mg protein) in the liver was also determined by using an ELISA method. Using gene ontology biological process showed genes with more than 65% activation included hormone biosynthetic, estrogen metabolic and estrogen biosynthetic process while molecular function genes above 65% activation included those involved in estradiol and steroid dehydrogenase activity. The fold changes compared to control showed different responses between male and female fish, where male fish had a greater response. The Cyp1 genes showed up regulation in male fish while no response was seen in female fish. Cyp11a1 and Cyp17a1 showed up regulation in the concentration range of 20mg/l and 40mg/l in both male and female fish but no change or down regulation was observed at the remaining concentrations. Cyp19a showed up regulation in male fish but slight down regulation in female fish. The P450 kit was showed no significant differences when compared to control but a higher standard deviation was present at concentrations of 25mg/l and above. Characterization of nAu revealed that at 20, 25, 40 and 45 mg/l the surface charge was anionic and further investigation revealed that nAu were present in the gut of the fish at 40 and 45 mg/l due to ingestion of particle agglomerations which sedimented out of solution. A hormetic response was seen in genes associated with steroidogenesis across a range of concentrations and similar genetic responses were activated regardless of uptake method.

357 The impact of graphene oxide and silver nanoparticles on immune pathways

E.J. Pool, K.L. Lategan, H. Alghadi, Univ of The Western Cape / Medical Bioscience; M. Fidalgo, Univ of Missouri Columbia / Civil and Environmental Engineering

Nanoparticles (NP) have attracted attention due to their unique properties. Due to the wide range of applications of NPs in products such as pharmaceuticals, energy trapping systems, clothes, and electrical components, concerns are raised over impacts that large scale production and use of NPs may have on human health and the environment. Although data is available on the acute toxicity of several types of NPs, very little is known about their impacts on physiological systems and biological pathways. The current study investigated the effects of graphene oxide and silver nanoparticles NPs on immune pathways. Commercially available silver nanoparticles and in-house prepared graphene oxide particles were used. Particles were partially characterized using physicochemical techniques to determine their composition, surface charge and diameter. Three cell culture systems were used namely human whole blood primary cultures, B-lymphocytes and RAW264.7 macrophages. Cells were incubated with nanoparticles in the presence and absence of mitogens (lipopolysaccharide or phytohemagglutinin). At the end of the incubation period the cells were screened for cell viability using the WST1 assay system and cytokines representative of inflammation (IL-6), humoral immunity (IL-10) and cell mediated immunity (IFN gamma) using ELISA. Supernatants of B-cells were screened for antibody synthesis using an ELISA. Raw264.7 cells were analysed for nitric oxide, heat shock protein, nitric oxide synthase and cyclooxygenase using Western Blotting. Cell viability assays show that silver NPs have no impact on cytotoxicity and nitric oxide, IL-10, IFN gamma and antibody synthesis. However, silver NPs stimulated IL-6 production by lipopolysaccharide activated whole blood cultures. Silver NPs increased the production of heat shock protein 70, but inhibited the production of nitric oxide synthase and cyclooxygenase in stimulated RAW cell macrophages. Studies using graphene oxide nanoparticles indicate that although these particles are not cytotoxic, they activate IL-6 and nitric oxide synthesis of lipopolysaccharide stimulated RAW264.7 macrophages. In conclusion, data generated shows that silver and graphene oxide nanoparticles are not cytotoxic. However, some results generated indicate that both nanoparticles may cause inflammation upon exposure.

358 Impact of silver nanowire length, diameter, and surface chemistry on rainbow trout RTgillW1 and RTgutGC cell lines

D. Arndt, Univ of Florida / CEHT; C. Vulpe, Univ of Florida, Gainesville / Physiological Science

Silver nanowires (AgNWs) are rapidly displacing the current technology for touchscreen displays, and additional AgNW applications are becoming available in the form of solar cells and conformational electronics like OLED displays. Despite a push to understand the impacts of engineered nanomaterials on human and environmental health, there is a lack of knowledge regarding AgNW toxicity to biological systems. This project used RTgillW1 and RTgutGC cell lines to probe specific characteristics of AgNWs that make them more or less toxic to organisms. AgNWs were synthesized with a variety of lengths, diameters, and surface chemistries. Cells were seeded at a density of 4,000 cells per well in 384 well plates and exposed to AgNWs (0-25 µg/mL) for different periods of time (4, 12, 24, and 48 hours). $AgNO_3$ was used as a positive control. Cytotoxicity was measured by nuclear morphology, plasma membrane and cytoskeleton integrity, mitochondrial membrane potential, H2AX DNA damage, ROS generation, lysosome pH and mass, and apoptosis. Changes to bioenergetics parameters (glycolysis, aerobic respiration, mitochondrial function) were also measured. Results indicate that AgNWs exhibit altered patterns of transport, cellular uptake, and asbestos-like toxic injury due to the high aspect ratio of the nanowires. Both short and long nanowires were internalized by the cells and induced cytotoxicity; however, long nanowires generated slightly higher levels of ROS and apoptosis-related events compared to short nanowires. Surface chemistry and media conditions were also found to influence toxicity. Future work will probe for toxic effects of AgNWs to rainbow trout larvae so that endpoints between in vitro and in vivo toxicity can be compared. These results will help scientists and engineers synthesize silver nanowires in ways that are safer to people and the environment.

359 Development of a Non-Toxic Carbon Nanomaterial-Based Filter for Virus Sequestration in Aquaculture Systems

C. Lavelle, Univ of Florida / Physiological Sciences; J.H. Bisesi, Univ of Florida / Environmental and Global Health; N.B. Saleh, Univ of Texas / Dept of Civil Architectural and Environmental Engineering; T. Waltzek, Univ of Florida; T. Sabo-Attwood, Univ of Florida / Environmental Global Health

Single-walled carbon nanotubes (SWCNTs) are highly sorptive materials that can potentially be used for environmental remediation of diverse water sources through removing pathogens. However, to our knowledge, the interactions between select pathogens, namely aquatic viruses and SWCNTs have not been well studied. We hypothesized that SWCNTs will sequester and inactivate a model fish virus that has relevance to the aquaculture industry which will mitigate infectivity to fish. The overall goal is to develop a filter that can be used by aquaculture facilities to minimize economic losses due to pathogens while also protecting ecosystem and human health. For our approach, SWCNT suspensions were prepared by sonication in DMSO and vacuumed deposited onto 10 µm pore Omnipore membranes (Millipore) at loadings of (0.35, 0.7, and 1.0 mg SWCNT/cm^2). After extensive washes with ethanol and water, suspensions of largemouth bass virus (LMBV) were passed through the filter followed by additional washes. Expression of the major capsid protein of LMBV was measured by qRT-PCR as a measure of viral retention. Results indicate that SWCNTs can more efficiently remove and retain LMBV compared to bare filters and activate charcoal by up to 50% and that this removal is dependent upon the mass of SWCNTs present on the filter. Additional studies investigated how a range of water chemistries (pH and hardness) relevant to aquaculture facilities in Florida influenced LMBV removal. We are currently testing the efficacy of this SWCNT-LMBV interaction to limit LMBV transmission through waterborne exposure while assessing SWCNT release and toxicity. While our group has previously shown SWCNTs are not acutely toxic to fish they may cause more subtle sub-lethal effects based on their ability to interact with various endogenous and exogenous molecules in the environment and in organisms. The current study has far reaching implications for the potential use of this technology for removal of pathogens and other aquatic contaminants in a safe way.

Fate and Effects of Metals: Marine Issues

360 Ocean acidification alleviates mercury toxicity to the life history traits in Tigriopus japonicus under multigenerational exposure scenario

M. Wang, Xiamen Univ

Ocean acidification (OA) and mercury (Hg) pollution are frequently concurrent problems in marine and coastal environments. And yet, very little information is known about the impact of OA on Hg toxicity to marine organisms, let alone under long-term multigenerational scenario. Here, we investigated the effects of OA and Hg pollution (i.e., ambient condition: pCO_2 400 ppm × control; and stress conditions: pCO_2 400 ppm × 10 µg/L Hg, pCO_2 1000 ppm × control, p CO_2 1000 ppm × 10 µg/L Hg) on development and reproduction of marine copepod Tigriopus japonicus under a multigenerational life-cycle exposure of four successive generations (F0-F3). Metal accumulation, as well as seven life history traits, that is, developmental time for nauplius phase, developmental time to maturation, survival rate, sex ratio (F/M) number of clutches, number of nauplii/clutch and fecundity was analyzed for each generation. The results indicated that, compared to single Hg exposure, CO_2 acidified seawaters led to a significantly lower Hg accumulation in adult copepods under the combine exposure, furthermore, with a trend for higher Hg accumulation from F0 to F3. Under most circumstances, OA exposure displayed negligible impacts on the seven traits in the copepod. Additionally, only number of nauplii/clutch was evidently suppressed by Hg treatment. Interestingly, OA could significantly alleviate the Hg inhibitory impacts on number of clutches, and number of nauplii/clutch, and it was attributable to less metal accumulation under the combined exposure than that under the single Hg treatment. Also, the combined exposure shortened the development time in contrast to the Hg exposure alone. Overall, OA could mitigate Hg toxicity to some important life traits in marine copepods during the long term exposure, and environmental risk assessment of Hg pollution must therefore integrate the elements in global climate change (e.g., OA) so as to provide a realistic measurement of the influences on aquatic ecosystem.

361 Antioxidant responses in relation to subcellular partitioning profiles of metals in transplanted clams: Implications for metabolic availability

Z. Wang, Key Laboratory of Urban Environment and Health; C. Yan, Insitute of Urban Environment, Chinese Academy of Sciences

Due to the complexity of heterogeneous sediment, the chemical speciation and mobility of metals were in dynamic conditions rather than steady states, resulting in high variability of contaminant bioavailability. Chemical analyses in traditional tests had disadvantages of inaccuracy for contamination characteristics and risk assessments, representing a worst-case scenario in terms of complex exposure dynamics. In this presentation, relevant scientific issues regarding the effects on subcellular distribution and molecular biomarkers with special emphasis on toxic mechanisms and their associations were investigated through powerful experimental designs and field-based manipulations of in-situ exposure and kinetic DGT approach. Understanding the degree of pollution and geochemical characteristics of sediment matrix, in-situ testing chambers were deployed combining the DGT and caged clam Ruditapes philippinarum, and the dynamic exchanges, translocation and mobilization were then clarified among the interface of particles and pore-water in sediments through measuring dynamic parameters and resultant induced fluxes in exposed organism. Integrating a wide battery of biomarkers, dynamic changing processes were assessed, and their interactions were established between exposure and biological effects. Furthermore, variations of transcript expression of functional genes in contaminant-specific biomarkers were obtained through high throughput oligo-DNA Microarray and quantitative reverse transcription polymerase chain reaction (Q-RT-PCR) in order to elucidate the mechanistic understanding of molecular biomarkers in biological responses. Simultaneously, the approach of in-situ evaluation was established considering the consistency of framework as protocols among sediment chemistry, contaminant bioavailability and adverse effect, which significantly improve accuracy and ecological relevancy in complex exposure situation and thus provide a robust tool to support more comprehensive processes of sediment risk assessment. Overall, the associations not only revealed the fates of accumulated metals, but scientifically favored an improved understanding of toxic effects in response to subcellular level, supporting the focus of metabolic availability assessment on the intracellular processes or events occurring within organism in future coastal biomonitoring. (The author acknowledge financial support by Grant No. 21377125/B070403 from National Nature Science Foundation of China)

362 Detailed Reconstruction of the Metal Exposure History of Whales from Chemical Analysis of Earwax Plugs

M.M. Shafer, Univ of Wisconsin-Madison / Environmental Chemistry Technology Dept; S. Trumble, Z. Winfield, Baylor Univ; S. Usenko, Baylor Univ / Dept of Environmental Science

Baleen whales, including fin whales, are known to accumulate cerumen or earwax from birth to death forming an earplug. Earplugs often contain alternating light- and dark-colored laminae which can be used to provide age estimates for the individual with approximately six month resolution. Whale earplugs have also been used to reconstruct lifetime chemical profiles in whales. This reconstruction technique combines age estimates (counting light and dark lamina) with chemical analysis (i.e. measuring organic compounds) in each lamina. Published reconstructions have focused on organic contaminants, hormones, and total mercury (THg). Here we present an analytical method capable of measuring a very large suite of metals including THg and methylmercury (MeHg) in whale earwax laminae and document method performance in a 4-lamina earwax plug from a young fin whale. We applied an automated mixed-acid microwave-aided digestion protocol to completely solubilize sub-samples (100 mg) of the laminae, followed by magnetic-sector ICPMS analysis for quantification of 45 elements. Separate sub-samples of earwax were processed for THg and MeHg analysis with cold vapor atomic fluorescence (CVAF) detection. Mercury analytical recoveries were quantitative and method blanks represented < 1% of a typical earwax sample. The major inorganic constituents of the fin whale earwax laminae were Ca and P (averaging 29 mg/g and 15 mg/g respectively), followed by Na (3.8 mg/g), K (0.59 mg/g), and Mg (0.43 mg/g). Three transition metals, Zn (22 µg/g), Fe (16 µg/g) and Cu (12 µg/g) ranked next in concentration. Levels of most other transition metals/semi-metals (3 to 40 ng/g) and rare earth elements (0.03 to 4 ng/g) were significantly lower. THg concentrations increased consistently from lamina 1 (10.4 ng/g) to lamina 4 (18.2 ng/g) a nearly two fold change. MeHg concentrations tracked those of THg (r = 0.98), increasing from 5 ng/g to 11.6 ng/g, representing 48% of THg in lamina 1 and 62-67% of THg in laminae 2-4. Mercury levels were strongly anti-correlated (r = > -0.8, r = > -0.95 for Ca and P) with the major inorganic elements, suggesting dilution of the mercury source(s) by bulk components. Mercury levels were however strongly positively correlated with Al, Cd, Pd, Pt, and V, all elements (with the exception of Cd) associated with catalysts and fuel oil combustion. Carbon and nitrogen stable isotope analyses are being performed to help identify diet sources and changes.

363 Understanding the complex effects of salinity on metal toxicity using toxicokinetic-toxicodynamic model as a framework

Q. Tan, S. Lu, Xiamen Univ / College of the Environment Ecology; W. Chen, Xiamen Univ

In estuarine waters, salinity is one of the most important factors that determine the toxicity of metals. The multiple effects of salinity include: changing metal speciation, providing competing cations and altering the physiology of organisms. Separation and quantification of these effects can provide better understanding of the complex effects of salinity. In this study, salinity effects on the toxicity of two metals (i.e., Cd and Cu) in the estuarine clam, Potamocorbula laevis, were delineated using the toxicokinetic-toxicodynamic model. Metal bioaccumulation at salinities ranging from 5 to 30 psu were quantified using a stable isotope tracer technique; in parallel, 96-h (for Cd) or 72-h (for Cu) toxicity tests were conducted also at those salinities. With the increase of salinity, the bioaccumulation of both Cd and Cu decreased monotonically, consistent with the stronger complexation effects of anions (e.g., Cl^- and HCO_3^-) and the competition effects of major cations (e.g., Na^+, Ca^{2+}). In contrast, increasing salinity led to different effects on the toxicity of the two metals, i.e., decreasing the toxicity of Cd, while increasing the toxicity of Cu. Toxicodynamic analyses showed that increasing salinity lowered the sensitivity of the clams to the internalized Cd (i.e., higher toxicity threshold and lower killing rate of Cd), whereas elevated the sensitivity of clams to the internalized Cu. This difference was presumably due to the different roles of the two metals in disrupting osmoregulation. The observed salinity effects in the toxicity tests were a combination of the effects on metal bioaccumulation and organisms' sensitivity to the internalized metals, and thus showed different patterns in different cases. In conclusion, the toxicokinetic-toxicodynamic model provided a useful framework for explaining the complex effects of salinity on metal toxicity, and can be used for better risk assessments of metals in estuarine waters.

364 Using the starlet anemone, Nematostella vectensis, for the assessment of effects and recovery in acute studies: development of a stress-response index

A.J. Smith, G.D. Miller, G.M. Rand, Florida International Univ / Southeast Environmental Research Center SERC

Cnidarians have not been routinely used and recovery is not a typical endpoint in aquatic toxicity studies to assess the effects of metal exposures on native species. We have developed a unique acute toxicity test with the starlet anemone, Nematostella vectensis, to evaluate general stress, toxicity, and recovery post exposure to metals. Juvenile anemones were used in acute toxicity studies with cadmium and copper and were subsequently held in clean control water for a duration of two weeks post-exposure to determine if highly stressed anemones were able to recover from potentially lethal exposures. A stress-response index matrix of macroscopically observable conditions was developed including parameters such as: anemone column shape, color, and condition; mesentery visibility and condition; tentacle shape and level of retraction; tissue color and level of opaqueness; and response to physical or optical stimuli. Anemones were assigned to a numerical level of stress based on exposure-effect relationships and conditions were monitored during the two week recovery process. Any change in anemone condition was recorded, all anemones were re-ranked at the end of the recovery duration, and toxicity endpoints were recalculated. Impact is demonstrated by comparing concentration-response curves for exposures pre- and post- recovery. When using novel or indigenous species in toxicity studies with limited toxicity data available in the literature, we recommend similar studies to understand the potential for recovery of those organisms.

365 Cellular biomarker responses in Aurelia aurita exposed to various copper concentrations as a novel pelagic & estuarine bioindicator

M. Lowder, UNC-Charlotte; A.H. Ringwood, UNC-Charlotte / Dept of Biology

Jellyfish are ubiquitous in marine systems, ranging from shallow bays and estuaries to great depths of pelagic areas. Due in part to the complexity of scyphozoan life histories, even slight changes in environmental factors can have an effect on fecundity, development and population fluctuations. Anthropogenic activities have been suggested as a major cause of increases in jellyfish. These include overfishing, eutrophication, and habitat modification. In addition, jellyfish, like other aquatic organisms, are exposed to a host of chemical contaminants in the ambient environment. Heavy metals, such as copper, are a major anthropogenic pollutant found throughout aquatic ecosystems. However, there are few accounts of copper contaminant effects on scyphozoans in terms of biochemical markers. This study evaluated a host of sub-lethal cellular biomarker assays combined with behavioral analyses to determine the effects of 48 hr. exposures to 5, 10, 25 and 50 ppb Cu concentrations on Aurelia aurita, the common moon jellyfish. No adverse effects were seen in medusae at 5 or 10 ppb. Results showed the lysosomal destabilization assay was the most sensitive assay when compared to glutathione and lipid peroxidation. Results for lipid peroxidation and total glutathione varied from exposure to exposure in both oral arm and bell tissues. Lipid peroxidation did not vary significantly as Cu concentration increased. Glutathione levels did increase as Cu concentration increased, suggesting that increased antioxidant capacity (glutathione) inhibited increased cellular damage by peroxidation of lipids. Behavioral differences were also observed as Cu concentration increased--decreased pulsation rate and a decline of suspension in the water column. Biochemical markers provide useful tools in determining molecular responses to contaminants that may have effects on A. aurita populations and are valuable for identifying species-specific sensitivities. These tests, coupled with behavioral analyses, can then further be used to assess ecological implications at the community and population levels.

366 Zinc and calcium pathways in the green crab Carcinus maenas

L. Nogueira, CAPES – Brazil; A. Cremazy, C.M. Wood, Univ of British Columbia / Dept of Zoology

Green shore crabs (Carcinus maenas) have been extensively used to determine impacts of metal contaminants, because of the high capacity of their carapace to retain metals from the aqueous solutions. The relationship between metals and ions provides an interesting focus since the crabs demand high amounts of Ca^{2+} and also because metals may possibly be taken up by Ca^{2+} transport pathways. This demand is directly related to carapace formation and molting which may mobilize Ca^{2+} to/from the carapace. We studied the pathways by which Ca^{2+} and Zn are taken up from ambient sea water by the green shore crabs (Carcinus maenas), by investigating the relative contribution of uptake through the gill versus uptake across the carapace. Alive, dead and carapace-covered crabs were exposed to radiolabelled Ca^{2+} and Zn individually for 24 h at 2°C, 12°C and 22°C and the spatio-temporal distribution of each element was determined. Our results indicate that Zn uptake pathway occurs mainly through the gills (~75%) and via biosorption in the carapace surface (~25%), while the Ca^{2+} uptake pathway is via the gills (~90%). At 24 h, radiolabelled Zn was mostly concentrated in the gills (~70%), while Ca^{2+} was mostly concentrated in the carapace (~60%). No change was observed between 2°C and 12°C. An increase of Zn in the gills (~290%) and both ions in the carapace (Ca^{2+}= ~280%; Zn= ~300%) was observed at 22°C relative to 12°C. Despite the increased uptake of the two metals, the pathway of Zn and Ca^{2+} uptake remained similar to 12°C (via gills, ~73% and ~88% respectively). However, the pathway of Zn deposition in the carapace differed. The deposition occurred via biosorption (~65%) and through the gills (~35%) followed by redistribution to the carapace (IDRC, NSERC Discovery).

367 Development of the marine amphipod Parhyale hawaiensis as a model organism for ecotoxicology

M. Artal, Univ of Sao Paulo – USP / Toxicology and Toxicology Analysis; A. dos Santos, L. Dornelas, M. Vannuci-Silva, Campinas State Univ; K. Pereira, São Paulo State Univ UNESP; A. Luchessi, Campinas State Univ; E.A. Almeida, UNESP/IBILCE/ Sao Jose do Rio Preto; T. Henry, Heriot-Watt Univ / School of Life Sciences; G. Umbuzeiro, School of Technology – UNICAMP / LEAL

Brazil has a huge abundance of surface water resources and many of these are threatened by anthropogenic pollutants. Investigation of the effects of pollutants on aquatic life is critical; however, there is a lack of ecotoxicity test organisms that are native to Brazil. The amphipod Parhyale hawaiensis is an important marine organism in Brazil and offers considerable potential to become a model for ecotoxicology. This amphipod is already a model organism in developmental and genetic studies and numerous tools are available for its use in ecotoxicology. Although some toxicity tests have been conducted with Parhyale, information regarding standardized methods, responses to reference toxicants, and test protocols are limited. Within our research program on the development of Parhyale for ecotoxicology, this study investigated the use of a miniaturized (96-well plate format) protocol to assess the acute toxicity of zinc, copper, silver, and cadmium. In addition, procedures for measurement of changes in expression of biomarker genes [Glutatione S-transferase (GST) and metallothionein (MT)] by quantitative PCR, and biomarker protein level (metallothionein) quantification by reversed-phase high-performance liquid chromatography were developed. Toxicity tests demonstrated the feasibility of the proposed protocol and showed that P. hawaiensis presents metal sensitivity in the range of other marine amphipods. LC50 (96 h) values were 1.63, 0.55, 3.73 and 1.09 mg L^{-1} for Ag, Cd, Cu and Zn, respectively (or 15.1, 4.93, 58.7 and 16.7 µM for Ag, Cd, Cu and Zn, respectively). Gene expression analyses and metallothionein quantification are still underway. This is the first report regarding metals toxicity and induction of toxicological biomarkers in this organism.

Science of Sediment Toxicity Testing: Method Advances, Interpreting Results and Use of Data in Ecological Risk Assessments

368 Analytical Challenges for Quantification of Test Materials in Prospective Sediment Toxicity Laboratory Investigations

D.A. Koch, ABC Laboratories, Inc.; J. Rhodes, ABC Laboratories

A key component of laboratory sediment toxicity testing for benthic organisms is the accurate measurement of the distribution of the test material between the sediment, pore water, and overlying water. For compounds having some degree of toxic effect, the lower concentrations which must be measured to elucidate dose response data present inherent challenges to the analytical chemist. Because of the unique nature of the sediment toxicity testing analytical measurement endpoints, the availability of applicable analytical methodology, in advance of this testing requirement being triggered, is not always a given. At times, the development of methods that can measure test compound concentrations at extremely low levels will be approaching the limits of currently available instrumental sensitivity. In particular, highly hydrophobic compounds can exacerbate the difficulty of the water measurements, as most of the compound will partition into the sediment phase, leaving very little to be measured in the water fractions. Practical approaches to these challenges will be discussed, along with possible strategies to employ when the measurements are particularly difficult for the levels being testing. Some representative strategies for the analysis of hydrophobic compounds in aqueous matrices will be presented.

369 SEDAG Spiked Sediment Database: A New Resource for Sediment Toxicology Data Discovery and Synthesis

S.M. Bay, Southern California Coastal Water Research Project / Toxicology Dept; P.L. Myre, Exa Data & Mapping Services; A.S. Bess, Chevron Energy Technology Company / Environmental Unit

Sediment toxicity is a key line of evidence for sediment quality evaluation and ecological risk assessment. Synthesis and analysis of field sediment toxicity data in the 1990's and 2000's resulted in the development of sediment quality guidelines (e.g., ERM, PEL) that are widely used to interpret sediment chemistry data. Most of these past synthesis efforts have focused on environmental sample toxicity results. Few resources are publicly available for discovery and use of spiked sediment toxicity test data, which are essential for stressor identification, developing models to predict contaminant bioavailability, and improving sediment quality guidelines. The SETAC Sediment Advisory Group (SEDAG) has coordinated a collaborative effort over the past two years to develop a web-accessible database containing results from spiked sediment toxicity tests. This effort has been successful, resulting in the development of a database structure, completion of the initial phase of database development, and creation of a web-accessible interface for accessing the data. This initial version of the database contains results from over 200 studies that have been compiled into a standardized format including information on test species, duration, toxicity response, spiking method, and sediment characteristics (e.g., TOC, grain size). Multiple effect endpoints (e.g., LC50, EC25, LOEC, NOEC) for over 100 types of chemicals, including metals, chlorinated pesticides, pyrethroid pesticides, and petroleum compounds are included. The database interface allows public access via internet browser and contains features to allow the user to design a customized query and download the data. Future plans for database development and maintenance will be described, including collaborative efforts for curation and addition of additional records.

370 The Challenges Associated With Achieving Freshwater Sediment Toxicity Testing Standardization in Australasia

W.T. Mehler, V.J. Pettigrove, Univ of Melbourne / Zoology

As stated in the description for this SETAC session – "Various acute, short-term, and chronic toxicity testing guidelines for freshwater (Chironomus, Hyalella) and marine (Leptocheirus) organisms are available." This statement, as based on North American species, also rings true, for much of Europe as well, as OECD and ASTM guidelines are available for both European native midges and amphipods (e.g. Chironomus riparius and Gammarus pulex). Unlike these developed countries, sediment toxicity testing (especially for freshwaters – which is the focus of this presentation) is still in its infancy in much of Australasia. The use of the aforementioned sediment toxicity testing guidelines is somewhat of limited use as these freshwater test organisms are not indigenous to these areas. This presentation will provide a snapshot of the current status of freshwater sediment toxicity testing in Australasia as well as the current challenges that standardization of freshwater sediment toxicology faces this area of the world.

371 Characterization of sediment chemistry, sediment toxicity and macroinvertebrate communities in wadeable streams of the Southeastern United States

P. Moran, USGS / Washington Water Science Center; N. Kemble, USGS / Columbia Environmental Research Center; L. Nowell, USGS / California Water Science Center; J. Hughes, C.G. Ingersoll, USGS / Columbia Environmental Research Center; I. Waite, USGS / Oregon Water Science Center; P.C. Van Metre, B. Mahler, USGS / Texas Water Science Center

As part of the US Geological Survey's (USGS) National Water-Quality Assessment (NAWQA) project, sediment samples from streams representative of an urban gradient and selected agricultural lands were evaluated from the southeastern United States (AL, GA, NC, SC, VA) in the summer of 2014 (DOI: 10.3133/ofr20151095). The study evaluated relationships between sediment toxicity, sediment chemistry (metals, pesticides, organochlorines, and polycyclic aromatic hydrocarbons) and co-located macroinvertebrate communities at 59 of those sites. Sediment toxicity was evaluated by conducting whole-sediment laboratory toxicity testing with the amphipod Hyalella azteca (28-d exposure), the midge Chironomus dilutus (10-d exposure), and the mussel Lampsilis siliquoidea (fatmucket; 28-d exposure) in accordance with ASTM and USEPA methods. Toxicity endpoints included survival, weight, and biomass. Mean control survival and growth at the end of the exposures met test acceptability criteria. Roughly half of the sediments were identified as toxic to at least one of the test species, based on a significant reduction of at least one endpoint relative to the control sediments. Amphipod survival, biomass, and weight declined significantly as the percentage of urban land within the basin increased. Concentrations of metals, PAHs, a few organochlorines and current use pesticides infrequently exceeded individual sediment quality guidelines (i.e., Probable Effect Concentrations (PEC) or recent Likely Effect Benchmarks (LEB) for pesticides). A Reference Envelope approach was also calculated that tended to increase the sensitivity of the toxicity endpoints due to strong and consistent control and reference site performances. Evaluation of concentrations relative to their benchmarks, both individually and as summed PEC or LEB quotients, was explored on both a carbon-normalized and a dry-weight basis. The use of these concentrations and benchmark exceedances in explaining both toxicity and macroinvertebrate communities co-located at these sites are presented.

372 Resolving Sediment Toxicity for Ecological Risk Assessment at Complex Urban Waterways

D.P. Hennessy, J. Volosin, Anchor QEA LLC; L. Logan, Anchor QEA; D.H. Haury, Anchor QEA LLC; D. Glaser, Anchor QEA

As part of the Baseline Ecological Risk Assessment for the Newtown Creek Remedial Investigation, 28-day sediment toxicity tests were completed for 36 creek stations and 24 reference area stations, using the amphipod Leptocheirus plumulosus. Reference area data were used to develop a reference envelope for comparison with the site that reflected the range of industrial and municipal point source/combined sewer overflow (CSO) impacts at the site. Bulk sediment was analyzed for more than 200 analytes and conventional parameters, as well as acid volatile sulfide (AVS) and simultaneously extracted metals (SEM), and pre- and post-toxicity testing, to evaluate metal bioavailability. Contaminant bioavailability was also evaluated by synoptically collecting porewater for polycyclic aromatic hydrocarbon (34) (PAH [34]), polychlorinated biphenyl congeners, and pesticides using solid-phase microextraction fibers, and for metals using mini-peepers. Concentration-response models were developed that included reference envelopes representing the 95% lower confidence limit on the 5th percentile for survival, growth (biomass and weight), and reproduction (per surviving amphipod and per surviving female amphipod). Using these models, a majority of the toxicity could be explained by porewater contaminant concentrations. For a number of locations, toxicity is likely due to PAH (34), with some contribution from metals. AVS and SEM indicated low bioavailability of cadmium, copper, lead, nickel, and zinc, with no change in bioavailability pre- and post-toxicity testing. However, for some stations, the cause of toxicity could not be resolved based on porewater contaminant concentrations or standard confounding factors such as sulfide, ammonia, and grain size. Given the proximity of these stations to municipal stormwater outfalls and CSOs, it is surmised that the unresolved toxicity may be expressed by other components of urban runoff or municipal discharges, which are currently under investigation. These findings strongly support the need for further evaluation of the factors confounding sediment toxicity test results in complex urban waterways.

373 Predicting sediment metal toxicity to Hyalella azteca using a metals mixtures version of the Biotic Ligand Model

R.C. Santore, K.E. Croteau, A.C. Ryan, Windward Environmental LLC

The Biotic Ligand Model (BLM) is a computational framework used for predicting the effects of water chemistry on metal bioavailability. In this presentation we describe the development of an extension of the BLM framework that can be applied to mixtures of multiple metals (the mBLM considers Cd, Cu, Ni, Pb, and Zn). The mBLM was used to predict toxicity in chronic exposures with Hyalella azteca. Calibration of the mBLM to H. azteca was accomplished by comparison with water-only toxicity tests. Equilibrium partitioning theory predicts that the toxic effect that may result from exposure to sediment pore-water is similar to effects resulting from exposure to the water column. The calibrated model was then used to predict whether field sediments from several sites characterized by elevated metal concentrations would be toxic to H. azteca. Predicted toxicity was compared with measured toxicity in chronic tests with H. azteca from several field sites and high predictability was observed. The mBLM analysis allows sediments to be ranked to identify which samples would be most likely to cause toxicity. The mBLM can also identify which metals in the mixture of metals are most likely to be responsible for any observed toxicity. The overall good performance of the mBLM suggests that it is a powerful predictive tool for use in assessing risk from metal concentrations in field sediments and could be used as part of a general methodology in the development of sediment guidelines.

374 Evaluating the relative sensitivity of endpoints generated during midge life-cycle for US FIFRA sediment toxicity test requirements-Part II

T.W. Valenti, Syngenta Crop Protection LLC / Environmental Safety; A.K. Kabler, Syngenta Crop Protection, Inc. / Ecological Risk Assessment; A. Samel, DuPont Crop Protection; A.J. Jones, DuPont Crop Protection / Inst of Environmental Toxicology; J.W. Green, DuPont / Applied Statistics Group; J.P. Staveley, Exponent; B. Sharma, FMC Corp/ Global Regulatory Sciences; M. McCoole, Bayer CropScience / Environmental Toxicology and Risk Assessment; J. Wang, BASF Corporation / Environmental Toxicology; M. Habekost, BASF Corporation; H.O. Krueger, Wildlife International / Aquatic Plant and Insect Toxicology; S. Thomas, Wildlife International; M.J. Bradley, Smithers Viscient / Sediment Toxicology; C.R. Picard, Smithers Viscient / Sediment and Plant Ecotoxicology; J.M. Giddings, Compliance Services International; J. Gates, M.A. Cafarella, Waterborne Environmental, Inc / Ecotoxicology; I. Saab, CropLife America; K. Henry, NovaSource / Tessenderlo Kerley, Inc. / Ecological Sciences

Currently, lethality-based endpoints for chironomid (midge) life-cycle experiments described in USEPA test guidelines include larval, pupal, and adult survival, while sublethal endpoints include larval growth, adult emergence (total/percent, cumulative rate, time to first emergence, time to death, and sex ratio), and reproduction (time to oviposition, mean eggs/female, egg cases/treatment, and egg hatchability). High variability in control response and redundancy of information gained from similar observations prompted questions about the utility and/or necessity of certain endpoints for defining biological effect thresholds. This research is a continuation of that presented by the CropLife America Ecotox Work Group Sediment team at the SETAC North America 2015 meeting that detailed insight gained following the compilation of recen midge toxicity studies into a database. Meta-analysis of the data demonstrated that larval endpoints (survival and growth) and adult emergence consistently established the lowest NOEC values for individual studies, whereas reproductive endpoints and adult survival were always less sensitive. This presentation continues to focus on the relative sensitivity of endpoints, but more closely examines inter- and intra-replicate variability as well as the presence or absence of dose-dependent responses. Based on further analysis of information in the CropLife America database, coupled with considerations related to the effort required to gather endpoint data, suggestions for streamlining the number of measured endpoints to improve test method efficiency and provide researchers with greater confidence that observed effects are indeed related to contaminant exposure will be discussed.

375 EPA's Method for the Amphipod, Hyalella azteca, Water-only Exposures for Acute, Short-Term Tests, and Chronic Toxicity Tests

T.J. Norberg-King, T.L. Highland, R. Hockett, D.R. Mount, USEPA / ORD NHEERL Mid-Continent Ecology Division

Hyalella azteca, a freshwater amphipod, is a common organism used for sediment toxicity testing in North America. USEPA/ASTM and Environment Canada have standard methods for short-term and longer-term sediment toxicity tests with H. azteca. However, a protocol has not been published or updated recently by USEPA/ASTM that provides guidance for the water-only testing of this species. Programs for registering chemicals, monitoring effluent discharges and receiving waters, and developing water quality guidelines have a need for data from additional freshwater invertebrates, particularly those that can be used to derive chronic effect data. At EPA-Duluth, we have successfully performed chronic water-only tests with H. azteca through reproduction, and these long-term tests can be adapted for shorter durations, such as the 28-day exposures with H. azteca (measuring growth and survival). We will present the methods that we currently use for tests of various durations, including 96-h, 10-d, 28-d, and full chronic tests of 42- to 49-d. Disclaimer: This presentation does not necessarily reflect the views or the policies of the U.S. Environmental Protection Agency.

Assessing Contaminant Effects in Multi-Stress Ecosystems – Part 1

376 Can a comprehensive understanding of real drivers of ecological degradation be drawn from presently available data? A case study for Europe

I. Rodea-Palomares, Univ of Florida / IFAS / Agricultural & Biological Engineering; R. Muñoz-Carpena, Univ of Florida / Agricultural Biological Engineering

During the last decades, Ecotoxicology has drawn the basic cartography of chemical pollution and its potential ecological impacts. However, these maps are still fragmented and not ready to answer apparently simple questions from the real world such as: what is the main driver on the observed ecological alterations at a certain scale?; is it organic chemical pollution or other factor such as just nutrient enrichment or hydrological alteration?; in a common scale metric, which of these factors are more important? Few studies addressed large-scale ecological effects of chemical pollution, and even fewer are examine the relative contribution of organic chemical pollution in the context of other relevant chemical (such as eutrophization, acidification, salination, etc.) or non-chemical (such as hydrological alterations, erosion, irrigation, land cover changes, etc.) factors. Data scarcity, data fragmentation and the unavailability of chemical pollution remote sensing data hampers such large scale integrated studies. The present talk will cover the aims, methods and preliminary results of a project that aims to infer large-scale patterns of ecological degradation that can be asigned to chemical pollutants in the context of other potential stressors. This will be addressed with a novel integration of data mining, mechanistic modelling and GSA/UA analysis. The ultimate aim is to build relative importance map for different chemical pollutats in the context of other ecological stressors at the continental scale (Europe). The project mines data from the largest database of chemical pollution in Europe made available by the European Commision (more that 4000 monitoring stations, with more than 140 monitored chemical pollutants). In addition we used publicly available remote sensing data (climatic information, land cover, vegetation, etc.), global biodiversity data (Global Biodiversity International Facility) and other sociological, hydrological and geomorphological data sources to inform the analysis. We will critically analyse the characteristics of available data, their strenghts and weaknesess, the inferential approaches followed and the results obtained. Results from this analysis will be of interest to valuate the suitability of present data sources to inform large-scale integrated analysis and to identify structural gaps and defects in present monitoring strategies that may hinder or limit the potential success of such large scale analysis.

377 Urban runoff differentially affects coho and chum salmon spawners

J. McIntyre, Washington State Univ; M. Chow, Univ of Washington / School of Aquatic and Fishery Sciences; J.A. Spromberg, Earth Resources Technology Inc. with NOAA Fisheries / Northwest Fisheries Science Center; J. Lundin, NRC with NOAA Fisheries / Northwest Fisheries Science Center; J. Davis, US Fish & Wildlife Service / Division of Environmental Assessment and Restoration; J.D. Stark, Washington State Univ / Dept of Entomology; J. Incardona, NOAA Fisheries / Env Fisheries Division; N. Scholz, NOAA Fisheries

Urban stormwater runoff contains a complex mixture of contaminants that enter receiving waters when it rains. This mixture can cause a variety of toxic responses in fish and invertebrates, including mortality and cardiovascular abnormalities. In the Pacific Northwest, stormwater runoff causes pre-spawning mortality (PSM) in adult coho salmon (Oncorhynchus kisutch) returning to spawn in urban-impacted streams. Within a few hours of exposure, symptoms progress from lethargy and disorientation to loss of equilibrium, immobility, and eventually death. Although we do not know the precise cause of PSM, we previously determined that coho PSM is linked to storm events. Chum salmon (O. keta) spawning runs often overlap with coho. To determine whether chum are similarly susceptible to PSM, we co-exposed pre-spawn adult coho and chum to urban road runoff or well water in controlled exposures for 6 storm events. We monitored water quality and individual behavior throughout exposure. Exposures were terminated after 4 h or when fish became symptomatic. Only coho exposed to runoff became symptomatic. Across the 4-h exposure, chum appeared behaviorally unaffected by urban runoff. Furthermore, a point-of-care blood analyzer was used to measure ion concentrations and gases, pH, hematocrit, glucose, and lactate in arterial blood. Multiple blood chemistry parameters were affected in runoff-exposed coho compared to control coho, leading to the hypothesis of metabolic acidosis as the cause of death. In contrast, chum exposed to runoff were much less sensitive than controls.

378 Climate change and contaminants: A recipe for trouble

S. Hasenbein, Univ of California, Davis / VMAPC; H.C. Poynton, Univ of Massachusetts, Boston / School for the Environment; R.E. Connon, Univ of California, Davis / School of Veterinary Medicine

Global climate change (GCC) is forecasted to increase water temperature and salinity in many aquatic ecosystems with predicted impacts to biodiversity within these systems. Synergistic effects between climate and other anthropogenic threats, such as water pollution, will likely intensify climate-change impacts. As climate change accelerates, pesticide use is predicted to increase to combat insect-pests and diseases, potentially affecting non-target organisms in sensitive habitats. Our previous research has shown that exposure to contaminants may elicit toxic effects even at concentrations below the limit of detection. As such it is critical to understand how organisms will respond to GCC stressors in the presence of contaminants. We exposed the amphipod Hyalella azteca to a matrix of temperatures and salinities ranging from 12 to 18°C and 0.2 to 8 parts per thousand (ppt), respectively, in combination with a low-level environmentally relevant concentration of the pyrethroid insecticide bifenthrin (1 ng/L) for 24h, 48h, and 96h. Cellular stress gene responses were monitored at all three time points using quantitative Polymerase Chain Reaction (qPCR). After 96h of exposure, an additional set of replicates was used to investigate changes in swimming behavior using the Ethovision video imaging software DanioScope and effects on growth among treatments and compared to controls. Our results demonstrate that compared to control conditions, the GCC related stressors salinity and temperature, result in negative effects to invertebrate motility, growth, and cellular stress gene response. However, the effects on all three endpoints are significantly more pronounced in the presence of bifenthrin compared to salinity and temperature alone. In addition, survival was significantly decreased in pyrethroid treatments combined with salinities of 4 and 8 ppt compared to treatments without the pyrethroid. These environmentally relevant exposures using the standard test species H. azteca provide essential information for understanding effects caused by GCC in conjunction with increasing pesticide use, further highlighting the need to incorporate GCC impacts into risk assessments of contaminants of concern.

379 Potential Effects of Pesticide Mixtures on Stream Quality in the Midwestern United States

L.H. Nowell, USGS / California Water Science Center; P.C. Van Metre, USGS / Texas Water Science Center; J.E. Norman, USGS / Oregon Water Science Center; D.A. Alvarez, USGS-CERC / Physiology and Biochemistry; P. Moran, USGS / Washington Water Science Center; A. Gellis, USGS / Maryland Delaware DC Water Science Center; I. Waite, USGS / Oregon Water Science Center; T.S. Schmidt, USGS / Colorado Water Science Center; H. Rogers, USGS / Fort Collins Science Center; B.J. Mahler, USGS / Water Mission Area; W.W. Stone, USGS / Indiana Water Science Center; M.E. Shoda, USGS / Indiana Kentucky Water Science Center; M.W. Sandstrom, USGS / National Water Quality Laboratory; M.L. Hladik, USGS / California Water Science Center

Pesticide occurrence and ecological condition were characterized in 100 wadeable streams in the Midwestern U.S. during May-August 2013 by the U.S. Geological Survey's National Water-Quality Assessment (NAWQA)

Project, in collaboration with the U.S. Environmental Protection Agency. Twelve weekly water samples and extracts from passive Polar Organic Compound Integrative Samplers (POCIS, deployed for about 5 weeks) were analyzed for 227 pesticide compounds (including degradates) at each site. Pesticides also were analyzed in daily composite water samples collected throughout the study period by microautosamplers at 7 streams. At the end of the study period, depositional bed sediment was sampled and analyzed for 118 pesticides and sediment-source tracking radioisotopes, and habitat and benthic invertebrate communities were surveyed. Complex pesticide mixtures were observed in weekly water samples (median 25 compounds) and in POCIS extracts (median 62 compounds). Herbicides and many degradates were detected in >90% of samples. Insecticides (often a single compound, especially imidacloprid) dominated the Pesticide Toxicity Index (PTI) in water for invertebrates, which reflects both concentrations and acute toxicity of pesticides in a mixture. Pesticide results for daily composite water samples showed that weekly discrete water samples frequently missed pesticide-concentration peaks, including insecticides present at potentially toxic levels. Compared to agricultural streams, urban streams tended to have higher PTI values, detection frequencies of most insecticides and fungicides in water, insecticide concentrations (bifenthrin and DDE) in bed sediment, and percentage of surface-derived bed sediment. The potential importance of pyrethroid insecticides was indicated by the predominance of bifenthrin in the sediment-PTI and by invertebrate community multistressor models, in which pyrethroid degradates in POCIS (cis-cyhalothric acid, 3-phenoxybenzoic acid) were significant explanatory variables. Mesocosm experiments supported these findings by showing that exposure to bifenthrin in suspended sediment caused effects on invertebrate communities that were consistent with bifenthrin concentrations and invertebrate community condition observed in Midwestern stream sediments.

380 Proteomics and Transcriptomics analyses of Florida Manatee (Trichechus Manatus Latirostris) Mortalities in 2013

R. Lazensky, Univ of Florida / Center for Environmental and Human Toxicology; N.D. Denslow, Univ of Florida / Physiological Sciences; M.T. Walsh, K. Kroll, Univ of Florida; M. de Wit, Florida Fish and Wildlife Conservation Commission; M. Hunter, USGS / The Wetland and Aquatic Research Center; C.J. Walsh, Mote Marine Laboratory; K. Tripp, Save the Manatee Club

In 2013, two large-scale Florida manatee (Trichechus manatus latirostris) mortality episodes were associated with 830 deaths and a substantial population loss. The mortality episodes occurred on separate coasts of Florida, near Fort Myers on the west coast and in the Indian River Lagoon (IRL) on the east coast. The IRL mortality episode was associated with an unknown etiology and the Southwest Florida episode was attributed to a persistent bloom of red tide (Karenia brevis) algae in the region. Proteomics experiments on serum from healthy and impacted manatees indicated effects to the immune system, including proteins involved in inflammation and wounds and injuries. Several protein biomarkers were elevated in manatees from the unknown mortality compared to health manatees including complement C4-a isoform 1 (average ratio 1.25), histidine-rich glycoprotein (1.34), kininogen-1 isoform 1 (1.38), properdin (1.30), and protein AMBP (1.38). In the group of manatees recovering from red tide, several proteins were elevated including, complement C3 (1.42), complement C4-A isoform 1 (1.83), ceruloplasmin-like (2.32), angiotensinogen (2.08), and pyruvate kinase isozymes M1/M2 isoform 3 (2.29). These proteins are associated with acute-phase response, amyloid formation and accumulation, copper and iron homeostasis, the complement cascade pathway, and other important cellular functions and may serve as informative biomarker proteins for manatees. RNAseq was also performed on total RNA isolated from white blood cells comparing the red tide group to other manatees. The genes with the highest fold changes (FCs) and p-value < 0.05 were the OSCAR gene (3.68, p-value 0.0485), transmembrane protein 56-like (3.53 fold, 0.000036), myotubularin related protein 2, transcript variant 2 (MTMR2) (3.53, 0.0015), thymocyte selection associated family member 2 (THEMIS2) (3.38, 0.0005), matrix metallopeptidase 9 (MMP9) (3.32, 0.0450) and haptoglobin (HP) (3.28, 0.0013). Several genes were down regulated including many involved in the immune system. This work indicated that the immune system, leukocyte production and differentiation, neuronal activity and synapse and tumor invasiveness were major pathways targeted by red tide exposure.

381 Environmental Temperature Moderates the Effects of Estrogenic Exposure on Larval Fathead Minnows

M. Cox, St. Cloud State Univ / Biology; K. Peterson, P. Novak, Univ of Minnesota / Civil Engineering; J. Ward, Univ of Minnesota / Dept of Fisheries Wildlife and Conservation Biology; H.I. Schoenfuss, St. Cloud State Univ / Aquatic Toxicology Laboratory

Exposure to wastewater estrogens been shown to adversely affect the survival and behavior of fish. However, evaluating the effects of estrogen exposure on individuals is complicated by the fact that rates of chemical uptake and environmental degradation are dependent on abiotic factors, such as temperature. A factorial experiment was conducted to assess the influences of temperature and estrogen concentration on larval fathead minnows (P. promelas). Larvae were exposed to 3 concentrations of estrone (low, high) or to an ethanol control, at 4 water temperatures (15, 18, 21, or 24 °C) for 21 days. Exposure-induced genetic and behavioral changes were assessed using established methodology for the quantification of fast-start (C-start) locomotive mechanics, a novel foraging efficiency behavioral assay, and gene expression analysis using SYBR-green RT-qPCR. A significant interaction between estrone concentration and temperature influenced predator evasion total escape response ($P = 0.027$), compared to control subjects, exposed subjects exhibited reduced escape performances at colder temperatures. Results for larval feeding efficiency did not show a significant interaction between temperature and estrone exposure, all larvae consumed prey at similar rates regardless of treatment. The analyses indicate that temperature has significant context-dependent modulating effects on behavioral interactions of exposed biota. Predicted scenarios for climate change, mounting pollution, and habitat loss continue to increase the environmental pressures on wildlife, therefore it is important to understand how abiotic factors moderate toxicant exposure during sensitive life stages of aquatic organisms.

382 Evaluating Stormwater Impacts on Coastal Sediment Recontamination

D.D. Reible, B. Anandha Rao, Texas Tech Univ / Civil and Environmental Engineering; D. Athanasiou, I. Drygiannaki, Texas Tech Univ; M. Rakowska, Texas Tech Univ / Civil Environmental and Construction Engineering; M. Bejar, Texas Tech Univ; M. Otto, B. Steets, Geosyntec Consultants; R. Pitt, The Univ of Alabama; M. Colvin, SPAWAR Systems Center San Diego; G.H. Rosen, SPAWAR Systems Center / Energy and Environmental Sustainability; B. Chadwick, SPAWAR Systems Center San Diego / Energy and Environmental Sciences; A. Burton, Univ of Michigan / School of Natural Resources Environment

Cleanup at contaminated sediment sites has often been initiated before land-based sources have been fully identified and controlled. Under such conditions, remediated sites may be re-contaminated by ephemeral inputs, e.g. from stormwater runoff which may contain high levels of solids-associated contaminants of concern (COCs). Historically stormwater assessment has been focused on loads rather than impacts on receiving sediments. Our objective is to develop and test techniques to assess the magnitude and characteristics of solid associated contaminants into receiving waters and sediments due to episodic storm events. Paleta Creek near Naval Base San Diego was selected for monitoring and modeling of stormwater and receiving environment response. Composite runoff samples were collected using auto-samplers, which were triggered at each location by site-specific criteria. The samples were analyzed for a variety of metals and organic contaminants as a function of particle size. Receiving waters were monitored for flow trajectory, sediment deposition and COCs. Sediments collected in outfalls, deposition traps and in the receiving environment were also subjected to chemical analysis and biological testing. The results show that the initial flush contained the highest COCs with zinc, fluoranthene and pyrene being among the dominant COCs. Over time the contaminant loadings decreased due to reduction in particulate contaminants while the concentrations in finer, colloidal and freely available size fractions remained relatively constant. Toxicity testing of stormwater runoff samples showed typical chronic toxicity, however, samples taken in the receiving environment over the course of the storm (~12hrs) showed decreasing toxicity with time. Toxicity testing of receiving sediments with amphipods also showed significant toxicity associated with stormwater sediment loads with increasing impairment as the wet season progressed.

383 Lessons Learned from the South River and Upper Shenandoah Series of Multiple Stressor Ecological and Human Well-being Risk Assessments

W.G. Landis, K. Kolb Ayre, Western Washington Univ / Inst of Environmental Toxicology; L. Gaasland-Tatro, Western Washington Univ / Environmental Science; S.E. Graham, Western Washington Univ / Inst of Environment Toxicology; C.E. Herring, Western Washington Univ / Inst of Environmental Toxicology; A. Johns, NOAA / OR&R / ARD / Inst of Environmental Toxicology; A.J. Markiewicz, M. Harris, Western Washington Univ / Inst of Environmental Toxicology; J.M. Stinson, Western Washington Univ / Inst of Enviromental Toxicology; H. Summers, Integral Consulting Inc. / Inst of Environmental Toxicology and Chemistry

We have conducted a series of regional scale risk assessments using the Bayesian Network Relative Risk Model (BN-RRM) to calculate the ecological and human well being risks to the South River and upper Shenandoah River study area abbreviated SSRA. The ecological endpoints were Smallmouth bass, White sucker, Belted Kingfisher and Carolina Wren and four abiotic endpoints; Fishing River Use, Swimming River Use, Boating River Use and Water Quality Standards. A further ecological risk assessment was performed incorporating two management options, bank stabilization and agricultural best management practices. The third risk assessment integrated human health and ecosystem services with the endpoints Human health, Water quality, Recreation, and the Recreational fishery. The final risk assessment in the series estimated the effects of an increase in temperature to three endpoints, smallmouth bass, white sucker and Caroline wren due to climate change in the 2071-2100 timeframe. Although mercury (Hg) contamination was the original imputes for the site being studied and remediation initiated, other chemical and physical stressors were critical and often were the largest contributor to risk depending on endpoint and location in the watershed. Bank stabilization does reduce risk to some of the endpoints but the design also needs to consider an increase in risk to belted kingfisher along bank habitats. The increase in temperature due to climate change did not increase risk to the three endpoints but in some instances reduced risk. In the integrated human health and ecosystem services assessment Hg was the first ranked stressor for human health. River temperature and E. coli were the major contributors to risk for water quality and recreational river use. The primary conclusion is that it is possible to build a risk assessment process using the BN-RRM approach that incorporates multiple types of stressor and endpoints over large spatial scales. Human health risk can be compared to those including water quality, biological endpoints and ecosystem services. The risk assessment process can also be incorporated into an adaptive management framework that incorporates governance, stakeholder engagement, decision making and the occurrence of Black Swans, factors such as climate change or unforeseen social or technological factors.

The Other Oil Spills

384 Effects of a petroleum spill on stream communities in West Creek, Colorado

S.B. Duggan, Colorado State Univ; P. Schaffer, Colorado State Univ / Veterinary Medicine and Biomedical Sciences; L. Martin, Colorado Parks and Wildlife / Aquatic Biology; W.H. Clements, Colorado State Univ / Dept of Fish Wildlife and Conservation Biology

Oil development has expanded dramatically in Colorado over the last decade. As a result, there has been a significant increase in the number of accidental releases into the environment. In 2014, over 300 petroleum spills were reported to the Colorado Department of Health. The Unaweep Canyon spill in January 2013 discharged 22,700 liters of gasoline and 7,300 liters of diesel fuel into West Creek, a tributary to the Dolores River, acutely killing an estimated 1,200 brown trout and 8,200 mottled sculpin. Five subsequent electrofishing surveys over the following three years indicated that the fishery was not recovering, particularly with regard to mottled sculpin abundance. In June and October 2015 we explored stream health indicators across multiple levels of biological organization in order to determine the long-term effects of this spill. Significantly elevated white blood cell counts were detected in mottled sculpin collected from the spill site. Histopathological abnormalities including hepatocyte necrosis and hepatocyte cytomegaly and karyomegaly were discovered. Increased melanomacrophage aggregates were observed in older fish relative to young fish, with a greater disparity between the age classes at downstream sites. Occasional congenital anomalies were also identified (cystic renal tubular ectasia; neural choristoma) in mottled sculpin at the spill site and downstream. Altered benthic macroinvertebrate community structure was detected at the spill site compared with a reference site one kilometer upstream. Interestingly, GC-MS finger-printing analysis of polycyclic aromatic hydrocarbons (PAH) in stream sediment revealed that by 2015 PAH concentrations, at all sites, were typical of a minimally impacted stream flowing adjacent to a road. These results indicate that the biological effects of the spill were persisting after sediment PAH concentrations had returned to ‘normal’.

385 Lac-Mégantic Oil Spill and Disaster – Quality and Toxicity Assessment: Results, Difficulties and Concerns

R. Galvez, Laval Univ / Génie Civil; A. De Santiago Martin, G. Guesdon, Laval Univ / Civil and Water Engineering

On the night of July 5, 2013, a freight train carrying light crude oil from North Dakota derailed in the town of Lac-Mégantic (Quebec, Canada), causing explosions, fires and the spill of close to 7000m^3 of oil. This catastrophe resulted in 47 human deaths, the destruction of the city’s downtown and significant environmental pollution. Indeed, oil infiltrated soils and contaminated Lac-Mégantic (lake) and the Chaudière River. Floating oil was observed up to 186 km from Lac-Mégantic in the direction of the St. Lawrence River. This emergency is considered the worst case of an inland oil spill in North America. Remediation actions included excavation and biotreatment of contaminated urban soils and monitoring of contaminated water and sediments along the Chaudiere River. Following the accident, quality assessments on water, soils and sediments within a 190Km corridor between the lake and river were undertaken by the Québec Government for the first two years. A multidisciplinary group of researchers from five of Quebec universities initiated a vast research program in order to use this case as a learning instrument for various environmental studies that included emergency actions and environmental impact evaluation. Within this second aspect, the group integrated and analyzed the data from the universities and government to give a more accurate portrait of the environmental short term and long term impacts following the disaster including chemistry, toxicity assessment and ecology. Special issues needed to be considered for these assessments given the presence of poorly known unconventional light crude from North Dakota that included a varied mixture of chemical additives. This paper aims to present the results concerning Lac-Mégantic’s soil’s and Chaudière River sediment quality and toxicity studies.

386 Diluted Bitumen (Oil Sands) Spills into Rivers--Lessons from the 2010 Enbridge Line 6B Pipeline Release into the Kalamazoo River

F. Fitzpatrick, USGS; R.H. Dollhopf, USEPA

New application of science is changing response strategies for spills of crude oil into freshwater ecosystems, especially for diluted bitumen spills. The Enbridge Line 6B pipeline release of diluted bitumen into the Kalamazoo River downstream of Marshall, MI in July 2010 was one of the largest freshwater oil spills in North American history. The unprecedented scale of impact and quantity of oil released required the development and implementation of new approaches for submerged oil detection and recovery. At the onset of cleanup, conventional recovery techniques were successfully employed for the initially floating oil. However, volatilization of lighter diluent, and mixing of oil with sediment during flooded, turbulent river conditions caused the oil to begin sinking within 10 days of the discharge. For the next four years, the cleanup would focus on the submerged oil that had collected in natural deposition areas along 38 miles of river corridor, including three impoundments. Total cleanup costs would eventually exceed a billion dollars. Recovery complexities for submerged oil mixed with sediment in depositional areas and chronic, spontaneous oil sheens along the river led to the development of a multiple-lines-of-evidence approach comprising six major components: geomorphic mapping, field assessments of submerged oil (poling), systematic mapping of oil sheen, hydrodynamic and sediment transport modeling, forensic oil chemistry, and net environmental benefit analysis (NEBA). The approach was developed through close communication between scientists and operations staff, especially concerning matters of prioritization and containment. Information from the integration of these six techniques was used by the Federal On-Scene Coordinator (FOSC) in determining the appropriate course of action for each impacted segment of the river. The NEBA allowed the FOSC to weigh the ecological risks associated with leaving residual submerged oil in place against potential negative effects associated with removing the oil. Eventually, dredging was determined to be the appropriate approach, mainly in the large impoundments where most of the submerged oil settled. The need for quick use of conventional recovery tactics, submerged oil containment, multidisciplinary science, and implementation of contingency planning for effective response organization are major lessons learned. All rely upon an understanding of the time continuum of diluted bitumen weathering processes.

387 The Montara Oil Spill, Timor Sea – Two Years of Fish Health Monitoring

M. Gagnon, C. Rawson, Curtin Univ / Environment and Agriculture

The Montara incident which occurred in 2009 in the Timor Sea, resulted in the release of an estimated 23,000 barrels of oil and gas condensate over 74 days. Following the operational response, the scientific monitoring focussed on commercially important fish in order to ascertain the suitability for human consumption, as well as inform on the long term effects of the oil spill on fish health. Red emperor (Lutjanus sebae, n = 807) and glodband snapper (Pristipomoides multidens, n = 1531) were sampled over 2 years flowing the accidental release, and biopsies collected. A suite of physiological indices (condition factor, liver somatic index and the gonadosomatic index), biomarkers (EROD activity, biliary polycyclic aromatic hydrocarbon (PAH) metabolites, liver integrity measured by serum sorbitol dehydrogenase activity (SDH), oxidative DNA damage) were measured. While fish initially showed signs of exposure to petroleum hydrocarbons, biomarker of exposure in fish collected in the most impacted area have returned to reference levels within 24 months. Only liver somatic index in fish collected at the spill site remained elevated two years after the spill, relative to fish from other locations. Two years of monitoring following the oil spill in a tropical open sea provided information on biomarker tools that are suited to short-term, or long-term monitoring of effects from discharged light crude oil.

388 Toxicity of organic fractions of hydraulic fracturing flowback and produced water (FPW) to early life stage of zebrafish

Y. He, E. Folkerts, Univ of Alberta / Biological Sciences; Y. Zhang, D. Ruan, J.W. Martin, Univ of Alberta / Laboratory Medicine and Pathology; G. Goss, Univ of Alberta / Biological Sciences

The potential environmental risk related to horizontal drilling with high-volume hydraulic fracturing (HF) has drawn a lot of public concerns. However, the toxic effects on fish embryo development posed by HF flowback and produced water (FPW) has not been well studied. FPW is a complex mixture of organic and inorganic constituents in HF fluids and deep formation water. The surface spills of FPW may cause acute and/or long term environmental impacts on aquatic ecosystems. Previous studies indicated FPW may have endocrine disruptive and embryotoxic effects on fish. In this study, the total organic fractions were extracted from sediment-free water and sediment phases of several representative FPW samples. Analyses of PAH profile were performed for each organic fractions, demonstrating that FPW samples have complicated and highly variable organic profiles based on but not limited to PAHs profile results. Zebrafish embryos were exposed to various concentrations of organic fractions for 96 h. Compared to the previous studies using the dilutions of original FPW samples, the organic fractions of FPWs have much higher LC50 values, demonstrating that the acute toxicity is dominated primarily by high salinity in original FPW samples. However, exposure to organic fractions of FPWs significantly increased the incidences of morphological deformities in zebrafish embryo development, including pericardial edema, yolk sac edema, and spinal curvature. The Ethoxyresorufin-O-deethylase (EROD) assay using hatched larvae demonstrated significant increases in EROD activity in each exposure groups. Expression of a series of genes related to xenobiotic metabolism, oxidative stress and endocrine disruption were also found to be altered in exposure groups through quantitative real-time polymerase chain reaction. These findings provided novel information on the toxicity of organic contents in FPWs, and suggested that the organic contaminants released from FPW spills may have potential long-term environmental effects of FPW spills on teleost early development.

389 Developmental and endocrine responses in a freshwater fish (Oreochromis mossambicus) and amphibian (Xenopus laevis), exposed to old bunkered crude oil

J.H. van Wyk, J.C. Truter, S. Ndlovu, Stellenbosch Univ / Botany and Zoology

Crude oil pollution has been linked to health disorders in various aquatic vertebrate species. Most published research reported on marine organisms whereas little is known about the health effects of crude oil on freshwater aquatic vertebrates. In this study we used African clawed frog (Xenopus laevis), and Mozambique tilapia fish (Oreochromis mossambicus), as model organisms to study effects of crude oil on the endocrine systems of freshwater vertebrates. For exposures, we prepared water accommodated fractions (WAF) of crude oil and collected surface water samples downstream of an old coal mine bunker. Following short- and long-term exposures we used several in vitro and in vivo bioassays, including recombinant yeast assays, frog testis cultures, frog embryo-toxicity and teratogenesis assays, juvenile fish and tadpole exposure, to assess morphological, histological and molecular endpoints associated with several pathways, including thy thyroid endocrine system. The bunker crude oil WAF did not exhibit teratogenic potential nor embryo-toxicity. However, a higher malformation incidence was observed in frog larvae exposed to surface water collected downstream from receiving waters. The crude oil did exhibit both anti-androgenic and anti-estrogenic activity. Anti-androgenic activity was also recorded in surface water samples, as well as water samples collected from two oil/water separation plants. No significant differences in male hormone production by testis tissue slices exposed to WAF, or in the expression of genes associated with reproductive or thyroid signaling were recorded. However, the expression of the polycyclic aromatic hydrocarbon (PAH) sensitive cytochrome P450 1a1 was significantly upregulated in response to WAF exposure. Gene expression biomarkers in Mozambique tilapia exposed for a short period to WAF indicated a risk of disruption of the male and thyroid hormonal systems, but only at a high WAF concentration. A longer term, premetamorphic tadpole exposure, showed that the WAF has the potential to disrupt the thyroid systems of exposed wildlife. In addition, the aromatase coding, cyp19a1 gene was significantly altered. However, none of the other 15 genes evaluated, representing multiple pathways, were significantly modulated following WAF exposure. In general, our data suggest a low risk for freshwater aquatic vertebrates, exposed to aged crude oil form this old underground bunker or in the downstream sites of the receiving waters.

390 Respirometry and Swim Performance Alterations in Zebrafish (Danio rerio) acutely exposed to Hydraulic Fracturing Flowback and Produced Water

E. Folkerts, G. Goss, Univ of Alberta / Biological Sciences

Horizontal hydraulic fracturing is an emerging practice in North America to extract oil and gas reserves. To date, little toxicological information is supplied for both the technologies and chemicals used during the fracturing process, and for the surface returned by-product fracturing flowback and produced water (FPW). Volumes of water used per well can often exceed 1 million m^3, resulting in potentially devastating environmental effects when spills of FPW occur. Although salinity dominates much of the toxicity observed, other inorganic (e.g. metals, radionuclides, etc) and organic (e.g. polyaromatic hydrocarbons, benzenes, etc.) molecules found in FPW can induce toxicological responses in exposed organisms. The current study uses zebrafish (Danio rerio) as a model organism to determine if acute exposures to FPW induce developmental changes in organismal oxygen uptake. To determine if exposure to dilute FPW resulted in changes in oxygen consumption, zebrafish embryos were acutely exposed to 2.5% and 5% FPW and oxygen consumption was measured. Transcriptional analyses of specific hypoxia, stress inducible, and cardiovascular genes were performed and paired with embryo metabolic rates to determine if FPW exposure affected immediate embryo oxygen consumption, and if FPW-induced respirometry changes persisted after exposure was terminated. Finally, juvenile zebrafish swim performance experiments were performed to determine if acute FPW exposure affected later stage fish fitness. This is one of the first studies to use respirometry as a metric for measuring FPW induced toxicity. Our results aim to validate respirometry as a potential toxicological biomarker for identifying biological zones of impact when FPW spills occur, and provide regulating agencies information to help shape future FPW spill/leak remediation protocols.

391 Rapid adaptation to oil exposure in the cosmopolitan copepod Acartia tonsa

K.E. Krause, Technical Univ of Denmark DTU / Section for Marine Ecology and Oceanography DTU Aqua; K. Dinh, DTU (Technical Univ of Denmark) / Section for Marine Ecology and Oceanography, DTU Aqua; T. Nielsen, DTU Aqua / Technical Univ of Denmark

Oil spills are potential environmental hazards to marine ecosystems worldwide. Oil spills may persist in seawater longer than one generation of many zooplankton species. However, whether populations of short-lived and fast growing marine organisms adapt to oil exposure through natural selection is not known. To test this, the cosmopolitan estuarine copepod Acartia tonsa was exposed to pyrene continuously for two generations, at the concentrations 0, acetone control, 1, 10, 100 and the saturated pyrene concentration in seawater, 100+ nM. Pyrene is one of the most toxic components in crude oil to marine copepods. The key fitness-related traits were quantified: survival, size at maturity, grazing rate and the reproductive success. Exposure to the concentration of pyrene saturated in seawater (100+ nM) resulted in 100 % mortality before adulthood in the first generation. In the other treatments (≤ 100nM), the first generation had a higher grazing rate than the second generation. Exposure to pyrene had no effect on the grazing rate. At the concentration of 100 nM, pyrene exposure caused reductions in survival, size at maturity of females, egg production and hatching success. The reduction in size at maturity of females was less pronounced in the second generation. Strikingly, both survival, egg production and hatching success were recovered in the second generation, indicating a rapid selection towards individuals with adaptations to deal with pyrene exposure. Our results show that populations of short-lived and fast-growing copepods have the potential of showing surprisingly strong resilience to the type of oil contamination they might face in their natural coastal habitats. *Joint first authors: Kamille Elvstrøm Krause and Khuong Van Dinh

EDCs and Pharmaceuticals in the Environment – Part 1

392 Analysis on the Effects of Pharmaceuticals and Their Uptake and Metabolism in Plants Using Liquid Chromatography Tandem Mass Spectrometry

R. Mullen, D.S. Aga, State Univ of New York-Buffalo / Dept of Chemistry

There has been recent interest in agriculture to recover and reuse nutrients in a renewable way. Specifically efforts have been contrived to replace typical chemical fertilizers with something more sustainable and recyclable from the environment including urine and wastewater. Both of these prospective fertilizers are known to contain pharmaceuticals and application of these to farm lands may further the release of biological contaminates into the environment. Chlorinated pharmaceuticals are of particular concern due to their potential for greater toxicity, specifically in regards to human health and exposure from chlorinated pharmaceuticals uptaken food crops. A study we have done on the analysis of lettuce and carrots exposed to pharmaceuticals by liquid chromatography tandem mass spectrometry (LC-MS) show that they do uptake both the chlorinated and unchlorinated pharmaceuticals. While all pharmaceuticals, including the chlorinated ones (diclofenac and sulfachloropyrazidine) may be uptaken in their native form, studies have shown that certain crops metabolize chlorinated pharmaceuticals and detoxify them. Our study focuses on the fate of pharmaceuticals in corn grown hydroponically. The same pharmaceuticals in the study with lettuce and carrots were used in the exposure with corn. The results showed that all the pharmaceuticals were uptaken except the chlorinated ones, suggesting some transformation or metabolism of these pharmaceuticals took place. The hypothesis is that glutathione transferase is catalyzing the removal of chlorine and conjugation of the pharmaceutical to the sulfur on the glutathione. This phenomena is investigated by LC-MS by first extracting the glutathione transferase from the plant (using affinity chromatography and confirmation by SDS-PAGE) and doing an in vitro study with the transferase, pharmaceutical, and glutathione. From there, the conjugated pharmaceutical is monitored for in the plant extract. This research is important for understanding the fate of pharmaceuticals in corn which is of utmost importance when considering the effects of using pharmaceutical containing fertilizers for agricultural use.

393 The fate of antibiotics and antimicrobial biocides in Swedish sewage treatment plants

M. Östman, R.H. Lindberg, J. Fick, M. Tysklind, Umeå Univ / Dept of Chemistry

Besides antibiotics, a large number of antimicrobial biocides, used as preservatives, disinfectants, and antiseptics, are entering our sewage system. There is a concern that biocides promote the development of antibiotic resistant bacteria through the mechanisms of co- and cross resistance. It is therefore important to measure the presence of these substances in sewage water and sludge in order to better understand their fate and transport in the environment. To address these issues, an analytical protocol using liquid chromatography tandem mass spectrometry (LC-MS/MS) was developed for measuring biocides and antibiotics in sewage sludge and waters. Further, 11 Swedish sewage treatment plants (STPs) were sampled for influent, effluent, and digested sludge during three consecutive days. In addition, three of the STPs were subjected to an extensive nine-day sampling campaign during three weeks including samples from various types of sludge, and water after the first sedimentation step. In total, 246 samples were collected for determination of their content of antimicrobial biocides and antibiotics. Several compounds could be detected in the different sample matrices including various quaternary ammonium compounds (QACs), isothiazolines, chlorhexidine, antibiotics, antimycotics and benzotriazoles. Mass flows could be calculated for many compounds and QACs, e.g. didecyldimethyl ammonium chloride (DDMAC), cetrimonium bromide (CTAB), and benzalkonium chloride, were the most abundant ones with levels of several kilograms/day in incoming waters (aqueous + solids). The outgoing water mass balances of QACs showed only a few grams and the majority of these compounds end up in the sludge where they could be detected in levels up to 200 µg/g d.w. The highest levels in outgoing water effluents were the benzotriazoles with levels exceeding 1 µg/L and mass balances of 100 g/day in some STPs. Interestingly, chlorhexidine was not only detected in high levels but also frequently in sludge of all studied STPs, results that stand in contrast to previously published studies. Common detected antibiotics were ciprofloxacin, tetracycline and trimethoprim. Knowledge of fate and occurrence of biocides within STPs are important to aid in risk assessments of the antibiotic resistance development and this work demonstrates a comprehensive data set for Swedish STPs.

394 Occurrence of contaminants of emerging concern (CECs) in reclaimed water intended for potential potable reuse

K. Dasu, M. Mills, USEPA / National Risk Management Research Laboratory; B. Wang, Wright State Univ / Civil and Environmental Engineering; W. Brashear, Pegasus Technical Services Inc; E. Villegas, USEPA

Due to the drought and water scarcity in some parts of the country, there is an increased attention to the sustainable water management. Wastewater effluent is a viable alternate option as source water. However, there are potential public health risks associated with exposure to the microbial and chemical contaminants present in the wastewater effluents. Additional research is needed to further characterize the microbial pathogens and contaminants of emerging concern (CECs) present in wastewater effluent and to evaluate overall efficacy of the advanced treatment processes used to further disinfect and treat the effluent. To better address these challenges, EPA ORD and EPA Region 6 have partnered on a research project focused on waterborne pathogens and CECs that are present in wastewater effluent from an advanced wastewater treatment plant and racetrack plants. The on-going research project characterizes microbial communities and occurrence and composition of selected CECs in wastewater effluent that will serve as source water to water reuse plants. The current presentation focuses on the concentration trends of selected CECs. Several classes of contaminants are monitored, such as poly and perfluoroalkylated substances (PFASs), steroid hormones, alkylphenol ethoxylates, alkylphenols, pharmaceuticals and personal care products. During a period of one year, monthly grab samples of influents and effluents are collected from 3 publicly Owned Treatment Works (POTW) in Region 6. The treatment processes used by these POTWs include chlorination, UV disinfection, and microfiltration, reverse osmosis followed by UV oxidation. The samples are extracted separately for different classes of CECs and are analyzed on UPLC/MS/MS. Based on the concentrations and compositions of CECs, seasonal effects and differences in the treatment processes will be evaluated. The data on the occurrence and concentrations of different CECs and potential impacts (e.g. increase in levels of contaminants) of using wastewater effluent as a drinking water source on the overall water quality of the drinking water produced will be discussed. This project will assist the States and Regions that use wastewater effluent as a drinking water source by providing data on the occurrence and persistence of potential waterborne pathogens and CECs.

395 Distribution of Endocrine Disrupting Compounds in the Aquatic Food Web, Lake Mead, Arizona and Nevada

M. Moran, S. Goodbred, USGS; D.A. Alvarez, USGS-CERC / Physiology and Biochemistry; K.R. Echols, USGS – Biological Resources Division / Columbia Environmental Research Center; M.R. Rosen, S. Gedo, USGS; S. Chandra, Univ of Nevada Reno; K. King, National Park Service

Water quality in Lake Mead, Arizona and Nevada, is affected by contaminants coming from the Las Vegas Wash, an urban perennial stream whose water is comprised almost entirely of treated wastewater effluent coming from the Las Vegas metropolitan area. Endocrine disruption, presumably resulting from the uptake and/or accumulation of contaminants, has already been demonstrated in common carp from Las Vegas Wash and both common carp and largemouth bass in Las Vegas Bay of Lake Mead. This study examined how various endocrine disrupting compounds (EDCs) are distributed in organisms throughout the food web in Lake Mead. Three areas of the lake were examined; Las Vegas Bay, Boulder Basin, and Overton Arm. Las Vegas Bay is the basin which receives contaminants from Las Vegas Wash while Overton Arm is farthest from Las Vegas Wash and represented a control site. Boulder Basin represented an intermediate position betwen these two. To determine water concentrations of contaminants, SPMDs and POCIS passive samplers were deployed at each site. Samples of periphyton, zooplankton, benthic invertebrates, quagga mussels, and a representative mix of forage fish were collected and analyzed for stable isotopes of carbon and nitrogen in order to determine trophic position and for over 200 organic compounds that have the potential to be EDCs. Some compounds show increasing concentrations with increasing trophic level while others do not. For some compounds sampled by POCIS, concentrations by trophic level relative to concentrations in water indicate potential accumulation from water. When examined by compound group, the slope of concentrations versus trophic level is higher in biota from Las Vegas Bay relative to biota from either Boulder Basin or Overton Arm indicating that accumulation of contaminants is greatest near the source. Although the concentrations of some compounds increased in the food web, the specific endocrine-disrupting effects of most are not clear. Since some compounds are estrogenic, a Yeast Estrogen Extract test was performed on water extracts from each site. Estrogen Equivalents were detected at 2 sites in Las Vegas Bay (0.22 pg/L and 0.08 pg/L) but were not detected in Boulder Basin and Overton Arm. These results suggest that contaminants with estrogenic activity, and thus possible endocrine-disrupting effects, are most closely associated with wastewater coming from Las Vegas Wash.

396 Mass loading, removal and environmental emission of select psychoactives, antihypertensives, and antibiotics from two sewage treatment plants in India

B. Subedi, Murray State Univ / Chemistry; K. Balakrishna, D.I. Joshua, Manipal Univ / Dept of Civil Engineering; K. Kannan, New York State Dept of Health / Wadsworth Center Dept of Health

Environmental contamination by pharmaceuticals and personal care products (PPCPs) is barely conceived in India despite being one of the largest global producers and consumers of pharmaceuticals. In this study, 29 pharmaceuticals and six metabolites were determined in a STP in Udupi (STP_U: population served ~150,000) and a STP in Mangalore (STP_M: population served ~450,000); the total concentrations were 99.5 µg/L and 51.8 µg/L, respectively. Atorvastatin (the most prescribed antihypercholesterolemic in India), mefenamic acid, and paraxanthine were found for the first time in wastewater in India at the mean concentrations of 395 ng/L, 1100 ng/L, and 13,000 ng/L, respectively. Select pharmaceutical metabolites (norverapamil and clopidogrel carboxylic acid) were found at concentrations of upto 7 times higher than their parent drugs in wastewater influent and effluent. This is the first study in India to report mass loading and emission of PPCPs and their select metabolites in STPs. The total mass load of all PPCPs analyzed in this study at STP_U (4.97 g/d/1000 inhabitants) was 3.6 times higher than calculated for STP_M. Select recalcitrant PPCPs such as carbamazepine, diazepam, and clopidogrel were found to have negative or no removal from STP_U while additional anaerobic treatment with upflow anaerobic sludge blanket reactor at STP_M removed (up to 95%) these PPCPs from STP_M. Overall, 5.1 kg of caffeine, 4.1 kg of atenolol, 2.7 g of ibuprofen, and 1.9 kg of triclocarban were discharged annually from STP_U. The PPCP contamination profile in the Indian STP was compared with a similar study in the USA.

397 High-throughput Based Screening of Waters for Endocrine Bioactive Chemicals

W. Heiger-Bernays, Boston Univ School of Public / Environmental Health; S. Wegner, ORISE Fellow at USEPA / Office of Science Coordination and Policy

The presence of industrial chemicals and pharmaceuticals is well documented in wastewater, surface waters, and to a lesser extent in drinking water. Many of these chemicals lack human health-protective guidelines, but many have been shown to have endocrine bioactivity and thus the potential for endocrine disruption. We present an approach for evaluating potential endocrine activity of chemicals detected in drinking water based on in vitro high throughput screening assays and predictive pathway models from the USEPA's ToxCast program. ToxCast bioactivity data for estrogen receptor (ER) and androgen receptor (AR) signaling pathways are currently available for over 1800 chemicals. The toxicokinetic data necessary for in vitro to in vivo extrapolation of dose response are available for a subset of 90 of these chemicals with ER or AR bioactivity; 47% are pesticides and 27% are pharmaceuticals. For each of these 90 chemicals, high throughput data were used to generate Ambient Water Bioactivity Concentrations (AWBC): water screening concentrations analogous to Ambient Water Quality Criteria for the protection of human health. A range of AWBCs for each chemical were calculated based on minimum and median ER or AR bioactivities across ToxCast assays, high-throughput toxicokinetic data, and data driven assumptions about consumption of water. For chemicals that are both ER and AR bioactive, AWBCs were calculated for both pathways and the lowest value in either pathway was selected. Using a 2015 monitoring dataset of waters in metropolitan Denver, measured concentrations of pesticides, steroids and waste indicators were compared with their chemical-specific AWBCs. The reporting limits and the maximum measured concentrations for 17 beta-Estradiol, 17alpha-Ethylnylestradiol and estrone exceed the lowest calculated AWBC variant. Triclosan was within one order of magnitude, and bisphenol A and oxazepam are within three orders of magnitude of their respective AWBCs. The results are dominated by measurements of estrogenic substances and the lack of water monitoring for androgenic chemicals. Cumulative endocrine activity of chemical mixtures contained in each sample was also evaluated using a hazard index-like approach. This analysis demonstrates an approach to screening for potential endocrine activity in drinking water and could inform prioritization of future monitoring, testing and pollution prevention efforts. This abstract does not necessarily reflect EPA policy.

398 Characterization of the endocrine potencies of municipal effluents across Canada using in vitro bioassays

T. Bagatim, Univ of Saskatchewan / School of Environment and Sustainability; S. Hanson, H. Yuan, K.B. Steeves, Univ of Saskatchewan / Toxicology Centre; S. Wiseman, Univ of Lethbridge / Biology; N.S. Hogan, Univ of Saskatchewan / Toxicology Centre; A. Hontela, Univ of Lethbridge / Dept of Biological Sciences; P.D. Jones, Univ of Saskatchewan / School of Environment and Sustainability; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; L. Bragg, Univ of Waterloo / Dept of Biology; H. Dhiyebi, Univ of Waterloo; M.R. Servos, Univ of Waterloo / Dept of Biology; C. Gauthier, InrsEte Universite Du Quebec / Biology; F. Gagne, Emerging Methods, Environment and Climate Change Canada / Emerging Methods; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre

Recent years have witnessed increasing concerns regarding the presence of contaminants in the environment that have the potential to adversely affect the endocrine system of humans and wildlife. Municipal wastewater effluents (MWWEs) are considered one of the major sources for such endocrine disrupting chemicals (EDCs) in surface waters, as conventional wastewater treatment technologies are frequently inefficient at removing these compounds from raw sewage. However, our understanding of the contribution of MWWEs to environmental endocrine disruption in Canadian surface waters is incomplete. Therefore, the aim of this project was to investigate the EDC removal efficiency of six wastewater treatment plants (WWTPs) across Canada. Specifically, samples of influents and effluents were collected during spring, summer and fall in 2014 and winter in 2015, to evaluate the influence of climatic conditions, season, population size and treatment level (tertiary, secondary, primary) on EDC removal efficiency. Endocrine potentials of wastewater were analyzed using two in vitrobioassays: MDAkb2 ((anti-)androgenicity), and MVLN ((anti-)estrogenicity). Preliminary results indicated that most influent samples collected had a significant increase in androgenicity relative to solvent controls, while most effluent samples were less potent and showed variability in response indicating that WWTPs had a high removal efficiency of androgenic activity. Removal efficiencies differed significantly among WWTPs, probably as a function of different levels of treatment. Greater removal efficiency was detected during summer, potentially due to greater metabolic activity, increased temperature and/or light exposure. A select number of influent and effluent samples showed anti-androgen response, suggesting there may be other compounds competing for the same receptor. Most spring effluent samples showed a trend towards elevated estrogenicity, as did fall samples from Regina and Saskatoon. Effluent samples showed higher estrogenic activity than influent samples, and anti-estrogenic trends were detected for the majority of influents and effluents, suggesting samples may contain compounds competing for the same receptor. This project will provide insights into the most effective approach for monitoring MWWEs, and will inform development of advanced wastewater treatment technologies for improved removal of EDCs.

399 Examining Urban Metabolism and Contaminants of Emerging Concern: A Sewage Epidemiology Pilot Study in Hong Kong

S.R. Burket, Baylor Univ / Environmental Science; J. Zheng, S. Chung, Hong Kong Baptist Univ; B.W. Brooks, Baylor Univ / Dept of Environmental Science

High concentration of human populations is readily observed in Hong Kong, which now represents the 4th most densely populated area in the world. Such population densities result in concentrated use of specialty and industrial chemicals, including pharmaceuticals and consumer products. Much like a watershed in the natural world includes a network of smaller streams flowing to larger river systems and ultimately coastlines, waste streams in urban areas are collected by diverse sewerage systems from residential, commercial and industrial users. In fact, different component of wastewater collection systems represent "sewersheds" because they are conceptual similar geospatial units to natural watersheds and thus can be characterized by differential fingerprints of urban metabolism. Whether pharmaceutical or elicit drug consumption differs among different areas of Hong Kong is not understood. In this pilot study, we focused on the wastewater primary treatment works (PTWs) in the Kowloon peninsular and north-east Hong Kong Island. Specifically, eight PTWs collect wastewater from different sewersheds, which collectively covers a significant proportion of the urban population in Hong Kong, and transports effluents to Stonecutter Island (SCI) Treatment Works. We sampled each of these sewersheds and the SCI influent and effluent to determine whether target analytes, including common pharmaceuticals, drugs of abuse and other anthropogenic tracers, and associated therapeutic hazards differed among various sewersheds. Our sampling effort accounted for travel times among each of the PTWs to SCI, based on previous tracer studies, which allowed us to apportion drug waste contributions among the 8 PTWs to SCI. From each sampling point, water analytes were extracted, separated and analyzed following previously reported methods using solid phase extraction and isotope dilution-liquid chromatography-tandem mass spectrometry. We then used a fish plasma modelling approach to determine whether water quality hazards differed among each PTW contribution to SCI. Consistent with reports from previous efforts, highest concentrations were consistently observed for caffeine, acetaminophen and the artificial sweetener sucralose. However, marked differences were observed among analytes and associated therapeutic hazards across various sewersheds examined in Hong Kong. These results may inform decisions regarding waste stream assessment and management in specific regions.

Fate, Toxicology, or Risk Assessment of Materials of Interest to the Military

400 Ecotoxicological risk of explosives and heavy metals on aquatic species in surrounding water system nearby active firing range

M. Kim, G. Yu, Seoul National Univ; K. Nam, Seoul National Univ / Dept of Civil and Environmental Engineering

Explosives contamination at firing ranges is known to have impact on the surrounding ecosystem. In addition, contaminants can be discharged to the neadby river due to precipitation. It is more reasonable to manage the contaminants in the runoff, since active soil remediation is impractical for most of highly active firing ranges. This study was performed to determine the ecotoxicological effects of explosives and heavy metal in the surrounding water system. Among explosives and heavy metals, 2,4,6-trinitrotoluene (TNT), hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX), lead (Pb), copper (Cu), cadmium (Cd), and zinc (Zn) were selected as target pollutants. Toxicological information of each contaminants was collected from ECOTOX of US Environment Protection Agency (EPA) and additional technical papers. Chronic no observable effect concentration (NOEC) and effective concentration (EC10) data were chosen and subsequently toxicity data without clear statement of experimental conditions were screened out in the screening procedure. Species Sensitivity Distribution (SSD) was used for the derivation of hazardous concentration (HC5, HC50) of each pollutants. Predicted no effect concentration (PNEC) was calculated and suggested as 40 – 88, 270 – 600, 1.9 – 9.4, 0.23 – 1.1, 0.19 – 0.96, 1.6 – 7.8 µg/L for TNT, RDX, Pb, Cu, Cd, Zn, respectively using uncertainty factor from 1 to 5. Hazard quotient (HQ) was derived using PNEC values and predicted environmental concentration (PEC) of active firing range in Korea. HQ values of TNT, RDX, Pb, Cu, Cd, Zn were calculated as 14.5 – 32.0, 0.78 – 0.35, 53.2 – 263.2, 45.5 – 217.4, 52.1 – 263.2, 56.2 – 273.8 indicating TNT, Pb, Cu, Cd, Zn have toxicological effect on aguatic species in nearby water system. This ecotoxicological study will be used to quantify the toxicological risk of explosives and heavy metals to the surrounding ecosystem after the remediation process.

401 Toxicological Effects of Munitions Compounds and their Breakdown Products on Coral

C. Woodley, NOAA/NOS / National Centers for Coastal Ocean Science; C.A. Downs, Haereticus Environmental Laboratory; A.R. Burnett, T. Bartlett, L.A. May, C. Miller, JHT, Inc. with NOAA; L.F. Webster, NOAA NOS / National Centers for Coastal Ocean Science; D. Downs, Haereticus Environmental Laboratory

Military activities in marine environments have resulted in munitions and unexploded ordnance being located throuout the world's oceans, yet the ecological impacts to marine life from the associated chemical constituents and their breakdown products remains largely unknown. Coral reefs are particularly vulnerable ecosystems found in proximity to many key U.S. military installations in the Caribbean and Pacific Islands. We investigated whether munitions compounds or their breakdown products impact coral health by conducting standard laboratory toxicity testing of nine munitions compounds (TNT, 2,4-DNT, 2,6-DNT, 2,3-DNT, 4-NT, 2-ADNT, RDX, HMX and picric acid) with Pocillopora damicornis coral. NOEC and LOEC values and effect-concentration (LC or EC) values were established using a coral cell toxicity assay. Effects of these compounds on the coral symbiont were also tested using Symbiodinium sp. in vitro cultures with photosynthetic efficiency and mortality as endpoints. Findings showed all nine munitions coumpounds had some level of toxicity, differences in coral species' sensitivity to munitions compounds, and photo-enhanced toxicity of certain compounds. The toxicity reference values for corals exposed to munitions compounds will provide metrics for assessing risk of munitions to coral and coral reef health while serving as a basis for establishing screening and action values for management of this vulnerable resource.

402 Aquatic Toxicity of the Insensitive Explosive DEMN

M.J. Quinn, US Army Public Health Command / Health Effects Research Program; W.S. Eck, Army Public Health Center Provisional / Health Effects Research Program

DEMN is an insensitive energetic mixture that consists of a eutectic mixture of diethylenetriamine trinitrate (DETN), ethylenediamine dinitrate (EDDN), methyl nitroguanidine (MeNQ), and nitroguanidine (NQ). It was developed by the Army Research Laboratory as a melt-cast explosive to replace trinitrotoluene (TNT), an explosive that can be sensitive to unintentional detonation and also known to negatively impact occupational health. Because the DEMN components are relatively soluble, data on their aquatic toxicity were needed to determine potential environmental impacts. All five elements of the composition were tested—the DEMN eutectic mix and each of the four components. The first round of tests consisted of acute range-finding tests with Daphnia, fathead minnow, and green algae. With the exception of the Daphnia values for the DEMN eutectic, DETN, and EDDN, all of the values obtained for the test systems exceeded Globalized Harmony System (GHS) Acute Aquatic Toxicity Category 3 (>100 mg/L), making them essentially non-toxic in an acute exposure scenario; the remaining values were between one and ten mg/L, which is GHS Acute Aquatic Toxicity Category 2. These initial tests were completed to help determine exposure levels for the chronic exposure tests. The chronic exposure tests included the Daphnia acute, fathead minnow acute, fathead minnow embryo-larval survival and teratogenicity, Ceriodaphnia survival and reproduction, and green algae growth toxicity tests. Only the DEMN eutectic, EDDN, and DETN were evaluated in this second round of tests due to the results of the initial acute toxicity evaluations and the chemicals' water solubility. All three of these substances were ranked as GHS Chronic Aquatic Toxicity Category 3 (LC_{50} >10 but < 100 mg/L) for the Daphnia acute, green algae, and Ceriodaphnia chronic tests, and Category 4 (LC_{50} >100 mg/L or above) for the fathead minnow acute and chronic tests. Chronic and multi-generation toxicity tests report adverse effects to TNT in fathead minnows at exposure levels as low as 0.24 and 0.04 mg/L, respectively. The data reported here suggest that DEMN and its constituents have a low potential for toxicity to aquatic organisms.

403 Birds are not feathered mammals: phylogenetic differences in toxicity from oral exposures to 3-Nitro-1,2,4-Triazol-5-One (NTO)

A. Jackovitz, US Army Public Health Center / Toxicology; E.M. Lent, L.C. Crouse, Army Public Health Center / Toxicology; M.J. Quinn, US Army Public Health Command / Health Effects Research Program; M.S. Johnson, US Army Public Health Center / Toxicology

Insensitive munitions (IM) are currently being developed to protect against unintentional detonation in theaters of operation. Testing and training with these materials at military ranges are expected to result in environmental releases which may constitute a risk to valued wildlife species. Acute oral studies conducted in rats did not result in overt toxicity from exposures exceeding 2000 mg/kg and subchronic oral exposures found reductions in testes and epididymides mass, as well as oligospermia, at 315 mg/kg-d but not at 100 mg/kg-d. An extended one-generation study conducted in rats from exposures to NTO in drinking water found testicular changes and delays in puberty for male offspring at exposures of 3600 mg/L (157-335 mg/kg-d). To investigate conservation of testicular toxicity among vertebrates, an extended one-generation reproductive toxicity test was conducted with Japanese quail (Coturnix japonica) where both sexes of the parental generation were exposed to NTO at 0, 20, 100, 500, and 1000 mg/kg-d via oral gavage beginning at two weeks of age. First generation (F1) birds were exposed to NTO via oral gavage beginning at day 2 of age. All birds were dosed for 10 weeks. Following 5 days of treatment, F0 birds from the 1000 mg/kg-d group exhibited neuromuscular toxicity (convulsions and ataxic wing activity) 3-4 hours post initial exposure. Birds from the 500 mg/kg-d group began displaying similar signs 17 days into treatment. In both dose groups, convulsions initially ceased after 3-4 hours. No birds from the 1000 mg/kg-d group survived and only a single male from the 500 mg/kg-d group survived until study completion. No changes in testes mass or sperm production were found in birds from the 20 and 100 mg/kg-d groups, though the single surviving male had a reduction in testes mass compared to males from the control, 20 and 100 mg/kg-d groups. Preliminary analysis show changes in electrolyte levels which may indicate nephrotoxicity of NTO specific to birds.

404 Geographical distribution of contaminants in the soil at a Canadian military test site

J. Olson, GHD

In the context of an ecological risk assessment (ERA) that is being conducted at a military test site in eastern Canada, data on soil quality collected over many years from the various areas on the site were pooled in order to assess the extent of the contamination. A sampling plan was then prepared in order to fill gaps in the data. This included measuring the concentration of potential contaminants of concern that had not been previously analyzed near active or historical sources. It also included the measurement of contaminants around known contaminated sites in order to circumscribe the extent of the contamination. This was particularly important from an ecotoxicological point of view, as there was little information on the level of contamination in the natural habitats surrounding the active ranges found on the site. The results indicated that some substances, such as 2,4,6-trinitrotoluene (TNT) as well as many other military specific compounds, are only found at levels above the ecological screening values at the center of the active test sites. These substances are therefore unlikely to be a source of risk to ecological receptors, as they are not found within the habitats used by these species. In other cases, notably aluminum, all measurements exceed the screening levels, indicating a high likelihood that the natural background of the site is higher than the ESL. Further analysis is therefore required to determine if the current and historical activities on the site constitute a significant source of this contaminant and to determine the extent of the contamination.

405 Verification Monitoring and Stability Assessment of In Situ Stabilized Range Metals

M. Wynter, USACE / ERDC / EL; A. Martin, US Army Corps of Engineers ERDC / Environmental Research and Development Center; C. Griggs, US Army Corps of Engineers ERDC

Where appropriate, several measures of long-term remedy effectiveness and technology performance should be evaluated at demonstration sites in addition to the key measure of long-term risk reduction. A major thrust of this effort is to validate best management practices for metals stabilization with phosphate amendments and answer questions regarding the long term stability of the approach under varying environmental conditions. The current study assesses the post remedial, long-term effectiveness of a field demonstration design on the M-60 range at Charleston Air Force Base (AFB) in Charleston, South Carolina. The Charleston AFB testing includes a 5% TRAPPS™ amendment, alone and in combination with, 5% fish bone based apatite for in situ stabilization of lead in berm soil. Soil samples have been collected and analyzed for metals, pH, soil fractionation, speciation, and other leaching tests by standard USEPA and ASTM methods. Findings from this effort are presented to evaluate long-term effectiveness and monitor the stability of Pb present at the demonstration site.

406 Exposure to munition specific carcinogens and cancer risks for civilians on Vieques following military exercises '47-'99

H. Sanderson, P. Fauser, Aarhus Univ / Environmental Science

The total loading of carcinogens to the island of Vieques has been documented by reviewing the records from to the U.S. National Archives on munitions used in testing and exercises on the island from 1947 to 2003. With these data, the exposure pathways (air; water; soil; food) specific to humans were modelled. Subsequently, the added cancer risks and Margins of Exposure (MoEs) for the different carcinogens for each year were derived. The results show that there was a potential for cancer risk concern with regards to RDX exposures in the 52 years of military activity due to a cancer risk of $5*10^{-5}$ in the general population. Furthermore, there was a potential for concern of health risks from TNT exposures with a MoE of 48. No other exposures indicate a concern for risk. Both of these exposures primary exposure route was oral via produce leafs, fruits and cereals. There is in general no significant difference in the cancer incidence rates between Vieques and Puerto Rico. However, the period 1992-1997 did show a significantly elevated lung and bronchus cancer incidence rate in Vieques compared to Puerto Rico mainly among women < 50 yr and men 50-64 yr, which correlate with exposures in the period 1977-1984. Both cancer and other public health impacts and risks are multi-causal, hence, the general stress impacts due to military training on Vieques towards public health of Viequenses, would warrant a wider community-based public health and risk assessment assessing past, current, future potential epigenetic, risks.

407 Mass Flux Characterization for Determination of Reasonable Maximum Exposures to Volatile Organic Compounds through the Vapor Intrusion Pathway

H. Dawson, W. Wertz, D. DeVoney, T. McAlary, Geosyntec Consultants

Vapor intrusion (VI) is challenging to assess using conventional discrete indoor air and sub-slab sampling because of spatial and temporal variability in volatile organic compound (VOC) concentrations, which leads to uncertainty in identifying a Reasonable Maximum Exposure (RME) for the occupants of a building. Characterization of vapor phase contaminant mass flux (mass per unit time per unit area) offers a promising alternative to conventional indoor air and sub-slab sampling because mass flux measurements have been found to exhibit considerably less temporal variability than indoor air measurements. Several methods of mass flux characterization are being studied as part of an ESTCP SERDP demonstration program (ER-201503), including measuring the mass flux through a building during "forced" depressurized conditions that enhance vapor transport into the building. The indoor air concentrations measured during building depressurization provide upper bound estimates of the indoor air concentrations that may arise from vapor intrusion under RME conditions. Additionally, the relative contribution of background (indoor) vapor sources to indoor air concentrations can potentially be identified by pressurizing the building to hinder or reverse vapor intrusion; any detected VOCs in indoor air under that condition necessarily arise from ambient or indoor sources. The combination of building depressurization and pressurization is referred to as Building Pressure Cycling (BPC). BPC can be conducted in a relatively short timeframe (e.g., 2 -12 hours) to characterize VI pathway impacts regardless of the season or climatic conditions. This paper describes the protocol used to conduct BPC to defensibly identify RME concentrations and compares the results from field application of BPC to historical VI characterization data. These results suggest that mass flux characterization may be a more effective and less expensive than VI site characterization using multiple conventional sampling events.

Toxicity Extrapolations in Aquatic Organisms and Wildlife

408 Rethinking the Use of Uncertainty Factors for the Derivation of Toxicity Reference Values

E. Mendelsohn, Integral Consulting Inc.; H. Summers, Integral Consulting Inc. / Inst of Environmental Toxicology and Chemistry; P. Goodrum, Integral Consulting

Uncertainty factors (UFs) are commonly used to account for multiple sources of uncertainty in the derivation of toxicity reference values in ecological risk assessment. Common examples include estimating the dose range between a lowest-observed-adverse-effect level (LOAEL) and a no-observed-adverse-effect level (NOAEL), extrapolating doses associated with chronic effects from doses associated with subchronic or acute effects, accounting for interspecies variability, and accounting for differences in laboratory and field conditions. While it is convenient to apply the simplifying assumption that UFs of unit values (e.g., 3, 5, 10) are sufficiently protective, it is important to revisit these assumptions as new studies and methods for extrapolating toxicity data become available. In this presentation, we revisit the basis for applying UFs to extrapolate between LOAELs and NOAELs and demonstrate how the use of dose-response relationships in ecological risk assessments can provide an alternative and more scientifically defensible representation of effect ranges between study dose levels. Using published toxicity data on methyl mercury effects in birds, we explore several ways to use dose-response information in lieu of NOAEL/LOAEL ratios and discuss data needed to extend the methods across chemicals and receptor groups.

409 The chemistry side of AOP: implications for toxicity extrapolation

M.G. Barron, USEPA / Gulf Ecology Division; S. Lee, ORISE/USEPA

An adverse outcome pathway (AOP) is a structured representation of the biological events that lead to adverse impacts following a molecular initiating event caused by chemical interaction with a macromolecule. AOPs have been proposed to facilitate toxicity extrapolation across species through understanding of species similarity in the sequence of molecular, cellular, organ and organismal level responses. However, AOPs are nonspecific regarding the identity of the chemical initiators, and the range of structures for which an AOP is considered applicable has generally been poorly defined. Applicability domain has been widely understood in the field of QSAR as the response and chemical structure space in which the model makes predictions with a given reliability, and has been traditionally applied to define the similarity of query molecules within the training set. Three dimensional (3D) receptor modeling offers an approach to better define the applicability domain for selected AOPs through determination of the chemical space of the molecular initiating event. Universal 3D-QSAR models were developed for acetylcholinesterase inhibitors and estrogen receptor agonists and antagonists using a combination of fingerprint, molecular docking and structure-based pharmacophore approaches. The models were based on the critical molecular interactions within each receptor ligand binding domain, and included the key amino acid residues responsible for high binding affinity. The approach allows for extrapolating species sensitivity based on taxa-specific differences in these key amino acids and estimating toxicity for a broad range of chemical structures. Continuing improvements in conformer generation and molecular docking tools, and increasing availability of x-ray crystal structures of receptor-ligand complexes will allow for more efficient and accurate 3D-QSARs and advancement of AOPs from organizing frameworks to predictive models.

410 Integrating Aquatic Interspecies Toxicity Estimates into Large Databases: Model Evaluations and Data Gains

A.C. Bejarano, Univ of South Carolina / Dept of Environmental Health Sciences; S. Raimondo, M.G. Barron, USEPA / Gulf Ecology Division

The Chemical Aquatic Fate and Effects (CAFE) database, developed by NOAA's Emergency Response Division (ERD), is a centralized data repository that allows for unrestricted access to fate and effects data. While this database was originally designed to help support decisions in the event of spill incidents in aquatic environments, this data repository could help address a diverse range of research and response needs. One of CAFE's features is that it contains aquatic toxicity data for several thousand chemicals allowing for the visualization of data in the form of probabilistic distributions of toxicity data across taxa or Species Sensitivity Distributions (SSDs). While CAFE has enough data to generate over 2,000 chemical-specific SSDs, 70% of compounds including hazardous substances with high spill risk have only limited data (< 5 species). These data gaps may be filled by integrating into CAFE Interspecies Correlation Estimation (ICE) models, which are log-linear regressions between a surrogate species and a predicted taxa. This integration required a multistep process to ensure data quality and identify the best available models. Evaluations of over 3,500 ICE models included the influence on SSD estimates from models that: 1) did not meet three reliability requirements (i.e., Mean Square Errors < 0.95, slope >0.6, adjusted coefficients of determination [adj-R^2] >0.6); and 2) were originally developed based on broad and specific mode of toxic action (MOA), or from combined MOA models. Preliminary evaluations of ICE-predicted toxicity data for a variety of chemicals and surrogate species suggest that in most cases (76%) the exclusion of those less reliable models does not lead to substantial changes in SSD estimates, which were generally within a 3-fold of values obtained with models meeting all reliability requirements. Although MOA appears to have a greater influence on SSD estimates than model reliability, MOA is uncertain for many chemicals, thus limiting their use. The most significant contribution of this work is that the integration of ICE models into CAFE would allow for the development of SSDs for least 67% of 4,800 total chemicals with limited aquatic toxicity data, while increasing the number of SSDs by 30%. Most data gains are for standard exposure durations (24, 48, 72 and 96 hours), which comprise 85% of data used to generate ICE-based estimates. The integration of ICE models may substantially enhance the current capabilities of CAFE.

411 Effects of Deepwater Horizon Oil on Red-Eared Sliders and Common Snapping Turtles as Surrogate Species for Sea Turtles

C. Mitchelmore, Univ of Maryland Center for Environmental Science / Chesapeake Biological Laboratory; C.L. Rowe, Univ of Maryland Center for Environmental Science; B. Stacy, NOAA Fisheries, Office of Protected Resources; L. Clayton, C. McDermot, National Aquarium, Baltimore; N.I. Stacy, Univ of Florida / College of Veterinary Medicine; C. Cray, Univ of Miami; G.M. Ylitalo, NOAA Fisheries / National Marine Fisheries Service Northwest Fisheries Science Center; D. Reavill, Zoo/ Exotic Pathology Service; B. Wallace, K. Dean, H. Forth, J.M. Morris, Abt Associates; S. Lamb, Cornell Univ; R. Takeshita, J. Lipton, D. Cacela, Abt Associates; H. Pie, S. Funck, M. Strauss, Univ of Maryland Center for Environmental Science

Hundreds of externally and internally oiled juvenile oceanic sea turtles were documented and rescued during the Deepwater Horizon (DWH) oil spill. Polycyclic aromatic hydrocarbon (PAH) metabolites in the bile and tissues of some individuals confirmed internal exposure and metabolism of oil. The adverse effects associated with becoming physically mired in oil were readily apparent in sea turtles rescued during the DWH spill, but data on potential effects of oil ingestion in sea turtles are limited. Therefore, a 14-day, controlled-dose ingestion laboratory study was undertaken using DWH oil (MC 252) to examine potential effects of internal oil exposure on common species of freshwater turtles, red-eared sliders and common snapping turtles as surrogates for endangered sea turtles. Numerous chemical, biological, and physiological endpoints were assessed, including those important for general clinical assessment, as well as additional endpoints known to respond to acute exposure to PAHs in other taxa (e.g., oxidative stress, DNA damage). Specifically, effects on the hypothalamic-pituitary-adrenal (HPA) axis, which regulates stress response and other vital functions, were investigated due to observations of potential HPA disruption in other vertebrate species exposed to DWH and other crude oil. We will present results from the full suite of physiological and toxicological endpoints examined in this study, as well as the implications for the DWH sea turtle injury assessment and for future assessments of toxic effects of oil to turtles.

412 Mercury Accumulation and Effects in the Brain of Atlantic Sharpnose Sharks (Rhizoprionodon terraenovae)

S.L. Ehnert, Univ of North Florida / Biology; J. Gelsleichter, Univ of North Florida

Sharks often bioaccumulate mercury (Hg) concentrations in their muscle to levels that threaten the health of human consumers. However, few published studies have examined if the high Hg levels seen in shark muscle also occur in the shark brain, or if Hg accumulation affects shark neurophysiology. Therefore, this study examined if shark brains accumulate significant levels of Hg, if Hg accumulation occurs in certain subcomponents of the brain, and if Hg accumulation is associated with effects on the shark central nervous system, with special focus on the Atlantic sharpnose shark (Rhizoprionodon terraenovae). Sharks were collected along the U.S. Southeastern coast. Muscle and brain Hg concentrations in the sharks were determined by the Direct Mercury Analyzer. Correlations were examined between brain Hg concentrations and levels of known biomarkers of Hg-induced neurological effects (e.g., levels of a protein biomarker of glial cell damage, S100b, and markers of oxidative stress) in shark cerebrospinal fluid (CSF). Brain Hg levels were correlated with muscle Hg levels, but were significantly lower and did not exceed most known thresholds for neurological effects, suggesting limited potential for such responses. Data on CSF biomarker levels support this premise, because they were not correlated with brain Hg levels. Higher Hg levels were measured in the forebrain of shark in comparison with the hindbrain, but levels in both were below threshold levels for effects. This study is the first to demonstrate the correlation and significant difference of Hg in the brain and muscle of sharks. It is also the first to identify significantly higher Hg levels in the forebrain. This study is the most extensive analysis of Hg in a single shark species, spanning most of its Atlantic range. It is also the first to examine neurological effects of Hg exposure in these animals.

413 Phylogenetic Signal in Fish Acute Toxicity

A. Hylton, Y. Chiari, Univ of South Alabama / Biology; M.G. Barron, USEPA / Gulf Ecology Division; S. Glaberman, Univ of South Alabama / Biology

Traditionally, risk assessment has focused on a few model test species to represent toxicity of chemicals to ecological receptors. Recently, significant advances have been made in extrapolating toxicity data across species to better understand the potential risks of chemicals to a variety of organisms. However, many of these extrapolation methods do not take into account the evolutionary relationships among species. Since shared evolutionary history is often highly associated with similary physiology, it is generally expected that sensitivity to chemicals should be similar among closely related species. We examine the phylogenetic basis of sensitivity to a variety of chemicals across fish using existing data on acute toxicity (i.e., LC50). Preliminary analyses suggest that the degree of phylogenetic signal in toxicity is highly variable across chemicals and may be a result of both real biological factors (e.g., chemical mode of action) as well as methodology (e.g., sample size).

414 A Petri Net Model for Physiologically Based ToxicoKinetics (PBTK) of Waterborne Fluoranthene in Rainbow Trout

I. Edhlund, Clemson Univ ENTOX

Physiologically Based Toxicokinetic (PBTK) Modeling has been instrumental in describing the Absorption, Distribution, Metabolism, and Excretion (ADME) of anthropogenic compounds in indicator species for decades. The models rely on relatively simple, straightforward formulas of mass balance uptake, blood/tissue and blood/water partitioning, metabolic kinetics, etc. As a whole, however, these models become complicated when all the formulas come together in large Ordinary Differential Equations (ODEs) which require programming and mathematical skill in order to solve. This study uses Petri Net (a graphical modeling technique) in Snoopy (an Integrated Development Environment [IDE]) to build and simulate a PBTK model of waterborne Fluoranthene uptake in Rainbow Trout. An existing ODE model was simulated in Matlab with code provided in the literature. A Petri Net model was created in Snoopy and the results compared to the ODE model. The goal is to make PBTK models more user friendly so that investigators can concentrate on the compounds, kinetics, and organisms rather than the programming. Petri Nets also offer advantages in simulation, documentation, and distribution of the models to the scientific community once they are created. In addition, Petri Nets are used extensively in modeling biochemical networks, which could be integrated with the Petri Net PBTK models.

415 Bioelectrical impedance analysis as a predictor of fish health using rainbow trout (Oncorhynchus mykiss)

J.K. Durante, Univ of Ontario Inst of Tech.; J. Guchardi, Univ of Ontario Inst of Technology / Faculty of Science Aquatic Toxicology; D.A. Holdway, Univ of Ontario Inst of Tech / Science

Bioelectrical impedance analysis (BIA) was used to create predictive models which could non-lethally estimate the body proximate composition of rainbow trout (Oncorhynchus mykiss). BIA readings were obtained from a mixed sex population of fish consisting of different sizes from which several predictive models were produced. Models predicting dry mass, water mass and total energy content of the fish were created with r^2 values of: 0.9064, 0.9170 and 0.9149 respectively. The effect of electrode position was also tested to determine if the position of the electrodes had an effect on the BIA measurements. Readings were taken along the dorsal, lateral and ventral sides of the trout. Models produced from the dorsal measurements were stronger predictors of body composition than models produced from lateral or ventral measurements. The ability of BIA to determine the sex of rainbow trout was also tested to determine if male and female fish could be separated based on resistance readings from the instrument. No significant difference was observed in the resistance values between male and female fish. Overall, BIA was shown to be an accurate biomarker of rainbow trout proximate composition and would be a useful tool for assessing contaminant effects on fish bioenergetics in both the laboratory and the field.

Experimental and Modeling Approaches to Account for Real-World Complexity in Environmental Toxicology

416 AQUATOX: A quantitative platform to identify and evaluate multiple interacting stressors in complex environments in an intensely farmed watershed

R.A. Park, Eco Modeling; E. Blancher, Moffatt & Nichol; J.S. Clough, Warren Pinnacle Consulting, Inc.

Agricultural runoff can impact receiving waters in many ways, generally leading to degradation of water quality and adverse effects on algae, invertebrates, and fish, and sometimes on humans through contamination of the food chain. A complex agricultural watershed has many potential stressors of differing impact and amenable to differing levels of mitigation; furthermore, these stressors often exhibit interactions that should be understood if management is to be effective. The AQUATOX model couples aquatic fate, toxicology, and ecosystem submodels to "close the loop," representing both direct and indirect effects (by interrupting the trophic structure of the food web); it also provides a platform to which other environmental stressors, such as sediments, scour, and elevated temperatures may be added for combined analysis. Zollner Creek, Oregon, was chosen as a test case because the watershed is 91% agricultural, with 43 different agricultural land uses identified, including row crops, orchards and vineyards, grain and grass fields, and large poultry farms. In 2006 water quality was found to be impaired for resident fish and shellfish, salmonid fish spawning, and anadromous fish passage. The ODEQ began monitoring pesticides in the creek in 2005; they found a variety of pesticides with a high frequency of detection and some, including chlorpyrifos, exceeded water quality standards. The frequency of sampling was sufficient so the empirical chlorpyrifos data were imported directly from the USGS file; the only conditioning of the data was to substitute very low concentrations when data were below detection limits. Total suspended solids were not identified in the TMDLs as an impairment, but they are a factor in nutrient and pesticide transport and bioavailability. Suspended detritus can cause anoxic conditions with serious impacts on coldwater and anadromous fisheries; both suspended inorganic and organic particles are thus important for an integrated environmental analysis. Because they were not measured continuously, TSS was regressed on discharge, which is measured continuously. Suspended organic detritus values are abnormally high in Zollner Creek; extensive poultry houses and waste disposal on fields can account for most of the detrital contamination. Nitrate concentrations are also high due to agricultural runoff, especially when carrying poultry wastes. We will continue to explore stressor interactions through factorial applications.

417 Assessing the Combined Effects of Metal Contamination and Sediment Deposition on Benthic Invertebrate Colonization

B. Dabney, Colorado State Univ / Fish, Wildlife, and Conservation Biology; J. Williamson, J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry; W.H. Clements, Colorado State Univ / Fish Wildlife and Conservation Biology

The combined effects of sediment deposition and metal contamination can pose serious risks to aquatic ecosystems, particularly in mountainous regions. To improve bioassessments and recovery potential of aquatic ecosystems, novel experimental approaches are needed to address the impacts of multi-stressors on biotic indicators. This research examines the effects of metal contamination and sediment infiltration on benthic invertebrate community colonization at the North Fork of Clear Creek, a USEPA Superfund site in Black Hawk, Colorado, USA. Metal-contaminated coarse and fine sediment was transported to an upstream reference site where the rate of colonization by benthic macroinvertebrates was observed for 30 days. In addition to the presence or absence of metal-contaminated sediment, results were interpreted using grain size, organic matter, and species traits. Abundance increased over time for all insect orders; however, these changes were much slower in treatments with metal-contaminated fine sediment. Further analysis from mesocosm experiments showed how patches of metal-contaminated sediment influence downstream community composition. This study indicates a need to focus on interpreting other abiotic variables and species traits when estimating stream recovery. In particular, colonization rate of dominant taxa should also be quantified when assessing ecosystem responses to stream restoration. This research has broad implications pertaining to management strategies and our understanding of benthic community recovery in impaired environments with the use of field experiments.

418 Utilizing Higher Tier Aquatic Exposure Modeling and Monitoring for Pesticide Risk Assessments

D.G. Dyer, Bayer CropScience / Environmental Safety

The pesticide industry is highly regulated by the United States Environmental Protection Agency (USEPA) and additionally by some state regulatory agencies. There are significant research demands necessary for the initial registration of a pesticide, as well in maintaining these registrations. Initial environmental fate laboratory data are used in conservative regulatory models to determine the potential exposure in the environment, and these exposures are used to determine potential risk to ecological systems. If predicted exposure exceeds the level of concern for a specific organism (e.g. non-target plants, aquatic organisms, etc.), higher-tier modeling can provide a more refined, 'real-world' exposure, however, there are regulatory limitations on the use of these refinements in the regulatory risk assessments. To resolve the uncertainty of the risks based of these modeled exposure estimates, higher-tier real-world studies and monitoring are necessary. Examples of the conservative nature of the regulatory models in aquatic assessments will be compared to real-world monitoring data -- including data generated by non-industry sources such as federal and state monitoring programs. The value and limitations of the modeling and monitoring data in the context of a real-world risk will be evaluated.

419 Building a Predictive Adverse Outcome Pathway for Multiple Acetylcholinesterase Inhibitors to Predict Effects to Population Scale Endpoints

W.G. Landis, S.E. Graham, Western Washington Univ / Inst of Environmental Toxicology; J.D. Stark, Washington State Univ / Dept of Entomology; K. von Stackelberg, NEK Associates LTD / Dept of Environmental Health

One of the major issues in environmental toxicology and risk assessment is the integration of molecular interactions to effects observed at landscape scales. Adverse outcome pathways (AOPs) are linear acyclic models to describe the interaction of a toxicant with the molecular, cellular, organs and eventually the organism. Currently AOPs do not predict population scale effects with the context of the landscape. This presentation describes how to extend the AOP framework to a Bayesian network to describe interactions at each biological scale to derive the key parameters for estimating population dynamics. These parameters are survival and timing to first reproduction, survivorship between age classes, and reproduction at each age class. Bayesian networks will be parameterized to include molecular interactions including synergistic and antagonistic effects. Age structured population models are used to incorporate ecological context to include carrying capacity, density dependent or independent population control, and patch dynamics. The initial examples are different organophosphate pesticides both individually and in mixture. The modes of action are clear; synergism has been identified and has well defined exposure-response curves. Finally we will present how this approach can be extrapolated to the estimates of effects and risk to endangered species, salmon in the Salish Sea.

420 Mixtures of Chemical Pollutants at Environmental Concentrations: How to deal with?

R. Carvalho, EU DG JRC; V.E. Ferrero, LGC; M. Potalivo, S. Balzamo, ISPRA Inst for Environmental Protection and Research; S. Tavazzi, R. Loos, T. Lettieri, European. Commission – Joint Research Centre / Inst for Environment and Sustainability IES

Thousands different chemicals are discharged into the environment from agriculture, industry, medical facilities, house-holds. Currently, there is an increasing concern for the environmental impact of mixture of compounds since the additive and eventual synergistic effects are unknown and could produce serious adverse effects. Recently, the European Commission has issued a Communication on combination effects of chemicals highlighting the need to ensure that risks associated with chemical mixtures are properly understood and assessed. To address this issue, a joint-effort of 16 European and associated research groups participated to an exercise to test a synthetic reference chemical mixture on the own routine bioassays to investigate the chemical mixtures effects (Carvalho et al., 2014)). The reference material was prepared by ISPRA (Italian reference Laboratory for chemical) included class of pesticides, pharmaceuticals, industrial products, heavy metals and polyaromatic hydrocarbons such as atrazine, diuron, isoproturon and simazine (herbicides), benzo[a]pyrene and fluoranthene (polycyclic aromatic hydrocarbons), cadmium and nickel (metals), DEHP (plasticizer), 17β-estradiol (naturally occurring estrogen), 4-Nonylphenol (surfactant), diclofenac (pain killer), chlorphenvinphos and chlorpyrifos (insecticides), and the emerging compounds bisphenol A, carbamazepine, sulfamethoxazole, triclosan and DEET. The mixures were prepared, each compound at Equivalent Quality Standard (EQS) value, the safety limit concentration allowed by the European Water Framework Directive (WFD). The bioassays covered the entire ecosystem from bacteria to fish as well in vitro assays providing an unique scenario from ecological risk assessment perspective. The results showed that effects were observed at very low concentration on algal-bacteria composition in a marine microcosm, immobilization in crustacean, fish embryo toxicity and frog embryo development. Transcriptomics was performed for the marine diatom Thalassosiria pseudonana exposed either to single compound or the mixture showing that the effects of the mixtures could be explained mainly by the combined exposure to the four herbicides. Preliminary results will be presented. We conclude that some precaution on the chemical mixture assessment should be taken even in case the individual compounds are present at EQS, the safety limit concentration under European legislation.

421 Restoration Scaling of Lost Ecosystem Services in Complex Aquatic Systems

D. Hanson, HansonRM / Earth Sciences; W. McConnaha, E.M. Britney, ICF International; T. Baker, NOAA / Office of Response Restoration

Environmental regulations in the U.S. and Europe require compensation of lost environmental services due to releases of hazardous substances,

oil spills, and other perturbations. Habitat Equivalency Analysis (HEA) has often been used to scale present value of lost services with compensatory restoration. HEA assumes that all areas within a habitat category are functionally equivalent and exchangeable. This can create challenges for complex aquatic sites for addressing issues associated with the biology and life history of the species, the dynamics of habitat, life history and functional connectivity, complex hydrology, and non-stationarity. HEA can be adjusted to align with the complexity of the environmental conditions to support settlements. However, difficulties in aligning HEA with complex environmental conditions can create obstacles to scaling services loss with compensatory restoration and impair settlement negotiations. For example, responsible parties can find it difficult to get management approval of a large settlement when the basis of the settlement is a simplified analysis of complex conditions. The objective of this presentation is to present an alternative approach for restoration scaling of lost services in complex aquatic systems. We suggest a habitat-based approach aligned with the life cycle of indicator species for evaluating complex aquatic systems. Such an approach allows consideration of habitat change in the context of the species life history and the interactions that occur across biological and physical scales. For example, the Ecosystem Diagnosis and Treatment model was developed to support species recovery and restoration planning for various salmonid species and has been used extensively for restoration planning. The model has been used to evaluate both the preservation and restoration potential associated with the impacts of various chemical, physical, and hydrological perturbations. The software code is publically available and editable making it possible to align the analysis with site-specific issues. Importantly, the model evaluates habitat change in biologically meaningful terms such as the change in potential productivity, capacity, abundance and life history diversity of the population as a function of habitat conditions. In addition to use for restoration scaling, the model provides an transparent framework for selecting and quantifying potential restoration alternatives, including geospatial implications.

422 Asymmetric effects of pharmaceutical exposure genarate unexpected ecological effects

T. Brodin, G. Hellström, M. Jonsson, Umeå Univ / Dept of Ecology and Environmental Science; J. Fick, Umeå Univ / Dept of Chemistry; J. Klaminder, F. Finn, Umeå Univ / Dept of Ecology and Environmental Science

Pharmaceuticals designed to modify behavior are found in waterways globally, but how these affect aquatic organisms and food webs is largely unknown. We have priorly shown that pharmaceuticals may invoke asymmetric effects when comparing species on different trophic levels, such as invertebrates and fish. Here we present results showing for the first time that pharmaceutically induced behavioral modifications differ between wild fish species, resulting in species-specific increases in predation risk, with ecosystem-level impacts. We found that, activity and boldness increased significantly in Eurasian perch (Perca fluviatilis), resulting significantly higher predation risk, while behaviors and predation risk of crucian carp (Carassius carassius) were unaffected. However, counter to our expectations, a tri-trophic level model based on our results show adverse impacts on the unaffected crucial carp, the top predator, and depletion of the basal resources. As such, our results indicate that asymmetric effects of pharmaceutical contamination may cascade both up and down aquatic food webs, with implications for overall ecosystem functioning.

423 Comparative potency and mechanisms of four model industrial chemicals to induce antioxidant and oxidative stress gene expression in zebrafish larvae

M. Mills, Univ of Washington / Dept of Environmental and Occupational Health Sciences; J. Kostal, George Washington Univ; J. Corrales, B.W. Brooks, Baylor Univ / Dept of Environmental Science; A. Voutchkova-Kostal, George Washington Univ / Chemistry; E.P. Gallagher, Univ of Washington

The question of what chemicals cause oxidative stress, and through which molecular pathways the oxidative stress generated by those chemicals acts, is an important one for toxicologists. In order to investigate the importance of the Nrf2 pathway in sensing and responding to oxidative stress in zebrafish, we examined changes in larval gene expression induced by exposure to four chemicals: two different peroxides (tertbutyl hydroperoxide and cumene hydroperoxide); and two potential Michael acceptors (hydroquinone and R-(-)-carvone). For each chemical, we analyzed expression of an array of ten antioxidant/oxidative response genes and three reference genes using the Affymetrix QuantiGene Plex (QGP) platform. The zebrafish genes contained in our array included those considered Nrf2 (Nfe2l2a)-dependent (hmox1, gstp1, gclc); potentially Nrf2-dependent (nqo1, prdx1, gpx1a); genes modulated by oxidative stress (sod1, sod2); genes responsive to cellular stress and DNA damage (hsp70, gadd45bb), and 3 reference genes (actb1, gapdh, hprt1). We measured expression of each gene in response to a range of concentrations of each chemical based on the LC_{50} of that particular chemical in embryonic/larval zebrafish. We used these data to compare the modes of action of the two pairs of chemicals. For the hydroperoxides, we modeled the O-O bond strength and radical stability. For hydroquinone and R-(-)-carvone, we modeled the relative reactivity and compared to the patterns of gene expression change caused by each to determine whether they both undergo Michael addition as the first step to causing oxidative stress, or whether hydroquinone instead causes oxidative stress through a radical mechanism. We then compared changes in gene expression of wild-type fish to those of fish harboring a mutation in the DNA binding domain of nfe2l2a (the mutant line nrf2^{fh318}), and used these data to predict the extent to which each chemical activates the Nrf2 response pathway. Our results demonstrate the power of combining genetic analysis and modeling to understand the complexities of chemical effects on whole organisms. Supported by NSF 339637 and NIH P42-ES04696.

Advanced Analytical Methods for Contaminant Discovery

424 Exploring environmental chemical space through HR/AM mass spectrometry and cheminformatics: The example of wastewater-derived organic micropollutants

L. Ferguson, Duke Univ / Dept of Civil and Environmental Engineering; G.J. Getzinger, Duke Univ / Nicholas School of the Environment

High-resolution accurate-mass mass spectrometry (HR/AM MS) provides a promising approach for comprehensive structural elucidation of numerous trace-level organic contaminants in aquatic media. However, comprehensive sample characterization is made difficult by inefficiencies in the prioritization of detected features and postulated structures based on tandem MS analysis. We have developed a holistic, non-targeted screening workflow to address these challenges, which combines ultra-high resolution tandem mass spectrometry, computational mass spectrometry. We illustrate the utility of this approach to evaluate the occurrence of organic micropollutants in the effluent of a conventional domestic wastewater treatment facility. Composite effluent samples from the North Durham Wastewater Reclamation Facility (Durham, NC, USA) were analyzed using an Orbitrap Fusion tribrid tandem HR/AM mass spectrometer. Resulting data were aligned and componentized to yield 3,701 unique features, for which >91% had associated tandem mass spectral data. Custom data processing scripts were deployed to pipe relevant feature data to computational mass spectrometry tools for molecular formula assignment based on isotope pattern and fragment spectrum decomposition (SIRIUS, formulas assigned to 90.2% of features), structure assignment from the PubChem compound repository (postulated structures returned for >77% of features) and automated tandem mass spectral annotation and scoring (MetFrag CL, MAGMa, and CFM-ID). Finally, postulated structures were scored based on their structural similarity to possible environmental contaminants (i.e., compounds known to be produced in commerce) and to known wastewater pollutants. Structure descriptors were calculated using 42-molecular quantum numbers (MQN), a unique descriptor set that implements simple atom, bond and topology counts. After rigorous data filtering, 607 micropollutants were tentatively identified, representing classes of pharmaceuticals, transformation products, consumer chemicals, and industrial compounds. Overall, our results highlight the benefit of combining of state-of-the-art computational mass spectrometry tools with chemoinformatic approaches for increased efficiency and annotation rate in non-targeted analysis of built and natural environments.

425 Nontarget Analysis of Polar Organic Chemical Integrating Sampler Extracts--complementary tools for unknowns analysis

E.T. Furlong, L.K. Kanagy, USGS / National Water Quality Laboratory; D.A. Alvarez, USGS-CERC / Physiology and Biochemistry

Comprehensive identification of known and suspected organic contaminants in surface water systems relies on sampling designs that reliably collect the fullest range of contaminants present. Integrating passive samplers, such as the polar organic compound integrative sampler (POCIS), provide the means to collect an integrated profile of many polar organic contaminants present in surface water whose presence may be continuous or episodic, reflecting changes in hydrologic or source input. Coupling POCIS with a comprehensive nontarget analysis scheme provides both qualitative identification and semiquantitative concentration estimation of targeted and nontargeted contaminants and permits comparing POCIS-derived contaminant profiles to assess varying presence of argeted and nontargeted contaminants. We present results from the structured nontarget analysis of POCIS extracts initially analysed using a targeted method for the determination of 109 pharmaceuticals. The extracts were analysed using a Waters Synapt G2S Quadrupole Time-of-Flight Mass Spectrometer (QToF MS) operated in the positive electrospray ionization mode and coupled to a Waters Aquity Ultra Performance Liquid Chromatograph, using reversed phase separation for separation of analytes. The QToF MS was operated in a scan mode combining spectra with alternating low and high collision cell energies. The resulting data were then aligned and analysed using Waters software and an extended pesticide and toxicology library to identify known and suspected contaminants. Results from the QToF analysis were compared to targeted analysis using high-performance liquid chromatography/tandem quadrupole mass spectrometry. Methyl-1H-benzotriazole, carbamazepine, citalopram, desvenlafaxine, fexofenadine, and tramadol were among the compounds in POCIS extracts detected by LC/MS/MS and confirmed by QToF MS. Lamotrigrine and DEET, not determined by the LC/MS/MS, but anticipated to likely be present, were identified by QtoF MS from elemental compositions of the parent pseudomolecular ions and the associated fragments from the linked high-energy collisional dissociation spectra. The hydroxyl degradation products of carbamazepine and lamotrigrine were similarly identified in these extracts. Procedures to identify these and other organic contaminants and contaminant degradates in POCIS extracts are further discussed, providing a clear demonstration of the value of combining POCIS and QToF MS for non-target analysis.

426 Occurrence of suspect and non-target contaminants and their transformation products in a linked surface water system influenced by treated wastewater

A. Huba, Florida International Univ / Chemistry Biochemistry; P.R. Gardinali, Florida International Univ / Chemistry Biochemistry and SERC

Due to the finite nature of the world's fresh water sources, the recycling of treated wastewaters has been a significant area of development in the past years. Water recycling, however, leads to considerable apprehension with respect to the presence and persistence of unregulated contaminants that are introduced through treated wastewater releases. Water treatment plants, although designed to remove a variety of contaminants, are not always efficient and may, additionally, introduce new products which are formed during the treatment. The monitoring of the composition of the incoming and outgoing water is therefore always important. Owing to the recent development of increasingly sensitive and selective analytical tools, non-target screening methods have gained significant interest. These approaches allow for a more comprehensive screening since the a priori selection of compounds is no longer needed, opening the possibility for retrospective analysis. The potential of suspect and non-target screening workflows was here demonstrated for the analysis of contaminants in surface and drinking water in a typical system impacted by a treated domestic effluent. High performance liquid chromatography-high resolution mass spectrometric (HPLC-HRMS) analysis was carried out on an Orbitrap Q Exactive, and subsequent data processing included peak picking, retention time alignment, blank subtraction, elemental formula assignment, ChemSpider search and MS/MS spectral matching, with the use of the Compound Discoverer 2.0 software, as well as the MassBank library, and the in silico fragmenter MetFrag. Suspect and non-target screening was able to tentatively identify over 70 compounds, including pharmaceuticals, plasticizers and other domestic use based contaminant classes, many of which were shown to be persistent along the entire system. Analysis of the drinking water treatment plant influent and effluent showed the presence of 242 not efficiently removed components (including the tentatively identified DEET, 4-nonylphenol, and hexamethoxymethylmelamine), as well as 269 newly formed components, likely by-products of the treatment process. Further analysis also yielded the identification of transformation products, including cotinine and O-desmethylvenlafaxine. Moreover, Kendrick mass defect plots were used to identify potential areas of interest, such as heteroatom containing byproducts, which represent an area for further development of advanced treatment technologies.

427 Evaluation of Emerging Contaminants in Great Lakes Fish using comprehensive two-dimensional gas chromatography high resolution mass spectrometry

S. Fernando, Clarkson Univ; B. Crimmins, Clarkson Univ / Civil and Environmental Engineering; T. Holsen, Clarkson Univ

The Great Lakes Fish Monitoring and Surveillance Program (GLFMSP) has traced the fate and transport of anthropogenic chemicals in the Great Lakes for decades. The contemporary impact of emerging contaminants was recently recognized and the program has dedicated significant resources to understanding the threat posed by non-legacy toxic chemicals. The identification of novel contaminants in top predator fish is a major challenge due to the complex biological matrix. Traditional legacy chemical purification steps can potentially discriminate against unknown toxic chemicals present in the original extracts. To enhance the comprehensive screening ability of GLFMSP, top predator fish extracts have been analyzed using a state-of-the-art two-dimensional gas chromatograph coupled to a High Resolution Time of flight mass spectrometer (GCxGC-HRMS, LECO GC-HRT). Due to the increased peak capacity and mass accuracy offered by GCxGC, and HRT, respectively, fish tissue extracts were injected with minimal sample cleanup. Identifications were performed by library spectral matching and molecular formula estimations using high resolution data. The efficacy of this technique as a targeted screening/confirmation and non-targeted discovery tool will be assessed with a summary of novel chemicals observed in Great Lakes top predator fish.

428 Chemical characterization of indoor dust by comprehensive target and non-target screening using GC- and LC-QTOF-MS/MS

C. Moschet, B. Lew, Univ of California Davis / Civil and Environmental Engineering; T. Anumol, Agilent Technologies Inc.; H. Shin, D.H. Bennett, Univ of California Davis / Dept of Public Health Sciences; T.M. Young, Univ of California-Davis / Civil and Environmental Engineering

House dust is contaminated with a broad range of chemicals such as pesticides, personal care products, plasticizers, flame retardants, and polyfluorinated compounds. It can serve as a marker of exposure to humans and is known to be a reservoir for many released compounds. Previous studies have focused on investigating one or several compound classes in a targeted analytical approach. The recent development of high-resolution mass spectrometers and corresponding software offers the possibility of screening for suspected or non-target chemicals. The goal of this study is to comprehensively characterize the chemical fingerprint in 50 dust samples collected from two groups of households: families with normal developing children and families with children having developmental issues. Over 130 frequently used chemicals that span the chemical space were selected to optimize the sample preparation and analytical methods. The final method consisted of sonication extraction using hexane and acetone without further sample clean-up. One part of the extract was measured on an Agilent GC-QTOF-MS using electron impact (EI), while the other extract was analyzed on an Agilent LC-QTOF-MS using electrospray ionization (ESI) in positive and negative mode. Absolute recoveries were above 50% for more than 95% of the chemicals, and method detection limits were below 100 ng/g for 80% of the chemicals. Following the quantification of the target chemicals, the dust samples were screened for several thousand additional compounds of interest in dust using different databases. Thereby, exact mass screening and MS/MS spectra comparison for chemicals measured by LC-QTOF-MS as well as comparison with library spectra for chemicals measured by GC-EI-QTOF-MS was used for the detection of these suspected chemicals. Finally, all features in the samples were extracted in a recursive way. Mass Profiler Professional (MPP, Agilent Tech.) was used to prioritize non-target features of interest, i.e. features with highest detection frequencies and features with significantly different abundances in samples from the two different household groups. Prioritized features were tentatively identified by MS/MS measurements, the use of the MetFrag software tool and the DSS-TOX database (EPA) containing over 100,000 household related chemicals. This multi-step screening will give new insights in the chemical fingerprint of US indoor dust by identifying unknown chemicals that should be further investigated.

429 Streamlining Non-Targeted GCxGC/TOFMS Data Analysis of Remediated Soil Samples using Python

I. Titaley, M. Ogba, L. Chibwe, Oregon State Univ / Dept of Chemistry; E. Hoh, San Diego State Univ / School of Public Health; P.H. Cheong, Oregon State Univ / Dept of Chemistry; S.L. Massey Simonich, Oregon State Univ / Dept of Environmental and Molecular Toxicology

Bioremediation of polycyclic aromatic hydrocarbon (PAH) contaminated soil samples may lead to the formation of polar toxic PAH transformation products, many that are non-routinely monitored. To identify these transformation products, an effect-directed analysis approach was used to determine toxic fractions of bioremediated samples. These toxic fractions were analyzed using comprehensive two-dimensional gas chromatography coupled to time-of-flight mass spectrometer (GC×GC/TOFMS) and ChromaTOF® software from LECO. While this non-targeted analysis approach is suitable for elucidating unknown compounds that cause increased toxicity following bioremediation, the list of potential compound candidates were in the range of tens of thousands. A Python program was developed to automate and accelerate the identification of the compounds in these toxic soil fractions. The program takes exported data from LECO ChromaTOF®'s Statistical Compare feature, which is a peak alignment tool that also show peak variations between groups, and returns a list of potential compounds with increased peak responses post-bioremediation. The peak tailing factor and the compound peak response before and after bioremediation were used as the parameters to identify candidate compounds. Comparison between the results from the script and manual identification were made. One of the fractions was the most toxic and comprised of over 1,000 compounds. The Python program select candidate compounds, based on peaks identified by Statistical Compare, within minutes, while manual selection required several days of pruning. In addition, the Python program standardizes the analysis of complex PAH mixtures in the environment by reducing the potential for human variability. Moreover, this program can be adopted across multiple laboratories and disciplines. Altogether, a Python script was written that streamlines the identification of compounds that are formed following bioremediation of soil samples by making the process more time efficient. While the program was written to determine PAH transformation products that were formed following bioremediation, the script can be modified to identify PAHs that were degraded as well. This program can aid researchers that use GC×GC-TOFMS for non-targeted analysis of chemicals in the environment by reducing the analysis time.

430 Identification of Novel Brominated Disinfection By-Products of Concern by Use of DIPIC-Frag Untargeted Screening and Effect-Directed Analysis

C. Watts, H. Peng, Univ of Saskatchewan / Toxicology Centre; P.D. Jones, J.P. Giesy, Univ of Saskatchewan

Disinfection byproducts (DBPs) are produced during drinking water treatment processes as a result of the reaction of disinfectants with natural organic matter (NOM). Brominated DBPs (Br-DBPs) are a specific class of concern due to consistent reports that they are more toxic than their chlorinated analogues; however, a large proportion of Br-DBPs in drinking water remained unidentified and subsequently uncharacterized. Identification of Br-DBPs in actual drinking water samples is challenging due to complicated interferences, the extremely low concentrations at which Br-DBPs exist, and their chemical diversity. To overcome these challenges, we adopted a data independent precursor isolation and characteristic fragment (DIPIC-Frag) method for the untargeted screening of Br-DBPs in drinking water. Analytical conditions were compared including sample pretreatment methods (SPE and freeze-drying), ionization modes (APCI and ESI), and HPLC columns (C18 and Amide) to expand the coverage of Br-DBPs detected. 1,857 Br-DBPs peaks were robustly detected by the DIPIC-Frag method and analytical conditions were deemed complimentary. Precursor ions and compound formulas for 1,303 Br-DBPs were predicted and structures were proposed for the 50 most abundant peaks. This represents the largest mass spectrometry library of Br-DBPs established to date, and most of these Br-DBPs have not been previously reported. To investigate what water treatment processes contribute to the formation or removal of Br-DBPs, water samples collected from each stage of treatment at two different plants located in Saskatchewan were compared. Then, effect-directed analysis was performed by use of the CHO-K1 cell line, with cytotoxicity and DNA damage being the toxic endpoints of interest. The most toxic fractions were determined and mass spectrometry results were used to identify novel Br-DBPs that likely present the greatest concern in drinking water.

431 Progress in the analysis of chlorinated paraffins – different methods and interlaboratory study results

L. Van Mourik, Univ of Queensland / ENTOX; S. Brandsma, VU Univ / IVM; C. Gaus, The Univ of Queensland / ENTOX; P.E. Leonards, J. de Boer, VU Univ / IVM

Chlorinated paraffins (CPs) complex industrial mixtures of >1000 polychlorinated n-alkanes, are globally being produced in high volumes of more than 1 million metric tonnes per year. They have many applications such as flame retardants, and additives in metal cutting fluids. The short chain CPs (SCCPs) have been placed on the persistent organic pollutants (POPs) list of the Stockholm Convention. They need to be monitored in various matrices, but, still, reliable analytical methods are lacking. Some information is available for methods for SCCPs, but conclusive data is very limited for medium-chained CPs (C14-17; MCCPs), and information on long-chained CPs (C>18; LCCPs) is entirely lacking. The suitability of the current instrumental techniques to determine these compounds in environmental samples and the potential to improve this determination needs to be investigated. We evaluated various instrumental techniques for the determination of SCCPs, MCCPs and LCCPs, for ease of use, analysis time, sensitivity, selectivity, repeatability, reproducibility, and approximation of the true CP concentration. To achieve this, a range of the most promising and currently most applied instrumental techniques were selected (e.g. GCxGC-ECD, GC-ECNI/LRMS, GC-EI/QQQMS, qTOF-MS). CP mixtures and environmental samples were analysed and methods validated. In addition, we organized three rounds of an international interlaboratory study and results of those studies, in which ca. 20 laboratories participated, will be discussed.

Climate Change and Water Resource Management: An Ever-Changing Challenge

432 Life in a Warmer More Acidic World: Physiological Implications of Climate Change on Aquatic Organisms

K. Brix, EcoTox / Zoology

Global climate change presents the single greatest environmental challenge of the 21st century. The Intergovernmental Panel on Climate Change (IPCC) has issued several reports making projections of future climate scenarios, largely dependent on the magnitude of CO_2 emissions for the remainder of this century. While there are uncertainties in these projections, it is clear that the climate has changed, and will continue to change, at a rate that has only been observed a few times over the last 300+ million years. Although the magnitude is uncertain, in aquatic systems we can expect elevated atmospheric CO_2 to result in warmer (~2-4 °C increase) more acidic (~0.2-0.4 pH decrease) waters. An overview of these projected changes in temperature and pH in aquatic systems is presented. Increases in temperature and acidity can directly affect multiple physiological processes including metabolism, oxygen transport, acid-base balance, ion transport, and oxidative stress. An overview of these effects will be presented with the objective of providing a physiological framework of how climate change may affect organisms from which to evaluate the interactions between climate change and other anthropogenic stressors.

433 Assessing Climate Change Effects on Freshwater Fish Distribution Using a Habitat Suitability Model

T. Shim, J. Jung, Korea Univ / Environmental Science and Ecological Engineering

Water quality and quantity are affected by climate change due to temperature and precipitation changes, which alters the habitat suitability of aquatic organisms. In order to predict effects of climate change on freshwater fish distribution, an ecological habitat suitability model (EHSM) was developed in this study. The EHSM is based on the concept of a habitat-hydraulic model, physical habitat simulation system (PHABSIM), with accommodation of a habitat-physiologic model, CLIMEX. The EHSM utilizes hydraulic variables (velocity, depth, substrate) and water quality variables including temperature to assess the habitat suitability of freshwater fish. Zacco platypus was selected as a model species because they are commonly found in Korea. Overall, the habitat suitability of Z. platypus tends to increase with increasing temperature by climate change, mainly due to their broad thermal habitat preference.

434 Protecting Aquatic Life from Effects of Streamflow Alteration

D.M. Eignor, USEPA / Office of Water; J. Kennen, USGS; R. Novak, US Bureau of Indian Affairs

Protecting aquatic life from the effects of streamflow alteration involves maintaining multiple components of the flow regime within their typical range of variation. The U.S. Environmental Protection Agency (EPA) in collaboration with the U.S. Geological Survey have developed a report to serve as a source of information for states, tribes, and territories on: 1) the natural flow regime and potential impacts of flow alteration on aquatic life; 2) Clean Water Act programs that can be used to support the natural flow regime and maintain healthy aquatic ecosystems; and 3) a flexible, non-prescriptive framework to quantify targets of the flow regime that are protective of aquatic life. This flexible framework incorporates EPA guidelines for ecological risk assessment and relevant concepts from contemporary environmental flow science literature. The framework does not prescribe any particular analytical approach (e.g., statistical modeling), but rather, it focuses on the process, information, and data needed to evaluate relations between flow and aquatic life and to select appropriate numeric flow targets. While this paper deals primarily with streams and rivers, non-flowing systems (e.g., lakes and wetlands) are inextricably connected to flowing systems and can therefore benefit from measures to maintain hydrologic conditions in flowing water bodies.

435 Ecotoxicological impact of re-mobilized sediments and flood events for look regulated rivers and wetlands

H. Hollert, RWTH Aachen Univ / Dept of Ecosystem Analysis; M. Brinkmann, Univ of Saskatchewan – Toxicology Centre / Dept of Ecosystem Analysis; M. Hecker, Univ of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre; H. Schuettrumpf, C. Cofalla, RWTH Aachen Univ / Inst of Hydraulic Engineering and Water Resources Management

In recent years, sediments have become a central topic of scientific and public discussion as an important factor for determining water quality. While the quality of surface waters in Germany has significantly improved during the past years, highly contaminated sediments still create a considerable threat to the quality of several European catchment areas. For several European river basis, including Neckar, Rhine and Elbe, highly contaminated old sediments can be described as “potential chemical time bombs”. An important process which may remobilize such sediments and which is still of increasing importance in relationship to the global climate change is more often occurrence of stronger floods in Europe as well as in other parts of the world. To understand and predict possible toxicological and ecotoxicological consequences of contaminants mobilized from sediments by flood events it is necessary to develop scientific approaches for the assessment of regularly flooded rivers. The combination of hydrodynamics and ecotoxicological investigations is devolving to an emerging field of research. Recently, it was shown that hydrodynamic aspects can be involved as additional line-of-evidence in Weight-of-evidence studies assessing the impact of sediments. In the last decade several studies were published addressing the ecotoxicological impact of flood events or using combined approaches for evaluating flood events and the risk of erosion. Here, we summarize different concepts and case studies for the assessment of sediment quality and report on some novel integrative test methods for assessing sediment toxicity including contaminant re-mobilization during simulated re-suspension events. Within the talk several case studies addressing the ecotoxicological impact of re-mobilized sediments and flood events for look regulated rivers and wetlands are presented. Combined investigations of sediment contamination and mobility as well as acute and mechanism specific biotests in effect directed analyses/weight-of-evidence studies show great potential for the assessment of chemically polluted rivers and should be included into the ‘programmes of measures’ within future management concepts.

436 Indirect effects of climate change on Zinc cycling in sediments: the role of changing water levels

S. Nedrich, Univ of Michigan; G.A. Burton, Univ of Michigan / School of Natural Resources Environment

Increased variability in lake and river water levels associated with changing climate, could impact the fate and effects of metals in redox sensitive sediments. Sediment metal binding is affected by a fluctuating water table through the alteration of microbial communities, acid-base and redox chemistry. The objective of this study is to determine the influence of water level fluctuation on metal speciation in pore water and predict environmental risk to benthic communities in high carbonate systems. We collected sediments from four metal contaminated coastal freshwater wetlands in Michigan and constructed experimental wetland microcosms. Water level fluctuation experiments emulated a short-term (seiche) and 32-day drought scenario. Porewater and sediment metals (Ca, Cu, Fe, Mg, Mn, Ni, Zn) and important metal binding phases (iron-oxide speciation, acid-volatile sulfide) were quantified. During the 32-day drought experiment, upon re-inundation of oxidized sediments, an increase in porewater Cu, Zn, Mg, Ca, was observed for most sites, after which the concentrations decreased slowly over 16 days. In lab studies porewater Zn increased upon inundation to levels exceeding the USEPA threshold for chronic and acute toxicity (mean = 219.2 ± 19.8 µg L^{-1}). These data show the dissolution of iron oxide bound Zn and kinetically slow reformation of metal sulfides contributes to the bioavailable metals after re-flooding. This study suggests increased ecological risk from metals to organisms present in drought sensitive regions. Climate induced changes in regional hydroperiods are likely to alter the bioavailability of metals to aquatic organisms.

437 The deal with diel: Effects of temperature fluctuations, asymmetrical warming, and ubiquitous metals contaminants on three amphibian species

M.L. Brooks, Biogeochemistry and Conservation Biology / Zoology; T.A. Hallman, Oregon State Univ

Climate projections over the next century include disproportionately warmer nighttime temperatures ("asymmetrical warming"). Cool nighttime temperatures lower metabolic rates of aquatic ectotherms. In contaminated waters, areas with cool nights may provide thermal refugia from high rates of daytime contaminant uptake. We exposed Cope's gray tree frogs (Hyla chrysoscelis), southern leopard frogs (Lithobates sphenocephalus), and spotted salamanders (Ambystoma maculatum) to five concentrations of a mixture of cadmium, copper, and lead in filtered lake water under three to four temperature regimes, representing asymmetrical warming. At concentrations with intermediate toxicosis at test termination (96 h), temperature effects on acute toxicity or escape distance were evident in all study species. Asymmetrical warming (day:night, 22:20 ^{o}C; 22:22 ^{o}C) doubled or tripled mortality relative to overall cooler temperatures (20:20 ^{o}C) or cool nights (22:18 ^{o}C). Escape distances in treatments with the same water quality were 40 to 70% shorter under asymmetrical warming. Results suggest potentially grave ecological impacts from unexpected toxicosis under climate change.

438 Exploring the impacts of multiple anthropogenic and environmental stressors: data needs for predicting ecological effects

L. Lockett, A. East, Towson Univ / Environmental Sciences; C.J. Salice, Towson Univ / Biological Sciences/ Environmental Science

The Organization for Economic Co-operation and Development (OECD) provides standardized guidelines for testing pesticide toxicity. For aquatic invertebrates, the cladoceran Daphnia magna is used as a model organism and is typically exposed to a range of chemical concentrations at a constant and optimal temperature for 48 hours (acute) or 21 days (chronic). The guidelines for these tests simplify experimental design and allow for straightforward data analysis to inform environmental regulations. Although these tests hold value, they do not consider fluctuations and variations in other environmental factors that are commonly experienced in nature. For example, organisms exposed to pesticides in natural water bodies are likely to experience non-optimal temperatures, variable food conditions and intra-specific competition along with a plethora of other stressors. In this study, D. magna was used to test the toxicity of the fungicide pyraclostrobin under different temperature regimes and at different conspecific densities. Pyraclostrobin is a strobilurin fungicide used nationally to combat 19 fungal diseases that impact crop yields. The objectives were to: (1) determine the toxicity of D. magna to pyraclostrobin under acute and chronic exposure conditions, (2) determine if elevated temperatures alter pyraclostrobin toxicity, (3) determine if conspecific density and competition for food alter toxicity to pyraclostrobin and, finally, (4) evaluate how results from standard toxicity tests compare to results from multi-stressor conditions. So far, our results show that pyraclostrobin toxicity increases with temperature (> TEMP) and that daphnids are very sensitive to conspecific density with lower survival and reproduction at 4X the control density. These results will inform the study design to evaluate the impacts of all three stressors simultaneously. We will also evaluate the utility of different multi-stressor models to determine if, by combining single stressor test results, we obtain insight into simultaneous exposure effects. Our overarching hypothesis is that standard toxicity assays only provide limited insight into effects that can occur in natural populations that also experience other, disparate stressors.

439 Acute thermal challenge potentiates benzo-a-pyrene-induced cardiac and metabolic toxicity in juvenile rainbow trout (Oncorhynchus mykiss)

L.P. Weber, K. Ma, Univ of Saskatchewan / Veterinary Biomedical Sciences; F. Leal, Univ of Saskatchewan – Toxicology Centre / Veterinary Biomedical Sciences

Fish are facing increasing impacts not only from aquatic contaminants, but simultaneously also from thermal stresses due to global warming. Increasing our understanding of their interaction is critical to predict future impacts on fish populations. Acute thermal challenges are known to increase metabolic rate that in turn increases heart rate, cardiac output and fatty acid oxidation except at high temperatures where fish switch to anaerobic glycolysis as cardiac output fails. In contrast, the petrogenic polycyclic aromatic hydrocarbon, benzo-a-pyrene (BaP) causes cardiorespiratory toxicity by also increasing oxygen consumption, but leads to cardiac arrhythmias (atrioventricular blockade), decreased ventricular contractile rate and impaired cardiac output. We hypothesized that an acute thermal challenge would exacerbate the cardiometabolic toxicity of acute BaP exposure in juvenile rainbow trout (Oncorhynchus mykiss). Trout were injected with BaP (i.p. on Days 1 and 2 with 0, 0.1 and 1 mg/kg; n=20 fish/group), then examined at Day 4 for cardiac function (high frequency echocardiography) and metabolic toxicity (plasma lactate, glucose, glycerol and triglycerides). Half of the trout were subjected to acute thermal challenge (3°C increase every 30 min from 12-30°C) and half were kept at 12°C for an equivalent time. In response to thermal challenge, control trout increased heart rate and decreased stroke volume, yet were able to maintain cardiac output until >27°C. In contrast, fish exposed to increasing BaP concentrations showed an impaired stroke volume at all temperatures and depressed heart rate plus arrhythmias >21°C, leading to consistently depressed cardiac output. Plasma lactate was decreased by thermal challenge, but unaffected by BaP. Glucose decreased with increasing BaP, but only in fish without thermal challenge. Moreover, while plasma triglycerides were unaffected by either thermal challenge or BaP, the ratio of free glycerol to triglycerides increased with increasing BaP dose in only thermally challenged trout. In conclusion, acute thermal challenge potentiated the ability of BaP to induce arrhythmias, depress cardiac output and alter metabolism in juvenile rainbow trout. This illustrates the potential for global warming to enhance sensitivity of trout to acute BaP toxicity and the need to re-evaluate toxicity of contaminants in the context of this environmental stressor.

Microplastics in the Aquatic Environment: Fate and Effects – Part 1

440 A Framework for Dynamic Estimation of Environmental Concentrations of Microplastics in WWTP Effluents and Receiving Waters at a National Scale

N. Maples-Reynolds, C.M. Holmes, R. Vamshi, Waterborne Environmental, Inc.; I. Davies, Personal Care Products Council / Science; B. Lange, PCPC Personal Care Products Council / Science

Down-the-drain exposure models provide a valuable screening-level tool for estimating environmental exposure to product ingredients which are treated and discharged at municipal wastewater treatment plants. Microplastics, plastic particles smaller than 5 mm diameter, enter wastewater treatment plants (WWTP) due to a variety of sources. Exposure modeling was performed using the iSTREEM® model, a publicly-available web-based model supported by the American Cleaning Institute (www.istreem.org) which estimates spatially-explicit concentrations of chemicals in effluent and receiving waters across the U.S. WWTP influent loadings of microbeads were estimated using per-capita usage derived from market manufacture survey (Gouin et al 2015) combined with individual facility population served and flow estimates within the iSTREEM® model. The analysis used multiple values for removal during treatment based on total suspended solid removal data and a wide range of in-stream decay rates, resulting in a variety of potential environmental exposure estimates. The removal and decay rates have a non-linear effect across the varying facilities & stream segments in the US landscape. Therefore, we developed an approach which leverages the advantages of the iSTREEM® model (national scope, individual facilities, and distributions of output) with the ability to screen for potential concern based on uncertain (and dynamic) removal and decay rates. This allows for flexibility in modeling the environmental concentration of microbeads regardless of size, weight, or physicochemical properties. We developed a 2-dimensional matrix with removal rate and decay rate as the primary axes. The individual cells within the array will then correspond to a reasonable worst-case Predicted Environmental Concentration (PEC) (e.g. 95th percentile) based on the national iSTREEM® results. These concentrations are based on a proxy quantity of microbeads which can be easily scaled. Therefore, with the matrix it is possible to supply an approximate removal and decay rate for the microplastic of interest and assess the estimated exposure by scaling the matrix value using the relationship between the substance quantity of interest and the proxy. This matrix framework can be used to help inform environmental exposure assessments by readily providing concentrations based on varying model inputs on WWTP removal and in-stream decay rates for microplastics, which continues to evolve as more research is conducted.

441 Sorption of triclosan and methyl-triclosan to microplastic and potential for facilitated release from wastewater treatment plants

B. Beckingham, College of Charleston / Environmental Geosciences; H. Lane, College of Charleston

Microplastics can be sourced from synthetic clothing, personal care products such as toothpaste or facial cleansers, or by the breakdown of larger plastic debris in the environment. Wastewater treatment plants serve to collect and concentrate wastes that have been shown to contain microplastics in addition to other contaminants of concern, such as triclosan (TCS), an antimicrobial agent common in personal care products, and its metabolite, methyl-triclosan (MTCS). The objective of this research is to measure the microplastic-water distribution coefficients for TCS and MTCS to polyethylene (PE) and a suite of textile fibers (polyester, nylon, polyester-cotton blend, and cotton) in spiked, aqueous batch tests in order to determine to what extent different microplastics can accumulate contaminants as they travel through wastewater treatment plants before being discharged to surface waters. Distribution coefficients (L/kg) for MTCS to PE and microplastic textiles decreased in the order: PE, nylon, polyester, polyester:cotton (65:35) blend, and cotton. Distribution coefficients for TCS followed the same order except for polyethylene, which was the lowest. Unlike the other materials, polyethylene does not contain any hydrophilic functional groups in the polymer backbone. Triclosan, with its hydroxyl functional group (pKa 8.1), is therefore likely participating in specific sorption interactions with the amide and carbonyl groups in nylon, polyester and cotton as has been observed for dyes. Sorption isotherms will provide further insight into this behavior. The observed distribution coefficients for the polyester:cotton blend could be predicted within 0.4% for TCS and 9.1% for MTCS using a weighted combination of the polyester and cotton values. Knowledge of sorption behavior will be combined with monitoring of microplastic in effluents to estimate the potential microplastic-facilitated release of these chemicals from a wastewater treatment plant.

442 The effects of tributaries on the transport of microplastics in the Hudson River Watershed

I. Krout, Marist College / Environmental Science

A new environmental threat known as microplastics is contaminating the Hudson River Watershed. Microplastics are entering the environment through a number of different means: drainage of personal care products containing microbeads, fragmentation and run off from larger plastic materials and fibers released from washing of nylon or acrylic fabrics. Recent studies have shown a growing presence of microplastics in the Hudson River. Due to their high resistance to degradation the accumulation of microplastics may result in harmfulimpact on human and environmental health. This study investigates the contribution of Hudson River tributaries and their role in transport of microplastics throughout surrounding watershed, directly to the Hudson River. The tributaries in the study were chosen based upon their use, pre-assessed water quality and their location in terms of population density and land usage. The four sampled tributaries were located in the State of New York. Sampling was performed using a flow through technique with a drift net submerged for 15 minutes collecting all particulate matter smaller than 333 µm. In each water sample collected from chosen streams the following water quality parameters were measured; pH, dissolved oxygen, salinity, temperature, conductivity and E. coli colonies. The overall particulate debris were observed and sorted into microplastic and organic contaminants (leaves, vegetation and invertebrates) using light microscope. The samples were analyzed using wet peroxide oxidation (WPO) method to decompose any naturally occurring material. The largest amount of microplastics found throughout all streams, were in the form of fibers and the lowest in the form of beads. Microplastics structural makeup was then verified using an infrared spectroscopy (IR). E. coli was tested using an enzyme plating technique (ColiPlate™). All four sampled stream had unsafe levels of E. coli colonies for drinking water (>1MPNs) with an average of 124.5 MPNs/100 ml, and three out of the four having unsafe levels of E. Coli for recreational water (>100MPNs) with an average of the three being 158 MPNs/100 ml. Results of the study call for immediate action in protecting tributaries and other water resources from entry of microplastics.

443 Uptake and Retention of Microplastic Particles by the Daggerblade Grass Shrimp, Palaemonetes pugio

A.D. Gray, Univ of North Carolina at Greensboro / Biology; J. Weinstein, The Citadel / Biology Dept

The incidence of microplastics in marine environments has been increasing over the past several decades. The objective of this study was to characterize the size and shape dependent effects of microplastic particles (spheres, fibers and fragments) on the adult Daggerblade Grass Shrimp, Palaemonetes pugio. Grass shrimp were initially exposed to one of the seven fractions of plastic spheres (30, 35, 59, 75, 83, 116, and 165 µm), two size fractions of fragments (34 and 93 µm), and two size fractions of fibers (34 and 93 µm) at a concentration of 50,000 particles/L for three hours, then placed in microsphere-free water and monitored for survival, ingested and ventilated microplastics, and residence time in the gills and gut. Mortality ranged from 0-55%. Beads and fragments under 50 microns were not acutely toxicity. Those above 50 microns had mortalities ranging from 5-40%. Fibers were acutely toxic at both size fractions tested (34 and 93 mm) with mortalities at 55 and 35%, respectively. Shape of the microplastic particle did not influence mortality ($p=0.1547$). Mortality was significantly higher in the 83 micron spheres and 93 micron fibers than other sizes tested ($p< 0.001$). The average amount of particles ingested ranged from 2.3±1.7 particles/shrimp in the 93 micron fiber exposure to 28.8±26.4 particles/shrimp in the 75 micron sphere exposure. The number of particles found within the gills following the three hour exposure period ranged from 1.3±1.6 particles/shrimp in the 75 micron sphere exposure to 12.5±9.4 particles/shrimp in the 116 micron sphere exposure. Shape of the particle had a significant influence on the number of particles ingested by the shrimp, with spheres having the highest amount ingested ($p< 0.001$). The time for particles to be cleared from the gut of the shrimp ranged from 27-75 hours with an average at 43.0±13.8 hours. Within the gill chamber of the shrimp, the time for particles to be removed ranged from 27-45 hours with an average of 36.9±5.4 hours. Shape had no significant influence on clearance time in either the gut ($p=0.1625$) or the gills ($p=0.1545$). Results from this study suggest that microplastics in the environment of various size and shapes can have acute effects on shrimp.

444 Ingestion and rejection of microplastics by suspension-feeding bivalves: implications for exposure and environmental fate

J. Ward, Univ of Connecticut / Marine Sciences; C. Herrick, Sacred Heart Academy; M. Rosa, Univ of Connecticut; V. Haynes, Univ of Connecticut / Marine Sciences; B. Holohan, Univ of Connecticut

Suspension-feeding bivalves are exposed to a manifold of natural and anthropogenically-derived particles in the aquatic environment. Which particles are actually captured and ultimately ingested depends on several physicochemical and biological factors including limitations of the feeding structures and particle-selection capabilities of the species. In a series of experiments with blue mussels (Mytilus edulis) and eastern oysters (Crassostrea virginica) we examined the capture, selection and ingestion of several different types of microplastics with different shapes, sizes and surface properties (wettability, surface charge). Particles < 2 µm are captured at a low efficiency unless they are incorporated into marine aggregations. Large (> 100 µm) fibers and angular / spherical particles are captured at a high efficiency but are rejected in pseudofeces and thus ingested in low proportions. Particles between 10 and 20 µm are more likely ingested if they have more hydrophobic surfaces or possess surfaces with a lower charge (Zeta potential < ca. -8 mV). These results advance our understanding of the types of microplastics that are ingested by bivalves and those that remain in the environment. Developing physicochemical profiles of different types of microplastics to predict which are rejected versus ingested is important for assessing internal exposure and environmental fate.

445 Cellular accumulation of polystyrene particles in the Eastern oyster: dependence on size

T.R. Gaspar, Univ of North Carolina at Charlotte / Biology; A.H. Ringwood, UNC-Charlotte / Dept of Biology; R. Chi, Univ of North Carolina at Charlotte / Biological Sciences

The global annual usage of plastics has increased dramatically over the last decade. Plastic polymers take on many forms with polystyrene being the fourth most common plastic material produced annually due to its many versatile applications. Consequently, there has been a coinciding increase in polystyrene wastes, much of which makes its way into waterways and oceanic habitats. While plastic debris has been shown to adversely affect many marine species as a result of ingestion and entanglement, less is known about the effects of plastic particles on marine invertebrates. We investigated the potential for particle uptake by hepatopancreas and gill cells in vitro and/or in vivo using fluorescent microscopy after exposure to 10ppb, 50ppb, and 100ppb of either 50nm or 3um fluorescent polystyrene particles. Epifluorescence microscopy indicated both 50nm and 3um particles were associated with both tissue types. More detailed studies using Deltavision Elite deconvolution microscopy revealed that the 50nm particles, but not the 3um particles, were intracellular. To assess the toxicity of the particles, lysosomal destabilization and lipid peroxidation were evaluated and the particles were found to have no effect on either. These results demonstrate that the Eastern oyster takes up polystyrene particles from the water column and that particles in the nano size range enter hepatopancreas and gill cells. Based on these short term studies plastic fragments in the nano size range are bioavailable to oysters and while no evidence of toxicity from polystyrene was observed, it is possible the plastic particles will cause long term stress to the animals by interfering with feeding processes.

446 Microplastic particle exposure and life-history traits of Chironomus riparius

W. Kunce, Uppsala Univ / Animal Ecology

Due to wide-spread detection in aquatic environments, microplastic particles are an emerging contaminant of concern. Research on the biological effects of microplastic ingestion in freshwater fauna is scarce. This two-part study investigated the impact of 1.0 µm and 10.0 µm fluorescent polyethylene spheres on life-history traits of the midge, Chironomus riparius. The impacts were assessed under restrained and unrestrained nutritional conditions as well as in combination with a low concentration of the commonly used pyrethroid pesticide, esfenvalerate. Sediment spiked with microplastic particles impacted both development time and survival of the midges with differences between the sexes; effects that were exasperated by food restriction but not esfenvalerate exposure.

447 Trophic transfer of microplastics and adsorbed contaminants

S. Au, Clemson Univ Inst of Environmental Toxicology / Environmental Toxicology; C.M. Lee, Clemson Univ / Environmental Engineering and Earth Sciences Dept; J.E. Weinstein, The Citadel / Dept of Biology; S.J. Klaine, Clemson Univ / Clemson Inst of Environmental Toxicology

Microplastics (MPs) are a widespread and ubiquitous contaminant in aquatic ecosystems. MPs are in the same size fraction as most sediment particles and microorganisms, allowing them to be easily ingested by a variety of organisms. Should ingested MPs have adsorbed organic contaminants, MPs may act as a source of environmental contaminants. The potential for MPs to alter the bioavailability of contaminants, and whether MPs and adsorbed contaminants can undergo trophic transfer has been investigated in very few studies. Polycyclic aromatic hydrocarbons (PAH) are a class of persistent organic pollutants that are ubiquitous in aquatic ecosystems. Fluoranthene (FLU) is one of the USEPA's 16 priority PAHs, and it's hydrophobic nature allows it to sorb easily to sediment and organic matter; FLU will likely sorb to the hydrophobic surfaces of most MPs. Freshwater amphipods exposed to FLU-contaminated polyethylene MPs resulted in the dose dependent uptake of both FLU and MPs during 10-d bioassays. FLU uptake via MP ingestion accounted for approximately 93% of the FLU body burden. To investigate the potential for MPs and adsorbed FLU to undergo trophic transfer, fathead minnows were trained to consume amphipods that had been previously exposed to FLU-contaminated MPs. The bile of exposed fathead minnows was analyzed for FLU by measuring bile fluorescence. Bile from fathead minnows that consumed amphipods previously exposed to FLU-contaminated MPs was 94% more fluorescent than that extracted from control organisms. Fathead minnows indirectly exposed to FLU via prey ingestion for 3 days resulted in the bioaccumulation of approximately 300 µg FLU/organism, demonstrating that trophic transfer is a pathway in which higher trophic level organisms can be exposed to MPs and associated contaminants. This study is one of the few that has quantified the bioaccumulation of MP-associated contaminants from living prey. Ongoing studies will demonstrate whether the ingestion of fathead minnows exposed to FLU-contaminated MPs by hybrid striped bass will result in increased bioavailability of FLU to larger predatory organisms.

From Phosphates to Food Webs: A Tribute to David Schindler's Legacy in Aquatic Sciences

448 David Schindler's legacy: Ecosystem-scale ecotoxicology

D. Orihel, Univ of Ottawa / Dept of Biology; P.J. Blanchfield, Fisheries and Oceans Canada; K.A. Kidd, Univ of New Brunswick; M.J. Paterson, IISD-Experimental Lakes Area

One of Dr. David Schindler's greatest contributions to the field of environmental toxicology and chemistry is his pioneering application of whole-ecosystem experimentation to answer questions about the fate and effects of aquatic pollutants. At the Experimental Lakes Area (ELA) in northwestern Ontario, Dr. Schindler led ground-breaking studies in which contaminants were intentionally added to pristine headwater lakes. By simulating pollution in a controlled manner and at a realistic scale, these studies led to discoveries of food web interactions, long-term biogeochemical processes, and unexpected indirect effects that could not have been determined from smaller-scale studies. Whole-lake additions of nutrients and acids to ELA lakes during the 1960s and 70s not only advanced our scientific understanding of eutrophication and acidification, but were instrumental in changes in policy to combat these environmental problems. Since Dr. Schindler's departure from the ELA, his legacy has flourished. Over the last four decades, more than 50 whole-ecosystem experiments have been conducted at the ELA, including studies on mercury, synthetic estrogen, and nanosilver. In this presentation, we will highlight recent examples of whole-ecosystem contaminant-loading experiments to demonstrate how this approach to ecotoxicology is incredibly powerful and influential.

449 Whole-lake manipulations at the Experimental Lakes Area do not support the need for nitrogen control to reduce eutrophication in lakes

M.J. Paterson, IISD-Experimental Lakes Area; D.W. Schindler, Univ of Alberta; R.E. Hecky, Univ of Minnesota Duluth; S. Higgins, IISD-Experimental Lakes Area; D.L. Findlay, Plankton R Us

In the 1960s and 1970s, whole-lake experiments undertaken at the Experimental Lakes Area (ELA) by David Schindler and his colleagues clearly demonstrated that cultural eutrophication was not caused by inputs of carbon (C) and that nutrient reduction efforts should focus on phosphorus (P). Considerable debate has persisted, however, about the need to regulate nitrogen (N) and several government agencies around the world are currently calling for dual control of both N and P. Over the 48-year history of the ELA, there have been 10 whole-lake experiments that involved additions of N, P, or N and P combined. Taken together, the results from these experiments provide no evidence that additions of N, either alone or in combination with P, result in substantially greater standing crops of algae in fertilized lakes. Recent data from Lake 227, which has been continuously fertilized since 1968, first with N and P and then only with P, provide no indication that reductions of N loading will mitigate eutrophication in lakes. Despite 25 years of high P loading without concomitant N additions, concentrations of total phytoplankton biomass and chlorophyll in Lake 227 have not declined. If anything, the reduction of N loading has adversely affected water quality by promoting the development of filamentous N-fixing algal blooms. The ELA data indicate that over-reliance on results obtained from small-scale studies, such as nutrient addition bottle assays, provides a poor indication of the long-term outcome of nutrient reduction strategies in natural lakes.

450 Recovery from Acidification: A Forty Year Experiment in the Killarney Park Area, Canada

J. Gunn, Laurentian Univ / Biology; W. Keller, Laurentian Univ; E. Snucins, Ontario Ministry of Environment and Climate Change; J. Heneberry, Ministry of Environment and Climate Change of Ontario; J. Bailey, Ontario Ministry of Environment Laurentian Univ / Biology; S. Arnott, Queens Univ

Killarney Park, a wilderness area of ultraclear lakes and white quartzite mountains located about 60km south of the giant Ni and Cu smelter in Sudbury, Canada, was one of the first places in North America where the link between atmospheric pollution, acidification of lakes, and loss of fish was clearly made. The severe damage to these once "pristine" lakes and landscapes, so treasured by artists, canoeists and fisherman, proved to be a significant match that ignited the regional, national and then international battles in the 1970s and 80s to reduce "acid rain" to acceptable levels. Regulatory agencies attempted to set targets of emission reduction that were tolerable to industry and were based on available technologies. Rarely, however, were the targets based on measured and modeled geochemical sensitivities (e.g. "Critical Load Models") of specific landscapes and lakes. Therefore in general we can view the emission reductions programs in North America very much as a large scale regional experiments, not unlike the whole lake acidification experiments that Dr. Schindler and his team conducted at L223 in the Experimental lakes Area, but conducted over a much longer time period. In this presentation I will review the history of acidification in the Killarney lakes and illustrate the variation of chemical and biological recovery in the key monitoring lakes. I will also show how the acidification monitoring program proved to be so valuable in detecting other environment changes (e.g. changing DOC and thermal structure, Ca decline, climate change impacts, invasive species, etc.) and will attempt to compare and contrast these findings from those of L223.

451 Following David Schindler's Lead: Understanding the Importance of Atmospheric Deposition of Polyaromatic Compounds in the Alberta Oil Sands Region

D.C. Muir, J.L. Kirk, C. Teixeira, C.A. Manzano, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A. Gleason, J. Keating, Environment and Climate Change Canada; X. Wang, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Atmospheric deposition of contaminants originating from a variety of sources, including bitumen upgrading facilities and blowing dusts from landscape disturbances is of concern in the Athabasca oil sands region of northern Alberta, Canada. This issue was first examined in detail by the Schindler research group who sampled the winter snowpack at 28 locations along the Athabasca River and its tributaries in March 2008 and reported elevated deposition of polyaromatic compounds (PACs) and metals (Kelly et al PNAS 2009; 2010). Since 2011 we have collected snowpack samples annually in late winters at varying distances from the main developments to confirm and extend that work. PAC concentration and deposition declined exponentially with distance, with pyrenes, chrysenes and dibenzothiophenes (DBT) dominating the distribution within the first 50 km. The distribution of PACs was different between sites located close to upgraders and others located close to mining facilities. PAC loadings were correlated with heavy metals and water chemistry parameters, while wind direction and speed were not strong contributors to the variability observed. PAC mass deposition within the first 50 km was initially estimated by integrating the exponential decay function fitted through the data, using the same sites as Kelly et al in 2008. Total loadings were estimated to have increased 2-fold between 2008 (636 kg) and 2014 (1,367 kg), although the increase observed was not constant. Finally, kriging interpolation was applied to the same data and proved to be a more robust approach to estimate PAC mass deposition in the area when sampling sites were located in a gridded pattern over the landscape. Using kriging the PAC mass deposition for 2014 was estimated to be 1,968 kg, about 30% higher than assuming uniform decline from a central site near the upgrading facilities. Our second approach to examining atmospheric deposition was to reconstruct long-term terms of PACs using dated sediment cores from isolated lakes in the oil sands region. Results for PACs from twenty-eight lakes show that sites within 50 km of the upgrading facilities show a striking increase in petrogenic sources based on 8-fold increase in DBTs and a 3-fold increase in alkylated PACs compared with less than 2-fold increases in lakes from 60-185 km distant. These increases began in the 1970s coinciding with the start of the oil sands mining and point to the increasing importance of atmospheric deposition over time.

452 Building on David Schindler's legacy: Assessing impacts on lakes across spatial and temporal scales using lake sediments as archives

J.M. Blais, J. Korosi, J. Thienpont, Univ of Ottawa / Dept of Biology; J.P. Smol, Queens Univ / Biology

David Schindler's career showed what a profound impact aquatic science can have on public policy over a wide range of environmental issues, including acid rain, eutrophication, and the impacts of extractive resource development. This presentation builds on that legacy and summarizes recent developments in assessing the effects of multiple stressors from resource development on lake ecosystems using lake sediments as archives. We focus on integrating the principles of ecotoxicology with lake sediment analyses in our work to develop the field of "paleo-ecotoxicology". We argue that this framework is useful to test predictions from laboratory bioassays in natural ecosystems to assess biotic responses to contaminant exposure. Using the example of legacy contamination from gold mining in Yellowknife lakes, we examine how lake sediment cores can be used in an interdisciplinary context to enhance our understanding of the response of aquatic biota to stressors, and we demonstrate how this science has informed policy and management of this region.

453 Integration of Indigenous knowledge and western science in studies of northern ecotoxicology: lessons from David Schindler and other revolutionaries

H. Swanson, Univ of Waterloo / Biology; E. Kelly, Government of the Northwest Territories

David Schindler's research legacy extends beyond cutting-edge science to include advocacy for environment-related rights, ethics, and knowledge of Indigenous peoples. Indigenous knowledge of water quality, fish health, fisheries, climate change, and cumulative effects is often overlooked or undervalued by western scientists and policy-makers because the two knowledge systems (western science, traditional knowledge) have different strengths, and because western scientists and policy-makers often believe that knowledge must be presented dispassionately; Indigenous peoples have an intergenerational emotional and spiritual bond with their environment that cannot be separated from their knowledge. In this presentation, we will use case studies to illustrate the strengths, opportunities, and pitfalls of collaborative projects that use both traditional knowledge and western science to investigate ecotoxicological questions. We will focus on Canada's North, where Indigenous people rely heavily on aquatic ecosystems for subsistence foods, drinking water, and spriritual and cultural purposes, and where jurisdictions are developing water-related policy and monitoring programs from a foundation of Indigenous values. Although much progress has yet to be made, it is obvious that the efforts and passion of David and countless others are having an effect on how research is conducted and policy is developed in Canada's North.

454 The influence of climatic trends and variability on fish growth and survival in freshwater lakes

M. Rennie, Lakehead Univ / Biology; C. Charles, Fisheries and Oceans Canada; R. Bartel, Univ of Manitoba / Biological Sciences; S. Higgins, IISD-Experimental Lakes Area; S. Chalanchuk, K. Mills, Fisheries and Oceans Canada

Though climate warming over the past half century is well documented, few datasets exist over a similar time frame with which to evaluate potential cimate effects on fishes in the absence of other potential stressors. At the IISD-Experimental Lakes Area (ELA) in Northwestern Ontario, mean annual air temperatures have increased by more than 1.5°C on average since 1969. Similarly, the ice-free period on Rawson Lake has increased by 17 days on average. Throughout this period, significant annual variation has also occurred, with mean annual temperature ranging nearly 5°C and ice free days by 47 days. Young-of-year fish make an excellent subject of study for evaluating climate effects on fish growth, for whom all surplus energy is reflected in somatic tissues. Additionally, overwinter survival of young-of-year in many fish species has been shown to be directly correlated with body size entering the winter. We investigated somatic growth patterns and associations with an index of overwinter survival in young-of-year fishes from reference lakes at the Experimental Lakes Area. Growth of Yellow Perch, Northern Redbelly Dace and White Sucker in their first year all demonstrate positive correlations with mean annual air temperature and growing degree days > 5C). Pearl Dace and Fathead Minnow young-of-year growth demonstrated a positive association with the number of mean annual precipitation, and Pearl Dace growth was also positively associated with the number of ice-free days. Variation in young-of-year fish growth in reference lakes due to climate variation was equivalent to or greater than that observed in lakes undergoing experimental manipulations. An initial assessment of overwinter survival did not appear to be linked to young-of-year body size. Associations of recruitment success with environmental conditions will also be presented.

455 Climate futures for temperate lakes: winter biogeochemistry and the vulnerability of lakes to change

H. Baulch, R. North, Univ of Saskatchewan, Global Inst for Water Security / School of Environment and Sustainability; M. Armstrong, Univ of Saskatchewan / Geography and Planning; E. Cavaliere, Univ of Saskatchewan, Global Inst for Water Security / School of Environment and Sustainability; N.L. Michel, Univ of Saskatchewan / School of Environment and Sustainability

There is considerable concern regarding how climate change will impact lakes via factors including changing solute loads, increased temperature and altered stratification regimes. Anticipated effects include the potential for higher productivity, longer duration of benthic hypoxia, increased bloom risk, and key impacts on cold water fish habitat. Our understanding of, and ability to manage for changing conditions hinge on our understanding of the open water season. Yet we see rapid declines in periods of ice cover, and significant spatial and interannual variation in snow. The limited amount of research to date on under-ice limnology constrains our ability to predict consequences of a changing climate. Here, we assess observational data, coupled with rate measurements, and literature meta-analyses to assess key drivers of changing nutrient biogeochemistry under ice, and identify ecosystems where shorter ice cover duration is most likely to affect nutrient availability. We identify shallow, eutrophic and hypereutrophic lakes as the systems where winter increases in phosphorus are most likely to occur, with evidence that internal loading is the key driver of winter increases. We see key nitrogen processes of nitrification and denitrification as surprisingly active, despite cold water temperatures, yet showing high spatial variation among ice-covered ecosystems. Winter is not a quiescent period, but instead one where the processing of nutrients change. A shorter winter period may affect nutrient availability at the end of the winter, with the most marked impacts potentially occurring in shallow, nutrient rich ecosystems. While a shorter winter may actually lead to lower concentrations of phosphorus in some ecosystems, we need to understand the fate of phosphorus at ice-out, and develop an integrated view of climate impacts on lakes, that incorporates both impacts on summer, and the under-studied winter period.

Fate and Effects of Metals: Biogeochemical Perspective

456 Effects of Oxidation on Metal Bioavailability and Metal Release from In-place Sediments: A Modeling Perspective

K.J. Farley, Manhattan College / Civil and Environmental Engineering; R.F. Carbonaro, Mutch Associates, LLC / Civil and Environmental Engr

The presence of sulfides in sediments has been shown to play an important role in sequestering metals (e.g., Cd, Cu, Ni, Pb, Zn) and in limiting metal bioavailability. This effect has been considered in regulatory decision-making through static or "snap-shot" measures of simultaneously extractable metals (SEM) and acid volatile sulfide (AVS) ratios. A potential weakness in this approach is the oxidation of metal sulfides and associated changes in metal bioavailability that are likely to occur during oxidation of in-place sediments (e.g., due to changes in overlying water quality or reductions in sediment diagenesis activity). A reactive-transport model was therefore developed using the TICKET framework and was applied in evaluating metal bioavailability and metal release during oxidation of in-place sediment. TICKET model results showed that metal bioavailability and metal release to the overlying water are intricately linked to reduced iron and metal sulfide oxidation rates, precipitation of hydrous ferric oxide (HFO), formation of metal-sulfide complexes, and binding of metals to natural organic matter and newly precipitated HFO. The TICKET model was subsequently used in evaluating the potential for increased metal bioavailability and metal release based on the initial ratios of metal, AVS and iron at contaminated sediment sites.

457 Sediment characteristics affecting internal loading of arsenic in a prairie reservoir, Buffalo Pound Lake, SK, Canada

L.P. D'Silva, K. Liber, Univ of Saskatchewan / Toxicology Centre; H. Baulch, Univ of Saskatchewan / School of Environment and Sustainability; L.E. Doig, Univ of Saskatchewan / Toxicology Centre

Buffalo Pound Lake, SK, Canada, is a shallow eutrophic reservoir that has experienced an increased frequency and severity of algal blooms in recent years. Lake sediments can naturally contain and release large quantities of phosphorus (P) to associated overlying waters, and are possibly stimulating these algal blooms. In addition to P, Buffalo Pound Lake sediments naturally contain high concentrations of arsenic (As; 13.2 mg/kg). Arsenic is a geochemical P analogue, which may be released concurrent to P. Experiments using sediment cores collected from Buffalo Pound Lake identified environmentally relevant mechanisms (warm temperatures, low dissolved oxygen (DO) concentrations, and alkaline pH (9.3)) in lake water that significantly increase As efflux from bottom sediment. The objectives of this study component were to determine summertime in situ dissolved As concentrations in the lake, mechanisms affecting in situ As remobilization, and differences in sediment As content and geochemistry among sites. Water samples and sediment cores were collected from Buffalo Pound Lake biweekly. Water samples were analyzed for dissolved metal(oid) s (As, aluminum (Al), iron (Fe), manganese (Mn)), temperature, DO, and pH. Sediment cores were sectioned and analyzed for porewater metal(oid) (As, Al, Fe, and Mn) content. Bulk field sediment was analyzed for total Al and Fe content, total organic content, and particle size distribution. Periods of warm temperatures and low DO concentrations were associated with greater As concentrations in bottom waters. One site in the down-reservoir region displayed lower efflux of As from sediment. This site had significantly elevated Al content relative to the other sites studied. Aluminum can act as a redox-insensitive sorbent of As, which likely mitigated reduction-induced release of As from sediment at this site. Arsenic concentrations in surface waters ranged from 3–9 µg/L, with several samples exceeding federal water quality guidelines (5 µg/L) for the long-term protection of aquatic life. Therefore, Buffalo Pound Lake sediment can release As to overlying waters during low DO and high temperatures periods. Additional work will investigate the availability of As during summer As release.

458 Arsenic sorption to bacteriogenic iron oxides (BIOS)

M. Moriarty, Univ of Ottawa; D. Fortin, Univ of Ottawa / Earth and Environmental Sciences

Bacteriogenic iron oxides (BIOS) form at water-rock interfaces, wherever anoxic waters rich in iron emerge, such as mine seep environments where arsenic concentrations may be elevated. BIOS are (mostly) amorphous iron oxides that contain large amounts of organic matter, rich in polysaccharides, and are less resistant to bacterial reduction than organic matter-free iron. They form quickly and are important sorbents for cationic metal ions due to the presence of negatively charged organic matter and high surface area. The sorption capacity of amorphous iron oxides appears to be constant for both the neutral As(III) and the anionic As(V) for a wide range of concentrations of organic content at circumneutral pH. We have built a diffusion growth chamber to model an iron seep environment in order to investigate the behaviour of arsenic, its redox transformations in water and resulting solids and the short-term stability of immobilized arsenic in mine seep environments with iron oxidizing bacteria present with varying dissolved Fe(II) concentrations, dissolved and solid organic matter and sulfate levels. Laboratory experiments are compared with a wide range of field data. This talk will discuss how the presence of bacteria in iron rich environments affects the speciation and mobility of arsenic.

459 Rare earth element sorption: lessons learned from field collected biofilm data

L. Ashby, Univ of Ottawa / Earth Sciences; D. Fortin, Univ of Ottawa / Dept of Earth and Environmental Sciences

The partitioning of metals from liquid to solid phase has been of interest for remediation of toxic metals for many years. Rare earth elements (REEs), historically not considered toxic metals, have received little attention regarding mechanisms of adsorption to the solid phase. Metal-oxides, organic matter and bacteria are all known to play important roles in removing REEs from solution, but their relative contributions and importance are not fully understood. Understanding biotic and abiotic sorption has both environmental and industrial implications. We examined the sorption of REEs to biofilms, which are a mixture of bacterial cells, oxyhydroxides, metal precipitates, and bacterially-derived organic matter, as these materials appear to be very good sorbents for REEs. This study compared field collected water and biofilm chemistry collected from a total of 8 locations (40+ sites) in North and South America, downstream of mining-affected areas (Au-Ag, Cu-Au-Ag and coal deposits), with 2 control locations (6 sites) and modelled data. Partitioning coefficients ranging from 1 to 1E6 were found within the dataset, and at least two binding mechanisms are suggested. Field-collected biofilm chemistries were compared with modelled biofilm chemistries predicted using a surface complexation model.

460 Role of Natural Organic Matter on Rare Earth Elements Speciation and Bioavailability with Chlamydomonas reinhardtii

J. Rowell, K. Wilkinson, Univ of Montreal / Dept of Chemistry

As technological interest for rare earth elements (REE) is growing, it is becoming more important to assess their potential environmental impact. Indeed, specific knowledge is required about the behaviour of these metals in rivers and soils, more precisely with respect to the factors that influence their speciation and bioavailability. Based upon models such as the Biotic Ligand Model (BLM) that have been successful for predicting the effects of divalent metals, the complexation of metal ions by natural organic matter is predicted to reduce the free ion concentration and simultaneously decrease metal bioavailability for aquatic organisms. Nonetheless, recent studies from our laboratory using simple organic ligands have shown that REE biouptake is higher than predicted and that internalization fluxes are higher than predicted in presence of fulvic acid. Thus, it becomes extremely relevant to carefully determine REE speciation in natural waters, especially in the presence of natural organic matter, in order to predict their bioavailability. In this study, a dynamic ion-exchange technique was used to determine free ion concentrations and in parallel, biouptake experiments were performed to measure the internalization flux of REE in algae. Samarium (Sm), an intermediate lanthanide, and the unicellular green alga Chlamydomonas reinhardtii were employed, and results were compared with modelling efforts in order to better understand the important factors leading to REE bioavailability.

461 Subcellular partitioning profiles and molecular biomarkers in in-situ exposure clam and their associations with metal speciation as measured by DGT

Z. Wang, Key Laboratory of Urban Environment and Health; C. Yan, Insitute of Urban Environment, Chinese Academy of Sciences

Due to the complexity of heterogeneous sediment, the chemical speciation and mobility of metals were in dynamic conditions rather than steady states, resulting in high variability of bioavailability. Chemical analyses in traditional tests had disadvantages of inaccuracy for contamination characteristics or risk assessments, representing a worst-case scenario in terms of complex biotic and abiotic exposure dynamics. In this presentation, relevant scientific issues regarding the impacts on subcellular distribution and molecular biomarkers with special emphasis on their associations with various metal species were investigated through powerful experimental designs and field-based manipulations of in-situ exposure and kinetic DGT approach. Understanding the degree of pollution and geochemical characteristics of sediment matrix, in-situ testing chambers were deployed combining the DGT and caged clam R. philippinarum, and the dynamic exchanges, translocation and mobilization were then clarified among the interfaces of particles and pore-water in sediments through measuring dynamic parameters and resultant induced fluxes in exposed organism. Integrating a wide battery of biomarkers, dynamic changing processes were assessed, and their interactions were established between exposure and biological effects. Furthermore, variations of transcript expression of functional genes in contaminant-specific biomarkers were obtained through high throughput oligo-DNA Microarray and quantitative reverse transcription polymerase chain reaction (Q-RT-PCR) in order to elucidate the mechanistic understanding of molecular effects metals induced. Simultaneously, the approach of in-situ evaluation was established considering the consistency of framework as protocols among sediment chemistry, contaminant bioavailability and adverse effect, which significantly improve accuracy and ecological relevancy in complex exposure situation and thus provide a robust tool to support more comprehensive processes of sediment risk assessment. Overall, the associations not only revealed the fates of accumulated metals, but scientifically favored an improved understanding of toxic effects in response to subcellular level and metal speciation, supporting the focus of metabolic availability on the intracellular processes or events occurring within organism in coastal biogeochemistry. (The author acknowledge financial support by Grant No. 21377125/B070403 from National Nature Science Foundation of China)

462 Bioaccumulation of Cu and Pb by fathead minnow and yellow lampmussel: Evaluation of DGT technique for predicting uptake of metal mixtures

R.R. Philipps, Univ of Georgia / Savannah River Ecology Laboratory; R. Bringolf, Univ of Georgia / Warnell School of Forestry and Natural Resources; G.L. Mills, Univ of Georgia / Savannah River Ecology Lab

Dissolved metal bioavailability in natural waters is strongly linked to metal speciation. Diffusive gradients in thin-films (DGT) were designed as a passive diffusion, in-situ sampling device with the goal of providing a rapid method for determining the free ions and labile complexes of total dissolved metal in surface waters, i.e. the bioavailable fraction. In this study, DGT were assessed for their predictive capability of fathead minnow and yellow lampmussel sublethal bioaccumulation in copper (Cu) and lead (Pb) mixed metal exposures. Nine treatments with a matrix of three Cu concentrations (0, 15, 25 µg L^{-1}) and three Pb concentrations (0, 30, 50 µg L^{-1}) were utilized. Exposures were coupled, with organisms and DGT exposed together in tanks, water only, no feeding for six day durations. Copper measured in fathead minnow, yellow lampmussel, and by DGT was found to not be influenced by lead treatment, whereas accumulated lead was impacted by the interaction of Cu treatment and Pb treatment. DGT significantly correlated with fathead minnow accumulated Cu and Pb. Yellow lampmussel bioaccumulated metal were not as highly linearly correlated with DGT. In addition, DGT was determined to better predict aquatic organism bioaccumulation of copper than the inorganic Cu fraction modeled by the Biotic Ligand Model speciation component.

463 Could climate change affect metal pollution in estuaries?

A. de Souza Machado, Leibniz Inst of Freshwater Ecology and Inland Fisheries / Ecophysiology and Aquaculture; C. Zarfl, Univ of Tuebingen / Center for Applied Geosciences; M. Toffolon, Univ of Trento / Dept of Civil Environmental and Mechanical Engineering; K. Cronin, DELTARES; F.T. O'Shea, K. Spencer, Queen Mary Univ of London / School of Geography

Estuaries are vulnerable to metal pollution and climate change consequences (sea level rise, shifts in river discharge, and coastal squeeze). While current metal sources are problematic, studies suggest that legacy metal on sediments might also be bioavailable. We measured metal concentration in estuarine sediments, mobility (leaching from sediments to water phase), and developed a state-of-the-art hydrodynamic-geochemical model for metal fate in an idealized estuary to infer the potential impacts of climate change. Surface (5cm) and subsurface (up to 2m) metal distribution and physicochemistry of sediments (N~600) in the tidal flats of the former Newlands Landfill (Thames Estuary, UK) were analyzed. Metal concentrations there were patchy and showing little continuity to the proximity of the landfill. In situ metals provided stronger evidence of chemical mobility as major actor on metal concentrations, e.g. Cu was correlated to organic matter, while Sr was influenced by Ca, and Co was determined by pH. Importance of chemical mobility was confirmed when we exposed (24h) the upper 2cm of these surface sediments (N~96) to environmentally relevant gradients of salinity, redox, and pH to determine the leaching of metals from those sediments to water. Under certain conditions (e.g. low salinity, negative redox and pH~ 6.5 for Fe^{++}), metal leached increased ~ 1000-fold. Using the coupled hydrodynamic-metal fate model (Delft3D), we simulated the fate of particulate and dissolved metals in water column and sediments under various climate change scenarios (i.e. 3 coastal squeeze scenarios, 3 altered discharges and 2 tidal conditions). The model results on total (particulate + dissolved) metal concentration in water column imply that salinity fronts and tides are critical for metal immobilization and increasing metal residence time, while remobilization was mainly occurring on tidal flats due to constant settling/reworking of particles. This caused a non-conservative behavior of metals. Thus, leaching experiments pointed that climate change could cause metal mobilization from sediments if it decreases pH, or changes redox conditions and sediment salinity. Also, our model suggests that climate change could increase metal pollution if salinity fronts and maxima turbidity migrate upstream implying higher residence time of metals within the estuary, or changes on tidal flats by coastal squeeze cause higher sediment reworking or residence time of suspended sediments.

Demonstrated Remediation Technologies Addressing Contaminated Soil, Sediment and Water

464 Enhanced degradation of benzo[a]pyrene in coal tar contaminated soils using biodiesel

T.O. Oriaku, Nigerian National Petroleum Corporation / Petroleum Engineering; M.D. Jones, Univ of Newcastle / Petroleum Geochemistry

The biodegradation of the potent carcinogen, benzo[a]pyrene (BaP), and other priority pollutants was investigated in un-weathered coal tar contaminated soil over a period of 150 days. Results from laboratory microcosm experiments showed that after 60 days, the concentrations of BaP were significantly reduced by 81%, in the biodiesel amended samples compared to the 26% and 34% depletion in the control and nutrient-only amended microcosms, respectively. A stepwise treatment approach also revealed a higher reduction in BaP (98%) using biodiesel. Toxicity assays showed that biodiesel amended microcosms stimulated phosphatase enzyme activity and exhibited a lower toxic response to Microtox Vibrio fischeri. The enhanced removal of carcinogenic PAH and the reduced toxicity observed in soil after biodiesel amendment, indicates that this bioremediation technique has potential for full scale field trials.

465 From bioavailability science to soil bioremediation: Sustainable stimulation of biological degradation for enhanced removal of PAHs

J. Ortega-Calvo, Instituto de Recursos Naturales y Agrobiologia / Agroquimica y Conservacion del Suelo; R. Posada-Baquero, IRNAS CSIC / Agroquimica y Conservacion del Suelo; C. Jimenez Sanchez, Inst de Recursos Naturales y Agrobiol. de Sevilla / Agroquimica y Conservacion de Suelos; J. Garcia, Instituto de Recursos Naturales y Agrobiologia de Sevilla CSIC; M. Cantos, CSIC – Spanish National Research Council

Polycyclic aromatic hydrocarbons (PAHs) are the best representatives of chemicals for which specific limitations in bioremediation exist due to low bioavailability. The residual concentrations of the PAHs after bioremediation are crucial because they may limit the use of the area after treatment, or land use might not even be possible if the residual concentrations do not meet the legal requirements. For bioavailability to be incorporated into soil bioremediation, three questions must be addressed: (1) how is "bioavailability" defined? (2) how should it be measured? and (3) is it possible to increase bioavailability but not environmental risk of the pollutants? Over the last 30 years, numerous publications have discussed the concepts and definitions of bioavailability of organic chemicals (Environ. Sci. Technol. 49:10255-10264, 2015). The main schools of thought consider bioavailability (focusing on the aqueous or dissolved contaminant), bioaccessibility (incorporating the rapidly desorbing contaminant in the exposure), and chemical activity (determining the potential of the dissolved contaminant for biological effects). These concepts are the basis for different methodologies (desorption extraction, passive sampling and biological tests) and mechanistic studies that consider the different processes that are involved (contaminant soil/sediment interactions, transport and passage across cell membrane, and biological responses such as toxic effects or biodegradation). Our group has proposed different ways to operate at different levels on these processes, in the context of biodegradation of PAHs, for a better bioremediation performance in risk reduction. The approach is relevant because in some circumstances bioremediation may even increase risk of PAHs.

466 Enhanced anaerobic biodegradation of petroleum hydrocarbons in sediments and water using bioelectrochemical systems (BES)

J.M. Morris, Abt Associates; S. Jin, Advanced Environmental Technologies LLC

Biodegradation rates of organic contaminants can be influenced by many factors including nutrient and terminal electron acceptor (TEA) availability. While nutrient addition can address the former issue, maintaining an aerobic environment that maximizes microbial activity can be costly in aqueous environments or nearly impossible in saturated soils and sediments. Once concentrations of more thermodynamically favorable TEAs like oxygen or nitrate are exhausted, facultative microbes must rely on less favorable TEAs such as sulfate, which ultimately reduce biodegradation rates. In this presentation we will discuss data from our research that indicates bioelectrochemical systems (BES) can enhance biodegradation of organic contaminants in anaerobic environments by providing microbes with an inexhaustible, solid state electrode that can be utilized as a TEA. The basic design of this system includes an electrically conductive anode that is placed in the anaerobic environment (water or saturated sediment), which is connected to a cathode that is in contact with oxygen. Microbes breaking down organic contaminants like hydrocarbons can pass electrons to the anode, which flow through a circuit to the cathode where they are used in the reduction of oxygen (producing water at the cathode). We will present and discuss hydrocarbon degradation rates in anaerobic environments, which were over 2.5 or 12 times higher using BES compared to controls in water or sediments, respectively. We will also discuss 16S rRNA gene sequencing results that characterize microbial consortia utilizing the solid state anode in some of these systems.

468 Use of Excretory Halophytes to Remediate a Salt-Impacted Site

K. Yun, A. Rutter, Queens Univ / School of Environmental Studies; B.A. Zeeb, Royal Military College / Chemistry Chemical Engineering Dept

Salt-impacted soils are an increasing environmental issue affecting global soil quality and plant productivity. Soils can become salinized via both natural and anthropogenic activities. A site located in Bath, ON, Canada was contaminated with cement kiln dust (CKD), a fine-grained, solid, highly saline waste product. CKD was landfilled at the site over a 30-year period from 1973 to 2003 resulting in a wasteland of 1 kilometer squared that is largely devoid of vegetation. Due to the water soluble nature of the predominant potassium and chloride ions, phytoremediation techniques were investigated. In previous work, Phragmites australis (a resident invasive species) was found to accumulate large quantities of K^+ and Cl^-, while two native, halophytic grasses, Distichlis spicata and Spartina pectinata were identified as having potential to remediate the soil via excretion and subsequent haloconduction. During this process, salt is transported into plant biomass, excreted through specialized salt glands onto the plant leaf surfaces, and then dispersed by the wind. The goal of the present research is to determine whether haloconduction could be a viable remediation strategy at the site (as an alternative to other remediation techniques). Analytical work using X-ray dispersive scanning electron microscopy is being carried out to identify chemical and physical properties of the salt crystals. Salt collection trials are ongoing both in the field and under controlled conditions in the greenhouse in order to model salt dispersion of the two species over time. Preliminary results will be presented, as well as a discussion of how this information could be used to model the transport of salts over space and time.

469 Integrated Restoration/Remediation of a Mercury Contaminated River

S.F. Haffey, C.R. Patmont, Anchor QEA, LLC; R. Davis, Anchor QEA LLC / Natural Resources; W. Dinicola, Anchor QEA LLC; M. Liberati, EI DuPont de Nemours and Company / Corporate Remediation Group; N.R. Grosso, EI DuPont de Nemours and Company; R.G. Stahl, EI DuPont de Nemours and Company / Corp Remediation; J. Collins, K. Hoffman, AECOM; C. Mancini, AECOM / Environmental Services

Historically released mercury (Hg) accumulated in depositional areas along the banks of the South River, Virginia. Natural erosion of river bank soils with elevated Hg concentrations is a primary mechanism for legacy Hg loading to the aquatic ecosystem. As part of initial measures under the regulatory authority of the Resource Conservation and Recovery Act (RCRA) Corrective Action, river banks are being remediated in an upstream-to-downstream sequence within an adaptive management framework. Initial review of conceptual remediation designs by stakeholders, including landowners and wildlife agencies, raised concerns regarding potential impacts to riparian and upland habitats (e.g., mature trees). The final designs strike a balance between the remedial objectives of RCRA and stakeholder objectives of maintaining riparian and near-bank aquatic habitat functions, improving access to the river for recreational activities, and minimizing disruption. Based on the outcome of collaborative design discussions between the involved parties, optimization and balancing of these objectives can be best achieved by focused soil removal actions in localized banks that contribute disproportionately to Hg loading. Less invasive enhanced vegetative stabilization designs have been developed for those banks that contribute relatively smaller Hg loading. This presentation will describe the collaborative approach and key consensus design elements applied to the various banks.

470 Altering Estuarine Sediment Transport Dynamics to Reduce Ecological Exposures: a Novel Form of Risk Management

C. Hauser, B. Bayne, AECOM; J. Mattei, Sacred Heart Univ; R.G. Stahl, E.I. DuPont de Nemours and Company / Corp Remediation; M. Liberati, EI DuPont de Nemours and Company / Corporate Remediation Group

Conventional methods of contaminated sediment remediation include monitored natural recovery, in-situ capping, and/or dredging. However, coastal and estuarine sites often pose unique challenges to the conventional remediation paradigm, which can undermine long-term effectiveness, delay site closure, and increase monetary and non-monetary costs. As a novel form of risk management, a “living shoreline” pilot project was constructed at a former gun club on the Housatonic River Estuary in Stratford, Connecticut. The site was operated as a trap and skeet shooting facility from 1926 to 1986, which resulted in the discharge of lead shot into surrounding waters and sediments. Large-scale remediation occurred from 2000 to 2001, and consisted of excavating the intertidal and nearshore subtidal zones and extracting lead shot using a mineral jig. Historically, the remedial area was a depositional environment; however, since remediation, the site has been subject to substantial shoreline erosion and associated changes in shot densities. The living shoreline was designed to dissipate wave energy and associated scour, and disrupt long-shore sediment transport to reduce ecological exposure. Results have been evaluated in the context of a Before-After-Control-Impact statistical framework. Bathymetric surveys show that the living shoreline is reducing erosion and increasing fine-grained sediment deposition.

471 Batch Adsorption Studies on the Use of Sorghum Husk for Treatment of Heavy Metal Contaminated Wastewater

S.V. Tatah, Federal Univ of Wukari / Biochemestry; O. Otitoju, Federal Univ Wukari / Dept of Biochemistry; I.N. Onwurah, Univ of Nigeria / Biochemistry

Contamination of environment by heavy metals has become a major concern worldwide. Therefore, it becomes imperative to explore a cost effective and efficient alternative method of removing heavy metals from polluted soils and waste water. In this study, the adsorption behavior of Sorghum husk, a low-cost adsorbent, with respect to Pb^{+2} and Cd^{2+} ions, has been studied in order to consider its application to the treatment of wastewater. The batch method was employed: parameters such as pH, contact time, particle size and initial metal concentration were studied. The influence of the pH of the metal ion solutions on the uptake levels of the metal ions by the adsorbent used was carried out between pH 3 and 8. The optimum pH for Pb^{+2} and Cd^{+2} removals by sorghum husk were 6 and 5 respectively. An equilibrium time of 80min was required for the adsorption of Pb^{+2} and 60min for Cd^{+2} ions onto sorghum husk. Percentage sorption of Pb^{+2} increased from 21 to 80% and that of Cd^{+2} from 15 to 55% as adsorbent dose was increased from 0.1 to 1g while adsorption capacity decreased from 14 to 5.3mg/g for Pb^{+2} and 32.5 to 9.3 mg/g for Cd^{+2} with increase concentration. Percentage removal of Pb^{+2} increased from 24.8 to 93.7% while that of Cd^{+2} from 22.4 to 91.6 % with decrease in adsorbent particle size from 1000μm to 100μm. The uptake capacity of the adsorbent increased from 6.5 to 12.4 mg/g for Pb^{+2} and 2.1 to 5.3mg/g for Cd^{+2} as the initial metal ion concentration was raised from 50 to 200mg/L. When two isotherms, the Langmuir and Freundlich models, were applied to the experimental data, the best fit was obtained with the Langmuir model. The results showed that sorghum husk has the potential to remove cationic heavy metal species from industrial wastewater.

Assessing Contaminant Effects in Multi-Stress Ecosystems – Part 2

472 A rapid screening approach for distinguishing multiple stressors in souther California streams

J.M. Diamond, Tetra Tech, Inc.; A. Roseberry-Lincoln, C. Boschen, Tetra Tech; R. Kolb, City of San Diego

Over 100 biologically impaired stream segments have been identified in southern California, all of which could involve multiple stressors including ion imbalance, pesticides, metals, nutrients, and others. We developed a rapid screening approach that can identify the major stressor(s) as well as help prioritize restoration efforts. The approach combines several region-specific tools including species tolerance information and species sensitivity distributions for commonly encountered pollutants and an innovative tool for identifying distributions of stressors for comparison. We developed a correspondence table between land cover and candidate causes for the region, which is used to refine the list of potential stressors based on land use and other mapped information. To further refine the likely stressor(s), we performed a cluster analysis to identify groups of sites with similar natural characteristics, such as gradient, flow, climate, and underlying soil and geology, and similar inflexible anthropogenic characteristics such as land cover. Using benthic macroinvertebrate data from 374 sites and 835 samples we identified six clusters based on 33 abiotic variables. Each cluster had a different characteristic distribution of the 33 variables enabling separation of stressors when compared against impaired site data. Our approach was able to separate stressors using several pilot sites in the region.

473 Integrating Contaminant and Other Stressors in an Ecological Risk Assessment of an Urban Waterway

D.H. Haury, Anchor QEA LLC; L. Logan, Anchor QEA; J. Volosin, D.P. Hennessy, Anchor QEA, LLC; D. Glaser, Anchor QEA

Assessing ecological risk at urban sites is challenging due to the presence of multiple contaminants and other stressors, including habitat degradation and low dissolved oxygen levels due to high organic point source discharges. The ecological risk assessment conducted as part of the Newtown Creek Remedial Investigation used multiple lines of evidence to identify contaminants of potential ecological concern, and included an evaluation of non-contaminant stressors. Sediment bioassays showed clear spatial differences in toxicity when compared to a reference envelope. Synoptic measurements of porewater contaminants using solid-phase microextraction fibers and mini-peepers indicate that toxicity is likely due to polycyclic aromatic hydrocarbon (34), with some contribution from metals. Test results appear to be confounded by other stressors for stations close to some of the large municipal point sources, including combined sewer overflows. Benthic community data from these locations scored below those in the reference areas during the summer months when dissolved oxygen fell below the 3-milligram-per-liter New York State threshold. Exposure estimates for wildlife were site-specific, based on survey data for site use, foraging activity, and prey type, as well as tissue chemistry in prey. Risks to wildlife were low, and the spatial distribution was similar to, and therefore supported, the results of sediment bioassays. Habitat surveys showed that 99% of the site shoreline comprises bulkhead materials (concrete, metal, wood), riprap, and rock. In contrast, for three of the four reference areas, only 6 to 27% of the shoreline is developed. This is reflected by higher species richness for aquatic-dependent birds in the reference areas, which provide habitat and refuge for foraging along the shoreline. For fish and crabs, species richness and diversity were found to be higher in the reference areas; however, these differences were attributed to differences in salinity. Overall, this risk assessment demonstrates that other stressors have an important influence on the habitat and biological communities of the site.

474 Phenotypic characterization of urban runoff toxicity in juvenile coho salmon, Oncorhynchus kisutch

M. Chow, Univ of Washington; J. McIntyre, Washington State Univ; G. Young, Univ of Washington / School of Aquatic and Fishery Sciences; N. Scholz, NOAA Fisheries

Urban runoff is a leading source of nonpoint pollution due to its ability to quickly mobilize a diverse mixture of contaminants. A decade of field observations near Seattle, Washington correlated acute die-offs of wild adult coho to urban runoff exposure. Ultimately, this study intends to identify if juvenile coho are similarly affected by urban runoff, characterize the behavioral response in juveniles, and investigate the physiological mechanisms causing mortality. In a series of experiments, juvenile coho were exposed to collected urban runoff or control water for 4-6 hours. Behavioral response was monitored using behavioral data acquisition software and response was characterized using a categorical scale. Observable symptoms included increased surface activity, gaping, hyperactivity, loss in equilibrium, and immobility. To understand the physiological mechanism of toxicity, we formed two main hypotheses: 1) urban runoff causes histotoxic hypoxia, the inability of oxygen uptake by the tissues, through mitochondrial enzyme dysfunction, and 2) urban runoff causes ischemia, localized reductions in blood flow due to coagulation, preventing oxygen delivery to the cells. For this study juvenile coho were exposed to urban runoff or control water and sampled in a time series throughout the exposure. Blood was analyzed for evidence of metabolic disruption and coagulation using a point-of-care blood analysis tool, clotting time assays, and blood smears. Initial blood analyses showed significant changes between control and urban runoff exposed juveniles, suggesting metabolic acidosis and increased coagulation in exposed fish. Further analyses are needed to explore the specific timeline for each physiological mechanism to confidently pinpoint the cause of death.

475 Environmental Exposure to an Urban Wastewater Effluent: Effects on the Energetic Metabolism of Northern Pike

J. Reinling, Université du Québec à Montréal / Departement des sciences biologiques; M. Houde, Environment and Climate Change Canada / St Lawrence Center; J. Verreault, Université du Québec à Montréal / Dept of Biological Sciences

Municipal wastewater effluents are complex mixtures of chemical and biological compounds that can impact aquatic organisms from receiving ecosystems. Adverse effects may occur at several levels of the biological organization. The aim of this study was to assess the effects of a major municipal wastewater effluent (Montreal, QC, Canada) on the energetic metabolism of environmentally exposed northern pike (Esox Lucius) using a multi-level approach. We hypothesized that effluent exposure is associated with greater halogenated flame retardant (HFR) concentrations in liver that are related to changes in thyroid status of fish and transcription level of genes involved in transport, synthesis, and metabolism of fatty acids. A total of 50 pikes were collected in 2014-2015 upstream and downstream of the point of discharge in the St. Lawrence River of Montreal's primary wastewater treatment plant (WWTP). Plasma levels of total and free triiodothyronine (T_3), percentages of total lipids (liver), body condition index (Fulton) and stable isotope signatures of carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) (plasma, liver, and muscle) were measured and compared to hepatic concentrations of 34 polybromodiphenylethers (PBDE) congeners and 12 emerging HFRs. Concentrations of liver Σ_{34}PBDE were approximately 4-fold greater in pike collected downstream of the WWTP and thus confirmed an important effluent exposure at this site. General $\delta^{13}C$ and $\delta^{15}N$ profiles in pike tissues corroborated effluent exposure at this site. Moreover, effluent exposure was associated with a significant increase (40%) in total lipids in fish liver and a tendency for increasing free T_3 levels and free T_3/total T_3 level ratios in plasma of females. No significant difference in body condition index was observed between sites. Results suggest that the energetic metabolism of this predator fish may be affected by the chronic exposure to the effluent. Ongoing work that will be presented at the conference will include hepatic peroxisomal acyl-coA oxydase activity (ACOX) and transcription levels of l-fabp, fasn, pparγ and acox genes implicated in hepatic transport, synthesis and metabolism of fatty acids in the liver. These findings will contribute to a better understanding of the mechanisms of toxicity associated with exposure to effluents.

476 Temperature and photoperiod-dependent sex determination in branchiopod crustaceans is modulated by the NMDA receptor antagonist MK-801

A. Camp, North Carolina State Univ / Environmental and Molecular Toxicology; M. Haeba, G.A. LeBlanc, North Carolina State Univ / Dept of Biological Sciences Toxicology Program

Branchiopod crustaceans are subject to environmental sex determination whereby the introduction of males into a population denotes the switch from asexual parthenogenetic reproduction to sexual reproduction. Sexual reproduction is initiated by environmental signals that cue the onset of adverse conditions, and diapausing eggs are produced in order to reestablish populations once favorable conditions resume. We determined the environmental cues necessary for male production in Daphnia magna and D. pulex by examining photoperiod (long day, 16 hrs and short day, 10 hrs) and temperature (16^o, 18^o, 20 and 22^o C). Additionally, we investigated the role of the NMDA receptor in male production with the NMDA receptor antagonist MK-801. Both species produced negligible or no male offspring when subjected to long day length regardless of temperature. D. pulex produced male offspring under the short day length at all four temperatures, with colder temperatures significantly increasing the proportion of males produced. D. magna alsoproduced male offspring under the short day length but with colder temperatures significantly decreasing the proportion of males produced. In all cases, male sex determination of offspring varied significantly among the first six broods where some broods appeared to be responsive to environmental cues and other broods were not. The NMDA receptor antagonist MK-801 increased male production in both species in broods where aged-matched control daphnids produced broods that were predominantly female, but reduced male production when control broods were predominantly male. Results suggest that daphnid male sex determination is triggered by a combination of photoperiodic and temperature cues that suppress the NMDA receptor. We propose that when the NMDA receptor is not actively suppressed by environmental cues, conditioning the organisms to produce female offspring, MK-801 functions as an antagonist resulting in increased male sex determination. However, when the NMDA receptor is actively suppressed by environmental cues, conditioning the organisms to produce male offspring, MK-801 functions as a weak agonist to decrease male sex determination of offspring. Thus, environmental contaminants interacting with the NMDA receptor may alter male production with adverse consequences on the spatial and temporal maintenance of these important primary consumers.

477 Evaluating arsenic additions and future trends in a complex ecosystem

L. Levin, Electric Power Research Inst / Air and Multimedia Toxics Health Risk Assessment

A case study was carried out in which a suite of air quality and watershed models was applied to track the ecosystem contributions of arsenic (As) emissions from three coal-fired power plants (CFPPs) located in the San Juan River basin in the Four Corners region of the American Southwest. Site and meteorological data from the period 1986-2012 were used to project air quality conditions and ecosystem impacts to the year 2074 using randomized sampling techniques. The arsenic depositing from the atmosphere originates from a variety of local, regional, and global sources. Lacking source-specific inventories, background arsenic was parameterized by application of background atmospheric concentrations. The watershed response to this deposition is a function of transport and transformation processes within the land and surface and ground waters. Because of the large storage capacity of soils, changes in the watershed due to changes in atmospheric inputs may take many years to become evident. Atmospheric arsenic was modeled using a nested modeling system employing the EPRI CMAQ-APT (national and regional) model. For the Four Corners region of the United States, where large-scale point source inventories of arsenic are lacking, power plant contributions were also quite small in comparison to background atmospheric concentrations. The WARMF watershed model integrated atmospheric deposition, soil-content inputs of arsenic, and direct discharge contributions of the substance to derive fluxes of arsenic for the soil and surface water constituents. The model was used to simulate watershed response to scenarios of future atmospheric deposition out to the year 2074. WARMF simulations showed the contribution of the primary power plant to surface water arsenic concentration was less than the 0.01% discernible by the model. Results from this study of arsenic, a multimedia toxic, were used to help guide research on potential health or ecosystem impacts in the region, including several ecological risk assessments at finer scale. Federal land management agencies in the region used the study results in connection with review of the power plants' environmental impact statements (EISs) and to gauge compliance with the Endangered Species Act (ESA).

478 Effects of Salinity on Oil Spill Dispersant Toxicity in Estuarine Organisms

M.E. DeLorenzo, NOAA / National Centers for Coastal Ocean Science; C. Eckmann, Univ of South Carolina; B. Evans, Eckerd College; K.W. Chung, P.B. Key, M.H. Fulton, NOAA / National Centers for Coastal Ocean Science

Chemical dispersants can be a useful tool to mitigate oil spills, but the potential risks to sensitive estuarine species should be carefully considered. To improve the decision making process, more information is needed regarding the effects of oil spill dispersants on the health of coastal ecosystems under variable environmental conditions such as salinity. The two oil dispersants used in this study were Corexit ® 9500 and Finasol ® OSR 52. Corexit ® 9500 was the primary dispersant used during the 2010 Deepwater Horizon oil spill event, while Finasol® OSR 52 is another dispersant approved for oil spill response in the U.S., yet considerably less is known regarding its toxicity to estuarine species. The grass shrimp, Palaemonetes pugio, and the mud snail, Ilyanassa obsoleta, were selected as common estuarine species that are tolerant of a wide salinity range. Adult and larval life stages were tested with each dispersant at different salinities, ranging from 5ppt to 30ppt. Median acute lethal toxicity thresholds and sublethal biomarker responses were determined. The toxicity of both dispersants was significantly influenced by salinity, with greatest toxicity observed at the lowest salinity tested. Larval life stages were significantly more sensitive than adults to both dispersants, and both life stages were significantly more sensitive to Finasol than to Corexit. These data will assist environmental managers in making informed decisions regarding dispersant use in future oil spills.

479 Multibiomarker evaluation of pollutant effects in Atlantic stingray (Dasyatis sabina) populations in Florida's St. Johns River

J. Whalen, J. Gelsleichter, Univ of North Florida / Biology

The goal of this study was to examine the potential health effects of polychlorinated biphenyl (PCB) and polycyclic aromatic hydrocarbon (PAH) exposure on Atlantic stingray populations in Florida's St. Johns River (SJR). Special emphasis was placed on identifying PAH- and/or PCB-related effects in stingrays from areas of the lower SJR basin that have been shown to possess elevated levels of these compounds, as well as characterizing baseline levels of pollutant exposure in other areas that may be subjected to dredging in the near future, potentially resuspending and redistributing contaminated sediments and increasing pollutant-associated effects. To accomplish this, we measured PCB and PAH biomarker levels in stingrays collected from contaminated sites and reference locations. We specifically examined the biomarkers cytochrome P4501a1 (CYP1a1), a Phase I detoxification enzyme; glutathione-S-transferase (GST), a Phase II detoxification enzyme; uridine diphosphate glucuronosyltransferase (UGT), a Phase II detoxifiocation enzyme; fluorescent aromatic compounds (FACs), PAH bile metabolites; lipid peroxidation (LPO), cell membrane damage; and thyroid epithelial height (TEH), an assessment of endocrine disruption-induced hypothyroidism. Enzymatic activity of CYP1a1, GST, and UGT was measured using an EROD assay, a commercially available GST Assay Kit, and a 4-methylumbelliferone assay, respectively. LPO was measured with an OxiSelect TBARS Assay Kit. FACs were measured using fixed wavelength fluorescence and TEH was analyzed histologically. Biomarker levels of individuals collected from contaminated sites were compared to individuals collected from reference sites. The data suggest that pollutant biomarker levels in SJR stingrays did not differ significantly from those measured in individuals from reference locations. However, the close proximity of high biomarker levels to known contaminated areas suggests continuous exposure.

Contaminant Flux Across Environmental Compartments and Implications for Global Distribution

480 Recent developments in methodologies for determining sediment to water fluxes of hydrophobic organic contaminants in situ

E. Eek, NGI / Environmental Technology; G. Cornelissen, Norwegian Geotechnical Inst; D. Lin, Stanford Univ / Dept of Civil and Environmental Engineering; L. Mustajärvi, Stockholm Univ; A.M. Oen, Norwegian Geotechnical Inst / Environmental Technology; A. Sobek, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry ACES; D. Gilbert, Norwegian Geotechnical Inst / Environmental Technology; N. Berrojalbiz, NGI / Environmental Chemistry; H.H. Arp, Norwegian Geotechnical Inst / Environmental Technology; R.G. Luthy, Stanford Univ; G.D. Breedveld, NGI / Dept of Environmental Engineering

Processes occurring at the sediment-water interface affect abiotic transfer of hydrophobic organic contaminants to overlying water, as well as contaminant exposure to benthic fauna and contaminant migration via the aquatic food chain. Organic contaminant transfer at the sediment-water interface is dependent on freely dissolved aqueous concentrations. This has led to an increased focus and research to determine in-situ the freely dissolved concentration gradients and the contaminant mass transfer across the sediment-water interface. Results from the use of several innovative methods to determine sediment-to-water fluxes in situ will be presented: 1) Use of a closed flux chamber to determine sediment-to-water fluxes before and after capping and activated carbon amendment 2) A novel flow through flux chamber enabling measurement of flux while renewing the water inside the chamber in order to supply oxygen to the benthic fauna. This enables measurement of sediment to water fluxes with conditions sustaining benthic life and therefore includes the effect of bioturbation on the flux. 3) A tripod pore water probe deploying passive samplers at different depth intervals both in the pore water and in the overlying water. The passive samplers are attached to a single steel probe penetrating the sediment bed to a predefined depth. The compact design of the probe ensures that the influence from the presence of the probe will have minimal effect on the overlaying water movements and therefore also minimal influence on the in situ sediment to water mass transfer coefficient and on the bioturbation activity of the benthic fauna. The novel tripod pore water probe is designed to be deployed at deep waters (used down to 120 m depth). The probe is also fitted with a releasable camera to monitor the deployment and to document the penetration depth of the probe in the sediment. This makes it possible to determine which passive samplers have been exposed to the pore water and which to the overlying waters. These new tools have been used to study the effect on sediment-to-water fluxes both from remedial actions such as capping and activated carbon amendment, and from natural mechanisms such as bioturbation and natural recovery processes in contaminated sediments.

481 Adapting passive samplers to investigate PAH and PCB flux from soil to air

C. Donald, K.A. Anderson, Oregon State Univ / Environmental and Molecular Toxicology

Magnitude and direction of flux of PCBs and PAHs were calculated using passive sampling devices to measure both air and soil pore air, that is, air that is in close proximity and equilibrium with soil. Existing methods to measure flux of semi-volatile compounds between soil and air require collecting soil samples from the top soil layer. This surface layer is hard to define, and existing extraction methods may overestimate the fraction of compounds available for partitioning into air in situ. In this modified design for sampling soil pore air in situ, an air-tight box is placed over low-density polyethylene passive samplers deployed 1 cm above the soil. Air exchange is limited to air that has equilibrated as it permeates through soil. In addition, passive air samplers were co-deployed at a height of 1.5 m above the soil to measure concentrations in air. Sampling occurred adjacent to two Superfund sites: a former PCB manufacturing facility in Anniston, Alabama, and a former creosoting site near Seattle, Washington. Following extraction in n-hexane, samplers were analyzed for PCBs with dual gas chromatography-electron capture detectors, and for PAHs with gas chromatography-mass spectrometry. Air and pore air concentrations were calculated using performance reference compounds. Flux calculations followed Fick's law of diffusion. Higher molecular-weight compounds were generally found to be volatilizing from the soil, while lower molecular weight compounds were depositing into the soil. Inter-sampler variability was greater among pore air samplers than air samplers, likely due to soil heterogeneity. This adapted method of measuring pore air in situ will allow for increased understanding of source-sink dynamics at sites with historical contamination.

482 Benthic Injury Dose-Response Models for PCB-Contaminated Sediment Using Equilibrium Partitioning

K. Finkelstein, N. Beckvar, NOAA / Office of Response and Restoration; T.M. Dillon, Dillon Environmental Consulting, LLC / NOAA, Assessment and Restoration Division

The goal of this study was to develop a sediment PCB dose-response model based on benthic invertebrate effects to PCBs. We used an equilibrium partitioning (EqP) approach to generate predicted PCB sediment effect concentrations (largely Aroclor 1254) associated with a gradient of toxic effects in benthic organisms from effects observed in the aquatic toxicity studies. This report differs from all other EqP collective sediment investigations in that we examined a common gradient of effects rather than a single, protective value. We reviewed the chronic aquatic toxicity literature to identify measured aqueous PCB concentrations and the associated benthic invertebrate effects. We control-normalized the aquatic toxic effect data and expressed results from various studies as a common metric, % injury. Then we calculated organic carbon (oc)-normalized sediment PCB concentrations (mg/kg-oc) from the aqueous PCB toxicity dataset using EqP theory based on EPA's (EPIWEB 4.1) derivation of Koc. Lastly, we constructed a non-linear dose-response numerical model for these synoptic sediment PCB concentrations and biological effects (Y = 100/1 + 10(logEC50-logX) • (Hill slope)). These models were used to generate easy to use "look-up" tables reporting % injury in benthic biota for a range of Aroclor-specific sediment concentrations. For example, the model using the EPIWEB 4.1 Koc estimate predicts the mean benthic injury of 23.3%, 46.0%, 70.6%, 87.1% and 95% for hypothetical sediment concentrations of 1, 2, 4, 8, 16 mg/kg dry wt. of Aroclor 1254, respectively (using 1% oc). Models for some Aroclors (1016, 1221, 1232, and 1268) could not be developed due to data gaps toxicity literature. Specific step-wise procedures are provided for predicting % benthic injury when sediment PCBs are reported as Aroclor, congeners, homolog groups or total PCBs. The report identifies and discusses the uncertainties associated with the numerical PCB dose-response models and the EqP approach and provides considerations for how other Koc values result in more or less conservative models. This paper provides recommendations for addressing outstanding issues, including the Koc calculation, the two-carbon model, and congener data. We recommend using the model presented for screening but suggest, when possible, to determine a site specific Koc; that along with the tables and equations herein allows users to create their own protective dose-response sediment concentration for a specific locale.

483 Comparison of modeled and measured persistent organic pollutant flux between sediments and water column on the Palos Verdes Shelf

L. Fernandez, G. Flavetta, Northeastern Univ / Civil and Environmental Engineering; R.M. Burgess, USEPA / Atlantic Ecology Division

The Palos Verdes Shelf (PVS) Superfund site is in over 50 meters of water on the continental shelf and slope off the coast of southern California (USA). The site includes more than 25 km^2 of sediments contaminated over several decades by municipal treatment plant effluent discharged via off-shore outfall pipes. Contaminants of concern include polychlorinated biphenyls (PCBs) and the pesticide DDT and its degradation products (e.g., DDE). Understanding the rate of exchange of these compounds between environmental media including sediments, water column and organisms, and the rate of transport off of the shelf are critical to predicting the fate of the persistent organic pollutant (POP) inventory at the site. In this work, results from water column and sediment porewater monitoring campaigns that employed passive sampling methods were used to calculate the flux of POPs between sediments and the water column and the advective transport of dissolved contaminants along the shelf. Further, the results were used as inputs to multi-box models of the Palos Verdes Shelf water column. The simplest model, a series of boxes along the 60-m isobath, using calculated molecular diffusive flux from the sediment bed to the water column as the only POP input, matched observed water concentrations within 70% for DDE and PCB congener 52. This supports the assumption that molecular diffusive flux between the sediment and water column media is a principal source of POPs to the water column at this site. In addition, box models were used to determine the potential magnitude of unaccounted sources or sinks for POPs on the shelf, and the time required to reduce sediment concentrations to values targeted by remedial project managers assuming only diffusive and advective transport of dissolved compounds.

484 Diffusive Flux of PAHs Across Sediment, Water, and Air Interfaces at Urban Superfund Sites

J. Minick, K.A. Anderson, Oregon State Univ / Environmental and Molecular Toxicology

Urban centers are often sources of polycyclic aromatic hydrocarbons (PAHs) to the surrounding environment. Knowledge of PAH transport and fate is important for understanding their relative source contributions which can help to inform remedial and management decisions. In this study, low density polyethylene (LDPE) passive samplers were co-deployed in sediment, water, and air, along the Willamette River in the city of Portland, Oregon. Sampling was conducted within and outside of the Portland Harbor Superfund Megasite (PHSM) and the McCormick and Baxter (MCB) Superfund Site. These Superfund sites have historical PAH contamination from industrial activities as well as ongoing PAH emissions from the Portland urban center. Samplers were analyzed for 62 PAHs using GC-MS/MS. Performance reference compounds were used to calculate freely dissolved PAH concentrations in water and sediment porewater and vapor phase concentrations in air. Flux due to diffusion was calculated across interfaces of the all three compartments following Fick's first law of diffusion. Results indicate that two and three-ring PAHs moved primarily from the sediment and the air into the water. This suggests that the Willamette River acts predominately as a sink for lighter molecular weight PAHs from both the sediment and the air. Additionally, comparison of these flux magnitudes suggest a similar level of source contribution. Sediment was also a source of four and five ring PAHs to the water at most locations. However, in contrast to the lighter molecular weight PAHs, the water was a source of these higher molecular weight PAHs to the air. At the remediated MCB Superfund Site, flux patterns reveal locations where contaminants may be breaking through the sand and rock sediment cap.

485 Distribution and Air-Water Exchange of Organic Flame Retardants in the Lower Great Lakes

C.A. McDonough, Univ of Rhode Island / Graduate School of Oceanography; G. Puggioni, Univ of Rhode Island / Dept of Computer Science and Statistics; P.A. Helm, Ontario Ministry of the Environment & Climate Change / Environmental Monitoring and Reporting Branch; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; R. Lohmann, Univ of Rhode Island / Graduate School of Oceanography

Organic flame retardants (OFRs), including polybrominated diphenyl ethers (PBDEs) and novel halogenated flame retardants (NHFRs), are ubiquitous, persistent contaminants that have been liberally added to a wide variety of consumer goods to slow combustion in the event of a fire. Recent studies have measured concentrations of OFRs in air, rain, and surface waters of the lower Great Lakes, but there are no published studies of regional spatial trends, nor are there reported measurements of air-water exchange fluxes. Polyethylene passive samplers (PEs) were deployed throughout the lower Great Lakes (Lake Erie and Lake Ontario) from 2011 to 2014 to (i) determine baseline concentrations of OFRs in air and water at a variety of shoreline, nearshore, and offshore sites, (ii) calculate exchange fluxes to determine whether the lakes were acting as sinks or secondary sources via diffusive air-water exchange, and (iii) investigate spatial trends and correlation with human population density. Dissolved Σ_{12}BDE was greatest in Lake Ontario near Toronto (18 pg/L) and gaseous Σ_{12}BDE was greatest on the southern shoreline of Lake Erie (11 pg/m^3). Air-water exchange was dominated by absorption of BDEs 47 and 99, ranging from -964 pg/m^2/day to -30 pg/m^2/day. Correlation between population and dissolved ?$_{12}$BDE was strongest when using a radius of 25 km around each site, while correlation with gaseous Σ_{12}BDE was strongest when using local (within 3 km) population to the south of each site, possibly due to the prevalence of southerly winds during the sampling campaign. Results for OFRs will be compared to other compound groups with distinct sources and usage histories, including polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs), which were measured in the same extracts. Bayesian kriging will be utilized as a geostatistical interpolation technique to predict dissolved OFR concentrations over the lakes, illustrating the utility of relatively highly spatially resolved measurements in identifying potential hot spots for future study.

486 Air-water exchange of POPs across the Atlantic Ocean

R. Lohmann, E. Markham, Univ of Rhode Island / Graduate School of Oceanography; J. Becanova, P. Karaskova, J. Klanova, Masaryk Univ / RECETOX Research Centre for Toxic Compounds in the Environment

The research cruise KN210-04 of the R/V Knorr in March-May 2013 from Uruguay to Barbados USA offered a unique opportunity to determine gradients of persistent organic pollutants (POPs) in air, water and their air-water exchange. The cruise track covered a fairly large north-south gradient off the South-American coast, along Brazil into the Caribbean, so far unexplored in terms of POPs concentrations and fluxes, far away from shore. Concentrations of PCBs and OCPs in the air ranged from < detection limit to 15 pg/m3, dominated by PCB 28 and hexachlorobenzene (HCB). In the water, concentrations were typically < 5 pg/L, with HCB and PCB 52 as the major compounds. Of the polybrominated diphenyl ethers (PBDEs), mostly only congeners 47 and 99 were detected in the gas-phase, at up tp 10 pg/m3, while dissolved concentrations were mostly at around 2 pg/L. Detection in water samples were spotty, implying larger-scale currents responsible for the presence and absence of measurable POPs concentrations. Air-water exchange gradients for PBDEs implied strong net gas-phase deposition along the western Atlantic Ocean.

487 A Rapid Decline of Persistent Organic Pollutant Concentrations in the Sarasota Bay, FL Bottlenose Dolphin Population

J.R. Kucklick, National Inst of Standards & Technology; R. Wells, Chicago Zoological Society; E. Davis, Butler Univ; J. Balmer, Mote Marine Laboratory; B.C. Balmer, NOAA; R. Pugh, A. Moors, NIST; J. Sweeney, Dolphin Quest; D. Fauquier, NOAA NMFS; F. Townsend, Bayside Veterinary Clinic; T. Rowles, NOAA NMFS

Declining trends of legacy persistent organic pollutants (POPs) have most frequently been documented in food webs from arctic and subarctic environments. Because of cold temperatures and slow degradation rates, arctic environments are considered sinks for POPs; however decay rates may not be reflective of other areas. Conversely, in tropical or subtropical environments, environmental conditions likely favor more rapid declines in POP concentrations with time because of warmer temperatures leading to greater POP volatilization and degradation. We hypothesized that POPs will decline with time more rapidly in a subtropical food web than samples from temperate or arctic food webs. Samples from the long-term resident Sarasota Bay bottlenose dolphin population provide an excellent opportunity to investigate POP trends in a subtropical estuary. The majority of bottlenose dolphins inhabiting Sarasota Bay are resident and have been cataloged through photo identification and nearly annual capture-release studies. Capture-release studies also provide access to blubber, blood and milk for POP analysis. Full depth blubber biopsies were collected from 2000 to 2016 (n=282) and analyzed for a suite of POPs including polychlorinated biphenyl congeners, organochlorine pesticides and polybrominated diphenyl ethers. Results for samples analyzed from 2000 to 2012 show large and significant declines of POPs in blubber. For example median wet weight blubber concentrations in males sampled from 2000 (n=12) to 2012 (n=8) declined from 26 mg/kg wet to 2.8 mg/kg, from 3.2 mg/kg to 0.32 mg/kg and from 0.91 mg/kg to 0.23 mg/kg for PCB 153, mirex and PBDE 47, respectively. Concentration declines were on the order of 20% per year for samples collected from 2000 to 2012. A meta-analysis of POP trends occurring in more northerly environments confirms that POPs in Sarasota dolphin blubber are declining at a faster rate than observed elsewhere. Concentration declines may contribute to improving health of Sarasota dolphins discounting other factors.

EDCs and Pharmaceuticals in the Environment – Part 2

488 Altered antimicrobial susceptibility in stream bacterial isolates exposed to triclosan

K.E. Trowbridge, A.E. Hershey, Univ of North Carolina at Greensboro / Dept of Biology

Globally, the development and transmission of multidrug-resistant (MDR) bacteria is a major medical challenge. A commonly used antimicrobial, triclosan, is detectable in human and environmental samples. Triclosan is associated with numerous health risks including increasing antimicrobial resistance in bacteria. Environmental exposures to triclosan can alter susceptibilities of bacteria and studies have shown development of resistance to triclosan and cross-resistance to antibiotics in clinical isolates. Bacteria can obtain antimicrobial resistance factors through horizontal gene transfer. If acquired resistance and cross-resistance in environmental bacteria is developing in streams or wastewater (WW) treatment plants, this poses a human health risk. The overall goal of the current study is to evaluate stream bacterial responses to environmentally-relevant triclosan exposure. Antimicrobial susceptibility was evaluated in periphyton bacteria from a WW-associated stream and forested, reference stream. Reference bacteria were hypothesized to exhibit greater susceptibility to triclosan than WW-associated bacteria. Exposure to triclosan was hypothesized to affect susceptibility. Reference bacteria were expected to experience a greater effect of exposure on susceptibility compared to WW-associated. Resistance to triclosan was hypothesized to associate with resistance to other antibiotics. Periphyton was exposed to 10 ppb triclosan in microcosms, then random isolates were cultured. Unexposed and exposed isolates from each stream were evaluated for susceptibilities to triclosan and five antibiotics through broth microdilution assays. Among unexposed isolates, higher overall susceptibility was observed in reference stream isolates compared to WW-associated isolates. Exposed WW-associated isolates show similar triclosan susceptibility the unexposed WW-associated isolates. Exposed reference stream isolates show lower triclosan susceptibility when compared to unexposed reference isolates. Similar trends were also observed with some of the other antibiotics tested. Most isolates showing resistance to the doses of triclosan tested also show low to no susceptibility to carbenicillin, chloramphenicol, erythromycin, and trimethoprim. Results of this study indicate that low levels of triclosan in streams may alter susceptibilities of environmental bacteria to triclosan and other antibiotics, possibly adding to the challenge of development of MDR bacteria.

489 Spatio-temporal bioaccumulation and trophic transfer of ionizable pharmaceuticals in a semi-arid stream influenced by snowmelt

S. Haddad, W.C. Scott, Baylor Univ / Dept of Environmental Science; A. Luek, Univ of Lethbridge / Dept of Biological Sciences; S.R. Burket, G. Saari, L.A. Kristofco, Baylor Univ / Dept of Environmental Science; J.B. Rasmussen, Univ of Lethbridge / Dept of Biological Science; K. Chambliss, Baylor Univ / Dept of Chemistry; M. Luers, Snyderville Basin Water Reclamation District; C. Rogers, Carollo Engineers; B.W. Brooks, Baylor Univ / Dept of Environmental Science

Bioaccumulation of pharmaceuticals and personal care products (PPCPs), and other contaminants of emerging concern (CECs) in aquatic systems has increasingly been reported in the literature. It is critically important to recognize that traditional approaches to understand and predict exposure, accumulation, and effects of classic contaminants (e.g., PCBs) may not be appropriate for many CECs. For example, many ionizable pharmaceuticals typically have lower log P values, are more water soluble, and accumulation is influenced by pH. However, during dry periods and droughts, base flows in rivers are increasingly dominated by or dependent on effluent discharge, resulting in longer exposure durations to aquatic life. Such urban waters represent worst case scenarios for potential aquatic exposure and ecological effects from consumer products. Exposure and accumulation of pharmaceuticals can be influenced by different species specific fitness traits (foraging range, feeding behavior, migration, morphology) and differential ability among species to biotransform compounds. Because a comprehensive review of pharmaceuticals and aquatic organisms recently identified that studies examining spatial and temporal factors influencing exposure, bioaccumulation, and risk of pharmaceuticals to aquatic life is decidedly lacking, we examined the spatio-temporal bioaccumulation of select pharmaceuticals in multiple trophic positions (periphyton, invertebrates, and fish) from East Canyon Creek, Park City, Utah, at increasing distances downstream from an effluent discharge (0.15, 1.44, and 13 miles) during three seasons (spring, summer, and fall) of 2014. Stable isotopes analysis identified trophic positions within functional food chains, and spatio-temporal trophic magnification factors (TMFs) were determined. Results of the current study emphasize the significance of characterizing pharmaceutical bioaccumulation in relation to seasonal and longitudinal variations, in pharmaceutical occurrence, and exposure scenarios based on species behavior and habitat use. Such considerations appear important for future bioaccumulation assessments of ionizable contaminants.

490 Stress-related symptom and detoxification mechanisms induced by PPCPs in plants

C. Sun, J. Jiang, J. Gan, Univ of California Riverside / Dept of Environmental Science

Crops irrigated with reclaimed wastewater may take up and accumulate pharmaceutical and personal care products (PPCPs), which have been recently shown to affect plant physiology and alter normal biochemical pathways. Existing studies tested toxicity of individual compounds. However, effluent-irrigated crops are exposed to PPCPs as mixtures, understanding mixture toxicity may be important for predicting plant bioaccumulation of PPCPs. The present study explores the uptake, translocation and oxidative stress response induced by 18 frequently-occurring PPCPs (100 $\mu g\ L^{-1}$) in cucumber seedlings grown in nutrient solution for 20 days. PPCPs concentration in leaves and roots is determined by HPLC-MS, and bioconcentration factor and translocation factor are calculated. Oxidative stress parameters, such as lipid peroxidation, cell death, hydrogen peroxide and superoxide content are determined both in roots and leaves. PPCPs induced root cell death, especially in root tips. MDA content was also enhanced by PPCPs. Non-antioxidant enzymes (ascorbic acid, glutathione) and antioxidant enzymes (superoxide dismutase, catalase, glutathione reductase and peroxidase) are evaluated. These results provide phytotoxic effects induced by PPCPs mixture, strengthing the need for the evaluation of the ecotoxicological effects of wastewater treated flows.

491 Bioaccumulation of pharmaceuticals and other emerging contaminants: What's in the lower aquatic trophic levels?

J. Wilkinson, P.S. Hooda, Kingston Univ London / Natural and Built Environments; J. Swinden, J. Barker, S. Barton, Kingston Univ London / Life Sciences Pharmacy Chemistry

Organic contaminants such as pharmaceuticals, personal care products (PPCPs) and other emerging contaminants (ECs) are known to persist in the aquatic environment and many are indicated as endocrine, epigenetic, or other ecotoxins. Typically, the study of such compounds in the aquatic environment is limited to their occurrence dissolved in river water. In this study, accumulation of thirteen PPCPs/ECs was assessed in aquatic sediment (n=23), plants Callitriche sp. (n=8) and Potamogeton sp. (n=7) as well as amphipod crustacean (Gammarus pulex, n=8) and aquatic snails (Bithynia tentaculata, n=6). All samples were collected from the Hogsmill, Blackwater and Bourne Rivers in southern England. The Hogsmill and Blackwater Rivers were studied from headwaters to the first confluence with another river. Targeted PPCPs/ECs included pharmaceuticals acetaminophen, diclofenac, and ethinylestradiol, plasticisers bisphenol-A (BPA), bisphenol-S (BPS) and 4'-hydroxyacetophenone (HAP), perfluorinated compounds (PFCs) perfluorooctanoic acid (PFOA), perfluorooctanesulfonic acid (PFOS), perfluorononanoic acid (PFNA) and perfluorobutane sulfonic acid (PFBS), and illicit drugs/metabolites methamphetamine, amphetamine and benzoylecgonine. Contaminants were extracted using ultrasonic-assisted extraction and analysed using an in-house validated method for solid phase extraction followed by liquid-chromatography tandem mass spectrometry. Ten of thirteen analytes were detected in sediments with frequencies ranging from 22-83% (benzoylecgonine and BPA respectively) and mean quantifiable concentrations ranging from 0.84-11.1 ng/g dry weight (dw) (BPS and BPA respectively). Seven of thirteen analytes were detected in Callitriche sp. with frequencies ranging from 13% (acetaminophen) to 100% (HAP, BPS, PFBS and PFOA) and mean concentrations ranging from 0.42-113 ng/g dw (diclofenac and PFOS respectively). Eight of thirteen analytes were detected in Potamogeton sp. with frequencies ranging from 14-100% (acetaminophen and HAP respectively) and mean concentrations of 0.38-71.0 ng/g dw (acetaminophen and HAP). Lower levels of selected contaminants were found in aquatic snails (0.69-25.8 ng/g dw, acetaminophen and PFBS respectively) and amphipod crustaceans (0.32-14.2 ng/g dw, BPA and PFNA respectively). These data form a detailed accounting of PPCP/EC fate and distribution in the aquatic environment highlighting accumulation at bottom trophic levels, a potential source for higher organisms.

492 Occurrence and Estrogenic Burden of Five Parabens in Sewage Sludge from the United States

J. Chen, B.F. Pycke, Arizona State Univ / Biodesign Center for Environmental Security; B.J. Brownawell, Stony Brook Univ / School of Marine and Atmospheric Sciences; C.A. Kinney, Colorado State Univ-Pueblo / Chemistry; E.T. Furlong, USGS / National Water Quality Laboratory; D.W. Kolpin, USGS / Iowa Water Science Center; R.U. Halden, Arizona State Univ / Center for Environmental Security

Parabens are a group of compounds that have been extensively used as preservatives in pharmaceutical and personal care products (PPCPs), food, beverages, and industrial products. Continuous use and discharge of parabens into the environment can lead to occurrence at steady-state levels despite their susceptibility to degradation. As parabens are considered to represent emerging endocrine disruptors and have raised concerns for human and animal health, monitoring the occurrence of parabens in the environment is important for both ecological and human health risk assessments. In this study, five parabens were quantified by liquid chromatography-tandem mass spectrometry (LC-MS/MS) in sewage sludges collected at 14 U.S. wastewater treatment plants (WWTPs) located in nine states. Detected concentration ranges (in units of ng/g dry weight sludge) and frequencies were as follows: methyl paraben (15.9 to 203.0; 100%), propyl paraben (0.5 to 7.7; 100%), ethyl paraben (< 0.6 to 2.6; 63%), butyl paraben (< 0.4 to 4.3; 42%) and benzyl paraben (< 0.4 to 3.3; 26%). The estrogenicity inherent to the sum of parabens detected in sewage sludge (ranging from 10.1 to 500.1 pg/kg in units of 17β-estradiol equivalents) was insignificant when compared to the 10^6-times higher value for natural estrogens, calculated based on literature data for sewage sludge. This is the first report on the occurrence of five parabens in U.S. sewage sludges. Study results will help to inform the risk assessment of biosolids, i.e., treated sewage sludge destined for application on land.

493 Risks Associated with the Environmental Release of 15 Active Pharmaceutical Ingredients on US Food and Drug Administration's "Flush List"

U. Khan, FDA/CDER / Center for Drug Evaluation and Research; J.P. Laurenson, R.A. Bloom, USFDA / Center for Drug Evaluation and Research

A select few prescription drugs can be especially harmful and, in some cases, fatal with just one dose when not used as prescribed. To prevent accidental ingestion of these drugs by children, or pets, the US Food and Drug Administration (FDA) recommends that unused portions of these drugs be disposed quickly through a take-back program. If such an option is not readily available, FDA recommends that they be flushed down the sink or toilet. The goal of the current investigation was to evaluate the sources and risks associated with the environmental release of the 15 active pharmaceutical ingredients (APIs) currently on this so-called "flush list". This list consists of 10 opioids – buprenorphine, fentanyl, hydrocodone, hydromorphone, meperidine, methadone, morphine, oxycodone, oxymorphone, tapentadol; 1 benzodiazepine – diazepam; 1 psychoanaleptic – methylphenidate; 1 nervous system depressant – sodium oxybate; and 2 opioid antagonists – naloxone, naltrexone. Source models were developed for the release of these APIs to US waterways. For some APIs, the models revealed the importance of sources other than their clinical use (e.g., endogenous production and excretion, the use of illicit drugs). A risk-based evaluation was performed to assess the environmental and human health relevance of the flushed APIs. Exposure assessment was performed using both modelled and, where available, measured concentrations. Eco-toxicological effects assessment was conducted by gathering eco-toxicological data from various sources. For those compounds for which sufficient eco-toxicological effects data was not available, the fish plasma model was used to establish the need for additional fish chronic studies. Safe levels for human-health exposure through drinking water were estimated by extrapolating the lowest oral therapeutic doses to no-effect concentrations. To date, the evaluation suggests that most of these APIs clearly present a de-minimis environmental risk, while for some, fish chronic endpoints will need to be developed. All APIs present de minimis human health risk through drinking water. Several caveats exist and additional data are needed to: (1) fully understand the significance of manufacturing as a contributor to environmental loading of such chemicals, (2) evaluate the potential to form hazardous transformation products, and (3) address mixture effects. The contents of this abstract neither constitute nor reflect official US FDA policy.

494 Role of Effluent Organic Matter in the Photodegradation of Compounds of Wastewater Origin

A. MacKay, The Ohio State Univ / Civil Environmental and Geodetic Engineering

Treated municipal effluent discharges are an important source of compounds that may be biologically active in aquatic systems. The co-released effluent organic matter from the engineered microbial treatment process may influence compound degradation by decreasing the available sunlight for direct photodegradation, or increasing production of triplet excited state organic matter (^{3}DOM*), singlet oxygen ($^1O_2$) or hydroxyl radicals (OH-dot) for indirect photodegradation. Degradation rates for common wastewater effluent compounds – sulfamethoxazole (direct photodegradation), sulfadimethoxine (^{3}DOM reaction), cimetidine ($^1O_2$ reaction) and caffeine (OH-dot reaction) – were measured in upstream river water, treated effluent and mixtures thereof. A conservative mixing model for estimating compound degradation rates from river water and effluent end members could predict degradation rates in mixtures for direct photodegradation and OH-dot reactions. Compound degradation reactions via ^{3}DOM* and $^1O_2$ exhibited quenching in mixtures such that observed reaction rates were lower than estimated. The high photoreactivity of effluent organic matter and its susceptibility to quenching by river organic matter seems to be consistent with effluent organic matter phenol content. Overall, compound degradation rates were correlated with the simple optical parameter, E_2/E_3 ratio (sample absorbance at 254 nm divided by absorbance at 365 nm), for all water samples and mixtures. This finding opens the door to predictive estimations of compound attenuation capacity via photodegradation in waters downstream from treated wastewater effluent discharges.

495 Optimizing Operating Parameters to Enhance the Removal of Emerging Contaminants in Wastewater Treatment Plants Using the STP Model

A. Benedicta, Univ of Houston Clear Lake / Biological and Environmental Science; C. Zhang, Univ of Houston Clear Lake / Dept of Environmental Sciences

Wastewater treatment plants (WWTPs) have become a significant source of emerging contaminants of concern; however, conventional WWTPs are not effective for the removal of emerging contaminants such as metabolites of alkylphenol ethoxylate surfactants, steroid hormones, plasticizers, pharmaceuticals and personal care products. The aim of this study was to evaluate if the removal efficiency can be improved by optimizing operational parameters through the simulation in a fugacity based sewage treatment plant (STP) model. Seven commonly detected organic wastewater contaminants in the U.S. streams, i.e., pyrene, bisphenol A (BPA), estriol, triclosan, diazinon, 4-nonylphenol and tetrachloroethylene (PCE) were subjected to STP modelling by varying hydraulic retention time (HRT), solids retention time (SRT), mixed liquid suspended solids (MLSS), and aeration rate. Results showed that the total % removal for all contaminants increased with increasing HRTs, particularly for BPA and estriol with relatively low logKow pertaining to their low sorption constants. Under optimized HRTs, % improvement for BPA and estriol removal was significant (ranged approximately 8~35% and 9~47%, respectively) and moderate for diazinon and PCE. Total removal for all contaminants increased with SRT, and the % improvement with increasing SRT was moderate for BPA and estriol, and slight for pyrene, triclosan, diazinon, 4-nonylphenol and PCE. Simulations with increasing MLSS failed to improve total removal for all contaminants and the optimal removal was achieved at 1000 mg/l which is markedly lower than the operating MLSS currently in practice for conventional plug flow and CFSTR activated sludge systems. With an increasing aeration rate, the result showed that the total % removal, % biodegradation removal, % sludge removal and % volatilization removal was the same for all contaminants except for PCE, indicating the trade-off between the removal and fugitive emissions for highly volatile compounds. While STP has its inherent limitations for the process modeling in WWTPs, our overall attempt clearly indicates the potential of improved treatment efficiency by optimizing operational parameters currently in use. This work also points to the fact that maintaining an extended HRT in some WWTPs is subjective to further feasibility evaluation, and the strategy of increasing SRT for an improved treatment efficiency need to be examined on each individual contaminant basis.

Making Your Research Relevant to Regulatory Science and Supportive of Decision Making

496 It's a two-way street... or at least it should be

V. Forbes, Univ of Minnesota / Ecology Evolution Behavior

Ensuring that our science is relevant to decision making and that our decision making is informed by good science should be an iterative process with multiple feedbacks in both directions. It should be a process that continuously improves as scientific knowledge, technological developments, and lessons learned from previous decisions all evolve. Unfortunately, studies conducted to address specific research questions do not necessarily meet the rigorous standards upon which regulatory risk assessments should be based. Yet, there can be hesitance on the part of regulators to discard or downplay such studies, particularly if their findings suggest that risks are high. On the other hand, when scientific evidence argues for improving the design and/or reporting of regulatory test protocols, there can be tremendous inertia in getting the needed improvements implemented in revised test protocols. This presentation will provide an example of each of these (the former related to the risk assessment of bisphenol-A in Europe, and the latter related to changes in the design of chronic reproduction test protocols. A conclusion is that both science and regulatory decision making could benefit from more seamless and efficient feedback.

497 Research Supportive of Aquatic Life Ambient Water Quality Criteria Development

K. Gallagher, M. Elias, J.R. Beaman, D.M. Eignor, USEPA / Office of Water

The U.S. Environmental Protection Agency's Office for Water develops Aquatic Life Ambient Water Quality Criteria recommendations (also known as 304(a) criteria) using available toxicity test data, typically data available through the open literature. The Clean Water Act, the statute under which Water Quality Criteria are developed and applied, does not enable EPA to directly request or require data generation by chemical manufacturers, unlike pesticide and industrial chemical statutes in the US. Therefore, the need for high quality, reproducible research is heightened for the development of robust Aquatic Life Criteria. EPA occasionally needs to contact publication authors in order to access underlying data, such that more complex statistical analyses can made, in addition to typical metrics reported in the open literature (e.g., LC_{50}, EC_x). Thus, ensuring data are gathered and reported in a way that facilitates further analysis would increase the utility of academic research for criteria development. Additionally, conducting research that supports development of quantitative linkages between sublethal effects and effects of regulatory concern, typically survival, growth and reproduction, would be useful to government regulators. For example, reporting results indicating binding of a particular receptor following chemical exposure, or effects on olfaction, would be most useful when tied quantitatively to an apical endpoint. Enhanced application of research can be furthered by increased information sharing and contact between academic and regulatory scientists through forums such as SETAC.

498 Making your research relevant to ecological risk assessments conducted by Environment and Climate Change Canada

J. Hill, A. Gosselin, D. Gutzman, Environment and Climate Change Canada / Ecological Assessment Division; N. Khera, Environment and Climate Change Canada / Emerging Priorities Division

Under the Canadian Environmental Protection Act, 1999, Environment and Climate Change Canada (ECCC) assesses and manages, where appropriate, the ecological risks of substances. When conducting risk assessments, ECCC gathers and evaluates studies obtained from a variety of sources, including peer-reviewed journals, environmental databases and industry submissions. Studies are useful to document physical and chemical properties of chemicals, their environmental fate and behavior (including persistence and bioaccumulation) as well as their toxicological effects on organisms. These studies also occasionally provide information on environmental concentrations of chemicals in water, sediment or soil. Environmental databases (e.g., from provincial and territorial governments in Canada) can be an invaluable source of data on environmental concentrations of chemicals. For ECCC to be able to fully evaluate and use physical-chemical, ecotoxicological and exposure data from studies and environmental databases, certain key ancillary information regarding study conditions must be available and clearly communicated in the published studies or in databases (or in readily available supporting documentation). Also, as ECCC and other regulatory agencies in the world are assessing an increasing number of chemicals for which very little data are available to conduct a risk assessment, the results of studies conducted on these chemicals can be highly critical to support regulatory decision-making. For such results to be fully useful, they ideally need to be aligned with priorities identified for risk assessments by regulatory agencies in the medium and long term (e.g., ≥3 years). This presentation will provide examples of how certain research results from peer-reviewed articles, industry submissions and environmental databases have been used in the past in risk assessments conducted by ECCC, and how they have supported regulatory decisions. Examples of research results, including their evaluation through use of Robust Study Summary forms, that could not be used, or that were used with caution, in risk assessments due to a lack of reported information on study protocol or results obtained will also be presented.

499 Better designing and reporting of animal studies to support regulatory decision making

N. Burden, NC3Rs

Regulatory bodies are increasingly considering data from the open literature when making decisions on chemical safety. Uncertainty regarding results reported in the literature can trigger new ecotoxicity studies for regulatory purposes. It is therefore crucial that published data is of the highest quality possible. This will ensure that all of the available information can be utilised, and that additional studies are only conducted where necessary. There is a particular need for in vivo studies to be robustly designed so that the information gained is reliable and repetition of studies minimised, reducing the overall numbers of animals that are used to meet the scientific objectives. Adherence to reporting guidelines such as ARRIVE (Animal Research: Reporting of In Vivo Experiments) also plays a central role in supporting the interpretation of published data, by ensuring that studies are comprehensively reported in a transparent manner. A programme led by the UK's National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) continues to address the key issues related to experimental design, analysis and reporting. While relevant to all areas of research, the application of best practice in study design and reporting of research has obvious benefits to the field of ecotoxicology, especially considering the implications of such studies on regulatory decision making. The NC3Rs also leads an expert Working Group in regulatory ecotoxicology, comprising of scientists across academia, regulatory bodies and industry. This presentation outlines the activities we are undertaking to maximise the utility of published data across the biosciences, plus more specific priorities recently identified by the Working Group pertinent to using published data in regulatory decision making.

500 Designing and Conducting Chemical Fate Research to Support Risk Assessment

M.T. Lee, USEPA / Office of Pollution Prevention and Toxics; K. Eisenreich, C.D. Penalva-Arana, USEPA / OPPTRAD

EPA's Office of Pollution Prevention and Toxics (OPPT) is responsible for evaluating new and existing chemicals for human health and ecological risk, under the Toxic Substances Control Act. Chemical fate in the environment is one aspect of risk assessment that informs regulatory decisions. Fate assessment incorporates data generated by academia, research laboratories, and industry. This talk will provide a background on the environmental fate "endpoints" used by EPA's OPPT fate assessors, will address common reporting errors and emissions made when reporting data generated using test guidelines, highlight specific deficiencies in chemical fate data availability, and suggest key contributions the research science community could make towards improving fate assessment that supports decision making. For example, interpretation of chemical fate in the environment is hindered by a lack of data on chemical degradants and metabolites in environmental systems. Further development in this research area has the potential to greatly advance risk assessment science. The views of the authors of this abstract are those of the authors and do not represent Agency policy or endorsement.

501 The use of environmental exposure data to support regulatory risk assessments for octamethylcyclotetrasiloxane (D4)

K. Thomas, Global Silicone Council

The availability of empirical environmental exposure data to support regulatory evaluations for industrial chemicals is often limited. This scarcity of exposure data is often made more complicated because the environmental fate models that are frequently used to estimate environmental exposure are not well suited for predicting the environmental loadings associated with many chemicals. Compounds that don't behave similarly to the carbon-based chemicals which have historically been used as training sets for development of environmental exposure models are especially challenging for predicting environmental exposure. D_4 is a compound where environmental exposure estimates are difficult using classical environmental exposure models. Consequently, generating empirical environmental exposure data is essential for developing scientifically-defensible regulatory environmental safety evaluations for D_4. Although environmental exposure data for D_4 has been generated by scientists in government, academia, and industry, these data have not been consistently used to support regulatory evaluations for D_4 in North America and Europe. Assessment of the persistence (P), bioaccumulation (B), and toxicity (T) characteristics of industrial chemicals, which represents the core of a risk-based environmental assessment, is benefited considerably by the use of reliable and robust environmental exposure data. The presentation will review the available environmental exposure data for D_4, highlight the extent to which environmental exposure data was used to support regulatory evaluations of D_4 in Canada and Europe, and review the impact on the outcome of those assessments from the use of environmental exposure data. The presentation will also explore the approaches used for the completed environmental assessments of D_4 conducted by Canada and Europe, and review the data that is being generated to support an environmental risk assessment of D_4 in the US.

502 Regulatory guided research to improve biodegradation assessments

T. Martin, Newcastle Univ / School of Civil Engineering and Geosciences; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; R. Davenport, Newcastle Univ / School of Civil Engineering and Geosciences

Microbial degradation is an important but poorly understood process that can determine the fate of organic chemicals in the environment. The investigation of biodegradation in the environment is stuck in the paradigm of low throughput "one sample-one test" systems that often ignore the considerable variation inherent in natural microbial communities. Systems such as these form the core basis for regulatory screening tests, including the OECD Ready Biodegradability Tests (RBTs) used for hazard classification, environmental risk assessment and persistency assessments. The Registration, Evaluation, Authorisation and restriction of CHemicals (REACH) was introduced in 2007 to streamline existing legislation. REACH advocates the prioritisation of chemicals based on hazards including persistence and acknowledges the limitations associated with existing screening tests, suggesting a series of enhancements and modifications to improve their reliability. RBTs are notoriously highly variable, producing a large number of false negatives which result in unneccessary, costly, higher tier assessments of chemicals which are inherently biodegradable. REACH requires Persistency, Bioaccumulation and Toxicity (PBT) data for all new and existing chemicals produced in volumes greater than 100 tonnes per annum. Previous legislation only applied to "new" chemicals introduced to market after 1981, accounting for less than 4% of all commercially available products. High-throughput biodegradation screening tests (HT-BSTs) have the potential to identfiy those chemicals which pose the greatest risk to the environment from the vast number awaiting registration and prioritise them for more intensive assessment. This presentation will discuss the investigation of enhancements to RBTs, recommended within REACH guidance, to improve reliability and enable a more effective prioritisation on persistence. Ongoing efforts to translate this research into policy and the outcome of engagement activities between regulators, industry and academia will be reported. Recommendations will be delivered on the best practice for validating new biodegradation tests. This presentation will also consider the potential use of HT-BSTs within the existing regulatory framework.

503 Assessment of Ecotoxicity Data for Regulatory Risk Assessment

J.W. Green, DuPont / Applied Statistics Group; T.A. Springer, Wildlife International, Ltd.

There is understandable interest in driving the statistical evaluation of ecotoxicity data performed for regulatory risk assessment towards regression based estimates of effects concentrations (ECx) and away from hypothesis testing, e.g. NOEC. However, no single statistical approach can be applied to every response from every study of every type of experiment in ecotoxicology. Careful assessment is needed to determine which statistical approach is relevant and useful for specific situation. Ecotoxicity data includes continuous responses such as weight, length, and yield; quantal responses such as seedling emergence, hatching, and mortality; count data such as number of offspring or some fish sexual characteristics; histopaathology severity scores; and time-to-event responses, such as time to reach some developomental stage or time to hatch or swim up. Methods based on idealized data that ignore the complexities of dealing with these diverse endpoints and the difficult situations often encountered in real-world testing are detrimental to regulatory risk assessment and are poor science. Limit tests have only 1 treatment grouip. Endocrine disruption tests often have only 3 test concentrations. The latter determine whether evidence of endocrine activity exists, give an idea of what concentrations have that potential, and permit at best simplistic regression models and ECx estimates with wide confidence intervals. Avian reproduction and multi-generation tests have many endpoints with divergent statistical properties. Animal welfare considerations speak against the addition of more treatment groups. Non-target plant and fish early life-stage studies have 5 or more treatment groups to allow regression models. Even so, in well designed and well performed studies, the data sometimes do not support a useful mathematical model but do provide sufficient information to make sound regulatory decisions. Examples illustrate this and decades of experience and simulation studies show such examples are not rare. Statistical approaches for risk assessment must include careful consideration of the realities of the data that arise in guideline studies. Failure to do so can mislead and do a disservice to the ecotoxicity community. An illustrative example will be provided that also serves to illustrate recommendations from a recent SETAC Pellston Workshop on ways to improve the science of ecotoxicology.

Bringing Probabilistic Risk Assessment into Criteria Development

504 Selecting Target Risk Levels When Deriving Criteria Using Probabilistic Methods

P.D. Anderson, Arcadis US, Inc.; M. Buonanduci, ARCADIS

Human health water quality criteria (HHWQC) are established using assumptions for a variety of parameters. Those include several necessary to estimate possible exposure, at least one to estimate potential toxicity, and another to establish the target risk. When using a deterministic approach to develop HHWQC only a single target risk is necessary (e.g., $1x10^{-6}$ or $1x10^{-5}$). When probabilistic methods are used, multiple target risk levels can be used. For example, a specific percentile of the exposed population (or other statistical representation of the exposed population such as the arithmetic mean) can be targeted at a $1x10^{-6}$ excess lifetime cancer risk and a different percentile at a $1x10^{-5}$ excess lifetime cancer risk level. This presentation will summarize and compare the various target risk levels that have been proposed by various regulatory agencies. Another advantage of a probabilistic approach is that the level of protection afforded different segments of the population is transparent compared to the more commonly used deterministic approach. Even though an HHWQC derived using a deterministic approach is based on a specific target risk level (e.g., an excess lifetime cancer risk of $1x10^{-6}$ or a hazard quotient of 1.0), because of a combination of several conservative assumptions, one does not know what fraction of the population is expected to experience the target risk. This presentation will compare the levels of protection afforded different segments of the population based on various deterministically derived criteria.

505 Challenges associated with the use of probabilistic methods to develop human health WQC

S. Replinger, N. Lewis, J. Toll, N. Judd, Windward Environmental, LLC

We used a probabilistic approach as part of work to develop revised human health water quality criteria (WQC) for the Idaho Department of Environmental Quality. The use of a probabilistic approach has known advantages (primarily the opportunity to understand and account for the effects of inherent uncertainty or variability in parameter values on WQC) and disadvantages (primarily the increased level of effort and time required for calculations and to communicate with the public on the process). A challenge that is often not immediately apparent is the importance of understanding how changes in the distributions and percentiles of the population that are targeted can have different impacts on WQC for different chemicals (e.g., those with low vs high bioaccumulation factors). Along these lines, it is useful to consider how these probabilistically-developed criteria compare with criteria developed using standard deterministic methods. Despite these challenges, a probabilistic approach allows information regarding the resulting criteria and associated risks to be displayed visually and in the context of the population, which provides for a more transparent presentation of the results. In this presentation we will talk about the challenges we encountered, how we dealt with them, and what advice we'd offer to others who are interested in using a probabilistic approach to develop human health WQC.

506 Generating a Distribution of Usual Fish Consumption Rates for Applying PRA to Human Health Criteria

D. Essig, Idaho DEQ / Water Quality

Applying probabilistic risk assessment (PRA) requires distributions to describe the various inputs. One key exposure input to calculating human health criteria is the rate of fish consumption in the population to be protected. Unfortunately most available fish consumption surveys, particularly local and regional surveys, report rates for only selected points in a distribution, typically focusing on upper percentiles, e.g. 90th, 95th or 99th, ignoring the bulk of the distribution. This is insufficient for performing PRA. In addition, most available surveys report short-term fish consumption rates that are not representative of long-term AKA usual fish consumption rates. Chronic human health criteria should be based on long-term fish consumption behavior. Fish consumption rate surveys that develop the information necessary to estimate long-term fish consumption rates require unique survey methodology characteristics that mesh with processing methods, such as the National Cancer Institute method, designed to estimate long-term averages from short-term recall data. The presentation will describe the effort that was undertaken by Idaho to conduct a State-specific fish consumption survey and process the data resulting in a full distribution of long-term fish consumption rates appropriate for a PRA.

507 Evaluation of Fish Consumption Rates for use in Florida's PRA-based Human Health Criteria Derivation

K. Weaver, Florida Dept of Environmental Protection / Water Quality Standards

The fish consumption rate (FCR) in the target population or populations is a key exposure input to the calculation of human health criteria (HHC). In 2014, USEPA published FCRs for the U.S. population and selected subpopulations based on NHANES survey data for the period 2003 to 2010. Most relevant to the task of deriving HHC for Florida, EPA included trophic level 2, 3, and 4 FCRs for the Gulf Coast, Atlantic Coast, and Inland South subpopulation. Florida DEP used the three sets of FCRs to derive HHC for Florida based on a probabilistic risk analysis (PRA). Lognormal distributions were used to define all nine FCRs for use in the Florida PRA. These nine FCRs were used in conjunction with a custom distribution to generate Florida-specific FCRs. The custom distribution described the probability of an individual being a member of a given subpopulation, and was based on the proportion of the Florida population residing within each region. States and authorized tribes could potentially use a similar methodology, regardless of whether a probabilistic or deterministic approach is used, to generate more state-specific FCRs for purposes of their own HHC calculations as an alternative to the national default rates. Additionally, Florida DEP also investigated, through a sensitivity analysis, the effect of assuming correlations between fish consumption and body weight. It was determined that assuming no correlation resulted in the broadest distribution of population risks from the PRA. Increasing the assumed correlation between BW and FCR resulted in a narrower risk range, decreased the average risk, decreased the 90th percentile risk, and ultimately would increase the HHC value.

508 Relative Source Contribution: Capturing the Full Potential of Exposure Characterization in Criteria Development

K. Summerfield, Florida Dept of Environmental Protection

States are tasked with developing surface water quality standards that are protective of human health with regard to ingestion of aquatic organisms and surface water derived drinking water. One input variable important to the derivation of human health criteria for non-carcinogenic parameters is the relative source contribution (RSC), which is a quantitative input that accounts for exposures from sources other than water and fresh/estuarine fish and shellfish ingestion (i.e., inhalation, other dietary exposures, soil and dust ingestion). The RSC can be calculated through two methodologies, the percentage approach and the subtraction approach, both of which are constrained by a floor of 0.20 and a ceiling of 0.80 as defined by the USEPA's policy. The Florida Department of Environmental Protection (department) attempted to develop parameter-specific RSCs alternative to the default floor and ceiling values used by the USEPA as part of their 2015 HHC recommendations. For this assessment, the department followed the USEPA's Exposure Decision Tree for defining RfD Apportionment and the percentage method to attempt to develop RSCs that were more reflective of exposure experienced by Florida's population. The department attempted to derive RSCs for 10 specific parameters using a combination of Florida-specific, regional, and national level data. One of the greatest challenges was accurately assessing exposure given the sometimes large gaps in available exposure data for state and even regional exposure scenarios. Given, rigorous data requirements and potential uncertainty with capturing the full range of chemical specific exposures, the department concluded the RSCs for our HHC would be the same as EPA's national recommended default values. Exposures to non-carcinogenic compounds is variable and dynamic within a state's population. More rigorous state-specific exposure data that accurately captures exposure variability and inter- and intra-agency collaboration would help state-level environmental regulators to refine RSCs developed for deriving protective human health-based surface water quality standards.

509 The Development of Data-Driven Exposure Distributions for Risk-Based Soil Cleanup Criteria

L. Stuchal, Univ of Florida / Physiological Scienes; S. Roberts, Univ of Florida, Gainesville

There has recently been renewed interest in using probabilistic methods to derive both default and site-specific soil cleanup criteria for protection of human health. Along with this interest has come increasing demand for scientifically defensible exposure distributions. Unfortunately, the exposure data needed to adequately define variability distributions are often limited, and in some cases non-existent. When a distribution for an exposure variable is not available from an accepted source (e.g., EPA Exposure Factors Handbook), or the distributions from accepted sources are not applicable to a site, a risk assessor must determine whether there are data of sufficient quality and quantity available to create a distribution, or if the cleanup criterion is better served by using a point value. The goal of the probabilistic approach should be to increase the accuracy as well as the understanding of complex risk questions. Common problems include: 1) Determining when data are good enough to derive an exposure distribution; 2) Whether, or to what extent, to re-sample data from observations over a limited period of time to reflect the distribution expected with chronic exposure; 3) How to manage uncertainty effectively without invoking a full 2-dimensional probabilistic analysis; and 4) Determining whether sensitive subpopulations and lifestages need to be addressed separately from the general population. Practical examples illustrating each of these problems will be presented, and the related science policy decisions that must be made will be discussed.

510 Deriving Health Human Criteria for Florida using a Probabilistic Approach

K. Weaver, Florida Dept of Environmental Protection / Water Quality Standards

In May of 2016 the state of Florida proposed an update to its human health based water quality criteria. Human health water quality criteria are established at the highest concentration of a pollutant in water that protects against a significant risk of adverse health effects over a lifetime. The criteria should provide adequate protection to the general population over a lifetime of exposures and to special subpopulations (those with high water or fish intake rates or higher sensitivities) that have an increased risk of receiving a dose that would elicit adverse effects. The state's proposed criteria were based, in part, on EPA's 2015 recommendations, but were derived using the probabilistic risk approach (PRA) and Florida-specific information. Florida's approach used national recommended toxicity factors and relative source contributions, and Florida-specific bioaccumulation factors as point measurements in the calculations. Drinking water rate, body weight, and regional fish consumption rates were entered into PRA analysis as distributions. Criteria were set at levels necessary to attain a priori risk management goals. For carcinogens, protective criteria were derived by iteratively conducting the probabilistic risk analysis until the target risk of 10^{-6} at the arithmetic mean of the risk distribution was attained. Additionally, the resulting risks associated with the calculated criteria were assessed to ensure that none of the criteria values produced risks exceeding 10^{-5} at the 90th percentile or 10^{-4} at the extreme upper end of the distribution (e.g., 95th, 99th percentiles, and subsistence fishers). For non-carcinogens, the criteria were derived by running the probabilistic analysis (Monte Carlo) to calculate surface water criteria, and then setting the criterion at the 10th percentile of the Monte Carlo calculated results. Florida's experience with PRA shows that PRA allows regulatory agencies to more accurately assess risks to the target population and sensitive sub-populations than the deterministic alternative. However, Florida's experience also shows that use of PRA adds complexity to an already complex issue, which can hinder public support.

511 Inclusion of Physiological, Metagenetic and Genetic Susceptibility Distributions in Exposed Human Populations for Probabilistic Risk Assessment

L.E. Fink, Waterwise Consulting, LLC

The U.S. Environmental Protection Agency (EPA) is responsible for ensuring the protection of the water quality of the nation's waters by reviewing and approving or rejecting and issuing for each state an enforceable Water Quality Standard (WQS) for each priority substance or mixture in each pollutant category for each fresh and salt water body based on a set of narrative and numerical Water Quality Criteria (WQC) to protect various human uses of those waters. Unless affirmatively demonstrated otherwise by a Use Attainability Analysis, all waters are assumed to be able to support and are protected for fishable and swimmable uses by humans. This requires that the fish and shellfish populations supported by those waters can be safely consumed by humans. A WQC to protect human health is derived by translating a reference dose (RfD) or cancer potency factor (CPF) with an ample margin of safety into an equivalent water concentration based on a set of reference human exposure assumptions. The EPA guidance for WQC derivation uses national average exposure assumptions, but states may choose state average exposure assumptions if they are more protective of human health than the national average exposure assumptions. The derivation of WQC using probabilistic risk assessment (PRA) generally focuses on the probability distributions functions (pdfs) for body weight, eating rate as a function of age, sex, and body weight, the proportions of various fish and shellfish species in the diet by age, sex, ethnicity, and region, and contaminant concentrations in each fish and shellfish species, without or with conditional influences of size or age, while holding the RfD or CPF constant. This is a one-sided approach to PRA. To comport with the recommendations of the National Academy of Sciences to EPA on the regulatory applications of risk assessment, this presentation considers the other side of the equation: the known distributions of physiological, metagenetic, and genetic susceptibilities to carcinogenic toxic effects endpoints by gender, race and country of origin and those inferable from the cumulative pdfs for age of onset. This is a more rigorous way to derive an ample margin of safety (AMOS) to protect the representative most sensitive citizen. This will avoid a class action lawsuit based on government-sanctioned minority discrimination and ensure an AMOS for states that use the implicit approach to calculate Total Maximum Daily Loads for water quality-impaired waters.

Advances in Exposure Modeling: Bridging the Gap Between Research and Application

512 Lifetime Exposome Modeling

O. Jolliet, Univ of Michigan

"Tell me when and where you lived and worked, what you consumed and ate… and I will tell you who you are (your exposome!). In the era of high-throughput biology and biomedicine, genome-wide associations need to be complemented by exposome wide associations, thus emphasizing the importance of developing high-throughput exposure strategies. Complementary to biomarker oriented approaches, this study explores how recent databases enables us to trace and predict the lifetime exposure of individuals to thousands of chemicals based on the time evolution of their home location, economy sector workplace, consumption patterns, and eating habits. We use the measured concentrations from the OSHA Chemical Exposure Health Database to characterize exposure to 250 chemicals per blue collars hour worked in 880 NAICS industrial sectors. These occupational exposures are confirmed by significantly higher biomarker levels measured in NHANES for blue collar workers compared to the rest of the population. Coupling of household product databases with near-field exposure models and near-field modeling of product intake fractions (PiFs) provide first estimate of ranges of exposure to cosmetics, building material or other consumer products. A spatialized multiscale multimedia model (Pangea) provides improved resolution to better assess environmental and food contaminants. This presentation will show how these recent developments in exposure data and modeling for ambient (food, drinking water), occupational and consumer product environment enables us to predict lifetime exposure across multiple chemicals. The approach will be illustrated through a case study in Michigan that has enabled us to determine the lifetime dioxin exposome of hundreds of habitants in a contaminated area, based on their dioxin blood measurements using a phamacokinetic based approach. The study identifies as major factors of influence the number of years lived in the contaminated area, the distance to the local incinerator and their consumption of potentially contaminated food. On a wider scale, we will finally shortly discuss how the exposome relates to the age response of multiple biomarker exposures measured in NHANES.

513 Spatial improvements leading to advances in down-the-drain chemical exposure modeling with iSTREEM® 2.0

R. Vamshi, K.E. Kapo, C.M. Holmes, Waterborne Environmental, Inc.; M.L. Sebasky, Waterborne Environmental; P. DeLeo, D. Ferrer, American Cleaning Inst

iSTREEM® ("in-stream exposure model") is a publically-available web-based model (www.istreem.org) that estimates down-the-drain chemical concentrations in waste water treatment plant (WWTP) effluents, drinking water intakes (DWI), and in streams impacted by domestic waste water effluent across the continental U.S. and a number of watersheds in Canada under mean annual and low-flow (7Q10) conditions. Major upgrades to the model's underlying data were made by incorporating higher-resolution and more current spatial datasets, leading to the release of iSTREEM® 2.0. The presentation provides an overview of the development of iSTREEM® 2.0, including how specific data needs were addressed and major assumptions considered in developing the model. The model river network was upgraded to a higher-resolution hydrologic dataset based on the USEPA and USGS NHDPlus version 2, which constitutes about 228,000 river segments totaling 243,000 river miles across continental U.S. For all the river segments, estimated mean annual flows were derived from NHDPlus, but low flows (7Q10) were exclusively developed for iSTREEM® 2.0. WWTP and associated facility level information were derived from the most recent USEPA Clean Watershed Needs Survey 2012 dataset, which includes about 13,000 facilities accounting for a total population of 175 million and effluent flow of 25,000 MGD. WWTP facilities were associated to the river network by applying techniques developed by USEPA. Enhancements to the model algorithm has made it possible to run the simulations efficiently and examine chemical exposure at a detailed spatial scale over a large geography (river basins or U.S.). Model simulation results are accessible to users in tabular (MS Excel) and spatial (MS Access) data formats for easy interpretation and further customization. A case study comparing prior version of the model and latest iSTREEM® 2.0 for the U.S will be presented to examine the impact of recent upgrades to model results – with focus on the national distribution of flows (mean and 7Q10's), effluent PEC's, water use, dilution factors, and receiving surface water PEC's. The developments to iSTREEM® improves its utility as a tool to support environmental exposure assessments by a variety of users for environmental risk assessments across multiple commodity groups (personal care products, pharmaceuticals, food additives, pesticides, etc.).

514 Impacts of Hydroelectric Power Expansion on Methylmercury Exposures of Northern Indigenous Communities

R. Calder, A.T. Schartup, Harvard T.H. Chan School of Public Health / Dept of Environmental Health; M. Li, Harvard. T.H. Chan School of Public Health / School of Public Health; A.P. Valberg, USEPA; E.M. Sunderland, Harvard Univ / School of Engineering and Applied Sciences

Renewable energy plans across North America depend on untapped hydroelectric resources across Northern Canada. Hydroelectric reservoirs accelerate production of methylmercury (MeHg) resulting in enhanced accumulation in fish and wildlife and pose risks to indigenous populations that rely on local foods. The magnitude of MeHg increases in local food webs is affected by the quality and quantity of organic carbon in the flooded reservoir. We use soil organic carbon data and the watershed characteristics of planned hydroelectric development areas across the Canadian North to develop a screening model for peak MeHg increases expected in each system. Over 90% of new capacity impacts the traditional hunting environments of local indigenous populations. We use extensive biogeochemical data from the region surrounding the Lower Churchill River in Labrador, Canada and human exposure information from three local Inuit communities to quantify increase in MeHg exposure due to flooding associated with hydroelectric facilities. More than half of the total exposure increases among this population are expected to fall on individuals who are in the top 10% of exposure levels prior to flooding. Among the Labrador Inuit, hydroelectric development is expected to roughly double the number of individuals exceeding EPA and Health Canada reference doses for MeHg. However, there may be as few as 20% more individuals exceeding these thresholds if topsoil is removed, as this is the main reservoir of labile organic carbon.

515 Assessing Exposure and Ecotoxicological Impacts in the State of Qatar

C.S. Warren, S. Saeed, ExxonMobil Research Qatar / Environment and Water Reuse Program; S. Prakash, V. Kolluru, Environmental Resources Management

Exposure science and ecological risk assessment continues to develop and evolve in the State of Qatar. Efforts have been taken to utilize appropriate tools and methodologies developed in North America, Europe as well as other relevant hot and arid countries. In many cases, however, the extreme environmental conditions (e.g., high water temperature and salinity) and differing ecosystem structures (e.g., warm water species such as corals) require adaptation of the typical approaches and tools. At EMRQ we are developing an integrated approach to assess discharges, fate, exposure and ecotoxicological impacts in the marine environment. Our initial focus is on the Liquefied Natural Gas (LNG) industry which is important to Qatar and other global regions; and increasingly so for North America, both in the United States and Canada. We have worked closely with our industry partners to robustly quantify discharges and model transport/fate using a spatially and temporally resolved hydrodynamic model combined with laboratory-based data. We also incorporate measured field data for evaluation of these tools and to assess ecological impacts. In the laboratory we have developed ecotoxicology protocols for reference species applicable to Qatari waters as well as dose-response relationships across various trophic levels and key contaminants. Current efforts include the continued development and application of an EcoRisk modeling framework which ties together these multiple components and environmental stressors into a tool that can be used by industry and government to assess ecological risk related to current discharge and exposure scenarios and also for future predictive and planning purposes. This presentation will include recent updates to the modeling framework and application to an environmentally-relevant case study.

516 Assessing the influence of secondary organic versus primary carbonaceous aerosols on long-range atmospheric PAH transport

C. Friedman, Maine Maritime Academy / Ocean Studies; N.E. Selin, MIT; J. Pierce, Colorado State Univ

We use the chemical transport model GEOS-Chem to evaluate the hypothesis that atmospheric polycyclic aromatic hydrocarbons (PAHs) are trapped in secondary organic aerosol (SOA) as it forms. Trapping of PAHs in SOA would prevent evaporation to the gas phase and protect PAHs from degradation; this could potentially explain why model-estimated PAH particulate fractions are frequently lower than those observed in the atmosphere. We test the ability of three different partitioning configurations within the model to reproduce observed total concentrations in the midlatitudes and the Arctic as well as midlatitude gas–particle phase distributions. The configurations tested are (1) the GEOS-Chem default configuration, which uses instantaneous equilibrium partitioning to divide PAHs among the gas phase, a primary organic matter (OM) phase (absorptive), and a black carbon (BC) phase (adsorptive), (2) an SOA configuration in which PAHs are trapped in SOA when emitted and slowly evaporate from SOA thereafter, and (3) a configuration in which PAHs are trapped in primary OM/BC upon emission and subsequently slowly evaporate. We also test the influence of changing the fraction of PAHs available for particle-phase oxidation. Trapping PAHs in SOA upon formation and protecting against particle-phase oxidation (configuration 2) better matches observed remote concentrations compared to our default configuration (configuration 1). However, we find that simulating adsorptive partitioning to BC is necessary to reproduce the magnitude and seasonal pattern of gas–particle phase distributions. Thus, the last configuration (configuration 3) results in the best agreement between observed and simulated concentration/phase distribution data. The importance of BC rather than SOA to PAH transport is consistent with strong observational evidence that PAHs and BC are co-emitted.

517 Sorptive capacities of leaves for organic pollutants measured using passive dosing: Lipid characterization and passive dosing experiments

D.J. Bolinius, M. MacLeod, A.H. Kierkegaard, F. Iaderasta, J. Holmbäck, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry ACES; A. Jahnke, Helmholtz Centre for Environmental Research – UFZ / Cell Toxicology

Leaves play an important role in the cycling of semi-volatile organic pollutants as a result of their large surface area and lipid-rich cuticle. Semi-volatile pollutants that are scavenged from the atmosphere by leaves can be transferred to the soil through the shedding of waxes and litter (Horstmann and McLachlan 1998), where they will either be trapped or re-released to the atmosphere upon decomposition of the plant material. Most multimedia chemical fate models use either an octanol-equivalent model for leaves (e.g., BETR, MacLeod et al. 2011) or reported values from the literature for specific species under the assumption that all plant species have the same sorptive capacity (e.g., CoZMo-POP, Wania et al. 2006). It has been shown, however, that the sorptive capacities of different plant species can vary considerably (Kömp and McLachlan 1997). In this study we modified an existing passive dosing system to measure the sorptive capacities of the solvent extractable organic matter (EOM) of a wide variety of leaves including; Norway spruce, douglas fir, red oak, common reed, European beech, rhododendron and European alder. Lipids present in the EOM were characterized by ^{1}H-NMR spectroscopy in combination with LC-MS and LC-ELSD. While the previous passive dosing setup via headspace reached equilibrium for cyclic volatile methylsiloxanes within 9 days, the kinetics of equilibration were slower for chlorobenzenes and low-chlorinated PCBs. Introducing a fan into the lid of the passive dosing system enhanced the kinetics such that equilibrium could be reached for chlorobenzenes, and estimated by extrapolation for several PCBs. Our measurements provide sorptive capacities of EOM from a range of species and provide additional data about variability between plant species that can be compared with existing literature data to support improved parameterization of multimedia models.

518 Characterizing the Health Impact of Chemicals from Use of Dishwasher Detergents

V. Nguyen, Univ of Michigan / Dept of Computational Medicine and Bioinformatics Dept of Environmental Health Sciences; O. Jolliet, Univ of Michigan

Dishwasher use is a common cleaning activity and can lead to detergent residues remaining on the dishes as well as being emitted during a run. The purpose of the current study is to 1) determine the mass intake and uptake of the chemicals in dishwasher detergents as well as 2) quantify their impact on human health by calculating the characterization factor. Sodium carbonate, pentasodium tripolyphosphate, formaldehyde, sodium perborate, and propylene glycol were selected for study based on their potentially harmful properties. The residual mass of the chemicals on the dishes was calculated by using the air to water partition coefficient. The mass uptake was estimated by taking 30% of the residual mass. A mass balance that models the dynamics in the kitchen and the rest of the apartment was developed in order to determine the cumulative mass of the chemicals released during a run of the dishwasher, so that a mass intake can be estimated. The body burden is estimated as the total mass of the chemical intake and uptake. Only the characterization factor due to ingestion was calculated due to data availability in the LD50 for ingestion, which is the dose at which death is observed in 50% of the population. Finally, seconds of life lost was calculated using data pertaining to percent composition and assumptions of 70 years in a human lifetime and the use of a dishwasher 35 times in a year. Of the studied chemicals, the more volatile chemicals such as sodium carbonate, propylene glycol, and formaldehyde resulted in a higher intake and overall body burden, while the more hydrophilic chemicals such as pentasodium tripolyphosphate and sodium perborate resulted in a higher uptake but a lower body burden. The amount of lifetime lost due to ingestion is ranked as follows: propylene glycol (88 s), sodium carbonate (0.58 s), formaldehyde (0.44 s), pentasodium tripolyphosphate (0.33 s), and sodium perborate (0.12 s). The analysis shows that chemicals with a low LD50 and high percent composition will result in a high negative health impact, which will be helpful to develop a ranking of detergent chemicals based on high exposure and high impact.

519 A Novel Spatial Aquatic Food-Web Bioaccumulation for Bridging Field Study Data and Regulatory Decision Making

F. Gobas, Simon Fraser Univ / School of Resource and Environmental Management; J. Kim, Dow Corning Corporation / Health and Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting / Dept of Physical Environmental Science, Dept of Pharmacology and Toxicology; D.E. Powell, Dow Corning Corporation / Environmental Sciences; R.M. Seston, K.B. Woodburn, Dow Corning Corporation / Health and Environmental Sciences

Increasingly, the value of field data is being recognized in the regulatory evaluation of the bioaccumulation properties of commercial chemicals as laboratory measurements of the bioconcentration factor (BCF) and the octanol-water partition coefficient (Kow) regularly fail to identify chemicals of concern. This study develops, tests and applies a novel, spatially based food-web bioaccumulation model to support empirical monitoring programs and the application of field monitoring data for making regulatory decisions regarding the bioaccumulation behavior of chemicals. The study reports on (i) the main features of the spatial food-web bioaccumulation ("Multi-Box AquaWeb"); (ii) its testing through a comparison of model estimated and measured TMFs for persistent PCB congeners and biotransformable phthalate esters in a marine aquatic food-web; (iii) the application of the model for making assessments of the bioaccumulation behavior of chemicals in food-webs. A model sensitivity analysis shows that species sampling designs that ignore the presence of concentration gradients can misidentify the distribution of chemicals in food-webs. The study shows that accurate measurements of trophic distribution of chemicals are strongly dependent on the characterization of spatial concentration gradients in the study area. Also, an accurate assessment of the food-web distribution of chemicals and the frequently used bioaccumulation metric Trophic Magnification Factor (TMF) are sensitive to concentration gradients and species migration patterns. The Multi-Box AquaWeb model is shown to be a useful tool in the assessment of the food-web distribution and also the TMF of chemicals, specifically in anticipating the effect of spatial concentration gradients on the determination of the TMF; guiding species collection strategies in TMF studies; and interpreting the results of field bioaccumulation studies in study locations that are subject to spatial differences in chemical concentration.

Canadian Oil Sands: Advancing Science in Chemical and Toxicological Characterization, Reclamation and Monitoring – Part 1

520 The toxicity of diluted bitumen to four fish species

S.J. Wallace, B.N. Madison, Royal Military College / Chemistry and Chemical Engineering; F. Alsaadi, Queens Univ / Biology; J. Adams, M. Sereneo, D. McDonnell, P.V. Hodson, Queens Univ / School of Environmental Studies; V.S. Langlois, Royal Military College of Canada / Dept of Chemistry and Chemical Engineering

The transport of diluted bitumen (dilbit) from Alberta's oil sands through pipelines occurs across many watersheds in Canada. However, little is known about its potential toxicological impact on different fish species in case of a spill. Embryos of four fish species were exposed to two predominant dilbit blends, Access Western (AWB) and Cold Lake (CLB): Japanese medaka (Oryzias latipes), fathead minnow (Pimephales promelas), yellow perch (Perca flavescens), and rainbow trout (Oncorhynchus mykiss). Static daily-renewal exposures were conducted through water-accommodated fraction (WAF) and chemically enhanced fractions (CEWAF, Corexit®9500 as dispersant) from fertilized eggs until hatch. Hatched fish were assessed for malformations and gene expression analysis. GC-MS and fluorescence methods revealed that the array of polycyclic aromatic hydrocarbons (PAHs) was similar between blends, the proportion of individual alkyl PAHs (APAHs) varied between WAF and CEWAF. Exposure to higher concentrations of dilbit increased the prevalence of malformations in all four species, but with species-specific developmental malformations, suggesting that some species are more sensitive to chronic dilbit exposure than others or accumulate more hydrocarbons. Related oils and compounds have shown to induce malformations by increasing oxidative stress. Dilbit has also been found to increase oxidative stress in fish species. Cytochrome P450 (cyp1a) mRNA levels were more than 10-and 100-fold higher in dilbit-exposed medaka and rainbow trout, respectively. Gene expression patterns observed for other biomarkers involved in phase I detoxification (ahr, arnt) and oxidative stress (cat, gpx, gst, gsr, g6pdh, hsp70)pathwayssuggest that fish respond to PAH toxicity in a concentration-dependent and species-specific manner. Comparing responses among fish species allows for development of a suite of biomarkers that indicate sensitivity of economically- and environmentally-important fish species to dilbit toxicity.

521 Review of methods for oil toxicity testing and implications for assessing dilbit toxicity

J. Adams, R. Brown, P.V. Hodson, Queens Univ / School of Environmental Studies

The production of diluted bitumen (dilbit) in Canada may soon exceed the transportation capacity of existing oil pipelines, which has stimulated several proposals to expand or build new pipelines to transport dilbit across Canada. Ecological risk assessments (ERAs) for potential dilbit spills have relied heavily on widely-used toxicity test methods with conventional crude oil to assess the risks of dilbit spills to aquatic species. Dilbit toxicity tests require gradients of dilbit concentrations in water, prepared from mechanical and chemical dispersions of oil in water. Methods for preparing Water Accommodated Fractions (WAFs) and Chemically Enhanced Water Accommodated Fractions (CEWAFs) have been developed by CROSERF (Chemical Response to Oil Spills: Ecological Effects Research Forum) and are widely used in toxicity testing. These standardized protocols were developed to allow the comparison of dispersant and dispersed oil toxicity among types of oil, dispersants, and aquatic species. The assumption is that the methods are appropriate for estimating dilbit toxicity and that the data will meet the needs for site-specific (i.e., realistic) ERAs. However, tests of the toxicity of different dilbit products and hydrocarbon analyses of test solutions have demonstrated the need for modifications to the standardized method. The unique physical and chemical properties of dilbit, particularly their rapid weathering, high viscosity, and adhesiveness, affect the extent to which the components of dilbit are incorporated into test solutions by the standard methods. There has been insufficient investigation of how the physical and chemical characteristics of dilbit products interact with procedures for solution preparation to affect the concentration and composition of test solutions and the outcome of toxicity tests. We will review the existing methods for preparing, analyzing, and testing the toxicity of WAFs and CEWAFs of dilbit to aquatic biota to assess their suitability to estimate the toxicity risks of dilbit spills.

522 Potential sources of methylmercury in snowpacks and tailings ponds of the Athabasca Oil Sands Region, Alberta, Canada

C. Willis, V. St.Louis, Univ of Alberta / Biological Sciences; J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; K. St Pierre, Univ of Alberta / Biological Sciences; C. Dodge, Univ of Alberta

Methylmercury (MeHg), a neurotoxin that biomagnifies through food-webs, is a contaminant of concern in the Athabasca Oil Sands Region (AOSR) of Alberta, Canada. Previous research demonstrated that winter loadings of MeHg in snowpacks increased with proximity to the major developments (0.66 ng/m^2 200 km away to 15.4 ng/m^2 nearby) and that the majority of the MeHg was particle bound (pMeHg) (Kirk et al. 2014, ES&T, 48, 7374). To determine if the pMeHg was produced by methylation of inorganic Hg (HgII) within snowpacks, we performed a series of in-situ incubation experiments using stable isotopes of HgII at four sites known to vary in pMeHg loadings. Those experiments demonstrated that there is net methylation of Hg(II) in snowpacks; however, rates were very low (k_m = 0.001 – 0.004/d), suggesting that in situ snowpack methylation is not a major source of MeHg to snowpacks. We also quantified concentrations of MeHg on particles themselves, as well as examined particle size, morphology, and elemental composition. Interestingly, although MeHg snowpack loads increased with proximity to the major development area, pMeHg concentrations themselves significantly decreased with proximity (0.53 (near) –10.35 (far) ng/g; R^2= 0.64, p< 0.0001). These results suggest that a large mass of particles is deposited to snowpacks near the major developments; these particles are not rich in MeHg relative to particles found further away. Although little is known about the sources of pMeHg to AOSR snowpacks, it was recently suggested fugitive petcoke dust may be an important source of wind-blown PAH contaminant deposition to the region (Zhang et al. 2016 ES&T, 50, 1711). MeHg concentrations in three petcoke samples were examined and were lower (0.02 ± 0.01 ng/g) than on particles in snowpacks (2.47 ± 0.56 ng/g), suggesting that petcoke is not an important source of MeHg to the region. Another potential source of MeHg to AOSR aquatic ecosystems is tailings ponds (TP), which may seep into the Athabasca River and tributaries. We therefore quantified concentrations of MeHg in TP water of four different ponds of varying size, age, and chemical composition. The four TP varied greatly in MeHg concentrations, from very low concentrations of 0.01 ng/L to relatively high concentrations of 0.50 ng/L. Potential factors driving MeHg sources in TP are being examined, including pH, nutrients, oxygen, and DOC, all of which are known to affect MeHg production in aquatic ecosystems.

523 Spatial and Temporal Variation of Trace Metals in the Athabasca Oil Sands Region Based on Dated Lake Sediment Cores

C. Cooke, Alberta Environmental Monitoring, Evaluation and Reporting Agency; J.L. Kirk, D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; M. Evans, Environment and Climate Change Canada; X. Wang, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A. Gleason, J. Keating, Environment and Climate Change Canada

Assessments of the environmental impacts of the Athabasca oil sands development in northeastern Alberta have noted the lack of long-term data and limited information on pre-impact conditions. The extraction of bitumen from the Athabasca oil sands – one of the largest energy deposits in the world – began in earnest during the 1960s. A steady increase in production has accelerated the release of environmental contaminants, including various trace elements known to be toxic at low concentrations. Of particular environmental concern are the atmospheric loadings and distributions of trace elements associated with oil sands surface-mining and processing activities. Establishing the magnitude of change in the regional deposition of trace elements requires knowledge about conditions prior to the onset of large-scale extraction activities. Here, we will present results from 23 dated sediment cores from lakes located across the Athabasca oil sands region. Lakes were cored between 2011 and 2013 as part of the Joint Canada-Alberta Oil Sands Monitoring Program. Lakes with small, undisturbed watersheds were targeted in order to better reconstruct atmospheric inputs through time. We categorized each sites based on its distance from the geographic center of mining operations as being near- (50 km). We observed increasing inputs of vanadium and lead, two key indicators of oil sands development, to near- and mid-field lake sediments after mining operations began in the 1960s. Other metals (e.g., Hg) are characterized by earlier increases that are of similar magnitude among near-, mid-, and far-field sties, suggesting non-oil sands sources are more important.

524 An omics platform for the advancing of the environmental monitoring program in the Alberta oil sands region

A. Pereira, J. Pretorius, Alberta Innovates Technology Futures; L. Fu, B. Leung, AEMERA

In Northern Alberta, Canada, the production of bitumen from open-pit oil sands mining requires 2-3 barrels of water for every barrel of bitumen produced. Large volumes of oil sands process-affected water (OSPW) are stored in large tailings ponds so that it can be recycled into the extraction process. Despite the water recycling efforts (80 to 95%), in 2012 the use of fresh water was approximately 187 million m^3 (Canadian Association of Petroleum producers 2013); which is about 40% of the City of Toronto's annual water consumption. Moreover, due to the large water volume used daily, tailings ponds are growing in volume and number, and in 2011 covered approximately 170 km^2. There are concerns that OSPW leaches from tailings ponds into groundwater, or into river water, but proving this is complicated by the fact that natural water can contain many of the same chemicals as OSPW (e.g. Naphthenic acids). As a consequence, there is an ongoing need to improve environmental monitoring in the Athabasca region. Due to the complex nature of OSPW, an 'omics' approach to interrogate and interpret the large volume of data generated during the analysis of water samples by LC-Orbitrap-MS (operated with resolution power from 120K to 480K) was developed. The approach was applied to river water samples collected in the Alberta oil sands region. Results indicate that the approach extends monitoring capabilities from the "classical" naphthenic acids to the inclusion of ionisable compounds with molecular formula $C_cH_hN_nO_oS_s$. It has recently been postulated that compounds belonging to this general class contribute to the toxicity of OSPW. Thus, obtaining information about these compounds will enable regulators and environmental managers to improve monitoring and reclamation programs in the region.

525 A spatial and temporal assessment of contaminants in otoliths from the Lower Athabasca region

M. Poesch, N. Sinnatamby, Univ of Alberta / Renewable Resources; Y. Luo, G. Pearson, Univ of Alberta; M.W. Donner, W. Shotyk, Univ of Alberta / Renewable Resources

Potential environmental impacts of anthropogenic water use and contaminant emissions from oil sands development in the Lower Athabasca region has gained public and scientific attention. Fish health and contaminant loads are of particular interest because of perceived increases in fish deformities, and complaints about unnatural tasting fish since the onset of industrial development in the region. Although the presence of bitumen-associated contaminants has typically been attributed to industrial activity within the public and media, the relative roles of natural seeps, which contribute salts and complex dissolved organic mixtures to the watershed, and industrial emissions of similar compounds are largely unknown. The aim of this research is to assess water quality along the Athabasca River, and its impact on fish. Trout perch, Percopsis omiscomaycus, were sampled from 31 sites along the Athabasca and Clearwater Rivers in the Fort McMurray region. The sites were categorized as reference sites, and potentially contaminated sites from either anthropogenic or natural sources. We used laser-ablation inductively coupled mass spectrometry (LA-ICP-MS) to analyse otoliths to assess spatial and temporal variation in concentrations of a large suite of elements. The suite of elements includes some present in water exclusively in ionic form (e.g. Na, Rb, Ca, Sr), some present in colloids (e.g. Al, Sc, Th), nutrients (e.g. Fe, Se), some known to be enriched in bitumen (e.g. V, Ni, Mo), and some potentially toxic "heavy metals" (e.g. Ag, As, Cd, Pb, Sb, Tl). In general, many of the elements included in this study were found in low concentrations and were challenging to measure. Concentrations may reflect the chemical characteristics of the elements (e.g. affinity for carbonate mineral formation) or biological function. Results of this study demonstrate whether and how potential contaminants and other elements that are present in varying concentrations along the stretches of river are present in fish inhabiting the river.

526 Fish Health in the Alberta Athabasca Oil Sands, Developing Baseline to Assess Future Change

M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate Aquatic Contaminants Research Division; H. Keith, Hatfield Consultants; G. Tetreault, Enviroment Canada / Water Science and Technology Directorate; C.J. Bennett, Environment Climate Change Canada / Water Science and Technology Directorate; M. Evans, Environment and Climate Change Canada; T. Clark, Environment Climate Change Canada / Water Science and Technology Directorate; R. Frank, Environment and Climate Change Canada / ACRD; J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division

As part of the Joint Canada-Alberta Oil Sands Monitoring Program (JOSM), fish health within the Athabasca River watershed is being evaluated using methods developed for the Canadian Environmental Effects Monitoring Program. Fish health assessments will be integrated with assessments of benthic invertebrate communities, water and sediment chemistry, toxicology and atmospheric deposition in order to evalute ecosystem health. Data will provide a baseline against whcih future changes in fish health will be judged and compared to historical studies to assess change. Information will be used to develop site-specific cumulative effects monitoring approaches and will contribute to the development of better predictive capabilities for oil sands environmental impact predictions. Additional physiological endpoints are also being evaluated in fish from these sites in attempts to better understand mechanisms of action and potential source identifiaction of changes. On the Athabasca mainstem, white sucker have been selected as a large bodied sentinel species and trout perch as a small bodied species. Walleye are also being used for fish contaminant monitoring within the mainstem as they are consumed by resident populations. Where possible our study design collects fish at sites off the oil sands deposit (reference), at sites within the natural deposit but upstream of development and at sites downstream of development so that fish are either unexposed, exposed naturally or exposed to a combination of natural and anthropogenic inputs. Design of the program is to look for differences, confirm the differences and to use developed critical effect sizes to make decisions on steps forward. We will discuss fish studies to date with recommendations on how to proceed with the monitoring program moving forward.

527 Where do we go from here? Lessons from 25 years of Environmental Effects Monitoring (EEM) in Canada

T. Arciszewski, K.R. Munkittrick, COSIA

Monitoring shouldn't be difficult, but it is. And despite the difficulty of detecting and attributing cause, its importance has not diminished. A Federal EEM program was developed in the early 1990s for determining the efficacy of guidelines regulating the discharge of pulp mill effluents and (later) metal mines. After 25 years of developing consistent monitoring for large industries in Canada, many lessons can be gleaned for application in other areas. Although implicitly included in the development of EEM, Adaptive Monitoring has recently been formalized and offers an opportunity to develop and operate meaningful monitoring programs. An Adaptive Monitoring program is characterized by hypothesis-driven questions linked to conceptual effect pathways, evolving through trigger-driven feedback loops that connect tiers of monitoring. Triggers describe background variability and notify us when an unexpected change has occurred. Tiers represent an escalation of effort or attention towards those unexpected observations. Tiering allows the simultaneous operation of both broad non-specific tools and targeted sampling. Other recent improvements include the development of adverse outcome pathways as simple expected effects pathways. A logical question in an AOP process as applied in monitoring is: if we see a change in some physiological indicator, and the difference matters, what will change next? These ideas and a more detailed discussion on improving environmental monitoring will be presented.

Thinking Outside the Laboratory Box: An Ecological Approach in Tackling Ecotoxicological Problems

528 Exploring the intersection between ecosystem ecology and ecotoxicology: Developing the field of ecosystem toxicology

E. Rosi-Marshall, Cary Inst of Ecosystem Studies; M. Hornberger, USGS / Water Resources Division; E. Bernhardt, Duke Univ / Biology; W.H. Clements, Colorado State Univ / Fish Wildlife and Conservation Biology; D. Walters, USGS / Fort Collins Science Center

Exploration of ecosystem-level phenomena within the field of ecotoxicology have been somewhat limited in the past, but this line of inquiry is receiving increasing attention from scientists across multiple disciplines. We convened a special session at SETAC 2015 to explore the intersection between ecosystem ecology and ecotoxicology and to take the initial efforts to delineate what we have identified as a new subdiscipline: ecosystem toxicology. This session highlighted that combining environmental chemistry, ecotoxicology, and ecosystem science is necessary to better understand contaminant exposures and their effects on the environment. Ecosystem toxicology provides a new platform for investing the influence of contaminants in the environment. We propose that ecosystem toxicology could focus on 4 broad themes: 1) Exploring both how ecosystems influence how chemicals behave once they enter the environment, which relies strongly on collaboration between environmental chemists and ecosystem scientists. 2) The influence of chemicals on ecosystem functions, e.g. primary and secondary production, nutrient cycling, etc. This requires investigation by ecosystem ecologists who typically measure these variables in ecosystems. 3) The flux of contaminants through ecosystems, which requires combining ecological measurements, e.g. organic matter fluxes, with measures of chemical concentrations in biotic and abiotic compartments. 4) That context, from the species to the ecosystem, is fundamental to the influence of contaminants in the environment and that responses to contaminants should be studied across a range of species and environmental contexts. We argue that these areas are ripe for collaboration among toxicologists, environmental chemists, and ecosystem scientists and that these collaborations will provide new insights into the influence of contaminants on the environment.

529 Aquatic agrochemical pollution increases the risk of human schistosomiasis

J.R. Rohr, Univ of South Florida / Dept of Integrative Biology; A. Arakala, Monash Univ; D.J. Civitello, Univ of South Florida / Dept of Integrative Biology; G. De Leo, Stanford Univ; M. Gambhir, Monash Univ; N. Halstead, Univ of South Florida; C.M. Hoover, Univ of California Berkeley; S.A. Johnson, Univ of Florida; T. McMahon, Univ of Tampa; K. Parker, Univ of South Florida; T. Raffel, Oakland Univ; J. Remais, Univ of California Berkeley; S.H. Sokolow, Stanford Univ

Agrochemical use is predicted to increase 2- to 4-fold by 2050 to satisfy the food demands of growing human populations, with much of this increase expected to occur in tropical and sub-tropical developing countries. At the same time, the expansion of irrigation-related agricultural activities has already been associated with the emergence of schistosomiasis, a neglected tropical disease caused by a flatworm parasite that is transmitted from aquatic snails to humans. This association is multidimensional and key pathways have been poorly characterized, including the role of agrochemical pollutants, which might increase numbers of the snail intermediate hosts by affecting the algal food resources and predators of snails. In a series of field mesocosm experiments, we show that a common insecticide, herbicide, and fertilizer, individually and as agrochemical mixtures, increased population densities of infected snails, thereby increasing production of parasite infective stages. Our mesocosm results showed that some agrochemicals caused a "bottom-up effect," increasing the growth of the algae snails eat, and others a "top-down effect," decreasing densities of snail predators through direct chemical-induced mortality. Mathematical models parameterized from the mesocosm and LC50 experiments and fit to schistosomiasis epidemiological data from Africa suggest that these observed effects of agrochemicals could significantly increase the risk of human schistosomiasis transmission. Separate mesocosm experiments have identified agrochemicals that do not yield a substantial increase in infected snail abundance; these represent candidate chemicals that might be useful for meeting the food demands of growing human populations without increasing human schistosomiasis. Our results highlight the value of mesocosms, models, and community ecology theory for addressing local to global problems in ecotoxicology and public health.

530 Are fungicides a threat for the functioning of heterotrophic systems?

M. Bundschuh, Swedish Univ of Agricultural Sciences / Dept of Aquatic Sciences and Assessment; J. Zubrod, R. Schulz, Univ of Koblenz-Landau / Inst for Environmental Sciences

Fungicides have the potential to affect inter alia heterotrophic organisms and the functions they provide via multiple pathways. In this study we will discuss the impact of organic and inorganic fungicides on leaf associated biofilms, in particular aquatic fungi, and how these modifications may modulate the quality of leaf material for detritivorous macroinvertebrates. With food selection assays it was, for instance, shown that the inorganic fungicide copper increased the palatability of leaf material for the leaf-shredding amphipod Gammarus fossarum. This preference was attributed to an increased fungal biomass accrual and a shift in the fungal community favoring species considered as more palatable for this amphipod. When, however, fed with these preferred but copper contaminated leaves over multiple weeks, Gammarus showed impairments in growth and energy reserves indicating long-term impacts in the population development of this species. Organic fungicides, in contrast, favored leaf associated fungal species, which are considered less palatable for gammarids, and thus – along with a repelling effect of these substances – induced a rejection of this leaf material. At the same time, this leaf material induced only limited effects in the growth of gammarids indicating, despite strong effects on food selection, low impairments in population development in the long-term. These insights, thus, suggest that the food choice of selectively feeding detritivores may not be predictive for implications on their physiological level, which is supported by similar results for larvae of a caddis fly. It was, nonetheless, shown that fungicides – despite being able to induce toxic effects via waterborne exposure – can modify the physiological fitness of detritivores via bottom-up directed effect pathways at field relevant levels.

531 Whole ecosystem experiments to assess effects of glyphosate and fertilizers on wetland communities

K.A. Kidd, Univ of New Brunswick; L. Baker, Baylor Univ / Dept of Environmental Sciences; C. Edge, Univ of Toronto / Ecology and Evolutionary Biology; J. Mudge, Co-operators General Insurance Company / Biology; J. Houlahan, Univ of New Brunswick / Centre for Environmental Management; D. Thompson, Canadian Forest Service / Natural Resources Canada

Glyphosate-based herbicides are some of the most commonly used herbicides in the world. They are generally considered to have a low direct toxicological risk to animals, but few studies have attempted to investigate the ecosystem-level effects of formulated glyphosate products either alone or in conjunction with other likely co-occurring environmental contaminants. Small wetlands are ubiquitous in agricultural landscapes, and have considerable potential for contamination by glyphosate herbicides and fertilizers. Twenty four split wetlands in New Brunswick, Canada, were used to examine the effects of two target concentrations of glyphosate-based herbicides with (G+F) or without (G) fertilizers on wetland macrophytes, plankton, macroinvertebrates and amphibians (n=6 wetland halves/treatment). Wetlands were treated twice with Roundup Weathermax® and four times with nitrogen and phosphorous to mimic agricultural exposures, and comparisons were made between treated and non-treated wetland halves. Initial treatment concentrations across ponds averaged 835 mg acid equivalents (a.e.)/L in the high G and G+F ponds and 27 mg a.e./L in the low G and G+F ponds and glyphosate half-lives in the water column averaged < 1 day. An immediate decline in phytoplankton edible carbon (by 8%) and zooplankton community similarity (by 27%) were observed in the G+F but not G only treated ponds. No short-term effects were observed on macroinvertebrate emergence or composition across any treatments. In contrast, after the macrophyte communities declined (up to 30%) from herbicide treatments and glyphosate was no longer detected in the water column, zooplankton richness and abundance in the G+F treated systems and macroinvertebrate emergence in all wetlands but the high G treatment increased. Wood frog larvae (Lithobates sylvaticus) on the treated sides of wetlands were slightly larger ($< 10\%$) than those on the control side, but no effect on survival or development was observed. The abundance of green frog larvae (Lithobates clamitans) was higher on the treated sides than the control sides of wetlands in the herbicide and nutrient treatments. Overall, direct effects of the herbicide treatments were transient and seen only in wetlands also treated with fertilizers whereas longer-term indirect effects were evident in the invertebrate communities and amphibian populations, indicating the value of assessing multiple stressors in whole-ecosystem experiments.

532 Effects of antihistamine on invertebrates and carbon and nutrient recycling in streams

T. Brodin, Umeå Univ / Dept of Ecology and Environmental Science; J. Fick, Umeå Univ / Dept of Chemistry; J. Klaminder, M. Jonsson, Umeå Univ / Dept of Ecology and Environmental Science

A wide variety of pharmaceuticals are found in many aquatic ecosystems all over the world. Groups of pharmaceuticals of particular interest for potential ecological effects have traditionally been EDC:s (endocrine disruption compounds) and anti-depressant/anxiolytic drugs, since they are

designed to alter human physiology and/or behavior. There is a growing awareness among scientists that behavioral variation and alterations are important for individual performance, ecosystem function, and species evolution. In ecotoxicology it has been recognised that behavioral alterations may be caused by contaminants found in natural systems. Recent studies have shown that both EDC:s and anxiolytic drugs can be found in the environment in high enough concentrations to affect behavior of fish. Very little is, however, known about how/if pharmaceuticals can affect the behavior of other aquatic organisms and how these effects in turn might affect ecosystem processes and functioning. Here I will present results from a sequence of experiments studying effects of the antihistamine fexofenadine on aquatic invertebrates. These studies were then used as a knowledge base for ultimately testing potential effects on important ecosystem processes (i.e. carbon and nutrient turnover). We tested this by investigating if the antihistamine fexofenadine alters rates of leaf litter decomposition in stream microcosms at concentrations 100 times lower than the predicted no-effect concentration. Stonefly larvae, together with natural microbial communities, served as main decomposer organisms on alder leaf litter. Interestingly, concentrations of organic carbon (TOC) and nitrogen (N) were strongly affected, with 20–26 and 24–31% lower concentrations of TOC and N, respectively, in the presence of fexofenadine. I will discuss potential reasons for the pronounced effect on carbon and nutrient turnover and why it could be important.

533 Aquatic insect emergence and pesticide flux from wetlands to terrestrial food webs in the Prairie Pothole Region

J.M. Kraus, R. Harrington, USGS; K.M. Kuivila, USGS / Oregon Water Science Center; M.L. Hladik, USGS / California Water Science Center; D. Mushet, R. Finocchiaro, USGS; N. Shook, US Fish and Wildlife Service

Pesticides can have adverse effects on aquatic insect communities and ultimately impact terrestrial consumers. Little is known about the effects of pesticides either on emergence production of adult aquatic insects or pesticide flux to terrestrial consumers such as insectivorous birds. In particular, a recent meta-analysis of contaminant transfer from larvae to adult insects suggest that some pesticides might also be retained in adult aquatic insects, but no current use pesticides were included. We measured insect emergence and pesticide flux in 2015 from 14 wetlands that varied widely in ponded water permanence and geochemistry (e.g., salinity) in agricultural and grassland land use sites in the Prairie Pothole Region (PPR) of North America. The PPR is covered with a range of wetland types that are a crucial breeding and feeding grounds for migrating birds, most notably waterfowl, embedded in a landscape predominantly used for cropland agriculture. Patterns of damselfly and dipteran emergence differed by land use with more damselflies emerging from grassland and more dipterans from cropland wetlands. However, cropland wetlands did not differ in productivity from the grassland wetlands. Pesticide residues including atrazine, bifenthrin, imidacloprid, fipronil sulfone, and p,p'- DDD were found in adult insects emerging from wetlands in all land use types. Pesticide tissue concentrations and flux estimates from wetlands in adult aquatic insects were generally highest from cropped sites. These data will be used to develop predictive spatial models of adult aquatic insect emergence and contaminant flux from wetlands to terrestrial bird consumers.

534 Selenium ecotoxicology in freshwater lakes receiving coal combustion residual effluents: A North Carolina example

J. Brandt, G. Dwyer, A. Vengosh, Duke Univ / Nicholas School of the Environment; H. Hsu-Kim, Duke Univ / Dept of Civil Environmental Engineering; E. Bernhardt, Duke Univ / Biology; R.T. Di Giulio, Duke Univ / Nicholas School of the Environment

Coal combustion residuals (CCRs), byproducts of coal combustion processes for electricity production, are characterized by elevated concentrations of toxicologically important contaminants including arsenic, cadmium, manganese, and selenium. Via permitted effluent streams, CCRs are chronically released to freshwater systems and accumulate to enriched levels in organisms at the base of the food web. Recently proposed changes for CCR handling and disposal prompted interested in the legacy effects of CCRs in lentic freshwater systems where prolonged water and contaminant retention times lead to sustained impacts on system biota. In the current study, six lakes in North Carolina were selected for comparison; three lakes that receive, or have historically received, coal-fired energy facility effluents, and three reference lakes paired on the bases of lake trophic status and geographical proximity. Surface water, sediment pore water, plankton, and three species of fish were collected from each lake and analyzed for CCR concentrations by ICP-MS in order to determine differences between CCR-impacted and reference systems, whether these differences are associated with lake trophic status, and evaluate potential toxicity in freshwater biota. For the purposes of this presentation, selenium ecotoxicology will be emphasized. Overall, CCR-impacted lakes were found to have significantly higher selenium concentrations in both abiotic and biotic compartments. Notably, fish tissues from CCR-impacted sites contained significantly elevated levels of selenium relative to those from reference lakes ($P < 0.05$) regardless of lake trophic status, selenium loading, or the level of hydrological connectivity. However, site-specific factors were found to influence selenium tissue accumulation. For example, muscle selenium concentrations were 6.2, 8.9, and 1.7-fold higher (all $P < 0.0001$) in fish collected from CCR-impacted lakes relative to those from paired reference lakes in the NC coastal plain, piedmont, and mountain geographical regions, respectively. Results from a field-collected plankton feeding and trophic transfer study and from pore water toxicity assays will also be presented. The implications of this work are pertinent to EPA's proposed selenium aquatic life criterion and recently decided final rule on CCR disposal. Funding support: WRRI Grant 15-03-W, NIEHS Award T32ES021432, and EPA FP917801010.

535 Lessons learned in application of field data to addressing ecogoxicological issues

S.N. Luoma, Univ of California, Davis / John Muir Inst of the Environment

The use of ecological and related ecotoxicological data from nature in addressing ecotoxicological problems has long been the subject of discussion. For example, early papers on development of contaminant guidelines suggested data from nature were desirable but were too complex to be useful. However, understanding of geochemistry, bioavailability, species-specific biological effects, ecological implications and models that tie these together has advanced greatly in the last three decades. This paper will review several approaches that are poised to be useful in both defining cause and effect and developing guidelines in cases of metal/metalloid contamination. The emphasis will be on lessons learned in early applications of these approaches. One example is the Presser-Luoma Ecosystem Scale Model (PLESM) that ties together the combined influences of loadings, hydrology, speciation in receiving waters, biogeochemical cycling (especially transformation to living and non-living material at the base of the food web), bioaccumulation at the base of the food web, trophic transfer to predators, transfer to gonads and eggs within animals, and toxicity (especially developmental toxicity). Uncertainties in predicting implications of dissolved Se concentrations are reduced by inclusion of robust geochemical and biological field data, especially time series data, and by careful verification of outcomes. The second example is built from published studies from the Clark Fork River, Montana, USA and streams in the historic Southwestern England mining district of the UK. In these cases metal concentrations in tolerant biomonitor species are calibrated against changes in the abundance of metal-sensitive species across multiple, complex metal gradients. This approach provides a practical, operational way to address several of the challenges faced in understanding thresholds of metal effects in streams and rivers; especially when combined with time series studies, multi-stream comparisons and models that tie ecological change to metal concentrations in different media. One of several advantages of these approaches is that they provide a framework for a constructive discussion among different interest groups of all the data available from an ecosystem of interest and thereby facilitate constructive data-based discussions of different policy choices.

Microplastics in the Aquatic Environment: Fate and Effects – Part 2

536 Microplastic mediated transport of persistent organic pollutants in Daphnia magna – an evaluation of a toxicokinetic model using experimental data

M. Ogonowski, Z. Gerdes, E. Gorokhova, Stockholm Univ / Dept of Environmental Science and Analytical Chemistry (ACES)

Microplastic (MP) contribution to the bioaccumulation of persistent organic pollutants (POPs) has been recently debated. Experimental studies have largely focused on MP as a vector of POPs to aquatic animals; however, depending on the relative concentrations of contaminants in the MP and biota, MP may also act as a cleaning agent. Kinetic models have taken this bi-directional transport into account but have, so far, only been evaluated for animals with relatively long gut retention times (hours) with high absorption/desorption efficiencies of chemicals to/from MPs. Here, we have evaluated a toxicokinetic model parameterized for Daphnia magna, a suspension feeding primary consumer with very short gut processing times (minutes). The results of a depuration study, where D. magna contaminated with four polychlorinated biphenyl (PCB) congeners (PCB18, 52, 128 and 209) were fed a mixture of clean MP and algae (1:1, MP:algae ratio by dry weight) was used to evaluate the model. The modelling results will be discussed in relation to observed experimental data.

537 Ingestion of microplastic associated with green algae by Daphnia magna and enhancement of PCBs bioaccumulation

P. Canniff, Loyola Univ Chicago / Inst of Environmental Science; P. Chiarelli, Loyola Univ Chicago; T. Hoang, Loyola Univ Chicago / Inst of Environment and Sustainability

The concern of plastic pollution has recently grown at global scale. Most research on potential effect of microplastics has focused on marine environment. Recent studies have found that the Great Lakes region has the highest concentration of plastic material in any freshwater source. Many areas of the Great Lakes ecosystem have been found to be contaminated with PCBs. Concurrently, it is the largest source of freshwater in the world and therefore instigates a need to address the effect of these plastics. The present study determined the effects of microplastics consumption in freshwater invertebrates, Daphnia magna and enhancement of microplastics on the bioaccumulation of PCBs in D. magna. Daphnia magna was chronically exposed to fluorescent green polyethylene microspheresof size 63µm-75µm at concentrations of 25, 50, and 100 mg/L. Ingestion of microplastics and reproduction of D. magna were measured. The present study found that D. magna ingested significant amount of microplastics. The average concentrations of microplastics in the gut of D.magna were 26.26 and 76.75 pieces/organism at the lowest and highest water concentrations of microplastics, respectively. However, no statistically significant difference in reproductive rate was found for D. magna of control and exposure treatments. Evidence of increased algal production on microplastics compared to control is present. These results suggest that adsorbed algae on microplastics would provide an additional energy source for reproduction performance of D. magna. In the bioaccumulation experiment, D. magna was chronically exposed to PCBs at a concentration of 1µg/L in presence of 1g/L microplastics or without microplastics (control). At the experiment termination, D. magna was collected for tissue PCBs analysis. Results of the bioaccumulation experiment indicate an enhancement of microplastics on PCBs accumulation in D. magna.

538 Can hydrophobic organic chemicals sorbed to microplastics affect aquatic organisms? A review of laboratory studies

K.J. Kulacki, Exponent, Inc.; L. Ziccardi, Alpine EcoSciences / EcoSciences; K.L. Hentz, Exponent Inc. / Toxicology Mechanistic Biology; S. Kane Driscoll, Exponent Inc.

The potential for microplastic particles (MPs) in the marine environment to cause adverse effects on organisms and ecosystems is an issue of public and scientific interest. One area of concern is the potential for MPs to act as vectors for the transfer of hydrophobic organic chemicals (HOCs) present in the environment to the marine food web. This analysis considered only exogenous HOCs that were not intrinsic to the manufacture of HOCs. We summarized the results of laboratory studies that examined the transfer of HOCs sorbed to MPs and effects on aquatic organisms. Most studies that reported adverse effects associated with exposure to MP + HOCs also reported adverse effects for treatments in which organisms were exposed only to MPs, indicating that reported effects may not be solely due to HOCs. Many studies used environmentally unrealistic concentrations of MPs, making extrapolation to natural environments difficult. Finally, we note that many laboratory studies used gradients of chemical activity (e.g., contaminated MPs and uncontaminated organisms) that might be higher than would be observed in the field where sources of HOCs exist in various environmental media (e.g., food, water). In summary, we conclude that available data from laboratory studies provide weak evidence that transfer of exogenous HOCs from MPs to marine organisms is likely to be an important route of exposure and contributor to adverse effects to marine organisms. More data are needed to fully understand the relative importance of exposure to HOCs from MPs in comparison to other pathways.

539 Microplastic as a vector of PCB uptake in Daphnia magna

Z. Gerdes, M. Ogonowski, M. Adolfsson-Erici, E. Gorokhova, Stockholm Univ / Dept of Applied Environmental Science and Analytical Chemistry ACES

Microplastic (MP) has been associated with the accumulation of persistent organic pollutants (POPs) through ingestion of contaminated plastics by various organisms. However, adequate experimental observations that can be used to test these theoretical expectations are very rare. We conducted a laboratory study to evaluate MP as a vector of POPs in Daphnia magna, a filter-feeding zooplankton model organism. The MPs were loaded with a mixture of polychlorinated biphenyl congeners (PCBs) of varying hydrophobicity ($\log K_{OW}$ 5.6-8.3), mixed with algal food, and fed to the daphnids during 21 days. The treatments included: control (no PCB and no MP), MP exposure (no PCB and 10-900 MP mL^{-1}, the volume of MP in relation to the volume of algal food was 0.02-1.4) and a combined exposure of PCB and MP (ΣPCB 1.46-131.62 ng mL^{-1} and 10-900 MP mL^{-1}). At the end of the experiment,mortality, total offspring production and somatic growth were analysed in concert with PCB accumulation. The congener specific uptake via MP was compared to PCB bioaccumulation in zooplankton samples from natural environments, laboratory experiments and modelled values. We found that at an intermediate exposure treatment, PCB loaded MP had positive effects on growth and reproduction. Whereas negative effects were observed at the highest exposure level, resulting in ~70% mortality. Congener specific bioaccumulation factors, based on the uptake from MP, were similar to earlier reports from natural environments and modelled values. Therefore, MP-mediated accumulation of PCBs in zooplankton, can be satisfactorily explained by the chemicals hydrophobicity and does not diverge from the uptake via other sources (food and water).

540 Ingestion of microplastics by the freshwater invertebrate Chironomus sancticaroli: effects on PBDE bioaccumulation and the gut microbiome

E. Lahive, A.A. Horton, NERC Centre for Ecology and Hydrology; A. Palacio, UFPR; L. Newbold, NERC Centre for Ecology Hydrology; M.G. Pereira, Centre for Ecology & Hydrology / Lancaster; R. Disner, M. Navarro da Silva, M.T. Grassi, UFPR; D. Spurgeon, Centre for Ecology & Hydrology

Microplastic particles in the environment can associate with persistent organic pollutants (POPs) due to the hydrophobic nature of plastics and organic chemicals. If ingested, the gut environment of an organism may favour desorption of adsorbed chemicals due to gut conditions such as pH and ionic strength as well as the presence of surfactants. Therefore the ingestion of microplastic particles has implications for uptake and bioaccumulation of these chemicals. Furthermore the presence of microplastics and chemicals in the gut of an organism can also influence the gut environment itself. PBDEs (polybrominated diphenyl ethers) are widely used as flame-retardants in products such as textiles and soft furnishings, with the potential to leach into the environment and therefore they can potentially associate with microplastics. The aims of this study were to investigate the ingestion of microplastics by the chironimid (Chironomus sancticaroli) and how microplastics affect PBDE bioaccumulation and the gut microbiome. In order to investigate the ingestion and elimination of microplastics by the freshwater midge larvae Chironomus sancticaroli were exposed tomicroplastic particles (fluorescently labelled nylon; < 50 µm) in sand for 48 hours at a concentration of 1%. Ingestion was measured by fluorescence microscopy after 6, 24 and 48 hours. After transfer to clean sand elimination of microplastics was also monitored after 6, 24 and 48 hours elimination period. In a second experiment chironomids were exposed to microplastics and PBDEs both independently and in combination for 96 hours. Microplastic particles were mixed with quartz sand sediment at 1% concentration. A PBDE mix (containing BDE-47, 99, 100, 153 and PBB-153) was added to the sediment-microplastic mix in glass vessels at six environmentally relevant concentrations (94, 188, 375, 750, 1500, 3000 ng g^{-1}). Artificial freshwater was added to each vessel once the solvent had evaporated. Microplastics were ingested by chironomids over the 48 hour period but microplastics were found to be still present in the gut following the 48 hour elimination period. After the 96 hour exposure there was no mortality observed, either for microplastics or PBDEs. However, the microbiome of the chironomids in the presence of microplastics were significantly different from chironomids not exposed to microplastic.

541 Microplastic Contamination at the Base of the Food Chain

A. Cook, H. Allen, USEPA Region 9 / Superfund Emergency Response; C. Rochman, Univ of California, Davis / Aquatic Health Program; M. Gassel, California Environmental Protection Agency / Office of Environmental Health Hazard Assessment

Microplastics (plastics < 5 mm in size) are reported in freshwater and marine ecosystems worldwide, and potential impacts on the food chain are beginning to be recognized. Lanternfishes (Myctophidae), with their global distribution at the base of the food chain, are of both commercial and ecological significance. In the present study, lanternfishes collected from the Pacific and Atlantic Oceans were analyzed to assess microplastic ingestion and contaminant uptake and accumulation. Fish were collected during an August 2009 Project Kaisei North Pacific Gyre expedition and during a November 2010 5Gyres Institute South Atlantic sampling cruise. Lanternfishes, captured during each of the voyages, were analyzed for presence and concentrations of persistent organic pollutants and plasticizers in their tissue. Kaplan-Meier (KM) sums of PCB concentrations were correlated to AP and BPA concentrations in fish tissues. The digestive tracts of individual fish exhibiting highest tissue contaminant loading were dissected and microplastics removed using pulsed ultrasonic extraction. Microplastic particles from both the Atlantic and Pacific Ocean fish guts were examined for size, morphology, and chemistry using optical microscopy, scanning electron microscopy (SEM), Fourier transform infrared spectroscopy (FTIR) and Raman to determine plastic type. Polyethylene(PE) and polypropylene(PP) microplastics were detected in fish stomachs from both locations. Additionally, Raman detected the presence of microplastic/fatty acid conjugates in the Atlantic Ocean fish stomach samples. In addition to the microplastics, the fish stomach contents contained a variety of particles easily misidentified as microplastics by optical examination. Ingested particles appeared to consist of both degradation products from larger plastic pieces as well as manufactured microbeads and microfibers. Important lessons on the aquatic distribution, characteristics and behavior of microplastics and their impact on the food chain can be learned from this study as well as requirements for methodologies to accurately identify plastic versus non-plastic particles.

542 Assessment of microplastic ingestion in commercial fish species Engraulis encrasicolus and Sardina pilchardus in the Western Mediterranean Sea

M. Compa, Instituto Español de Oceanografia / Ecology; C.A. Mascaró, S. Deudero, Instituto Español de Oceanografia / Centro Oceanográfico de Baleares

Microplastics in the marine environment are ubiquitous globally. Recent studies are reporting microplastics found inside the gastrointestinal tracts of several marine species such as the semi-pelagic Boops boops. The ingestion of microplastics highlights the potential risk of heavy metals and persistent organic pollutants adhering to microplastic particles, potentially entering the food web affecting marine and human health. For the current study, the European anchovy (Engraulis encrasicolus) and the European pilchard (Sardina pilchardus) were sampled at several geographic locations in the Western Mediterranean Sea to determine the ingested abundance of microplastics in the gastrointestinal tract from both pelagic and benthic samples. Pelagic samples for both species were collected at an average depth of 111.67 m on the continental platform at of the Spanish Mediterranean Sea. Gastrointestinal tracts of 92 fish from 7 locations were examined with 14% of individuals found with ingested microplastics. To determine the chemical composition of the microplastic particles, Fourier Transform Infrared (FT-IR) is used to identify the polymer type. Results from this study will aid in determining the variation in microplastic ingestion between pelagic and benthic schools of the commercial fish species E. encrasicolus and S. pilchardus giving insight into the potential implications of microplastics in fish species for human consumption.

543 Microplastic ingestion in commercial and shark species in the Western Mediterranean Sea

C.A. Mascaró, Instituto Español de Oceanografia / Centro Oceanográfico de Baleares; M. Compa, Instituto Español de Oceanografia / Ecology; S. Deudero, Instituto Español de Oceanografia / Centro Oceanográfico de Baleares

Samples of Mullus surmuletus and Galeus melastomus were obtained with commercial bottom trawling vessels in two areas of the Balearic Islands (western Mediterranean). Both species were seen to ingest microplastics, mainly blue filaments. However, analyses under the stereomicroscope and FTIR analyses revealed film type microplastics in gastrointestinal guts of G. melastomus and not in M. surmuletus. Microplastic ingestion ranged from 0.04 ± 0.04 to 0.92 ± 0.29 MPs/fish. According to M. surmuletus, highest percentage of affected individuals were given in the southwest area while for G. melastomus, percentage of affectation was highest in the northwest area. Variability of the results remark the need of sampling at multiple geographical scales and integrate different species in order to improve the approach to study micro-plastics in marine biota. In addition, chemical biomarkers were analysed for M. surmuletus, providing preliminary data on the response of antioxidant enzymes – catalase and superoxide dismutase, detoxification enzyme glutathione s-transferase (GST) and malondialdehyde (MDA) levels to microplastic ingestion.

Novel Mechanisms of Nanomaterial Toxicity Through Direct Exposure or Indirect Interactions with Environmental Components – Part 3

544 Elucidating the role of nonmaterial coating on uptake and translocation mechanisms at the sub-cellular level in plants using a hard X-ray nano probe

J. Unrine, J. Li, Univ of Kentucky; R. Tappero, Brookhaven National Laboratory; A. Acerbo, Univ of Chicago

The objective of this project was to understand the role of polymer coating charge on the uptake, translocation and subcellular distribution of CeO_2 in the tomato (Solanum lycopersicum cv Micro-Tom). Dextran (DEX; neutral), diethylaminoethyl dextran (DEAE; positive) and carboxymethyl detran (CM; negative)-coated CeO2NP (3-5 nm primary particle size) were synthesized and characterized for primary particle size (TEM), hydrodynamic diameter (DLS) and zeta potential (PALS) in exposure media. Tomato seedlings were grown in 10% Hoagland solution are exposed to DEAE, DEX and CM CeO_2NPs and control media for 2 weeks. The bulk tissue concentrations of Ce were determined in shoots, leaves alone and roots by inductively coupled plasma mass spectrometry (ICP-MS). Tissues were also collected from the root tip region and prepared by thin sectioning for Ce mapping using a synchrotron based X-ray fluorescence nanoprobe (nXRF) using the hard X-ray nanoprobe (HXN) at the National Synchrotron Light Source-II (Upton, NY, USA). The results indicate that CeO_2NP with positively charged coatings have the greatest impact on seedling growth. There is a trend of decreasing values of bioconcentration factor for all three CeO_2NP with increasing exposure concentration. Ce was concentrated mostly in the root tissue although there is significant translocation of Ce from the roots to shoots. The distribution of Ce in the root tip cells (down to 10-15 nm resolution) vary with the charge states of the coatings, with the apoplastic spaces showing the highest Ce accumulation concentrations, suggesting an apoplastic uptake mechanism. Entry into the root tip appears to occur in gaps between cells in the epidermis formed as cells are being shed from the root tip. Dissolution data showed that there was minimal Ce dissolution from the particles in the nutrient media used in the study. As the first general users of HXN, which is the highest resolution X-ray fluorescence microscope in existence, this study provides perhaps the highest resolution X-ray fluorescence imaging of nanomaterials in a biological tissue to date.

545 Nanoparticle Detection in Environmentally Relevant Matrices Using DMA-ICP-MS

S.T. Wolf, 3M Company / EHSS Environmental Lab; C. Chan, 3M / CRAL Elemental Chemical Analysis Laboratory; C. Loza, M. Ellefson, B.T. Mader, 3M Company / EHSS Environmental Lab

Engineered nanoparticles frequently are used as additives to consumer products to enhance product properties. Understanding the environmental fate and impact of engineered nanoparticles relies on the ability to characterize them at relatively low levels in complex media, which often contains additional naturally occurring nanoparticles. We present the application of a recently developed hyphenated technique combining electrospray aerosol generation, particle size selection using differential mobility analysis (DMA), and elemental analysis using inductively coupled plasma mass spectrometry (ICP-MS) to characterize gold and silver nanoparticles in environmentally relevant water samples including ground water, industrial wastewater, and ecotoxicology test media. The method is capable of detecting nanoparticles of 20-100 nm diameter at part-per-billion (ppb) levels in environmentally relevant aqueous solutions. Following instrument characterization, the DMA-ICP-MS was used to assess the fate of gold nanoparticles in a solution containing daphnia magna. Insights into dose verifications obtained by DMA-ICP-MS will be discussed as well as the method's performance and the advantages of the hyphenated DMA-ICP-MS over single-particle ICP-MS.

546 Development of Gold-labeled Titanium Dioxide Nanoparticles for Examining Exposure and Biodistribution in Complex Matrices

A.R. Deline, Oregon State Univ / Environmental Engineering; W.M. Young, J.A. Nason, Oregon State Univ / Chemical Biological and Environmental Engineering

Titanium dioxide nanoparticles (TiO_2 NPs) are produced in large quantities for multiple consumer and industrial applications, many of which will lead to the direct release of these materials into natural and engineered systems. Understanding the environmental effects of TiO_2 NPs is critical, but researchers must first overcome the challenge of distinguishing engineered NPs from high concentrations of naturally-occurring titanium. To better facilitate detection and quantification of TiO_2 NPs in complex systems, labeled particles with gold cores and TiO_2 shells were developed. The properties and behavior of the gold-labeled TiO_2 NPs were compared with those of unlabeled particles, with the goal of modifying synthetic procedures to minimize differences between the two NP types. The gold label is sensitive to a variety of analytical techniques useful for studying NP transport and behavior, including inductively coupled plasma mass spectrometry, hyperspectral imaging, and neutron activation analysis. The labeled NPs have been accurately quantified at parts-per-billion level concentrations in environmental samples containing background titanium. Ongoing experiments are designed to demonstrate the utility of the labeled particles in toxicity experiments by examining relevant properties like the potential to generate reactive oxygen species. The presence of a label that is easy to detect will allow for a wider range of experiments to be performed in environmentally-relevant exposure scenarios, including scenarios containing multiple organisms or nanoparticle types.

547 Does nanoclay technology adversely affect aquatic biota relative to natural nanoclays?

S. Tullio, D. Chalcraft, East Carolina Univ / Biology

Nanoclays represent a large class of manufactured nanomaterials (NMs) that have received great attention from the scientific and industrial communities. One important use of nanoclays is in wastewater treatment and pollution control as they can remove toxic chemicals from water supplies. Nevertheless, many concerns have been raised about the effect of manufactured nanomaterials on aquatic ecosystems as the nanomaterials themselves could have adverse effects. In this study, we investigated the potential toxic effects of a natural nanoclay (Na^+ montmorillonite) and two manufactured nanoclays (Cloisite®30B and Novaclay™) on Clamydomonas reinhardtii and Daphnia magna. Both freshwater specieswere exposed to a range of nanoclay concentrations to determine the NOAEL (No Observed Adverse Effect Level) and LOAEL (Lowest Observed Adverse Effect Level) of each type of nanoclay on the population growth of C. reinhardtii, and survivorship and growth rate of D. magna during acute (48h) and chronic tests (10 days). Our results indicated that an increase in nanoclay concentration negatively affected algal population growth but the effects manifested at a lower concentration for Cloisite® 30B (NOAEL: 1 mgL^{-1} and LOAEL: 10 mgL^{-1}) than it did for the other nanoclays (NOAEL: 1000 mgL^{-1} and LOAEL: 10000 mgL^{-1}). In addition, a very low concentration of Cloisite® 30B severely reduced the survivorship of Daphnia magna (NOAEL: 0.1 mgL^{-1} and LOAEL: 1 mgL^{-1}) for both acute and chronic tests. Novaclay™ also reduced daphnid survivorship at low concentrations (NOAEL: 0.1 mgL^{-1} and LOAEL: 1 mgL^{-1}) but only after chronic exposure. Natural nanoclays only reduced daphnid survival at higher concentrations (NOAEL: 10 mgL^{-1} and LOAEL: 100 mgL^{-1}) and only with acute exposure. We found little effect of natural nanoclays and Novaclay™ on the body growth of Daphnia and we were unable to assess the effects of Cloisite® 30B on the body growth of daphnids at higher concentrations, because all organisms died when exposed to Cloisite® 30B. Our work highlights that aquatic organisms are differentially susceptible to natural and manufactured nanoclays and most sensitive to Cloisite® 30B. Consequently, we should be careful about the kinds of manufactured nanoclays that we introduce into aquatic environments.

548 Differential uptake and toxicity of CuO nanoparticle to Daphnia magna from chronic exposure using two delivery scenarios

F. Wu, Oregon State Univ / Chemical, Biological and Environmental Engineering; A.E. Bortvedt, Oregon State Univ; B.J. Harper, Oregon State Univ / Dept of Environmental and Molecular Toxicology; L. Crandon, Oregon State Univ / CBEE; S.L. Harper, Oregon State Univ / EMT

Copper oxide nanoparticles (CuO NPs) are highly toxic to aquatic species, yet their extensive use in consumer products and industrial applications inevitably results in release into surface water. Currently, few studies have addressed whether CuO NPs can be transferred through the aquatic food chain. Here, we investigated the uptake and trophic transfer of CuO NPs from the algae Chlorella vulgaris to the crustacean Daphnia magna. We hypothesized that CuO NPs associated with algal cells could be transported to predators through feeding, and that the chronic toxicity resulting from this delivery scenario would differ from a direct CuO NP exposure. To test our hypothesis, D. magna were fed algae that had been incubated with CuO NPs or were directly exposed to CuO NPs while uptake and toxicity were evaluated. Strong surface associations and potential internalization of CuO NPs into algae were observed using hyperspectral imaging, and uptake was quantified with ICP-OES. We found high concentrations of Cu in D. magna bodies and molted carapaces in both exposure scenarios, suggesting that CuO NPs were taken up by D. magna and could be regulated through molting. We detected Cu in the neonates produced in the feeding exposure but not the direct exposure, implying that D. magna may metabolize CuO NPs differently depending on the method of delivery. Mean bioaccumulation factors were 12382 and 9899 in feeding and direct exposure scenarios, respectively, suggesting that CuO NPs had a high tendency to accumulate in D. manga bodies in both delivery scenarios. Significantly higher D. magna mortality was found in the direct exposure compared to the feeding exposure, which is likely due to decreased surface reactivity and dissolution caused by algae-particle hetero-aggregation as Cu^{2+} was undetectable. In addition, CuO NPs delivered through a feeding exposure significantly reduced neonate production compared to control. Thus, nanoparticle interaction with biota at one trophic level may alter the biological response to that nanoparticle at the next trophic level. This study highlights the importance of assessing nanomaterial ecological impacts in more environmentally relevant scenarios including multiple delivery scenarios and chronic sub-lethal exposures.

549 The release of "transparent blue" automobile coatings containing nanoscale copper phthalocyanine and their effects to aquatic organisms

C. Pang, Univ CaFoscari Venice / Dept of Environmental Sciences Informatics and Statistics; N. Neubauer, BASF, Germany; D. Brown, Heriot Watt Univ, UK; D. Hristozov, Univ CaFoscari Venice, Italy; T. Fernandes, V. Stone, Heriot Watt Univ, UK; A. Marcomini, Univ CaFoscari Venice, Italy; W. Wolleben, BASF, Germany

Nanoscale copper phthalocyanine (n-CuPc) has been increasingly used in different products, including printing inks, coating for automotive products, plastics, and textiles. Its use can improve the mechanical properties and add new features to the products, such as exhibit excellent transparency, lightfastness, heat stability, chemical and bleed resistance, processing capabilities and durability. It is estimated that Europe consumed an estimated 8 thousand metric tons of n-CuPc pigments (dry weight basis) in 2010. The automotive industry is the largest consumer of organic pigments, where increasing market requires stylish automobile coatings with vibrant colors "transparent blue" due to the pigments. This application of n-CuPc may result in release of n-CuPc release into the aquatic environment, especially during washing or repairing the automobile. Presently, very little is known about the exposure and hazard of n-CuPc in the aquatic environment, where n-CuPc may pose risks to freshwater and sediment organisms. The aim of the study is to develop methods and to generate data to assess the exposure and effects of n-CuPc in the aquatic environment. We estimate the release of n-CuPc from "transparent blue" automobile coatings through sanding approach, which is representative of a car repair process. Typically such repair operations are done in repair facilities where sanding dusts is collected and disposed, but an indirect emission from disposal into aquatic environment (e.g. freshwater) cannot be completely ruled out. Further, risk management measures (local exhaust on the sanding equipment, face masks) are typically in place at such operations to reduce occupational exposure. However, knowledge of the fate and hazard of sanding fragments in occupational settings is required. Accordingly, we investigated how the physicochemical properties of the released fragment n-CuPc from automobile coating changes in environmental (freshwater) and biological (cell culture) media and their potential effects to macrophages and aquatic environmental organisms.

550 Accumulation of Silver Nanoparticles in Aquatic Food Webs Following Pulsed vs. Repeated Exposure in Artificial Streams

S. Petersen, Georgia Southern Univ / Biology; R. Cohen, Georgia Southern Univ / Dept of Biological Science

Given the rapid growth of the nanoparticle industry, the potential for nanoparticle discharge into the environment to incur ecological damage must be investigated. Silver nanoparticles (AgNPs) are commonly used in cleaning agents, clothing, and pharmaceuticals to eliminate unwanted bacterial growth. This diversity of applications increases the likelihood of AgNP entry into aquatic environments and subsequent exposure to organisms. Results from single species laboratory studies revealed that single pulse additions of < 100µg L^{-1}AgNPs cause mortality in algae, zooplankton, and gastropods, and accumulation of silver in sediment, periphyton, macroinvertebrates, and fish in lentic (wetland and pond) mesocosms. However, the fate of AgNPs in flowing water have not been examined lotic systems (i.e. streams) despite their potential to receive industrial and wastewater discharge as pulses or as repeated small amounts over time. We hypothesized that the fate of silver from small, frequent AgNP exposures differs from that following one-time large pulse exposure. We predicted that a large pulse should result in greater silver accumulation in sediments and bottom-dwelling stream inhabitants such as periphyton and C. decisum. In contrast, repeated smaller doses are more likely to maintain AgNPs in the water column and accumulate in Gambusia sp. due to increased exposure time. Artificial, recirculating streams were created by adding water from the Ogeechee River, GA, USA along with a simplified community consisting of sediment, primary producers (periphyton), a grazer (the snail C. decisum), and a consumer (the mosquitofish Gambusia sp.). The stream communities were exposed to one of five treatments for two-weeks: no-addition control, AgNP doses of 5µg L^{-1} every two days, AgNP doses of 10µg L^{-1} every two days, a one-time addition of 35µg L^{-1}, and a one-time addition of 70µg L^{-1}. Water samples were analyzed for Ag content initially, and one and two weeks post-exposure to treatments. Sediment, periphyton, C. decisum, and Gambusia sp. were analyzed initially and at the end of the experiment to determine AgNP accumulation. Ag content was quantified using inductively coupled plasma-mass spectrometry (ICP-MS). Results from this study will provide valuable information to assist in determining the need for additional monitoring and regulation of AgNPs entering the environment.

551 Multigenerational Effects of Silver Nanomaterials in Caenorhabditis elegans

O.V. Tsyusko, Univ of Kentucky / Dept of Plant Soil Sciences; A. Wamucho, Univ of Kentucky / Toxicology and Cancer Biology; J. Unrine, Univ of Kentucky / Plant and Soil Sciences; S. Miller, Univ of Kentucky

Studies of the effects of as-synthesized and transformed sulfidized silver nanomaterials (Ag-NMs) to a model organism, a nematode Caenorhabditis elegans have shown increase in toxicity as well as unique transcriptomic responses after single-generation exposure. Recent multigenerational study has also shown enhanced sensitivity for reproductive toxicity over multiple generations. However, genomic effects (e.g. mutations and epimutations) that can be induced by exposing C. elegans continuously to nanomaterials over multiple generations have not yet been investigated. In this study, we used wild type and DNA mismatch repair mutant (msh-2) strains of C. elegans to determine if mutations resulting from Ag-NM and ion exposures can contribute to the observed multigenerational effects. Exposures to both as synthesized and sulfidized Ag-NMs as well as their respective ions were conducted for 10 generations using sub-lethal concentrations of EC_{30} for reproduction. Whole genome DNA sequencing approach using NextSeq was applied to a wild-type C. elegans to examine and compare mutations before and after multigenerational exposures within and among treatments between F_0 and F_{10} generations. In addition, individual 72-96 nematodes from N2 and msh-2 strains from F_0 and F_5 generations were collected for microsatellite instability analysis. The sequencing data have been aligned to the reference genome and comparisons within (from F0 to F10) and among treatments are being made to test whether exposure to Ag-NPs can induce mutations and result in germline instability. Our preliminary results suggest that exposure to as-synthesized Ag-NMs resulted in increase in missense, deletion and insertion mutations and these mutations were observed in coding, regulatory 5' and 3' untranslated regions, intergenic regions, and introns. For microsatellite analysis, there were no mutations detected at the four analyzed microsatellite loci for the wild type nematodes. However, mutations were detected for the mismatch repair deficient msh-2 mutant at one locus with mutation rate slightly increasing over four generations from 1.04 x 10^{-2} in controlsto 4.17x 10^{-2} after exposure to as synthesized Ag-NPs. The nature of mutations differed between control (deletions) and exposed (insertions) treatments. Analyses of the sequencing data and more microsatellite loci are ongoing to determine if exposure to Ag-NMs can lead to accumulation of mutations resulting in overall genomic instability.

Fate and Effects of Metals in the Environment: Modeling and Interpreting Effects of Metals Mixtures

552 Internal versus external dose for describing ternary metal mixture (Ni, Cu, Cd) chronic toxicity to Lemna minor

Y. Gopalapillai, B.A. Hale, Univ of Guelph / School of Environmental Sciences

Resolving the inability to predict risk from metal mixtures in waters surrounding Canada's many current and legacy extractive mining sites is a high priority for the government and base metal mining companies. Mixtures of metals may have toxicity that would not be predicted additively, as uptake of metals into an aquatic organism is influenced by water chemistry factors, which in turn impacts bioavailability (i.e. interaction of the metal with the biological receptor called the biotic ligand or BL). Our study aimed to validate the 'concentration addition' (CA) approach to predict the toxicity of a ternary metal mixture (Ni, Cu, Cd) to Lemna minor (one of Environment Canada's recommended test plant species for bio-monitoring of mining effluents). Simultaneous determination of total metal concentration and free metal ion activity in solution (external dose) and metal accumulation in plants (internal dose) was done to assess the best representative of 'bioavailable dose' for use with the CA approach. In addition, a mechanistic investigation using accumulation kinetics and response surface regression of internal dose versus root growth inhibition was conducted. The results of this indicate that Ni-Cu-Cd likely compete with each other for uptake into the plant, but once inside, Cu-Cd share binding site while Ni does not. A synergistic interaction between Cu-Cd was suggested by the increase in binding affinity (Kd) from single metal to mixture exposure for the two metals (Ni had the opposite effect). This study also demonstrates that concentration addition is an appropriate model for estimating mixture toxicity when dose metric approximates amount of metal delivered to plant (internal dose), suggesting that risk assessments for metals in water should utilize internal tissue metal concentration as an indicator of dose.

553 The unexpected effects of metal mixtures on zebrafish gills

F.X. Domingos, Instituto Nacional de Pesquisas da Amazonia – INPA / Biodiversidade; J. Wilson, Wilfrid Laurier Univ; C.M. Wood, Univ of British Columbia / Dept of Zoology

It is challenging to predict the effects of metal mixtures. When in combination they not necessarily follow the trends of effects presented during single metal exposures, the effects can be more than additive, similar or even antagonistic. In order to expand the knowledge on the effects of metal mixtures in fish we evaluated the influence of isolated or binary combinations of metals on unidirectional (measured with ^{22}Na) and net sodium fluxes and immunolabeling of gill ion transporters and metallothionein in zebrafish (Danio rerio). In order to challenge fish with comparable toxicity levels we exposed them to 10% of their LC50 in single and binary tests with copper (Cu), nickel (Ni) and cadmium (Cd). The concentrations used were 6.2 ug/L of copper, 280 ug/L of cadmium and 1200 ug/L of nickel during 3 and 96h exposures in static and semi-static systems, respectively. The 3h net ion fluxes were significantly different from 96h fluxes in fish exposed to Cu and Cd; in both cases they switched from a net gain to a net loss of sodium. The common response observed in other fish species is to present sodium net loss after exposure to metals as copper. Indeed, zebrafish seems to respond differently in this regard, presenting net sodium gain when exposed to single Cu and Cd, while the cadmium combinations Cu+Cd and Ni+Cd induced the opposite effect, with the fish presenting significant sodium losses after 96h of exposure. The indirect immunofluorescent localization of metallothionein was increased in all treatments. Interestingly the metallothionein was not labeled exclusively in mitochondria rich cells in zebrafish as usually observed in other fish species. We observed that metals can modulate the immunolabelling of ion transporters such as vH-ATPase and Na,K,ATPase on zebrafish gills. Our findings indicate that the very short-term response (3h) cannot be used to predict a longer term response (96h), and also that single metal effects are not good predictors of combined metal effects (CNPq, NSERC Discovery, IDRC).

554 Effects of binary mixtures of Ag, Cd, Cu, Ni, Pb and Zn to the freshwater snail Lymnaea stagnalis – short term uptake and chronic toxicity

A. Cremazy, Univ of British Columbia / Dept of Zoology; K. Brix, EcoTox / Zoology; C.M. Wood, Univ of British Columbia / Dept of Zoology

Incorporating metal mixture toxicity into regulatory frameworks has been an important focus of environmental scientists and regulators over the past decade. As a result, great progress has been made in the development of new experimental, statistical and modeling approaches for the interpretation of metal mixture toxicity. Nevertheless, more data are needed to continue improving our understanding on this complex subject. Specifically, the chronic toxicity of metal mixtures have been sparsely investigated in contrast to acute toxicity, despite its generally greater relevance for environmental risk assessment. The freshwater snail Lymnaea stagnalis is chronically highly sensitive to a range of trace metals. In the present study, metal interactions were assessed in juvenile L. stagnalis exposed to binary mixtures of six environmentally relevant metals (Ag, Cd, Cu, Ni, Pb and Zn), with 14-d growth, 2-h metal uptake and tissue distribution experiments. Results so far indicate that metals do not strongly interact with each other in both growth and short-term uptake tests. [This work is funded with a CRD grant from NSERC, in partnership with Rio Tinto, ICA, CDA, NiPERA and IZA].

555 The toxicity of mixtures of selenium, cadmium, nitrate, and sulphate to Ceriodaphnia dubia

E. Costa, Golder Associates Ltd.; J.R. Elphick, Nautilus Environmental; G. Lawrence, Golder Associates Ltd.; A. deBruyn, Golder Associates / Environmental Science

The potential for unexpected interactions among constituents to result in increased toxicity has been identified by the scientific community and regulatory bodies as a source of uncertainty in the development of water quality guidelines and objectives that are protective of aquatic life. The purpose of this research was to assess the potential for the toxicity of mixtures of selenium (Se), cadmium (Cd), nitrate (NO3) and sulphate (SO4) to differ from the toxicity of individual constituents. Test solutions were evaluated with a Ceriodaphnia dubia 7-d reproduction and survival test according to Environment Canada procedures. Eleven mixture toxicity tests were conducted with constituent concentrations ranging from 0.02 to 1 µg Cd/L, 3.7 to 52.7 mg NO3-N/L, 19.5 to 139 µg Se /L and 117 to 934 mg SO4/L in laboratory water or water from a site in British Columbia, Canada. The sensitivity of C. dubia to NO3 and SO4 was also assessed by conducting constituent-specific toxicity tests in a range of water types. Survival and reproduction effects were observed at higher mixture concentrations and were attributed to NO3 and SO4.

556 X-ray fluorescence based examination of zinc distribution and speciation in rainbow trout gills: interactions with copper or cadmium

S. Niyogi, Univ of Saskatchewan; Y. Saibu, Univ of Saskatchewan / Toxicology; A. Jamwal, Univ of Saskatchewan / Biology Dept; R. Feng, Candian Light Source

The current framework of the biotic ligand model (BLM) is based on the metal binding to the fish gills. Although the BLM approach has been successfully used to predict the toxicity of single metals in aquatic organisms, its potential to evaluate the metal mixture toxicity is presently under investigation. Understanding metal interactions in the fish gills would be a key step in the process of developing a sound metal mixture BLM. To this end, we employed X-ray fluorescence imaging (XFI) and micro X-ray absorption near-edge spectroscopy (XANES), which are both synchrotron based techniques, to examine: (i) the spatial distribution and chemical speciation of Zn and its co-localization pattern with other essential elements (Ca, S and Fe), and (ii) the effect of competing metals (Cd and Cu) on the Zn distribution and speciation in fish gills. Ranbow trout (150-200g) were exposed to acute (96-h LC-50) levels of waterborne Zn, singly and in combination with Cu or Cd, for 24-h. Following exposure, gills were dissected out, and 5 micron thick sections were prepared to anylyze Zn distribution and speciation profiles in the rainbow trout gills using the multi-element hard X-ray microprobe at the VESPER beamline, Canadian Light Source, Saskatoon, Canada. Zinc was found to accumulate mainly in the primary lamellae of the gill, which corresponded to the high density of chloride cell localization, supporting the putative roles of these cells in branchial metal uptake. In addition, Zn was found to predominantly co-localize with Ca and S, but not with Fe, indicating that the Ca- and S- containing moieties are involved in intracellular Zn handling. The spatial distribution of Zn in the gills was markedly reduced during co-exposure to Cd, but not to Cu, suggesting a competitive interaction between Zn and Cd for branchial uptake. Moreover, the predominant chemical species of Zn in the trout gills were Zn-phosphate, Zn-oxide and Zn-cysteine. Co-exposure to Zn and Cu did not alter the chemical speciation of Zn, however a notable increase in the fraction of Zn-cysteine was recorded during co-exposure to Zn and Cd, possibly due to the metallothionein induction (increased detoxification capacity) in fish. To the best of our knowledge, this is the first study to examine how metal mixture interactions influence the spatial distribution and chamical speciation of metals in the fish gills, and our findings have important implications for understanding metal mixture toxicity in fish.

557 Interaction and toxicity of cadmium, copper, and nickel on the olfactory system of rainbow trout Oncorhynchus mykiss Walbaum, 1792

E. Lari, S. Bogart, A. Manek, Univ of Lethbridge / Dept of Biological Sciences; W.A. Dew, Trent Univ / Biology; G.G. Pyle, Univ of Lethbridge / Biological Sciences

Water quality criteria are mainly based on the effects of individual contaminants, even though numerous studies have demonstrated that interactions among contaminants may affect the overall toxicity. In the present study the toxic effects and interactions of nickel (Ni), cadmium (Cd), and copper (Cu) on the olfactory response of rainbow trout were determined. To study the toxic effect of single metals on the olfactory system, rainbow trout were exposed to a geometric dilution series of each metal for 24 h. Olfactory acuity was tested using electro-olfactography (EOG). Based on the inhibitory concentration (IC) curves the 20% inhibitory concentration (IC20) of each metal was calculated. Fish were exposed to binary and ternary mixtures of the three metals at the determined IC20 for each metal for 24 h and the acuity of the olfactory system was measured using EOG. In order to find out whether or not rainbow trout can detect the metals using olfaction, fish were tested for their EOG response to 10^{-6} M and water quality criterion concentrations of each metal. The IC20 of Cd and Cu on olfactory function of rainbow trout was calculated at 24.4 and 4.6 µg/L (2.2×10^{-7} and 7.2×10^{-8} M), respectively. Nickel did not impair rainbow trout olfactory function at environmentally relevant concentrations, therefore, in the mixture experiment the acute water quality criterion for Ni 770 µg/L (13.6×10^{-6} M) was used. Binary mixtures of Ni + Cd and Ni + Cu showed synergic olfactory impairment, while Cd + Cu showed an antagonistic olfactory impairment. Rainbow trout were able to detect all three metals at both 10^{-6} M and water quality criteria concentrations. The results of the current study suggest that some of the criteria used for the protection of aquatic life, such as the Cu acute criterion, might not be protective against adverse effects of even single contaminants on the olfactory system of fish. Additionally, interactions between some specific contaminant mixtures, such as Ni with Cd or Cu, might increase the toxicity of each individual contaminant. Current water quality criteria do not take these mixture interactions into account. On the other hand, rainbow trout may be able to detect and probably avoid contaminant metals at criteria concentrations.

558 Metal-mixture toxicity (Copper + Nickel + Zinc) to aquatic insect communities in mesocosms

T.S. Schmidt, USGS / Colorado Water Science Center; J. Miller, USGS / Fort Collins Science Center; C. Mebane, USGS / Water; L.S. Balistrieri, USGS

Surface waters are nearly always comprised of mixtures of metals while aquatic life criterions are applied one metal at a time. There is virtually no data on metal mixture effects on aquatic insect communities, thus it is generally unknown if metal-mixtures are more or less toxic than expected from the sum of effects of metals individually (response addition). We have conducted four, 30-day mesocosm evaluations of metal-mixtures with the goal of developing a predictive model of the effects of metal-mixtures on aquatic ecosystems. Having executed experiments using Copper (Cu), Cadmium (Cd), and Zinc (Zn) singularly and in mixture, here we present early results of a Cu, Nickel (Ni), and Zn experiment. Nominal aqueous dissolved concentrations ranged from 1 – 100 µg/L for Cu, 0.3 – 800 µg/L for Ni, and 1 – 1600 µg/L for Zn. Average water quality characteristics were 15 mg/L alkalinity as $CaCO_3$, 16.6 mg/L hardness as $CaCO_3$, and 3.2 mg/L dissolved organic carbon. Toxicity to mayfly abundance was greater for Cu (LC50 = 16.6 µg/L nominal) then for Ni (53.62 µg/L nominal) or Zn (198.5 µg/L nominal). LC50 values are expected to fall once measured concentrations are available because observed concentrations in mesocosms are regularly 30-60% lower than nominals. In all cases, given the assumptions of response addition, Ni + Zn mixtures were less toxic than expected, as was true for Cu + Ni + Zn. Prior mesocosm tests also support this finding; generally metal-mixtures are less toxic than expected but not grossly different from additivity. Thus, the assumption of additivity commonly used in risk assessments of the effects of metal-mixtures on aquatic insect communities continues to be a reasonable assumption.

559 Modeling the Chronic Effects of Metal Mixtures to Aquatic Organisms: A Meta-analysis

C. Nys, T. Van Regenmortel, C. Janssen, Ghent Univ / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab Unit; R. Blust, Univ of Antwerp / Systemic Physiological and Ecotoxicological Research Group; E.E. Smolders, Katholieke Universiteit Leuven / Division Soil and Water Management; K. De Schamphelaere, Ghent Univ (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab Unit

Although metals in the aquatic environment mostly occur as mixtures, ecological risk assessment procedures are currently based on a metal-by-metal approach. Recently, different methods to evaluate risks of metal mixture exposures have been proposed. These methods combine the bioavailability-based SSD-approaches of the individual metals with two generally used mixture reference models, concentration addition (CA) and independent action (IA). However, the assumptions underlying each of these methods have not yet been tested. In several experiments conducted over the past years, we investigated chronic toxicity of Ni, Zn, Pb, Cu and Cd mixtures in different combinations to the crustacean Ceriodaphnia dubia (7d reproduction), Daphnia magna (21d reproduction) and the algae

Pseudokirchneriella subcapitata (72h growth). In the present study, we combined all our mixture toxicity data in a meta-analysis to evaluate two risk assessment related questions at the single species-level: I) Which of the two commonly applied mixture reference models (CA or IA) describe metal mixture toxicity most accurately; II) Which of those two models is most conservative for chronic mixture toxicity? For C. dubia, the IA model described metal mixture toxicity clearly more accurately than the CA model. However, for D. magna and P. subcapitata the CA model performed slightly better than the IA model. In general, the CA model was the most conservative model. In addition, we observed that the CA model was generally protective at the effect sizes relevant for environmental risk assessment frameworks, but also overestimated metal mixture toxicity at the EC10 level on average by 1.4 fold. Finally, we compared the prediction performance of two metal mixture bioavailability models (MMBM), an IA based MMBM and a CA based MMBM (WHAM-F_{Tox}) for predicting chronic Ni-Zn-Pb mixture toxicity to C. dubia. The IA MMBM predicted metal mixture toxicity more accurately than the WHAM-F_{Tox} model. In addition, the MMBM had a higher predictive potential than an IA model simply relying on free metal activity or on the dissolved metal concentration. Overall, our study confirms that the CA reference model can be used as a conservative first tier in a tiered metal mixture risk evaluation scheme, but more accurate models are needed in higher tiers. Calibrated metal mixture bioavailability models can predict mixture toxicity more accurately than models merely based on dissolved concentrations or free ion activities.

Developments and Barriers in the Adoption of Amendments for Soil and Sediment Remediation

560 Tools to overcome barriers for in-situ sediment treatment in the U.S

J.H. Stern, Dept of Natural Resources and Parks; C.R. Patmont, Anchor QEA, LLC; R.G. Luthy, Stanford Univ

Extensive experimental studies and field trials have shown that, when applied correctly, in-situ treatment via contaminant sequestration and immobilization using a sorbent material such as activated carbon has now progressed from an innovative sediment remediation approach to a proven, reliable technology. However, there are still significant institutional barriers that limit its application. This presentation will summarize key tools that have proven effective in advancing this technology and getting in-situ treatment incorporated into the remedy at a site. First, an important initial step is to develop a robust conceptual site model that presents a clear understanding of sediment dynamics and stability, and ongoing sources and background levels of contamination. This step is essential for gaining regulatory and stakeholder acceptance of sites for which in-situ treatment can be effective. Second, comparative evaluations of remedial alternatives, building on laboratory and field studies and using modeling as appropriate, are needed to accurately contrast the short- and long-term impacts and effectiveness of in-situ treatment versus more traditional remediation methods such as dredging and capping or natural recovery processes. This allows for proper site-specific balancing of the potential benefits, risks, ecological effects, and costs of in-situ treatment relative to other sediment cleanup technologies. In particular, the type and size of amendments can have effects on persistence, kinetics driving bioavailability, and ecological effects, often defining clear tradeoffs that have differing importance with key stakeholders and resource and regulatory agencies. Third, while there are few remaining technical issues associated with in-situ treatment that have not already been thoroughly addressed in previous field trials and full-scale applications, performing pilot studies focused on specific agency or stakeholder concerns can be pivotal to achieving acceptance. Such trials are important because contaminated sediment sites often have unique physical, chemical, and hydrodynamic factors affecting remedial design. Finally, early identification and focus on cost-effective designs and application methods that appropriately address site-specific conditions can streamline the overall evaluation. Lessons learned from completed and ongoing in-situ treatment projects will be reviewed.

561 Modeling Activated Carbon Amendments in Shallow Ecosystems

M. Rakowska, Texas Tech Univ / Civil Environmental and Construction Engineering; D. Kupryianchyk, Umeå Univ / Dept of Chemistry; D.D. Reible, Texas Tech Univ / Civil and Environmental Engineering; A. Koelmans, Wageningen Univ / Aquatic Ecology and Water Quality Management Group

In the past decade significant advancements have been made to understand the effectiveness and ecological benefits of amending activated carbon (AC) to sediments contaminated with hydrophobic organic compounds (HOCs). Laboratory as well as pilot-scale field studies have shown that application of up to 4% AC results in effective removal of sediment porewater HOC and consecutively reduced bioaccumulation in benthic invertebrates and fish [1,2]. Therefore, amendment strategies involving AC are rapidly gaining popularity and viewed as a sediment management option. However, integrative models of the fate and transfer of HOCs in AC amended ecological systems in situ are scarce. Current biouptake models may not adequately explain responses to different AC treatments in natural ecosystems with varying food availability and thus predict long-term bioaccumulation of HOCs in aquatic organisms. In this study, we developed an integrated mass balancing approach to model fate and transfer of polychlorinated biphenyls (PCBs) in ditch ecosystems amended with powdered (PAC), granular AC (GAC) and with subsequent removal of AC granules, i.e. sediment stripping to interpret the bioaccumulation results in our test systems. The PCB concentrations in the aqueous phase was modeled using multiple terms for exchange between (a) porewater, (b) overlying water, (c) air (d) fish, (e) macrophytes, (f) zooplankton, (g) invertebrates, (h) slow sediment sorption domains, (i) PAC or GAC and (j) degradation. This presentation will focus on the development and application of the ecosystem model and discuss the application of the model for AC amended systems. Specifically, the agreement of the model with observed PCB body burdens for fish, macrophytes and zooplankton with and without sorbent amendment will be discussed. The model integrates across the various phases and fauna and provides a more realistic assessment of the ecological response to AC in field settings.

562 Activated carbon amendments in PCB contaminated sediment: full life cycle test with Chironomus riparius

I. Nybom, Univ of Eastern Finland; S. Abel, J. Akkanen, Univ of Eastern Finland / Dept of Environmental and Biological Sciences

Carbon amendments have been shown to be an effective in-situ remediation method for contaminated sediments. Especially activated carbon (AC) amendments have a strong sorption capacity towards many hydrophobic organic compounds, and they have been shown to reduce aqueous and bioaccumulated concentrations both in laboratory and field studies. Along with the remedial benefits, direct adverse effects of these amendments have been reported, but the mechanism behind the adverse effects is still unknown. In addition, the effects of amendments on transport of contaminants directly from aquatic to terrestrial ecosystems by metamorphic species has not been considered before. The objectives of this study were to examine the remediation potential and possible secondary effects of AC on Chironomus riparius in a full life cycle test. AC (ø 63−200 µm) mixed into the sediment efficiently reduced PCB bioavailability determined by C. riparius bioaccumulation tests and passive samplers. Additionally, the PCB concentrations in midges emerging from AC treated sediments were reduced. Slightly improved reproduction, survival, larvae growth and gut wall microvilli length was observed with low AC (0.5% sediment dw) dose in the sediment with low organic carbon content. However, higher AC doses (2.5% sediment dw) caused adverse effects on emergence and larval development in both study sediments. In addition, morphological changes in the gut wall microvilli layer were observed. Metamorphic species, such as C. riparius, may act as a vector for organic pollutants from aquatic to terrestrial ecosystems and according to this study AC amendments may reduce this transport. The fundamental question of balancing between the effective remedial efficiency and possible secondary effects is central in every remedial action designed. With carefully selected AC dosages and by knowing the sediment characteristics the degree of the adverse effects may be reduced. The carbon amendment method is promising, but further research is still needed to thoroughly understand the mechanism behind the secondary effects.

563 Remediation of PCB contaminated sediments using activated carbon: Thermodynamic exposure assessment

S.N. Schmidt, Technical Univ of Denmark / Dept of Environmental Engineering; T.S. Bridges, P.T. Gidley, G.R. Lotufo, C.E. Ruiz, US Army Corps of Engineers / ERDC; A.J. Kennedy, CEERD-EPR / Environmental Laboratory; N.S. Rogers, US Army Corps of Engineers / ERDC; U. Ghosh, Univ of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering; R.M. Burgess, USEPA / Atlantic Ecology Division; A. Wang, Northeastern Univ / Civil & Environmental Engineering; L.A. Fernandez, Northeastern Univ / Quantitative Landscape Ecology; P. Mayer, Technical Univ of Denmark / Dept of Environmental Engineering

The overall aim of this project was to reveal how activated carbon (AC) amendments can be most effectively applied to (1) reduce exposure of polychlorinated biphenyls (PCBs) in sediment and (2) enhance resilience of in situ sediment remedies challenged by ongoing influx of contamination. For this purpose, exposure assessments were conducted in a series of mesocosms experiments: Nereis virens (worm), Mercenaria mercenaria (clam) and Cyprinodon variegatus (fish) were exposed to PCB contaminated sediment (New Bedford Harbour, MA, USA) that was (i) amended with AC, (ii) covered by a sand cap, (iii) covered by an AC amended sand cap and (iv) covered by a mobile AC amended sand cap. Half of the mesocosms received an ongoing influx of contamination during the 90-d experiments. Quantitative thermodynamic exposure assessment (Q-TEA) was conducted before and after AC treatment based on in situ passive sampling using polyethylene discs/strips and ex situ equilibrium sampling using jars coated with µm-thin layers of silicone. Up to 130 PCB congeners were measured by each method. Based on equilibrium concentrations in polymers, activity ratios between treatments (i-iv) were determined in order to assess exposure reduction efficiency, whereas resilience of remedies was assessed from activity ratios between treatments receiving ongoing non-spiked and PCB-spiked sediment. From equilibrium sampling results, PCB sorption by AC was found to depend on the level of chlorination and ranged from 37% exposure reduction of hepta-chlorinated PCBs to 99% exposure reduction of tri-chlorinated PCBs. These results were supported by measurements in worms, clams and fish. Then, polymer concentrations were translated into freely dissolved PCB concentrations in sediment pore water (C_{free}, ng/L), and results based on in situ passive sampling and ex situ equilibrium sampling cross validated each other. Further, passive sampling was used to determine C_{free} in surface water, and these results were applied to determine the equilibrium status between sediment and water. Finally, equilibrium sampling was used to determine PCB concentrations in lipid at thermodynamic equilibrium with sediment ($C_{lipid \rightleftharpoons sediment}$, mmol/kg) that was compared to lipid normalised concentrations in biota in order to determine the equilibrium status between sediment and organisms. Further results of Q-TEA and tissue analyses will be used to assess how application impacts in situ AC treatment effectiveness.

564 How much is enough? What more is needed to gain acceptance on the use of amendments as a safe and viable treatment technology

D.S. Jones, B.J. Reese, AECOM; N.R. Grosso, EI DuPont de Nemours and Company; R.G. Stahl, EI DuPont de Nemours and Company / Corp Remediation

Sorbent amendments are well-established treatments of organic chemicals in water supplies and groundwater. Increasingly, they are being tested on metals in surface water, sediment, and soils. Approval to remediate these media in situ with sorbent amendments requires demonstration of effectiveness and evaluation of potential adverse ecological effects. A suite of such studies is focused on Biochar treatment of mercury (Hg) in surface water, sediment, and soils at a Hg impacted site on the South River, Virginia. Test methodologies included bench top, mesocosm, and pilot-scale field studies. Effectivenesswas measured as reduced concentrations of bioavailable mercury and reduced bioaccumulation in lower trophic level organisms. Geochemical analyses generally confirmed that biochar effectively reduced concentrations of Hg and methylmercury (MeHg) in, soil, pore water, and surface water from the South River. Additionally, Biochar reduced Hg methylation rates in pore water. Bioaccumulation was reduced in multiple biological end-points that were evaluated including algae, aquatic and terrestrial invertebrates, amphibians and young-of-year fish. Unintended consequences of biochar were measured as potential adverse effects on lower trophic level organisms and plants in laboratory studies. Biochar produced little or no effect on detrital processing, and plant and earthworm survival/growth in lab studies. Although studies of lotic macroinvertebrate communities suggest the potential for effects of fine-grained biochar (but not larger sizes) on community metabolism, no effects were observed for community composition in a treated pond. Further studies on benthic community effects and Hg reduction in floodplain soils and earthworms are on-going. In aggregate, these studies demonstrate that biochar effectively reduces Hg and MeHg bioavailability in this system, and suggest limited (or no) adverse effects.

565 Ongoing Degradation of an Organophilic Clay Amendment in a Sediment Cap 11 Years after Placement

H.H. Blischke, E.C. Hughes, GSI Water Solutions, Inc

A one foot thick layer of granular organophilic clay (Aqua Technologies ET-1) (OC) was placed within the McCormick & Baxter sediment cap in Portland, Oregon to reduce the potential of creosote seeps from reaching the river. Immediately after its emplacement in summer 2004, ebullition was observed overtop the footprint of the OC placement at significantly higher rates than what was observed in other locations within the sediment cap or elsewhere in the river adjacent to the sediment cap. In order to understand the ebullition, extensive study was conducted on the OC from the sediment cap. No creosote observed in any of the OC cores from the site, and it was assumed that due to the installation of a barrier wall, the source to potential creosote seeps had been eliminated by the wall. Organic matter and PAHs were analyzed from the ET-1 in 2008, 2009 and 2015. Low level PAHs were detected within the OC that are consistent with low level PAHs present in groundwater passing through the sediment cap. Low-level PAHs were detected at concentrations that typically fell between the method detection limit and reported detection limit. The summation of carcinogenic PAHs range from 0.03 mg/kg to 0.4591 mg/kg. In a 2008 study, the average organic matter content of several site OC samples was 15.9 percent (+/- 2.6 percent). Fresh OC organic content has an average of 24.1 percent (+/- 0.16 percent). At that time, the OC had been in place within the sediment cap for 4 years, which results in an estimated half-life for the organic matter within the clay of 6.6 years. Since the PAH concentrations within the OC are very low and there are no other significant sources of organic carbon expected to sorb to the OC within the sediment cap, the primary source of organic matter measured in the OC is within the structure of the OC itself. In 2015, the organic content ranged from 7.78 to 9.85 percent with an average of 8.56 percent. These results indicate that the OC is continuing to degrade with a half-life on the order of approximately 6 to 7 years. If the clay continues to degrade at this rate, it will return to its original bentonite form in approximately 40 years after installation of the sediment cap. While the degradation of the OC has not resulted in protectiveness issues at the Site, it has likely caused the limited buckling of the sediment cap observable in areas where the OC was placed due to loss of mass.

566 Predicting Cu and Zn sorption capacity of biochars based on source material and pyrolysis temperature

A. Rodríguez-Vila, Univ of Vigo; H. Selwyn-Smith, L. Enunwa, Univ of Reading; T. Sizmur, Univ of Reading / Geography and Environmental Science

Biochars are produced by combusting organic materials in the absence of oxygen (pyrolysis). There has been recent interest in using biochars to remediate metal contaminated soils and sediments due to their low cost, high surface area, resistance to degradation and high sorption capacity for metals. The diversity of biochars is huge because they can be produced from almost any organic material under a range of conditions (e.g. pyrolysis temperature, heating rate, and duration, or surrounding gases). However, a mechanistic understanding of how source materials and pyrolysis conditions contribute to the metal sorption capacity of the resulting biochar is lacking. This lack of understanding prevents us from predicting the performance of a biochar, and thus prevents us from producing custom biochars under defined conditions for specific applications, without experimentation. We produced biochars form 10 different organic materials by pyrolysing at 450°C. We then produced a further 10 biochars from one organic material (cedar wood) by pyrolysing at 10 different temperatures, increasing at 50°C intervals from 250°C to 700°C. Batch sorption experiments were conducted on all 20 biochar samples to construct Cu and Zn sorption isotherms. Isotherms were fitted to a Langmuir sorption model to derive the maximum Cu and Zn sorption capacity of each biochar. Cu and Zn sorption capacity of 450°C biochars could be predicted from the C:N ratio of the source material prior to pyrolysis. We also found a positive sigmoidal relationship between the pyrolysis temperature of the cedar wood biochar and the maximum Cu and Zn sorption capacity. FTIR analysis of the biochars revealed that as pyrolysis temperature increased there was a reduction in the abundance of oxygenated functional groups on the surface of the biochar and an increase in aromaticity. We therefore conclude that the higher sorption capacity of biochar produced at a higher temperature is due to an electrostatic attraction between the positively charged Cu and Zn ions and the delocalised pi-electrons on aromatic structures on the electronegative surface of the biochar. These relationships between biochar production parameters (source material and pyrolysis temperature) and the metal sorption capacity of the resulting biochar are the first step towards creating a biochar sorption model that will enable us to predict and produce custom biochars for specific applications, without costly experimentation.

567 Contaminant remediation: lessons learned from an ongoing field experiment with biochar to remediate a petroleum contaminated soil in Havana, Cuba

D.S. Pacheco, CENSA; I. Hilber, Agroscope ART; A. Escobar Medina, CENSA; N. Bartolomé, Agroscope ISS / Analytical Chemistry Natural Resources Environmental Protection in Agriculture; T. Bucheli, Agroscope ART / Environmental Analytics Natural Resources and Agriculture

Our recent monitoring campaign to determine organic contaminants in soils of the Havana province in Cuba revealed elevated (>10 mg/kg) polycyclic aromatic hydrocarbon (PAHs) concentrations at some sites. An area close to Havana bay contained the highest concentrations (40 mg/kg for the sum of the 16 USEPA PAHs). At this site soil is used to clean empty petroleum tanks. The petroleum-soil mixture is added to natural soil, homogenized again, and disposed on a field of 7.2 ha. The petroleum soil layer is weekly ploughed to air the soil surface layer and thus stimulate petroleum degrading microorganisms. After about a year of natural biodegradation, total hydrocarbons, fats and oils are analysed. Only when these contaminants are below a certain threshold value, the soil will be re-used to clean petroleum tanks. However, there is no data and therefore quality control about the fate of PAHs in the contaminated soil. Currently, we are about to establish a field experiment at this location. Its overall aim is to (i) shed light on the PAH biodegradation potential of the current remediation procedure, and (ii) to evaluate whether biochar amendment leads to a PAH exposure reduction. The field experiment includes 3 plots of 5 m x 5 m that serve as control and 3 plots where 5% biochar will be added to a fresh petroleum-soil layer. Biochar is locally produced from wood logs in a traditional kiln, and will be milled before use. This setup is repeated at a site of the field where bioremediation had been going on for almost a year. To quantify the freely dissolved concentration of PAHs in the pore water low density polyethylene strips will be deployed in the soil. The strips are loaded with PAH-like performance reference compounds to account for sorption kinetics. Current barriers of our activities are manifold and encompass, among others, the following aspects: i) limited awareness and/or prioritization of environmental risks by the different stakeholders mostly due to the lack of legislation and ii) technical and infrastructural limitations in Cuba, and iii) limited knowledge of new remediation approaches such as biochar amendment.

Strategies for Assessing Chemicals for Endocrine Activity: Making the Best Use of Screening-Level Information

568 Harnessing High-Throughput Monitoring Methods to Strengthen 21st Century Risk-Based Evaluations

J. Sobus, USEPA; A. Williams, A. Richard, C. Grulke, USEPA / ORDNCCT; K. Mansouri, USEPA / Environmental Sciences; B. Beverly, USEPA / Reproductive Toxicology Branch; J.E. Rager, USEPA; E.M. Ulrich, USEPA / Office of Research and Development National Exposure Research Laboratory; M.J. Strynar, USEPA / National Exposure Research Laboratory

Over the past ten years, the US government has invested in high-throughput (HT) methods to screen chemicals for biological activity. Under the interagency Tox21 consortium and the US Environmental Protection Agency's (EPA) ToxCast™ program, thousands of chemicals have been evaluated for bioactivity across hundreds of assays. While these efforts support hazard-based prioritizations, exposure-focused programs have also emerged (e.g., EPA's ExpoCast™ program) to translate hazard data into risk- based decisions. This integrated screening framework offers an unprecedented means to improve chemical safety assessments in the US. Despite their obvious benefits, HT screening programs are not without challenges. The ToxCast program faces the daunting task of measuring bioactivity for thousands of registered chemicals, while attempting to model activity for unknown numbers of potential biological metabolites and environmental transformation products – data are needed to help prioritize the larger universe of candidate chemicals for further testing. The ExpoCast program is developing efficient models to estimate potential exposures, but lacks measurement data needed for parameterization and evaluation. This lack of measurement data, in both environmental and biological systems, often leads to large uncertainties in final exposure estimates. Clearly, HT chemical monitoring methods are needed to support ongoing efforts in the ToxCast and ExpoCast programs. Suspect screening and non- targeted analysis methods (SSA and NTA, respectively) are well suited to meet these needs, as they can rapidly generate measurement data for thousands of previously unstudied chemicals. Noting the opportunity to fill critical knowledge gaps, efforts are underway at EPA to develop, evaluate, and effectively use SSA and NTA workflows and data. As a reflection of these efforts, this presentation will highlight: 1) a framework for integrating SSA/NTA research within EPA's ToxCast and ExpoCast programs; 2) results of a SSA case study that exploited ToxCast and ExpoCast data to identify emerging contaminants in house dust; and 3) software tools and databases being developed within EPA to support SSA/NTA activities across the broader research community. The goals of this presentation are to communicate EPA's ongoing SSA/NTA research efforts, and to foster discussion on the potential contributions of HT monitoring methods towards advancing 21st century risk-based evaluations.

569 Application of ToxCast High-Throughput Screening and Modeling Approaches to Identify Steroidogenesis Disruptors

A. Karmaus, Integrated Laboratory Systems, Inc. / NTP Interagency Center for the Evaluation of Alternative Toxicological Methods (NICEATM); M. Martin, USEPA / National Center for Computational Toxicology

Environmental chemicals can elicit endocrine disruption by altering steroid hormone biosynthesis and metabolism (steroidogenesis) causing adverse reproductive and developmental effects across mammalian and aquatic species. Historically, a lack of assays resulted in few chemicals having been evaluated for effects on steroidogenesis. The steroidogenic pathway is a series of hydroxylation and dehydrogenation steps carried out by CYP450 and hydroxysteroid dehydrogenase enzymes, yet the only enzyme in the pathway for which a high-throughput screening (HTS) assay has been developed is aromatase (CYP19A1), responsible for the aromatization of androgens to estrogens. Recently, the ToxCast HTS program adapted the OECD validated H295R steroidogenesis assay using human adrenocortical carcinoma cells into a high-throughput model to quantitatively assess the concentration-dependent (0.003-100 µM) effects of chemicals on 10 steroid hormones including progestagens, androgens, estrogens and glucocorticoids. These results, in combination with two CYP19A1 inhibition assays, comprise a large dataset amenable to clustering approaches supporting the identification and characterization of putative mechanisms of action (pMOA) for steroidogenesis disruption. In total, 514 chemicals were tested in all CYP19A1 and steroidogenesis assays. Of these, 216 chemicals were identified as CYP19A1 inhibitors in at least one CYP19A1 assay, and 208 of these chemicals also altered hormone levels in the H295R assay, suggesting 96% sensitivity in the ability of hormone quantification to identify CYP19A1 inhibitors. The steroidogenesis data were also used to model CYP17A1 inhibition. Using increases in progestagens and glucocorticoids with simultaneous decreases in androgens and estrogens as a profile indicative of CYP17A1 inhibition, known CYP17A1 inhibitors such as conazole fungicides including prochloraz were correctly identified. Cumulatively, our examples demonstrate that computational profiling of in vitro data provides a model that characterizes pMOAs for steroidogenesis disruption to support the identification of endocrine disruptive chemicals. This abstract does not necessarily reflect USEPA policy.

570 The developing fathead minnow as a screen for thyroid disrupting compounds: Identification of sensitive endpoints

E. Path, Texas Christian Univ; M.K. Sellin Jeffries, Texas Christian Univ / Dept of Biology

The fathead minnow (Pimephales promelas) is often used as a model organism to assess acute and chronic toxicity and to screen for reproductive endocrine disrupting compounds. In recent years, developing fathead minnows have also been used to evaluate the impacts of environmental contaminants, including ammonium perchlorate and polybrominated diphenyl ethers, on thyroid function. Their use in this capacity suggests that early life stage fathead minnows may be an adequate model for the screening of compounds with suspected thyroid hormone disrupting activity. However, no studies to date have examined the impacts of model thyroid disrupting compounds on this species. With this in mind, the objective of this study was to further develop the fathead minnow as a model for the screening of thyroid disruptors by identifying sensitive indicators of thyroid disruption in this species. Newly hatched fathead minnows were exposed to low, medium, and high doses of 6-propylthiouracil (PTU; a known thyroid inhibitor) or thyroxine (T4) for 35 days. On days 7, 21 and 35, fish were evaluated for size, general physical appearance and the expression of thyroid hormone related genes. Fish exposed to PTU experienced significant reductions in wet weight and length, decreases in pigmentation, alterations in body morphology and changes in the expression of four of ten thyroid related genes evaluated (trβ, ttr, di2, di3). In contrast, the only alterations noted in fish exposed to T4 were the expression of two thyroid related genes (ttr and di3). Taken together, these results suggest that developing fathead minnows may be well suited for assays aimed at detecting compounds suspected to inhibit thyroid hormone synthesis or signaling, but may be more limited in their ability to screen for thyroid hormone mimics.

571 Leveraging high-throughput screening data to define alternative adverse outcome pathways for impaired vitellogenesis

D.A. Dreier, N.D. Denslow, C.J. Martyniuk, Univ of Florida / Physiological Sciences

Recent advances in high-throughput screening (HTS) have provided unprecedented information about the modes of actions of chemicals in the environment. Within the adverse outcome pathway (AOP) framework, this information is particularly useful for understanding molecular initiating events and early cellular responses that lead to apical effects of regulatory concern. For example, several endocrine modes of action (i.e., AR agonism, ER antagonism, aromatase inhibition) are linked to impaired synthesis of vitellogenin, the egg-yolk precursor, leading to reproductive impairment in fish and other oviparous animals. However, non-endocrine mediated pathways such as mitochondrial dysfunction, oxidative stress, and other degenerative changes in the liver can also impede the production of vitellogenin. These alternative mechanisms confound interpretations of the Fish Short-Term Reproduction Assay (FSTRA), which is used to identify endocrine-active substances in the USEPA Endocrine Disruptor Screening Program. The objective of this study was to leverage HTS data and identify compounds that act specifically through non-endocrine toxicity pathways for future AOP development. Twenty-eight assays related to mitochondrial dysfunction, oxidative stress, and endocrine disruption were compiled for 1797 compounds from ToxCast, transformed into nonparametric ranks, and imported into ToxPi. Compounds were further ranked by comparing ToxPi slice values for mitochondrial dysfunction and oxidative stress relative to endocrine signaling pathways. The analysis determined that many endocrine disrupting compounds, particularly androgen receptor agonists, also cause mitochondrial dysfunction and oxidative stress. Furthermore, nitrophenol, anthraquinone, and a subset of chlorophenol compounds were those most likely to impact mitochondrial function, while also having limited effects on endocrine signaling. Results from HTS assays were also compared for 9 compounds that decreased vitellogenin in the FSTRA, and it was determined that 4 compounds (Tetrachlorvinphos, Metolachlor, Flutolanil, Propargite) caused mitochondrial dysfunction or oxidative stress at lower doses than assays for endocrine disruption. These results suggest that mitochondrial dysfunction and oxidative stress are likely involved in the AOP for impaired vitellogenesis, and the chemicals identified through this novel computational approach should be investigated to define these alternative toxicity pathways.

572 Assessing the Potential Impact of an Amine Oxide Surfactant on Estrogenic, Androgenic and Aromatase Endpoints in a Fish Endocrine Screening Assay

S.L. Levine, Monsanto Company / Global Regulatory Sciences; G. von Mérey, Monsanto Europe S.A. / Regulatory

Amine oxides (AO) surfactants have a diverse set of applications with 95% of the volume produced in North America used in household cleaning products (e.g., dishwashing, laundry detergents and hard surface cleaners). Because of their wide-spread use they are classified as a high production volume class of compounds in several member countries by the Organizations for Economic Co-operation and Development (OECD). AO surfactants have a low potential to bioaccumulate in aquatic tissues and the AO that was tested demonstrated relatively low aquatic toxicity. These characteristics minimize the potential for environmental exposure and toxicity to aquatic organisms. The purpose of this investigation was to evaluate the potential for estrogenic, anti-estrogenic, androgenic and impacts to steroidogenesis from an AOsurfactant using a model aquatic vertebrate. Based on the non-cyclic structure of this AO surfactant, it was not predicted to be a ligand for the estrogen or androgen receptors or to disrupt steroidogenesis at environmentally relevant exposure concentrations and this is consistent with mammalian studies which have shown no reproductive and developmental effects. Fathead minnows were tested following the OECD 230 test guideline at concentrations of 0.14, 1.4 and 14 mg/L in a flow-through system after a 21-day continuous exposure. It was established in 14-day range-finding study that the highest test concentration did not result in overt toxicity. Endpoints used to assess activity were secondary sexual characteristics (tubercle scores) and vitellogenin levels (VTG). There were no effects on survival, growth, secondary sexual characteristics or VTG levels. Based on the endpoints evaluated, this AO surfactant has been shown to not have estrogenic, anti-estrogenic, androgenic effects or produce aromatase inhibition in fish, which confirms initial predictions based on its structures and results from mammalian studies for structurally similar AO surfactants. The no observed effect concentration (NOEC) was concluded to be 14 mg/L, a level that greatly exceeds predicted aquatic exposure concentrations.

573 Thinking outside the thyroid: Implications of disrupted thyroid hormone signaling on reproduction

P. Bruns, Texas Christian Univ; L. Thornton, Univ of North Texas / Biology; M.K. Sellin Jeffries, Texas Christian Univ / Dept of Biology

Traditionally, research into the effects of endocrine disrupting compounds (EDCs) has focused on one endocrine axis independent of all others. This approach may be shortsighted given evidence that alterations in signaling along one endocrine axis can affect signaling in others. For example, changes in thyroid hormone levels are known to alter reproductive function in a variety of vertebrates suggesting that thyroidal EDCs have the potential to alter reproductive function via novel mechanisms. Understanding thyroid-reproductive system interactions in model organisms, such as the fathead minnow (Pimephales promelas), is important when screening for EDCs and in establishing potential adverse outcome pathways for a compound. The objective of this study was to determine the reproductive outcomes of thyroid disruption as evaluated across multiple levels of biological organization (e.g., molecular, cellular and whole organism). Fathead minnows were exposed to the known thyroid disruptors polybrominated diphenyl ether 47 (PBDE-47), thyroxine (T4) or propylthiouracil (PTU) for 28 days via the diet. On day 7 of the exposure period, minnows were subjected to a 21 d breeding study during which time fecundity, clutch size, fertilization success and hatching success were evaluated. Upon termination of exposure, thyroid hormone- and sex steroid hormone-related gene expression, plasma sex steroid levels, gonadal histology, and sperm motility were evaluated. The results of this study revealed that thyroidal EDCs are capable of altering not only thyroid signaling in minnows, but also reproductive endpoints. For example, minnows exposed to PBDE-47 experienced significant alterations in the expression of thyroid-hormone related genes including deiodinase II and transthyretin confirming alterations along the HPT axis. In addition, females exposed to PBDE-47 were found to have significantly reduced gonadal expression of aromatase and estrogen receptor alpha than controls, while males were shown to have decreased plasma 11-ketotestosterone levels. The low binding affinity of PBDE-47 to sex steroid hormone receptors, combined with a lack of alteration in vitellogenin, suggest that the impacts of PBDE-47 on the HPG axis are the result of thyroid disruption, rather than direct interaction with sex steroid hormone receptors. Overall, this study shows that the impacts of thyroidal EDCs extend beyond the HPT axis to the HPG axis, which should be considered in EDC screening assays.

574 Reliance on whole animal tests to detect the reproductive effects of municipal wastewater effluents

G.J. Van Der Kraak, Univ of Guelph; J. Matsumoto, Univ of Guelph / Integrative Biology; M.R. Servos, Univ of Waterloo / Dept of Biology; C.R. Schilling, Univ of Guelph / Dept of Integrative Biology

We conducted lab based experiments to determine the potential of effluents from different municipal wastewater plants to affect the reproduction of adult zebrafish. The endpoints measured included whole animal reproductive performance based on the numbers of eggs spawned over a 7-day exposure period and biomarkers of reproductive function including the levels of sex steroid hormones levels in ovarian tissue and the expression of selected genes in the ovary. In studies conducted in 2013 and 2015, a 50% dilution water collected immediately downstream of the wastewater treatment plant in Waterloo Ontario resulted in a significant reduction (50 and 85% in the two years) in the numbers of eggs spawned. In contrast effluent collected downstream of two different sewage treatment plants (Kitchener and Guelph, Ontario), an upstream reference site on the Grand River (Hespler) and the laboratory control water had no effects on spawning success. Measurement of ovarian testosterone and 17β-estradiol levels did not reveal an effect for fish exposed to the Waterloo effluent whereas zebrafish exposed to the Guelph effluent had lower levels of 17β-estradiol but only for the 2013 study. Expression of genes involved in steroid hormone biosynthesis including steroid acute regulatory protein, aromatase and the luteinizing hormone receptor also failed to reveal a consistent pattern of response. A reduction in aromatase expression was seen in fish exposed to the Waterloo effluent in 2013 but not 2015 whereas the other genes were not affected. Similarly fish from the Guelph site showed a reduction in aromatase in the 2013 but not the 2015 studies. We detected high concentrations of ammonia in the Waterloo effluent which we suspect is responsible for the reproductive impairment. Indeed other studies in which zebrafish were exposed to ammonia led to impairment in spawning success but inconsistent effects on steroid hormone levels or the expression of genes involved in steroid hormone biosynthesis. Collectively these studies suggest that the inclusion of endpoints of whole animal performance such as spawning success are a far more robust screen of reproductive toxicants than measurements of hormone levels or gene expression particularly when the underlying mechanisms of reproductive impairment are unknown.

575 Testing for Endocrine-Mediated Effects in Vertebrate Ecological Receptors: Potential for Read-across

J.P. Staveley, Exponent; E. Freeman, M.E. McArdle, Exponent, Inc.; L.S. Ortego, Bayer CropScience / Environmental Toxicology and Risk Assessment; K.K. Coady, The Dow Chemical Company / Toxicology Environmental Research and Consulting; L. Weltje, BASF SE

The U.S. Environmental Protection Agency (EPA) and the Organisation for Economic Cooperation and Development (OECD) have developed numerous tests to evaluate whether a chemical has the potential to interact with the endocrine system. Testing programs such as the EPA's Endocrine Disruptor Screening Program have purposefully included redundant tests to avoid false negatives. Given the impracticality of testing all man-made chemicals using traditional animal tests, predictive models and screening methodologies are needed. Approaches based on adverse outcome pathways (AOPs) may be advantageous in assessing species susceptibility and helping to prioritize chemicals for further testing. Certain axes, such as the hypothalamus-pituitary-gonadal (HPG) axis, are highly conserved among vertebrates; thus, there is a potential to use existing data for mammalian models to evaluate other vertebrates (fish, amphibians, birds, and reptiles). Read-across and computational approaches are promising for chemicals that interact with endocrine systems with known modes of action. We reviewed the HPG axis, hypothalamic-pituitary-thyroid (HPT) axis, hypothalamic-pituitary-adrenocortical axis, somatotropic axis, retinoid signaling pathway, vitamin D signaling pathway and peroxisome proliferator-activated receptor signaling pathway for homology and potential for read-across application. Important considerations for read-across and computational approaches include potency and internal dosimetry. Read-across and computational approaches that rely upon molecular or cellular assays may be difficult to interpret for chemicals that are activated through metabolism. In addition, conserved hormones may have different roles among vertebrates (e.g., prolactin controls osmoregulation in fish and lactation in mammals) and will need to be considered. The most promising read-across approaches for chemicals that interact with the endocrine system based on availability of data are between mammals and fish. Validation of read-across and computational approaches will be needed and the type and degree of necessary validation has yet to be determined. Future research should focus on filling data gaps to current read-across and computational approaches, instead of testing more species.

Passive Sampling in the Aquatic Environment: Recent Developments and Advances

576 Visibly-detectable Dyes as Performance Reference Compounds in Passive Sampling Devices

J.M. Conder, M. Vanderkooy, Geosyntec Consultants; M. Healey, SiREM; J. Thompson, Geosyntec Consultants; C.L. Thomas, The Univ of Texas at Austin / Civil Architectural and Environmental Engineering; J. Roberts, SiREM; M.M. Grover, Geosyntec Consultants

Dozens of research efforts in the previous 10+ years have demonstrated that measurements made using Passive Sampling Devices (PSDs) represent precise and accurate estimates of available organic compounds in aquatic sediment, surface water, and soil. To overcome the challenges of impractical PSD deployment times in environmental matrices, the PSD research community has adopted the use of Performance Reference Compounds (PRCs) which are loaded into PSDs prior to deployment and used to infer the fraction of steady state attained during the deployment. Traditional PRCs have included compounds with a similar hydrophobicity to the compounds of interest such as stable isotope-labeled or deuterated forms of the compounds of interest or compounds that are not expected to be absorbed in significant amounts (e.g., rare Polychlorinated Biphenyl (PCB) congeners). Adding these PRCs to PSDs is expensive and requires complicated and time-consuming PRC measurement techniques (e.g., GC or HPLC methods). This presentation will highlight the application of a potentially more time- and cost-efficient suite of compounds for PRCs: visibly-detectable dye compounds. Compared to compounds traditionally used as PRCs, dyes are orders of magnitude less expensive, generally less toxic, can be added and extracted from PSDs in amounts easily measured via Ultraviolent/Visible (UV/VIS) spectroscopy or other visible/ colorimetric means, and can be observed in the PSDs with the naked eye. Measurement of dyes in PSDs can be performed with an inexpensive benchtop UV/VIS spectrophotometer via a non-destructive technique in a matter of seconds for a fraction of the cost to measure traditional PRCs. This presentation will detail the approaches and benefits of using dyes as PRCs in a commercially-available PSD, as well as empirical evidence that demonstrates the proof of concept. Our experiments in static and mixed PSD deployments in the laboratory, as well as deployments in the field, indicate the kinetics of dye PRC desorption match those of target analytes (and traditional PRCs) such that dye PRCs can serve as replacements for traditional PRCs. Overall, the use of dye PRCs will allow a much more streamlined and efficient approach for PSD research and development and will also enable more cost-effective analytical chemistry techniques.

577 Cross-validation of passive sampler measurements at the sediment-water interface by parallel use of PE and silicone sheets on a new porewater probe

D. Gilbert, N. Berrojalbiz, NE. Eek, A.M. Oen, H.H. Arp, Norwegian Geotechnical Inst / Environmental Technology

In situ data from passive samplers in water and sediment are often challenged by the fact that passive samplers do not reach equilibrium for all compounds within the deployment time. Another challenge is the availability and quality of polymer-water partition coefficients that are needed to convert measured concentrations in polymers to freely dissolved aqueous concentrations. We followed a new strategy of deploying two types of polymers in multiple thicknesses simultaneously to offer means of cross-validating passive sampler field data. To quantify chemical activity gradients over the sediment-water interface, we deployed µm-thin LDPE films and silicone PDMS membranes as passive samplers integrated in a recently developed sediment porewater probe that offers a 2.5cm vertical resolution of the contamination profile within the sediment. Based on the various thicknesses of the deployed passive samplers, the equilibration status of the samplers was assessed and compared to the results from dissipation rates of performance reference compounds (PRCs) that had been spiked into all polymers prior to field exposure. At the same time, it was possible to cross-validate estimated freely dissolved concentrations on the basis of both polymer-water and polymer-polymer partition coefficients for the two types of polymers. Finally, all in-situ sediment data were compared to ex-situ equilibrations with passive samplers of multiple thicknesses. Both silicone and LDPE seemed suited for sampling PAHs and alkyl-PAHs, PCBs and chlorinated pesticides. In conclusion, parallel deployment of thin sheets of LDPE and silicone in various thicknesses proved to be a simple and effective tool to validate obtained passive sampling data for a wide range of hydrophobic organic chemicals. At the same time, the results raise the question whether a PRC correction for non-equilibrium situations should be applied in all instances.

578 Method comparison for measurement of porewater Fe(II) and sulfide: in situ DET and DGT vs. ex situ centrifugation followed by colorimetric analysis

R. Nadeeka Suranganee, Griffith Univ / Environmental Future Research Inst, School of Environmental Science; P.R. Teasdale, Griffith Univ / Griffith School of Environment; D. Welsh, Griffith Univ / Environmental Futures Research Inst; W.W. Bennett, Griffith Univ / Griffith School of Environment

In productive coastal sediments, the distance between the oxic and anoxic layers may be as little as a few millimeters. In such sediment the distributions of products of different respiration types can form a complex 'mosaics' resulting in iron(II) and sulphide being present at the same depth horizons on scales sampled by common methods. Many porewater sampling and analysis methods simply cannot distinguish changes over such small distances. Therefore, in sediment with complex, three-dimensional, time-dependent heterogeneity, it can be extremely difficult to examine the fine-scale (mm to sub-mm) chemical distributions of important chemical species using typical sampling and measurement methods. Typical porewater sampling techniques require the removal and processing of sediment cores. Porewater profiles are obtained by slicing the collected cores at 1 cm resolution, homogenizing the material and centrifugation of the section to extract pore waters, which are then analysed. This mixes the porewater solutes, which is likely to result in chemical reactions (e.g. formation of FeS) that change the solute concentrations considerably, making the final porewater concentrations measured inaccurate and non-representative. The diffusive equilibration in thin films (DET) and the diffusive gradients in thin films (DGT) techniques allow the in situ determination of elemental solute concentration profiles in sediment pore waters and also provide two-dimensional distributions at higher spatial resolution than is possible employing conventional techniques. This allows measurement of mm-scale features, facilitating the investigation of small scale biogeochemical processes and heterogeneity within the sediment. Furthermore, the in situ nature of the DGT and DET techniques limits inaccuracies caused by removal and processing of sediment pore waters. This study has obtained measurements of sediment porewater Fe(II) and sulphide co-distributions using conventional core sampling technique and new colorimetric passive sampler techniques. This study suggests that the colorimetric Fe(II)-DET and sulphide-DGT measurements are both more accurate and more representative than the conventional analysis of porewaters separated by centrifugation, even with the precautions taken against oxidation. This comparison will be an important validation step that will lead to the new techniques being accepted. Recent results of comparison of metal analysis will also be presented.

579 Strategies for transferring mixtures of organic contaminants from multimedia environments into bioassays

A. Jahnke, Helmholtz Centre for Environmental Research – UFZ / Cell Toxicology; P. Mayer, Technical Univ of Denmark / Dept of Environmental Engineering; S. Schaefer, Federal Inst of Hydrology / Biochemistry Ecotoxicology; G. Witt, HAW Hamburg / Dept of Environmental Engineering; N. Haase, B. Escher, Helmholtz Centre for Environmental Research GmbH – UFZ / Cell Toxicology

Many of the chemicals that we use in our daily lives end up in multimedia environments including biota where they may pose a risk to ecosystems and human health as part of mixtures and together with their transformation products. Depending on the persistence and physicochemical properties of the organic contaminants, individual chemicals that make up the mixture partition and distribute within the environment and might then jointly elicit toxicological effects. For the assessment of the hazard potential and for the monitoring of such mixtures, a variety of cell-based in vitro and low-complexity in vivo bioassays based on algae, daphnids or fish embryos are available. Bioassays provide an integrative measure of the overall toxic potential of a sample and are hence complementary to chemical analysis that provides quantitative information on selected chemicals. However, the quantitative link between the exposure in the environment and that in the bioassay is not always taken into account. Establishing this link is difficult because different chemicals have distinct enrichment factors and sampling rates. Furthermore, they sorb to different extents to sorptive phases present in bioassays, which reduces exposure. The major obstacles to successfully applying bioassays for assessing environmentally relevant mixtures of organic pollutants are to collect, extract and dose the mixture into the bioassay without the mixture composition being altered while linking the observed effect back to the concentrations in the original medium. This presentation outlines various strategies of quantifiable transfer of organic contaminants from the aquatic environment including water, sediment and biota into bioassays covering sampling, extraction (exhaustive extraction vs. passive sampling) and dosing (solvent spiking vs. passive dosing) to transfer the mixtures into bioassays, while conserving or re-establishing their chemical composition at adjustable levels for concentration-effect assessment.

580 A Non-Selective Passive Sampling Device to Measure Both Polar and Non-Polar Organic Chemicals in Water

D. Shea, North Carolina State Univ; K. O'Neal, CH2M; X.R. Xia, North Carolina State Univ / CCTRP / CVM; X. Kong, P. Lazaro, North Carolina State Univ

The use of hydrophobic passive sampling devices (PSDs) such as low-density polyethylene (LDPE) and semi-permeable membrane devices (SPMDs) have proven reliable for measuring longer-term (e.g., 30-day) time-weighted average (TWA) exposure to hydrophobic chemicals with log KOW values above about 4.5. However, making similar TWA measurements for more polar chemicals with log KOW below about 4.5 have not been so reliable. The polar organic chemical integrative sampler (POCIS) was developed for more water soluble organic chemicals with log < 3.0, but the POCIS often does not provide reliable quantitative exposure estimates. There also remains a gap between what LDPE/SPMDs and POCIS can accumulate with chemicals in the log KOW range of about 3.0 to 4.5 not accumulating reproducibly in either device. We have developed a more universal non-selective passive sampling device (nsPSD), which is composed of a non-selective porous stainless steel cartridge or screen and a mixed-polymer sequestration sorbent. The nsPSD has been calibrated in the laboratory for over 500 organic chemicals with log Kow values ranging from 0.2-8.15. These chemicals include polychlorinated biphenyls, current-use pesticides, organochlorine pesticides, polycyclic aromatic compounds, pharmaceutical and personal care chemicals, algal toxins, and many metabolites and other degradation products of these chemicals. We have deployed these samplers at numerous field sites and in most cases the TWA exposure estimates using the nsPSDs closely match those using sequential grab sampling (every 1-2 days) over the time of deployment. We report here on the field verification of this new nsPSD using data from numerous Superfund Sites in the US. We believe this new nsPSD has the potential to significantly advance our capability to estimate chronic exposure of chemicals in water.

581 In situ equilibrium passive sampling of hydrophobic organic compounds in coastal marine sediments

G. Witt, H. Hercht, N.C. Niehus, M. Reininghaus, HAW Hamburg / Environmental Engineering; F. Schweikert, Aldebaran Marine Research & Broadcast

The study provides the first comprehensive dataset on in situ measurements of freely dissolved concentrations and chemical activities of PAHs and PCBs in coastal sediments of the North Sea and the Baltic Sea. During a research cruise in summer 2015, 50 in situ samplers were deployed in the coastal area of Germany. After three months 37 of the samplers were recovered. SPME fibers with different coating thickness (10 µm and 40 µm) were collected and analyzed in the laboratory. During both cruises surface sediment samples were simultaneously collected at the same sampling stations. For in situ sampling an equilibrium passive sampling device was used that facilitates the in situ measurement of hydrophobic organic chemicals (PCBs and PAHs) bioavailability in sediments in terms of freely dissolved concentrations. The sampler is applicable in a multitude of aquatic environments, especially where currents are low and sediments are muddy and well-mixed e.g. by bioturbation. Examples for such environments are mud flats, harbor basins, river banks and lakes. The field sampler allows PDMS fibers and hollow fibers to be immersed and equilibrated in situ, whereas an automated liner exchanger (ALEX) facilitates the quantitative transfer of analytes to the GC without the use of extraction solvents. Additionally, ex situ SPME experiments of these sediments were performed in the laboratory with the same analytical method. Experimental parameters like temperature and exposure time were adjusted as to meet the conditions of the corresponding experiment with the in situ sampling device. Finally, the results of the in situ sampling were compared with ex situ laboratory experiments. On the basis of the experimental findings, advantages and disadvantages of ex situ versus in situ measurements are discussed. From the in situ and ex situ experiments we examined (i) spatially resolved freely dissolved PAH concentrations (C_{free}); (ii) baseline toxicity potential on the basis of chemical activities (a); (iii) site specific mixture compositions and (iv) site specific distribution ratios.

582 Current Use Pesticides in Water Resources in Ontario, Canada: Can POCIS Passive Samplers Be the Basis for a Monitoring Program?

C.D. Metcalfe, Trent Univ / Water Quality Centre; T. Sultana, Trent Univ / Environmental and Resource Studies; S. Kleywegt, Ontario Ministry of the Environment & Climate Change / Standards Development Branch; P.A. Helm, Ontario Ministry of the Environment & Climate Change / Environmental Monitoring and Reporting Branch

Current use pesticides (CUPs) enter the aquatic environment from many point and non-point sources, including runoff from agricultural areas, turf farms, public spaces, golf courses and lawns and gardens, as well as discharges from wastewater treatment plants. Over the past five years, we have been developing a monitoring program to determine the distribution and sources of CUPs in watersheds impacted by both urban and rural sources of contamination. We have deployed Polar Organic Chemical Integrative Samplers (POCIS) in rivers and streams, the nearshore zone of Lake Ontario and in sources of raw drinking water. These monitoring efforts have shown that current use herbicides, fungicides and neonicotinoid insecticides are widespread in these aquatic resources. The herbicides, atrazine, diuron and 2,4-D, and the fungicides, carbendazim, thiophanate-methyl and a hydroxy-metabolite of chlorothalonil were widely detected at estimated time weighted average concentrations in the ng/L range. POCIS deployments in raw drinking water indicated that several neonicotinoid insecticides, including thiamethoxam, clothianidin and imidacloprid were present at low concentrations in the sources of drinking water for municipalities located in rural areas. Overall, these data indicate that there are point and non-point sources of CUPs that could affect aquatic life in receiving waters and contaminate sources of drinking water. However, it is currently unclear whether data generated from POCIS passive samplers are accepted scientifically due to uncertainties regarding appropriate methods for estimating sampling rates for these devices and approaches for applying Performance Reference Compounds (PRCs) to adjust sampling rates in the field. We will describe our experience with two methods for determining sampling rates for CUPs and for applying PRCs, and we will compare our results to data reported in the literature.

583 Answering the "So What?" question: Integrating toxicological databases into passive sampler studies

D.A. Alvarez, USGS-CERC / Physiology and Biochemistry; S. Corsi, USGS; L. De Cicco, USGS / Office of Water Information; S. Perkins, USGS

The identification and quantification of chemicals in the environment has been the backbone of passive sampling studies for decades. Adding a biological effects component to those studies has required screening of extracts from passive samplers with a variety of in vitro and in vivo assays. Although informative, this requires testing one endpoint at a time which can quickly exhaust available sample volume and funding. In 2010 and 2014, semipermeable membrane devices (SPMDs) and polar organic chemical integrative samplers (POCIS) were deployed at a total of 69 sites in tributaries of the Great Lakes region. Extracts from these samplers were analyzed for a broad suite of legacy and emerging contaminants and these chemical data were compared to benchmark biological effect concentrations from the USEPA's ToxCast program. Numerous chemicals or chemical classes were frequently detected including atrazine, DEET, fragrances, phosphate-based flame retardants, PAHs, PCBs, chlordanes, endosulfan, and PBDE-47. The estimated time-weighted average water concentrations for many of these chemicals ranged from low nanogram per liter to low microgram per liter levels. Of the 170+ chemicals targeted in the SPMDs and POCIS, 66 were represented in the ToxCast database. Chemicals were screened for relative potential impact based on the ratio of concentrations in the passive samplers to the AC50 values (concentration at half maximal activity) from ToxCast. Although several chemicals exhibited some calculated activity, only a few of the PAHs were present at sufficient concentrations to suggest a potential for biological impact. This study demonstrated the utility of combining chemical data with toxicological databases to provide screening level toxicological information which can be used to direct additional in-depth study.

Complexity Kills the Minnow: Predicting the Ecological Consequences of Complex Pharmaceutical Mixtures

584 Unexpected drivers of low dose complex pharmaceutical pollutant mixture sublethal effects: when additivity in not enough

I. Rodea-Palomares, Univ of Florida / IFAS / Agricultural & Biological Engineering; R. Muñoz-Carpena, Univ of Florida / Agricultural Biological Engineering; M. González-Pleiter, Universidad Autónoma de Madrid / Biology; S. Gonzalo, Universidad de Alcala; F. Leganes, Universidad Autónoma de Madrid / Biology; S. Sabater, Universitat de Girona; M. Casellas, ICRA; F. Fernandez-Piñas, Universidad Autónoma de Madrid / Biology

Pharmaceutical pollution in freshwater systems has emerged as a major concern over the past decade. Currently, toxicity of these products is typically studied at high doses on a chemical-by-chemical basis under laboratory conditions. However, the identification of the true environmental impacts of pharmaceutical pollutants remains elusive due to complexity associated with their presence in "low doses" and "mixtures" in real world conditions. This presentation addresses the pervasive problem of low-dose pharmaceutical mixtures by developing and applying a novel experimental and statistical integrated analysis framework (GSA-QHTS). This framework combines Global Sensitivity Analysis (GSA) with Quantitative High-Throughput Screening (QHTS) as a cost-effective integrated framework that allows to screen main drivers of an experimental system respose when evaluated under a combined high-dimensional set of candidate drivers. This set of candidate drivers may include any chemical, physical or biotic factor/stressor that can be set up and control under laboratory experiments. We present a case study where GSA-QHTS allowed for the identification of the main pharmaceutical pollutants (and their interactions) driving non-linear/non-additive low-dose mixture effects at the microbial population level. Furthermore, the main pharmaceutical pollutants identified as important by GSA-QHTS at the population level were also found to be important at the community level in mesocosm experiments. Contrary to our expectations, the bioactivity of the mixtures was not predicted by the Concentration Addition additive mixture effect model. Our results suggest that we may be largely misidentifying most important emerging environmental pollutants under real world conditions.

585 Multi-Generational Exposure of Fathead Minnows to a Complex Urban Mixture of Contaminants of Emerging Concern

L. Wang, St. Cloud State Univ; U. Hasaby, W. Stanley, J. Robinson, St. Cloud State Univ / Aquatic Toxicity Laboratory; J. Ward, Univ of Minnesota / Dept of Fisheries Wildlife and Conservation Biology; H.I. Schoenfuss, St. Cloud State Univ / Aquatic Toxicology Laboratory

Complex mixtures containing contaminants of emerging concerns are present in many Great Lakes tributaries. Using existing chemical and concentration data, the study assessed how an urban derived complex mixture affected multiple generations of fathead minnows (Pimephales promelas) exposed continuously under controlled laboratory conditions. Mature and larval minnows were exposed to a mixture comprised of Galaxolide (synthetic musk), TBEP (plasticizer), Estrone, Bisphenol-A (Plasticizer), DEET, Methyl-1H-benzotriazole (anti-icing agent), Desvenlafaxine (anti-depressant), Fexofenadine (allergy medication), Metformin (diabetes medication), and Nonylphenol at low (1/10th environmental), medium (environmental), and high (10x environmental) concentrations. F1 fathead minnows were exposed while sexually mature and produced F2 generation fathead minnows that were exposed throughout their entire life cycle. F3 generation fish were exposed during early development. Multiple endpoints were measured to assess the effects of the urban mixture on fish health and development. F1 minnows exposed to the urban mixture had higher plasma vitellogenin concentrations than control fish (mean: 2.73 ug/mL and 1.91 ug/mL respectively, $p< 0.05$). Exposure did not have a significant effect on male feeding performance, but it did reduce female feeding performance in the medium and high treatments (p-value: 0.01 and 0.03). F2 larvae had a greater predator avoidance escape angle when exposed to any mixture (p-values: 0.01, 0.02, 0.03). F2 larvae exposed to the high concentration were also smaller in size (p-value 0.01). The direct impact of reduced feeding efficiency and alteration in apical endpoints central to sustaining fish populations confirms that complex urban mixtures can adversely affect fish populations.

586 Molecular and behavioural responses of caged goldfish to pharmaceuticals and personal care products exposure in Cootes' Paradise

D. Simmons, Univ of Waterloo / Biology; J. Sherry, Environment and Climate Change Canada / Water Science Technology Directorate; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; E. McCallum, McMaster Univ / Dept of Psychology Neuroscience Behaviour; S. Balshine, McMaster Univ / Dept of Psychology Neuroscience Behaviour; B. Chandramouli, J. Cosgrove, SGS AXYS

Cootes Paradise is a wetland on the western tip of Lake Ontario, and is part of the Hamilton Harbour Area of Concern. Cootes Paradise is also an important site of biological diversity and a fish nursery. The primary source of contaminants in Cootes Paradise is the Dundas municipal sewage treatment plant (STP) which discharges in to the marsh. Pharmaceuticals and personal care products (PPCPs) have been associated with STPs and their recipient waters. Some PPCPs are known to cause endocrine disruption. To assess the endocrine disrupting potential of Dundas STP effluents to wild fish in Cootes paradise, male goldfish were caged for 21-days (5/cage, 10 cages/site) at three sites along a contamination gradient within Cootes Paradise. We also caged fish at a reference site in Lake Ontario: Jordan Harbour. Twenty male wild goldfish were captured from Cootes Paradise in the summer of 2012. Concentrations of PPCPs and profiles of endogenous proteins and metabolites were determined in plasma from both the caged and wild goldfish. Half of the caged fish were assessed in behavioural assays. This talk will (1) describe the observed behavioral changes and the protein and metabolite expression patterns of the caged fish, (2) relate those changes to the burden of PPCPs in the fish plasma, and (3) assess the ability of the caged fish to predict whether similar effects are likely in wild fish populations.

587 Potential metabolic disruption in juvenile Chinook salmon exposed to a mixture of CECs in the lab and field

J. Meador, NOAA Fisheries / Ecotoxicology and Environmental Fish Health Program; A. Yeh, Univ of Washington / Dept of Environmental and Occupational Health Sciences; E.P. Gallagher, Univ of Washington

Our recent study assessed the occurrence and concentrations of a select number of chemicals of emerging concern (CECs) in water and 2 species of fish from 3 estuaries in Puget Sound, WA, USA including pharmaceuticals, personal care products (PPCPs) and industrial compounds. For samples collected over all sites, 81 analytes were detected in effluent, 25 in estuary water, and 42 in fish tissue, many at ng/g concentrations. Most of the detected compounds were antibiotics (15), neurological drugs (17), antihistamines, metabolic regulators, and several industrial compounds. Based on these data, we conducted a 50-day dose-response experiment with a dietary mixture of the most commonly detected analytes in fish tissue. The mixture included SSRIs, antibiotics, perfluorinated compounds, and drugs to treat diabetes, lipid imbalance, and hypertension. Fish were dosed for 32 days and fed clean food for 18 days. On days 32 and 50 we weighed fish and collected blood for assessment of 12 parameters including plasma glucose, triglycerides, lipase, cholesterol, and others as indicators of metabolic disruption. These blood plasma parameters were also quantified in juvenile Chinook sampled in the field from two local estuaries receiving wastewater effluent and one reference estuary. Significant differences were observed between impacted and unimpacted estuaries for several of the blood chemistry parameters. Additionally, significant differences for body mass and many blood chemistry parameters were observed in fish from the lab study that were exposed to the dietary mixture as compared to those in the control. The results from the laboratory and field studies will be presented, compared, and discussed. Supported by WA Department of Ecology G1300089 and NIEHS ES-04696.

588 Estrogenicity of wastewater and surface water: considering unknown compounds and mixture effects using an in vitro cell based assay

V.V. Yargeau, A.R. Petosa, M. Pineda, McGill Univ / Chemical Engineering

Wastewater treatment plants are point sources of contamination and regulating the quality of these discharges using chemical analysis data presents many challenges, including the selection of relevant target contaminants and the lack of consideration of potential mixture effects. The use of in vitro biological tests (bioassays) is proposed as a complementary method to assess the potential risks associated with discharges of treated wastewater. The ERα-CALUX® (BDS, Amsterdam) was used as an in vitro bioassay to assess estrogenicity of environmental waters: influents and effluents collected three sewage treatment plants and impacted surface waters. The samples were prepared by solid phase extraction (Waters® cartridges MCX and MAX) and analyzed by liquid chromatography coupled to high resolution mass spectrometry (LC-HRMS) for the quantification of 18 indicator compounds, including known estrogenic compounds. The results indicated that effluents of the wastewater treatment plants had estrogenic activity (from 1.1 to 13.7 ng E2 EQ / L) significantly lower than their corresponding influent samples (from 26.6 to 173 ng E2 EQ / L). This estrogenic activity could not be accounted for based on the concentrations of estrogens detected: concentrations of 17α-ethinylestradiol (EE2) were usually below the detection limit. This suggests the presence of other compounds which contributed to the estrogenic activity. Estrogenic activities measured in surface water varied from 4.9 to 17.1 ng E2 EEQ/L, which are higher than the estrogenic activity trigger values of 0.1 to 0.4 ng E2 EEQ/L currently proposed in literature (Jarosova et al. 2014). These results underline the importance of using biological tests in addition to chemical analyzes in assessing the quality of treated wastewater and the potential impact of treated wastewater discharges on the receiving ecosystems.

589 Pharmaceuticals in Hudson River Water: Potential Toxicological Effects and Bioaccumulation in Aquatic Vegetation Using P. virginica as a Model

A. Lee, Marist College

Rapid increase of anthropogenic pollutants such as commonly used prescription drugs and pharmaceutical personal care products (PPCPs) is raising concern among the public and scientific community. Currently, there are no available methods to remove these compounds from wastewater, potentially affecting the environment and human health. In this study, the effects of fluoxetine, amphetamine, and triclosan on potential bioaccumulation, growth and development were investigated in controlled laboratory conditions using the aquatic plant arrow arum (Peltandra virginica) as a model. The following experimental treatments were established: 0.05 and 5.00 mg/L (fluoxetine), 0.002 and 0.2 mg/L ((S)-amphetamine), 0.0023 and 0.23 mg/L (triclosan). The concentrations were based on known ambient levels. Experimental treatments were dissolved in aquaria containing 23 L of raw (unfiltered) Hudson River water and three arrow arum specimens. There were two replicates of each treatment for 12 total experimental aquaria. Two controls were set up: a stationary control with raw Hudson River water, and a flow-through control having a continuous current of Hudson River water. After 18 days of exposure the experiment was terminated and both biomass and growth were recorded. Histological analysis was conducted on paraffin imbedded tissue sections. Total chlorophyll content was determined by cold extraction with N,N-Dimethylformamide. Spectro Genesis ICP-OES was used to analyze magnesium and calcium content. Presence of amphetamine was determined using a Torion Tridion 9 gas chromatography spectrometer. Histological analysis of leaf blades, petioles and roots showed signs of cellular deformation and lysis across treatments. Chemical analysis demonstrated an increase in chlorophyll content in triclosan treatments (80 mg/L) compared to control (30 mg/L). Additional chemical analysis suggested the potential bioaccumulation of (S)-amphetamine within the respective treatments. ICP-OES analysis showed decreased magnesium levels in low and high amphetamine exposure (483.3 and 581.9 µg/g dry weight respectively) in comparison to the flow-through control (736.4 µg/g dry weight). Gas chromatography revealed the presence of amphetamine in plant tissue. The results of histological and chemical analysis show pathological and physiological tissue alteration and suggest potential bioaccumulation of pharmaceuticals in aquatic vegetation.

590 Mixture Effects on Plant Uptake of Pharmaceuticals and Personal Care Products

S.L. Nason, Univ of Wisconsin – Madison / Environmental Chemistry and Technology Program; E.L. Miller, Univ of Wisconsin – Madison / Molecular and Environmental Toxicology Center; K. Karthikeyan, Univ of Wisconsin – Madison / Biological Systems Engineering; J.A. Pedersen, Univ of Wisconsin – Madison / Soil Science

Municipal wastewater treatment plant effluents typically contain a variety of pharmaceutical and personal care product ingredients (PPCPs). In arid and semi-arid areas of the U.S. and other countries, reclaimed wastewater (RWW) is often used for irrigation, resulting in exposure of crop plants to complex mixtures of PPCPs. Crops irrigated with RWW may take up PPCPs through their roots, but the extent of their bioaccumulation in food crops is not well understood. Plants may respond to PPCPs in a concentration-dependent manner that affects their uptake, and some PPCPs may exert toxicity on plants. The effects of mixtures on plant interactions with PPCPs are not addressed in the current literature. Using the model plant Arabidopsis thaliana, we conducted root elongation assays to evaluate potential interactions between PPCPs that are commonly found in RWW. We identified several mixtures with effects of interest including synergistic toxicity when plants are exposed to both sulfamethoxazole and trimethoprim (antibiotics), and a reduction in toxicity when plants exposed to toxic levels of lamotrigine are also exposed to carbamazepine (antiepileptic drugs). Next, we conducted uptake experiments with single compounds and the identified mixtures at environmentally relevant levels. Uptake results from both A. thaliana and crop plants will be presented. Root elongation assays may be a useful tool for identifying compound combinations that affect PPCP bioaccumulation in crops plants.

591 In vitro estrogenic activity of representative endocrine disrupting chemical mixtures at environmentally relevant concentrations

D.J. Caldwell, Johnson & Johnson / Environment Health Safety Sustainability; H. Yu, Temple Univ / NSF WET Center; R. Suri, NSF Water & Environmental Technology (WET) Center, Temple Univ, Philadelphia, PA / Dept of Civil and Environmental Engineering

A wide range of natural and synthetic estrogen hormones, pharmaceuticals, pesticides and industrial chemicals may alter the function of endocrine systems and consequently cause adverse effects in wildlife and humans. These are commonly referred to as endocrine disrupting compounds (EDCs). Exposure to a mixture of EDCs has been hypothesized to have potential synergistic or antagonistic effects and can cause undesired effects that are not reflected by the individual compound. In this study, the estrogenic activities of 11 EDCs of global environmental concern were systematically investigated using the yeast estrogen screen (YES). The contribution of the individual chemical to the total endocrine activity of environmentally relevant mixtures was evaluated. For single chemicals, the relative estrogenic potency is, in order: ethinyl estradiol (EE2) > 17β-estradiol (E2) > estrone (E1) > estriol (E3) > 4-tert-octyl phenol (OP) > nonyl phenol (NP) > genistein (GEN) > bisphenol-A (BPA). Two chemicals, n-butyl benzyl phthalate (BBP) and dibutyl phthalate (DBP), showed only partial agonistic activity. Bis(2-ethylhexyl) phthalate (DEHP) showed almost no estrogenic activity in the YES assay. For binary mixtures using E2 as standard, E1, E3, EE2, BPA, GEN showed estrogenic effects, while DBP, BBP, DEHP, NP and OP showed anti-estrogenic effects. The full mixture of all these chemicals at an environmentally relevant ratio also showed weak estrogenic activity. The mixtures data were fitted to concentration addition (CA), response addition (RA) and interaction models (IR), respectively. The IR model is superior to the CA and RA models for the full mixtures containing both estrogens and antiestrogens. For the mixtures with the estrogenic group only, the mixture showed some additive effect, and results fit both CA and IR models well. Further, EE2 did not make a prominent contribution to the estrogenic activity of the mixture.

Differing Biotransformation Capacity Across Species: Measurements, Modeling and Implications for Decision Making

592 Toxicokinetics and biotransformation in aquatic invertebrates

E. Finessi, R. Ashauer, Univ of York / Environment

Pesticides, pharmaceuticals and other chemicals support our modern standard of life, but their use can have detrimental impacts on our environment. We studied the uptake, biotransformation and elimination (toxicokinetics) of pharmaceuticals in aquatic invertebrates because toxicokinetics determine the internal dose, which in turn determines toxicity. Here we present experimental evidence that biotransformation rates and pathways differ across different species of aquatic invertebrates. In particular we will present new data on ibuprofen toxicokinetics in Daphnia magna, Hyalella azteca and Lymnaea stagnalis. Further, we will place this new data in the context of recently published studies with other species and substances to reflect on the current understanding of biotransformation capacity across different species of aquatic invertebrates. Studying the comparative toxicokinetics of small, aquatic invertebrates is of great interest because it contributes to understanding evolutionary and environmental mechanisms and causes of differences in species sensitivity to chemicals.

593 Bioconcentration tests with fish and the freshwater amphipod Hyalella azteca. Are the results comparable?

C. Schlechtriem, Fraunhofer IME Inst for Molecular Biology and Applied Ecology / Bioaccumulation and Animal Metabolism; S. Kampe, H. Bruckert, Fraunhofer IME Inst for Molecular Biology and Applied Ecology; M. Kotthoff, Fraunhofer IME Inst for Molecular Biology and Applied Ecology / Environmental and Food Analysis; C. Schaefers, Fraunhofer-Institut / Ecotoxicology; I. Bischof, I. Ebersbach, Fraunhofer IME Inst for Molecular Biology and Applied Ecology; J. Lharidon, LOréal Research & Innovation / Life Sciences Direction

Bioconcentration factors (BCF) for regulatory purposes are usually determined by fish flow-through tests according to TGD OECD 305. Fish bioaccumulation studies are time consuming, expensive, and use many laboratory animals. Alternative methods that replace the use of fish for BCF testing would therefore be of value. The aim of this study was to investigate whether the freshwater amphipod Hyalella azteca can be used as alternative test organism for bioaccumulation studies, providing the opportunity to explain bioaccumulation from water (bioconcentration). Fourteen compounds of different lipophilicity (logKow 2.2 – 7.8) were tested under flow-through conditions to determine steady-state and kinetic bioconcentration factors (BCF_{ss} and BCFk). The results were compared with fish BCF estimates for the same compounds described in the literature. We could show that any of the compounds tested have no potential for bioaccumulation in H. azteca while being bioaccumulated in fish, i.e. no "false negative" prediction of bioaccumulation in fish. This means that the H. azteca bioaccumulation test could be an appropriate test to predict no B-vB classification (BCF < 2000) in the standard fish test. Bioaccumulation studies with H. azteca would support laboratory animal welfare considerations using a non-vertebrate species, improve efficiency and reduce costs for BCF-testing. However, a more detailed understanding of comparative metabolic profiles and metabolic activity when employing H. azteca, compared to fish, is needed. Preliminary studies carried out with H. azteca suggest CYP450 mediated bio-transformation comparable to fish. This is in accordance with the results obtained for other crustaceans e.g. Daphnia magna.

594 Variation among invertebrates in their capacity to biotransform sediment-associated hydrophobic organic contaminants

H. Selck, Roskilde Univ / Dept Science and Environment

Hydrophobic organic contaminants (HOCs) are generally assessed based on their potential to persist (P) in the environment, bioaccumulate (B) in biota and their potential toxicity (T). One challenge regarding hydrophobic organic contaminants HOCs is that they accumulate in sediments often to levels several orders of magnitude higher than in the overlying water, and that sediment assessment tools are scares as environmental risk assessment historically has focused on uptake from the water compartment. There are a number of papers illustrating that sediment-associated HOCs are available for uptake in benthic organisms, whereas there is considerably less information on the capacity of benthic invertebrates to metabolize organic contaminants (i.e., biotransform). These factors are likely to impact PBT assessment and categorization by, for example, adding uncertainty to predictions of accumulation and trophic transfer. Based on results from a number of experiments and literature values, this presentation will provide examples of 1) how biotransformation capacity varies among benthic invertebrates, 2) how biotransformation may reduce body burden and facilitate the removal of sediment-associated contaminants, and 3) compare aquatic vertebrate and invertebrate biotransformation capabilities.

595 Animal models in aquatic dietary toxicity testing: is there a suitable alternative?

L.M. Langan, Plymouth Univ / Biological Sciences; S.K. Jackson, W.M. Purcell, Plymouth Univ / School of Biomedical Biological Sciences; S.F. Owen, AstraZeneca / Safety Health Environment; A.N. Jha, Plymouth Univ / Biological Sciences

The need for non-animal based models is growing day by day due to regulatory requirements to reduce animal usage in toxicity testing. Until recently, in vitro intestinal models which can be used to address the dietary route of exposure were dominated by the mammalian models, with an absence of any comparable aquatic models. Recently, the development of the rainbow trout intestinal cell line (RTgutGC) has dramatically changed this by providing an aquatic alternative. This study presents data on the characterisation of this model in terms of metabolism and cellular change after exposure to two well characterised environmental pollutants, that of Benzo[a]pyrene and copper sulphate. These pollutants were carefully chosen due to previously reported uptake in the mid and posterior region of the fish intestine which is the region the cell line was developed from. Exposures were carried out in a saline solution after preliminary tests showed evidence of no significant damage to the cells using this carrier. Despite BaP being known to adsorb to various plastics/glass ware, active metabolism by the RTgutGC cells was verified both by fluorescent microscopy and GC-MS. Metabolic activity (EROD assay) between regions (mid and posterior) was assessed through a simple modification of solution pH, and indicated significant differences between regions based on pH when using the model toxicant BNF and BaP. BaP was shown to have a higher induction of CYP1A activity making it a more suitable CYP1A control for the intestine. Indeed further metabolic characterisation of BaP using the GST assay indicated while significant differences exists between pH's, BaP induced response in vitro plateaus above its known soluble range in vivo. This significant difference between regions is also evident in the copper uptake and is directly comparable to "gut sac" experiments presented in the literature for this fish and these regions. Not only does the cell line demonstrate active uptake via micro villi projections visible via TEM, but is also supported through staining for mucolytic substances. Analysis of gene expression at higher concentrations of copper also demonstrate comparable metabolic activity after metal exposure via increased expression in CYP3A, GST and Pgp. This study provides compelling evidence that the aquatic intestinal model derived from the cell line could potentially be used to supplement/replace dietary toxicity testing of specific compounds.

596 Physiologically based modeling of hepatic and gastrointestinal biotransformation in fish

J.W. Nichols, USEPA / ORD NHEERL Mid-Continent Ecology Division; L.J. Saunders, Simon Fraser Univ; F. Gobas, Simon Fraser Univ / School of Resource and Environmental Management

In fish, as in mammals, the liver generally viewed as the principal site of chemical biotransformation. For waterborne exposures, such as those conducted in support of standardized BCF testing, the effects of hepatic metabolism on chemical accumulation can be simulated using relatively simple models which assume, as a first approximation, that the liver operates on chemicals in blood, and that the blood is fully equilibrated with the rest of the animal. Such models may be inadequate, however, when biotransformation occurs elsewhere in the organism (e.g., gills or gut). This is particularly true when the diet is the primary route of exposure, as may be expected for hydrophobic chemicals in a natural setting, or when the organism is purposefully dosed in this manner (e.g., as part of recently developed dietary testing protocols). Here we use physiologically based toxicokinetic (PBTK) models to simulate how biotransformation occurrning in the liver and gut, alone or in combination, could be expected to impact chemical accumulation occurring as a result of water-only, diet-only, and combined water and dietary exposures. Of special interest was the desire to develop the simplest model capable of adequately representing these processes. To support this effort we developed a set of scaling factors needed to extrapolate in vitro activity in gut subcellular fractions to the intact tissue. The modeled results indicate the need to represent the liver and gut as tissues operating in series against a fraction of the total cardiac output. Failure to model these processes correctly could result in underestimation of either tissue's true impact on chemical accumulation, particularly when the model is used to solve for apparent rates of activity based on measured chemical residues in the organism or apparent dietary assimilation efficiencies. The contents of this abstract neither constitute nor necessarily reflect USEPA policy.

597 Are we there yet? How different fish species biotransform xenobiotics

K.M. Johanning, KJ Scientific LLC / dba of Pura Vida Connections LLC; A. Strobel, H. Segner, Univ of Bern / Centre for Fish and Wildlife Health; B.W. Brooks, Baylor Univ / Dept of Environmental Science; S.R. Burket, Baylor Univ / Environmental Science; C. Kropf, Univ of Bern / Centre for Fish an Wildlife Health; Q. Fontenot, A. Ferrara, Nicholls State Univ / Biological Sciences

One of the greatest knowledge gaps in the study of xenobiotic metabolism is understanding how different species biotransform chemicals found in the environment. Fish are the most diverse group of vertebrates displaying a wide range of feeding modes and reproductive strategies and live in variety of environments. Biotransformation of xenobiotics also varies among fish species. Therefore, we compared xenobiotic metabolism of different fish species across a range of environmental conditions. We compared red and white-blooded Antarctic fishes (Notothenia rossii, Gobionotothen gibberifrons, Champsocephalus gunnari, and Chaenocephalus aceratus) that live in high dissolved oxygen(DO) concentrations and very low temperatures (T= 0^oC), alligator gar Atractosteus spatula that inhabits higher temperature waters (T > 30^oC) with low DO, and a wide range of salinities to rainbow trout Oncorhynchus mykiss, the reference fish that has been used for in vivo and in vitro metabolism and bioaccumulation studies. Antarctic fish were collected from the Elephant-South Shetland Islands region and the northern tip of the Antarctic Peninsula. Livers were frozen at -80 °C, transported to the lab, pulverized in liquid nitrogen and later homogenized on ice to prepare the liver S9 fraction for use in metabolism studies. Trout and garfish were maintained for 2 to 4 weeks under corresponding natural temperature and photoperiod regimes. Fish were euthanized and livers perfused with a buffered clearing solution (pH = 7.8), excised, homogenized, and centrifuged to obtain the liver S9 sub cellular fraction. The liver S9 fraction of the different fishes were used to perform metabolism studies with pharmaceuticals, B(a)P, and to determine conventional enzyme activities (EROD, GST). Our results indicate that the Antarctic fish species had significantly lower EROD and GST activities and no B(a)p metabolism when compared to trout. Alligator gar EROD and GST activities were similar to rainbow trout and exhibited significant metabolism of pharmaceuticals such as diclofenac. Alligator gar diverged from the teleost evolutionary line prior to the teleost genome duplication (TGD) and are therefore genetically more similar to tetrapods than are teleost fish, such as rainbow trout and Antarctic fishes. Alligator gar may possess unique adaptations to cope with xenobiotics.

598 Comparison of trout hepatocytes and liver S9 fractions as in vitro models for predicting hepatic clearance in fish

K.A. Fay, Univ of Minnesota – Duluth / Biology; P. Fitzsimmons, A.D. Hoffman, J.W. Nichols, USEPA / ORD NHEERL Mid-Continent Ecology Division

Isolated hepatocytes and liver S9 fractions have been used to collect in vitro biotransformation data for fish as a means of improving modeled estimates of chemical bioaccumulation. To date, however, there have been few direct comparisons of these two methods. In the present study, cryopreserved trout hepatocytes were used to measure in vitro intrinsic clearance rates for 6 polycyclic aromatic hydrocarbons (PAHs). These rates were extrapolated to estimates of in vivo intrinsic clearance and used as inputs to a well-stirred liver model to predict hepatic clearance. Predicted rates of hepatic clearance were then evaluated by comparison to measured rates determined previously using isolated perfused livers (IPL) from well-matched animals. Hepatic clearance rates predicted using hepatocytes corresponded closely to measured values (< 2.1 fold difference for 5 of 6 compounds) under two competing binding assumptions. These findings, which may be attributed in part to high rates of PAH metabolism, are similar to those obtained previously using data from liver S9 fractions obtained from animals closely matching those used for the hepatocyte assays and IPL studies. For one compound (benzo[a]pyrene), the in vivo intrinsic clearance rate calculated using S9 data was 10-fold higher than that determined using hepatocytes, possibly due to a diffusion limitation on cellular uptake. Generally, however, there was good agreement between calculated in vivo intrinsic clearance rates obtained using either in vitro test system. These results suggest that both systems can be used to improve bioaccumulation assessments for fish, particularly when vitro rates of activity are relatively high, although additional work is needed to determine if the chemical domain of applicability for each system differs. The contents of this abstract neither constitute nor necessarily reflect USEPA policy.

599 Comparisons of in vitro, in vivo and in silico biotransformation rates in fish and humans

J.A. Arnot, ARC Arnot Research & Consulting / Dept of Physical Environmental Science, Dept of Pharmacology and Toxicology; K. Foster, Karen Foster Environmental Research / Dept of Chemistry; A. Looky, ARC Arnot Research & Consulting; T.N. Brown, ARC Arnot Research & Consulting / Dept of Chemistry; J.M. Armitage, Univ of Toronto – Scarborough / Physical and Environmental Sciences; E. Papa, Univ of Insubria / Dept of Theoretical and Applied Sciences; B. Wetmore, USEPA / National Exposure Research Laboratory; J.W. Nichols, USEPA / ORD NHEERL Mid-Continent Ecology Division

Chemicals are being evaluated for Persistence, Bioaccumulation and Toxicity (PBT) properties and high-throughput models are being developed and applied for hazard-, exposure- and risk-based screening for prioritization. Biotransformation is a crucial process that can influence total elimination half-life and hence the relationship between chemical intake rate and internal concentration. Biotransformation is a key mitigating process for hydrophobic chemicals that could otherwise exhibit high bioaccumulation potential in aquatic and terrestrial organisms. Biotransformation can also be relevant in the context of toxicity due to bioactivation (e.g., PAHs). In the absence of measured in vivo data, in vitro and in silico models are often required to address data gaps. Despite the fundamental value of biotransformation rate information, relatively few measured in vivo data are available compared to the thousands of chemicals requiring evaluation. Our objective is to compile, evaluate and compare existing in vivo, in vitro and in silico data streams for estimating biotransformation rates for organic chemicals in fish and mammalian species. We have compiled a large database of in vitro assay estimates of metabolism (half-lives, clearance rates and rate constants) derived from liver microsomes, S9 fraction, and hepatocytes from on-line databases and the scientific literature. The in vitro database consists of 19,634 entries for 11 species (56% human data). We have also developed databases for whole body (in vivo) biotransformation rate constant estimates for approximately 940 chemicals in humans and 700 organic chemicals in fish. In vitro to in vivo extrapolation models are being developed and applied to the in vitro data to obtain estimates of hepatic clearance, and as applicable, whole body biotransformation rate (clearance, or half-life) estimates. In vitro biotransformation rate estimates and in silico predictions from existing screening-level quantitative structure-activity relationships (QSARs) are compared to in vivo biotransformation rate estimates. Key uncertainties and challenges comparing the datasets are described and a strategy to address data gaps and uncertainty is discussed.

Neonicotinoid Insecticides: Current Research on Fate and Effects

600 Water Quality Assessment of Potential Imidacloprid Impacts in Great Smoky Mountains National Park

E. Benton, Univ of Georgia / Warnell School of Forestry and Natural Resources; J.F. Grant, Univ of Tennessee / Dept of Entomology and Plant Pathology; T.C. Mueller, Univ of Tennessee / Dept of Plant Sciences; R.J. Webster, R.J. Nichols, National Park Service / Great Smoky Mountains National Park; J.S. Schwartz, Univ of Tennessee / Dept of Civil and Environmental Engineering

Imidacloprid treatments are used for the suppression of hemlock woolly adelgid (Adelges tsugae [Annand]) (HWA) (Hemiptera: Adelgidae) in Great Smoky Mountains National Park (GRSM). The presence of imidacloprid and possible effects on aquatic macroinvertebrate communities in streams associated with HWA imidacloprid treatment areas were assessed as part of a retrospective analysis GRSM's HWA management program, Ten conservation areas in which hemlocks in riparian areas were given soil imidacloprid applications were selected. Stream sampling sites were chosen upstream and downstream from each conservation area, for a total of ten paired upstream – downstream sites. Baseline aquatic macroinvertebrate data collected before imidacloprid use in GRSM were available. Surface water samples and aquatic macroinvertebrate samples were collected from each sampling location. Concentration of imidacloprid in parts per trillion (ppt) was determined using liquid chromatography mass spectroscopy (LC/MS). Aquatic macroinvertebrate communities were assessed as indicators of water quality. Imidacloprid was detected in seven of ten downstream locations. Concentrations ranged from 28.5 to 379 ppt, which are below USEPA chronic and acute aquatic macroinvertebrate aquatic life benchmarks. Aquatic macroinvertebrate taxa was similar at downstream sites compared to both upstream sites and baseline data. While potential impacts of HWA imidacloprid treatments on surface water quality are minimal, the extent of treatments should be carefully considered for overall system health.

601 Residue of the neonicotinoid imidacloprid in greenhous and landscape plants and effects on beneficial insects

V. Krischik, Univ of Minnesota / Entomology

Integrated Pest Management (IPM) is a decision making process used to manage pests that relies on many tactics, including cultural and biological control, which are practices that conserve beneficial insects and mites. Neonicotinoid insecticide use was embraced by IPM as it was applied to the soil and not sprayed on foliage and was thought to reduce drift and nontarget effects on foraging beneficial insects on flowers and leaves. However, systemic, soil-applied neonicotinoid insecticides are translocated to pollen and nectar of flowers, often for months, and may reduce survival of flower-feeding beneficial insects. Neonicotinoid insecticide residues in pollen and nectar differ widely depending on the amount that is applied to crops and landscape plants. Seed treatments result in relatively low levels, less than 10 ppb in pollen and nectar from an application of 1.2 mg AI imidacloprid on corn seed or 0.05 mg AI on canola seed. The imidacloprid field crop rate is 4 mg/ sq. ft. A soil application of imidacloprid on a greenhouse label is 300 mg/12L pot. This is a 250 times higher rate when compared to a seed treatment rate on corn and a 75 times higher rate when compared to a field crop rate. Rates for trees are higher with 14 g deposited on the soil surface and 2.8 g injected into 10 in DBH trees. Imidacloprid residue in flowers for 5 species of herbaceous plants, rose, and linden trees from label rate applications are high. Translocation of imidacloprid from soil (300 mg AI) to flowers of Asclepias curassavica and Agastache foeniculum resulted in residue of 1500 to 6,030 ppb. Residue from pollen cut from treated flowers resulted in residue of around 100 ppb which is the amount that would alter behavior and colony health of bumblebees. Tree injections resulted in 1300 ppb and soil drenches 81 ppb in linden flowers. Greenhouse label rates of soil applied imidacloprid altered behavior and cause mortality in 6 species of beneficial insects and bumblebees, Bombus impatiens. In bumblebees, foraging and food consumption was reduced and resulted in less stored nectar and lower queen survivorship.

602 Effects of neonicotinoid seed-treatment use on non-target native pollinator communities in Missouri field margins and agricultural fields

A. Main, Univ of Missouri-Columbia / Fisheries and Wildlife Sciences; L. Webb, USGS / Missouri Cooperative Fish and Wildlife Research Unit; K. Goyne, Univ of Missouri-Columbia / Soils Environmental and Atmospheric Sciences; D. Mengel, Missouri Dept of Conservation

Neonicotinoid insecticides are the most widely used insecticide class in the world. Pervasive use of neonicotinoid seed treatments (e.g., corn, soybeans) across vast agricultural regions has led to increased scrutiny due to potential toxicity and sub-lethal effects on non-target organisms such as beneficial insects (e.g., bees). Neonicotinoids are persistent, highly water soluble, and have been shown to be transported via surface run-off and wind deposition of dust. Previous terrestrial research has focused on neonicotinoid effects on introduced species such as honeybees and to a lesser extent wild species such as bumblebees. However, it is unclear if neonicotinoid use reduces native pollinator abundance, diversity and/or alters ecosystem services (e.g., pollination, seed production) within agroecosystems. As numerous wild bee populations nest in the ground and forage on a range of flowering plants, it is unknown if many native bee species are equally exposed to neonicotinoids through transport and accumulation in soils and plants surrounding cropped fields (i.e., field margins). To evaluate effects of neonicotinoid exposure on native pollinator communities, we sampled 30 agricultural fields planted with treated or untreated seeds on five conservation areas throughout Missouri from pre-seeding through harvest. We hypothesized that native pollinators would be more abundant and diverse in fields never treated with a neonicotinoid compared to annually treated fields. We collected soils from agricultural fields and their associated field margins, sampled herbaceous and woody flowering species in field margins, and surveyed and collected a wide variety of native pollinators including bees and butterflies over time in fields and field margins. Here, we present our preliminary findings and discuss how this research improves our understanding of the potential impacts of neonicotinoid seed-treatment use on non-target native pollinator communities in agroecosystems.

603 Population Trends and Neonicotinoid Pesticide Exposures in Hummingbirds

C.A. Bishop, Environment and Climate Change Canada / Wildlife Research Divsion Science and Technology Branch; M. Toshack, Simon Fraser Univ / Biological Science; S. Wilson, Environment and Climate Change Canada / Wildlife Research Division; A.C. Smith, Environment and Climate Canada / Canadian Wildlife Service; J.E. Elliott, Environment and Climate Change Canada / Science and Technology Branch / Ecotoxicology and Wildlife Health Division; A.J. Moran, Rocky Point Bird Observatory / The Hummingbird Project

Fourteen species of hummingbirds co-occur in North America, and among the seven with reliable data, three species are showing significant population declines in populations as indicated by analysis of the North American Breeding Bird Survey BBS. The steepest negative trends annually are for pacific coastal Rufous Hummingbirds and Allen's Hummingbirds although Broad-tailed Hummingbirds are also declining. There may be multiple factors underlying those declines and stressors may act at different life stages and locales throughout the year as hummingbirds migrate, breed and overwinter. We examined neonicotinoid pesticide exposure in hummingbirds using agricultural regions in the Fraser Valley, southern British Columbia, and within the core of Rufous Hummingbird range. We quantified hummingbird presence and use of blueberry fields that were conventionally sprayed or organic and compared them to natural areas. While hummingbirds were commonly present in hedgerows of farms, nectaring on blueberry blossoms was not commonly observed. However, neonicotinoid insecticide concentrations were detected in blueberry flowers a year post spray and detected at 3 ng/g in pooled samples of cloacal fluid of Rufous and Anna's hummingbirds collected within 0.5 to 1 km of conventionally sprayed blueberry fields.

604 Consistent Patterns of Toxicity of the Nitroguanidine Neonicotinoid Insecticides to Honey Bee (Apis mellifera) Colonies

A.W. Olmstead, Bayer CropScience / Environmental Toxicology and Risk Assessment; S. Hinarejos, Valent USA. Corporation / Valent Technical Center; R. Hummel, Landis International Inc; J. Overmyer, Syngenta Crop Protection, LLC. / Environmental Safety

In response to ongoing registration review activities in the US and Canada, studies were conducted on free-ranging honey bee (Apis mellifera) colonies fed sucrose solutions treated with either imidacloprid, thiamethoxam, or clothianidin. Each study consisted of five test concentrations in which treated sucrose solution was provided twice a week for six weeks during the summer. Each study was replicated across 12 separate apiaries in an area with low agricultural activity (central NC, USA). Colonies were assessed before, during, and after the treatment period and again the following spring. Across all the tested compounds, pollen stores and capped brood were the first and most affected endpoints with reductions beginning after three weeks of treatment. In subsequent assessments, reductions in adult bee strength, eggs, and open brood occurred and were likely downstream of initiating effects. These effects were characterized by concentration-response curves with a tendency towards recovery after the treatment period ended. Assessments at later time points did not result in effects at lower test levels indicating that the most significant effects occur during or proximal to the exposure period. Likewise, impacts on overwintering were not observed to be more sensitive. The results of these studies, carried out with a harmonized testing protocol, generated hazard values integral ot higher tier honey bee risk assessment. In addition, these studies allow for direct comparisons across the nitroguanidine neonicotinoid insecticides revealing consistent patterns of chronic effects which may be driven by reductions in pollen stores.

605 Assessing variation in neonicotinoid toxicity to freshwater invertebrates using species sensitivity distributions

M. Raby, Univ of Guelph / School of Environmental Sciences; M. Nowierski, Ontario Ministry of the Environment & Climate Change / Standards Development Branch; D.G. Poirier, Ontario Ministry of the Environment / Laboratory Services Branch; P.K. Sibley, Univ of Guelph / School of Environmental Sciences

Neonicotinoids, a group of water-soluble pesticides commonly used in agriculture, have the potential to be toxicants to aquatic species. Sensitivity to neonicotinoid toxicity varies greatly among aquatic invertebrate taxa. Here we present the results of acute and chronic toxicity tests for six neonicotinoids: acetamiprid, clothianidin, dinotefuran, imidacloprid, thiacloprid, and thiamethoxam, for several aquatic invertebrate taxa including Ephemeroptera (Hexagenia sp., Caenis sp., Siphlonurus sp., Ephemera guttulata, Neocloeon triangulifer, Stenonema sp., Isonychia sp.), Hemiptera (Corixidae sp.), Diptera (Aedes sp., Chironomus dilutus), Odonata or damselflies (Coenagrion sp.), Amphipoda (Hyalella azteca), and Cladocera (Daphnia magna, Ceriodaphnia dubia). Standard model organisms were cultured under laboratory conditions and others were field-collected. Lentic invertebrates were exposed under static conditions, while lotic invertebrates were exposed using a recirculating apparatus that simulated a stream flow. All acute exposures were 48 to 96 hours in duration. Using these data, in conjunction with literature data, we plotted species sensitivity distributions (SSDs) to model the variation in neonicotinoid toxicity. 96-hour LC50 values ranged from 2 – >100 000 µg/L, with cladocerans being the least sensitive. Chronic (>21 day) growth and reproduction tests were conducted with select neonicotinoids for sensitive species (H. azteca, C. dilutus, N. triangulifer) and relatively insensitive cladoceran species (D. magna, C. dubia). Together with literature data, we used this chronic dataset to generate a long-term SSD for select neonicotinoids. This study is in partnership with the Ontario Ministry of the Environment and Climate Change, and will help to develop a comprehensive dataset from which to derive water quality criteria for the protection of aquatic life.

606 Detecting the sublethal effects of imidacloprid for bumble bee (Bombus impatiens) workers

A.J. Krueger, M. Dillon, Univ of Wyoming / Zoology and Physiology

The agriculture industry relies on pesticides for crop production, but growing evidence suggests that sublethal effects of pesticides, in addition to other stressors, may contribute to the decline of insect pollinators. Neonicotinoids are a widely-used, advanced class of insecticides that are incredibly effective for crop protection but, at low levels, can have pronounced sublethal effects on bees. Our understanding of bee toxicology comes primarily from studies on honeybees, and the few studies on bumblebees (genus Bombus) have assessed toxicity on a colony level. We investigated how imidacloprid, a first generation neonicotinoid, affects the diet consumption, long term survival, and activity of individual bumblebees (Bombus impatiens) under different exposure scenarios and at a range of concentrations. We saw no significant effects when continuously fed 10 ppb imidacloprid in nectar but at 32 ppb, we saw a significant effect on diet consumption, long term survival (χ^2=6.042, p< 0.05), and activity (χ^2=13.89, p< 0.001). Knowing that 32 ppb produced effects with all three metrics, we looked at whether access to clean nectar following each day of exposure to 20 ppb imidacloprid would diminish the effects seen with continuous exposure. We saw a slight recovery in diet consumption and activity after the first day of clean nectar, however, after a second day on 20 ppb imidacloprid, we no longer saw this recovery. When individuals were exposed under different temperature conditions, those exposed at 16°C and 30°C showed elevated levels of activity and increased rates of diet consumption. Effects were seen within one hour of exposure with sustained elevated activity at 30°C and a gradual onset of immobilization at 16°C following a brief window of hyperactivity. Our data suggests that 1) individuals exposed to imidacloprid concentrations exceeding roughly 20 ppb may be behaviorally impaired, 2) these effects are dependent upon the temperature in which individuals are exposed, and 3) provided with clean nectar, individuals exposed to these concentrations are able to recover.

607 Effect of sublethal exposures of adult Northern Leopard Frog and larval African Clawed Frog to clothianidin and thiamethoxam

J.A. Jenkins, USGS / National Wetlands Research Center; B.L. Brown, K. Hartop, Virginia Commonwealth Univ / Biology; S. Mize, USGS / SE Region; A.J. Dickinson, Virginia Commonwealth Univ Qatar / Biology; D. Pridgen, Virginia Commonwealth Univ / Biology; K.L. Smalling, USGS / NJ Water Science Center; B.K. Hopkins, WSU / Dept of Entomology; S. Kirschner, SR Veterinary Technologies / Development; M.L. Hladik, USGS / California Water Science Center

Detections of neonicotinoid insecticides (NEO) in global surface waters often exceed water quality guidelines for aquatic species. Amphibians, which breed and develop in wetlands and ephemeral ponds, may be considered sentinel species in aquatic habitats because crucial phases of their development occur in water, and they generally do not venture far from where they were hatched. As such, they are valuable indicators of environmental stressors. To explore potential sublethal effects of two NEOs, clothianidin (CLO) and thiamethoxam (THX), African clawed frog, Xenopus laevis, tadpoles (n= 20/treatment) were exposed for 21 days to Belay® containing active ingredient (a.i.) CLO at high (100 ppm) and low (20 ppm) concentrations and to Platinum 75 SG® with a.i. THX at the same concentrations. Adult Northern Leopard Frog, Lithobates pipiens, (n= 20/treatment) were exposed to CLO and THX at high (100ppm) and low 20 (ppm) concentrations by virtue of an implanted carrier compound that provided for slow release delivery imitating a long-term chronic exposure of the a.i. over 28 days, with both carrier and uninjected control treatments. The mode of action of the a.i. is interference of neurotransmission at the conserved nicotinic acetylcholine receptor (nAChR), thus the hypothesis was that sublethal effects of NEOs could occur across taxa and at different life stages of amphibians. A biomarker approach allowed for quantifying responses. Hepatosomatic indices were obtained and genomic biomarker endpoints for tadpoles included RNA expression measured by quantitative real-time polymerase chain reaction of cytochrome P450 1A from livers and alpha-7 subunit of nAChR from brains. Genomic biomarker endpoints for the adults were the same, and included nAChR expression from testes. Cellular biomarker endpoints for adults included whole blood DNA fragmentation (an indicator of genoxity) and liver enzyme activity, both measured by flow cytometry. Adult brain acetylcholine was measured (an indicator of neurotransmission), and hepatosomatic- and gonadosomatic indices were generated. Sperm quality parameters and antibody-stained nAChR on sperm of adult frogs in this study and from other studies on honeybees implies NEOs may influence reproductive processes. Indications of NEO-induced stress were evident in both the tadpole and adult amphibians.

Alternative Assessments Best Practices for Safer Chemistry

608 Advancing the Applicability of Alternatives Assessment for Engineered Nanomaterials

R. Hjorth, DTU Technical Univ of Denmark / Dept of Environmental Engineering; S.F. Hansen, DTU Technical Univ of Denmark / Environment; M. Jacobs, Univ of Massachusetts Lowell / Lowell Center for Sustainable Production; J.A. Tickner, UMass Lowell / Community Health and Sustainability; M. Ellenbecker, Massachusetts Toxics Use Reduction Inst; A. Baun, DTU Environment / Dept of Environmental Engineering

The future design of products incorporating nanomaterials and the redesign of existing products using engineered nanomaterials with an emphasis on reducing the potential hazards for human health and the environment is key to the success of the innovations made possible through nanotechnology. Alternatives assessment has the potential to be used as a tool for product designers to ensure the safety of products being developed. However, there is a need to assess the overall applicability of alternatives assessment methods for nanomaterials as these methods were originally developed for the evaluation of chemicals, not materials. This presentation reviews an assessment of the overall applicability of alternatives assessment for nanomaterials, focusing on the hazard assessment and exposure characterization components. The review focuses on several issues such as whether the novelty of these substances precludes the utility of an alternatives assessment approach, complexities involving the lack of an analogous Chemical Abstract Service (CAS) system for nanomaterials, differences in hazard assessment metrics for bulk chemicals versus nanomaterials, and differences in the environmental fate and transport of nanomaterials compared to chemicals that complicate existing exposure models. Several recommendations and suggested modifications to existing alternatives assessment frameworks that aid in the selection of safer nanomaterials were identified and will be reviewed, including: the critical importance of a functional use focus, safer nanomaterial design principles that reveal inherent hazard assessment criteria, and the use of control-banding techniques for exposure evaluation.

609 Use of Automated Tools to Facilitate Rapid Chemical Hazard Assessment of Consumer Product Chemicals

J.P. Rinkevich, P. Beattie, J. Orchard-Hays, M.C. Ruhter, SciVera LLC; J.L. Tunkel, C. Rudisill, SRC, Inc. / Environmental Health Analysis

There is a growing need on the part of consumer product manufacturers and their suppliers to rapidly assess large numbers of chemicals for human and environmental hazard. This need is increasingly apparent in the area of chemicals used in articles such as plastics, textiles, coatings, adhesives, and other common consumer product materials for a variety of applications. Many chemicals have not undergone toxicological testing and therefore often lack experimental data to help to determine characteristics of human or environmental concern or preference. Computer software can enable clustering of chemicals by similar molecular structures, then evaluate the chemicals within each group for representative toxicity data, and apply a read-across process to fill data-gaps within the group. Our project examined the utility of chemical structure clustering software combined with aggregated available chemical hazard data for a subset of the chemicals of interest in facilitating rapid assessment of chemicals with limited human and environmental health data. Our team used the EPA Chemical Assessment Clustering Engine (ChemACE) tool to cluster chemicals into groups with similar structural characteristics. Our dataset consisted of approximately 2200 chemicals and chemical-specific SMILES notation to indicate molecular structure. 1100 of these chemicals fit into 223-257 clusters, depending on the ChemACE settings used. Our team then evaluated clusters for hazard characteristics using the SciVeraLENS® automated chemical assessment platform. This combination of platforms allowed us to compare the chemicals with experimental hazard data and determine if they could be used to model the hazards of chemicals within the same cluster that do not currently have experimental data available. Our conclusions were: 1) In clusters where a chemical was high hazard for a critical endpoint (e.g., carcinogenicity, mutagenicity, developmental toxicity), the process highlighted the need for careful evaluation of the other chemicals in that cluster; 2) The results clearly indicated hazard characteristic trends across a cluster allowing for higher confidence in the use of analogous data, and 3) Having the ability to view the chemical structures in ChemACE for the compounds in the cluster was helpful for understanding subtle differences that could impact potential toxicity.

610 Data-Driven Assessments for Data-Poor Chemicals: Expanding the USEPA's Safer Chemical Ingredients List

C. Rudisill, SRC, Inc. / Environmental Health Analysis; C. Menasche, ORISE with USEPA / Safer Choice Program; L. Morlacci, J.L. Tunkel, SRC, Inc. / Environmental Health Analysis; E. Lavoie, U.S Environmental Protection Agency / Office of Pollution Prevention and Toxics

Since its inception in 2012 with 500 chemicals, the Safer Chemical Ingredients List (SCIL) has served as a resource for consumers and other purchasers by disclosing the ingredients formulated in Safer Choice-labeled products. Currently the list contains over 750 chemicals and is regularly expanded to reflect new chemistries used in labeled products and other substances that meet the rigorous Criteria for Safer Chemical Ingredients. Not only do these activities support the expansion of the Safer Choice program, but also help to expand the use of safer chemicals across the market. New candidates for the list were identified during a re-evaluation process of currently listed chemicals. Additional candidates were identified by evaluating other chemicals used in consumer products that are analogous to those chemicals currently listed on the SCIL. A candidate for the SCIL must meet criteria for multiple human health and ecological endpoints that prioritize the use of measured data. But data gaps for these substances are prevalent, complicating these data-driven assessments. To reduce uncertainties when assessing candidate chemicals, a cluster or category approach is often implemented. This approach incorporates several structurally-similar chemicals to aid in the filling of data gaps using read across and is often used for human health endpoints and ecotoxicity endpoints where reliable Quantitative Structure Activity Relationship (QSAR) estimates cannot be obtained in a transparent manner. The cluster approach has the added benefit of increasing certainty in the assessment by maximizing the integration of experimental data. This presentation will discuss the incorporation of cluster and QSAR approaches into assessments for new chemical additions to the SCIL, as well as the re-review process for existing SCIL chemicals. Examples illustrating the development and assessment of SCIL re-reviews and candidates will be included, as well as a summary of the "state of the data" available for these assessments in order to highlight the current challenges in identifying safer chemistry alternatives. The views expressed in this abstract are those of the authors and do not represent U.S. Environmental Protection Agency policy or endorsement.

611 Data Mining To Answer Complex Environmental Questions

L.A. Rodenburg, Rutgers Univ / Dept of Environmental Sciences; S.L. Capozzi, Rutgers Univ / Environmental Science

Like most fields of endeavor, Environmental Science has begun to produce volumes of data larger than can be understood or managed by traditional techniques. At the same time, Environmental Science seeks to understand complex systems at multiple temporal and spatial scales. Data mining of these new, large data sets is an ideal approach to answer complex questions. Our research group has pioneering the use of large data sets to answer questions about where chemical contaminants come from, how they are processed in watersheds, how and where they are degraded, and how long they might persist. This presentation will use case studies to describe the kinds of data that are publicly available and what questions these data can answer. We will describe some of the major methods we have used to parse large data sets to investigate patterns of organic pollutants in air, water, and sediment. Chemical classes we have investigated include Polychlorinated Biphenyls (PCBs), Polychlorinated Dibenzo-p-dioxins and –furans (PCDD/Fs), Polybrominated Diphenyl Ethers (PBDEs), chlorinated ethylenes, chlorinated benzenes, and antibiotics. This approach has allowed source apportionment across different manufactured formulations (such as Aroclors) and has identified processes (such as microbial dehalogenation and volatilization) and sometimes even surprising, inadvertent sources (such as PCBs from pigments). This presentation will describe some of the main challenges of applying data mining techniques to a variety of data sets from the east coast (Delaware River and New York/New Jersey Harbor) to the west (Portland, OR; San Francisco Bay), and will suggest future directions in data mining to answer complex environmental questions.

612 Building Your Toolbox: Read-across Tools for Alternatives Assessment

J.W. Rice, Gradient / Chemistry; J.M. Cohen, T. Lewandowski, Gradient

Alternatives assessment (AA) provides a framework for evaluating chemicals of concern and their possible substitutes. The goal is to reduce inherent chemical hazard in order to address unforeseen exposure scenarios. However, incomplete health effects data may limit the ability to evaluate safer alternatives. Read-across approaches are increasingly used to address such data gaps. The available computational tools and approaches to support read-across vary in terms of sophistication, ease of use, and comprehensiveness, leading to analyses of variable quality and reliability. There are two critical steps in a robust read-across methodology: 1) quantifying structural similarity between proposed surrogates and a target chemical, and 2) showing an expected common mode of action (e.g. via structural alerts). To explore the utility of different analytical tools, we established a set of 37 chemicals with structural similarity to a target chemical – the established skin sensitizer hydroxyethyl acrylate. We first evaluated chemical similarity between individual chemicals and the target using two computational tools, ToxMatch and ChemMine. After ranking the chemical test set by similarity score, the two programs demonstrated statistically significant agreement (Kendall's coefficient of concordance, $W = 0.85$, $p = 0.005$). We also evaluated the dataset for skin sensitization structural alerts using the structure-activity relationship (SAR) programs Toxtree and Derek™, and compared the predictions to animal test data obtained using standard assays. These programs in combination exhibited a sensitivity of 85% (correct prediction of hazard for 17 out of 20 animal test positives), and a specificity of 89% (at least one program did not report an alert for 16 of 18 animal test negatives). For read-across, we refined our surrogate selection approach by considering physicochemical data relevant for skin sensitization (e.g., molecular weight, water solubility, and vapor pressure). This improved the overall accuracy of our read-across approach by 49% (51% vs. 100% accurate prediction rate). These results are consistent with those from an earlier evaluation of 67 possible chemical analogues for p-phenylenediamine, another skin sensitizer, suggesting that read-across can be used to bolster AAs when multiple tools and information sources are carefully implemented to fill data gaps and reduce uncertainty.

613 Improved Read Across in Alternatives Assessments

H. Plugge, 3E Company

Data quality and quantity has always been the limiting factor in Alternatives Assessment. Given the newly legislated need for screening techniques, input data becomes ever more important. Data curation for screening has major limitations: the increase in data quality is often not worth the investment for screening purposes. Various simple statistical techniques can be used to improve the overall uncertainty in uncurated data – examples will be provided of uncurated vs curated data and best practice estimates of screening input data. Using (semi) curated data will allow a faster screening of read across of datapoints for alternatives assessment screening. We will discuss overall hazard screening of an analog series of aldehydes and ketones, using 3E Green Score methods. Using these data one can identify datagaps and anomalies. Both of these can be addressed (to some extent) by performing a read across matrix. This matrix approaches uses both analogues and homologues to provide continuous series of matrices for various endpoints. Often only selected data is missing within these matrices. Both overall screening assessments and drill down data will be provided allowing the assessor to visually appraise the need for filling in datagaps and addressing the most useful matrix comparison per endpoint. Examples will be provided of the actual filling in of datagaps using these matrices. Notably given their overall reactivity, aldehydes are often less toxic that the corresponding ketones. Some of this is perhaps due to different metabolic pathways, e.g. hexanal vs 2-hexanone. Different isomers will also react very differently , an example being 2- vs 3-hexanone which have very different postulated metabolic pathways, although it is unclear which pathways are in use at the often high test doses.

614 Real-World Implementation of Alternatives Assessment Resulting in Safer Chemical Substitutions

C.D. Robertson, Hewlett-Packard

A business case for screening alternatives using alternatives assessment based on the cost savings realized by avoiding multiple substitutions will be discussed. Selection of inherently less hazardous alternatives as the first step in the assessment process reduces the risk that the substitutes will face future restrictions. Examples of the inherent benefits of this green chemistry approach will be presented. Transitions away from chemicals of concern to safer alternatives is difficult and expensive, especially in a complex supply chain. Proactive use of alternatives assessment on emerging chemicals of concern can help manufacturers prepare to replace these chemicals with better alternatives. The trigger for actually making the transition has traditionally been regulation but other motivating factors are emerging. Recently, alternative assessment and hazard assessment have been incorporated into ecolabels and certification criteria. The U.S. Green Building Council's LEED certification now incorporates hazard assessment into building material requirements. An important ecolabel for the electronics industry is TCO Development's TCO Certified label. TCO has incorporated an accepted substance list for flame retardants based on the GreenScreen™ for Safer Chemicals. In the United States, EPEAT certification is a "Green Public Procurement" requirement that must be met before bidding on many government purchasing contracts. Alternatives assessment is being discussed for inclusion in the next revision of the EPEAT standard and should be complete by the time of this presentation. Aspects of these ecolabels will be presented as well as a discussion of their ability to influence real-world adoption of safer chemicals.

615 Boat Antifouling Technology Alternatives Assessment

L.G. Heine, Lauren Heine Group LLC; A. Nestler, Northwest Green Chemistry; A. Stone, Washington Dept of Ecology / Hazardous Waste and Toxics Reduction

Copper is used in antifouling boat paints to prevent marine life from attaching or growing on boat hulls, which results in poor fuel efficiency, less maneuverability, and lower top speeds. In 2007, an Ecology study found high levels of copper in two Puget Sound marinas – most of it coming from antifouling paints. Copper build-up is a concern because of its adverse effects on fish, especially to young salmon. In Washington, fishing accounts for $3.18 billion of economic activity and supports over 17,256 jobs in the state. As a result, the Washington Legislature passed a law that phases out the use of copper-based anti-fouling paints in recreational boats beginning in 2018. Similar regulations are being considered in other states and countries. Problems with antifouling paints are not new. For many years, paints containing mercury or tributyltin were used as anti-fouling paints. Tributyltin was also initially identified as environmentally safe. When concerns arose in the 1970's about the environmental effects of tributyltin, copper became the preferred alternative. Now research has revealed the environmental issues surrounding copper. In the interest of avoiding yet another regrettable substitution—replacing one toxic chemical with another -- the WA Department of Ecology and Northwest Green Chemistry have partnered with industry leaders like the Clean Boating Foundation to evaluate alternatives to copper antifouling boat paint. A variety of anti-fouling technologies are considered including those that are currently on the market and those that are emerging. Some technologies involve substitution of copper with zinc-based coatings. Others involve the synthesis of organic chemicals that do not contain metals and still others involve completely different approaches to anti-fouling such as the use of ultrasound or "slippery" coatings to which organisms cannot attach. The alternatives assessment approach used is based upon the framework developed in the Interstate Chemicals Clearinghouse (IC2) Alternatives Assessment Guide (IC2 Guide). The toxicity of chemicals in each of the alternatives along with other factors inherent in an alternatives assessment such as performance, cost and availability, exposure, etc. are considered as part of the assessment and analysis process. Here, we present our preliminary results.

Toward Sustainable Environmental Quality: Identifying Global Research Needs Through the SETAC Horizon Scanning Project

616 Towards Sustainable Environmental Quality: Overview and Methods of a Novel Effort to Identify Global Research Needs

B.W. Brooks, Baylor Univ / Environmental Health Science Program Dept of Environmental Science; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; A. Boxall, Univ of York / Environment Dept; M. Rudd, Emory Univ

The SETAC World Council launched the Global Horizon Scanning and Prioritization Project aimed at identifying geographically specific research needs to address stressor impacts on environmental quality. Priority research questions were solicited from SETAC members and other environmental professionals within the five SETAC geographical units (GU), then synthesized by expert teams of academic, industry and government representatives to form lists of the top research questions that, if answered, would substantially advance our understanding of how a range of environmental stressors (chemical, physical, biological) impact environmental quality in different geographic regions. During 2015, workshops were held for SETAC Africa (in Langebaan, South Africa), SETAC Europe (in Barcelona, Spain), SETAC Latin America (in Buenos Aires, Argentina) and SETAC North America (in Salt Lake City, USA). For SETAC Asia-Pacific, an initial workshop in 2015 focused on Oceania (in Nelson, New Zealand) while a second workshop in Singapore during 2016 focuses on other parts of Asia-Pacific. Each workshop was chaired by SETAC members representing academic, business and government sectors. Questions received were scientific in orientation, and covered diverse aspects of fields related to SETAC's mission to advance sustainable environmental quality. This presentation provides a project overview and methods to identify major research themes emerging within and across SETAC Geographic Units. It is anticipated that outputs from this effort will help increase the quality and relevance of environmental research, decrease scientific uncertainty in assessing and managing environmental risks, and increase the credibility of technical and policy responses to global environmental stressors.

617 Towards Sustainable Environmental Quality: Priority Research Needs for Europe

P. van den Brink, Alterra and Wageningen Univ / Aquatic Ecology and Water Quality Management Group; V. Verougstraete, Eurometaux / EHS; J. Van Wensem, Ministry of Infrstructure and the Environment / Dept of Knowledge, Innovation and Strategy; L. Maltby, The Univ of Sheffield / Dept of Animal & Plant Sciences; C. Ajao, ECHA-European Chemicals Agency; S.E. Apitz, SEA Environmental Decisions Ltd; K. Arnold, Univ of York / Environment; T. Backhaus, Univ of Gothenburg / Dept of Biological and Environmental Sciences; T. Brodin, Umeå Univ / Dept of Ecology and Environmental Science; M. Canedo-Arguelles, Univ of Vic, Spain / BETA Technology Centre Aquatic Ecology Group; J. Chapman, Univ of York / Environmental Dept; J. Corrales, Baylor Univ / Environmental Science; M. Coutellec, INRA / Ecology and Ecosystem Health UMR INRA Agrocampus Ouest; T.F. Fernandes, Heriot-Watt Univ / School of Life Sciences; J. Fick, Umeå Univ; G. Giménez Papiol; K. Groh, Eawag / UTOX Environmental Toxicology; T. Hutchinson, School of Biological Sciences, Plymouth Univ / School of Biological Sciences; J.V. Kukkonen, Univ of Jyvaskyla / Biological and Environmental Science; S. Loutseti, DuPont De Nemour Hellas S.A.; S. Marshall, Unilever / SEAC; K. Paul, Blue Frog Scientific Limited / SLS; A. Rico, Wageningen Univ / Environmental Risk Assessment Team; I. Rodea-Palomares, Univ of Florida / IFAS / Agricultural & Biological Engineering; J. Römbke, ECT Oekotoxikologie GmbH; T. Rydberg, IVL Swedish Environmental Research Inst; M. Ortiz Santaliestra, Univ of Koblenz-Landau / Inst for Environmental Sciences; H. Segner, Univ of Bern / Centre for Fish and Wildlife Health; M.G. Smit, Shell Global Solutions Int.; D. Spurgeon, Centre for Ecology & Hydrology; C. van Gestel, VU Univ Amsterdam / Ecological Science; M. Vighi, IMDEA Water Inst / Earth and Environmental Sciences; I. Werner, Swiss Centre for Applied Ecotoxicology / Dept of Anatomy Physiology and Cell Biology; E. Zimmer, IBACON GmbH; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; A. Boxall, Univ of York / Environment Dept; M. Rudd, Emory Univ; B.W. Brooks, Baylor Univ / Dept of Environmental Science

The SETAC World Council launched the Global Horizon Scanning and Prioritization Project aimed at identifying geographically specific research needs to address stressor impacts on environmental quality. Priority research questions were solicited from SETAC Europe members and other environmental professionals. A total of 151 questions were received, which were scientific in orientation, and covered diverse aspects of fields related to SETAC's mission to advance sustainable environmental quality. Research questions were initially partitioned among the following breakout themes: 1. Aquatic and terrestrial ecotoxicology: ecology and field; 2. Aquatic and terrestrial ecotoxicology: tiered testing; 3. Analysis, fate and behavior of contaminants; 4. Ecosystem responses and services under multistress: multistress; 5. Ecosystem responses and services under multistress: mixtures; 6. Exposure and effect modeling & predictive toxicology (environment & human); 7. Risk assessment, regulation and public perception: validity of assessment; 8. Risk assessment, regulation and public perception: methods and standards; and 9. Characterization, fate and effects of nanomaterials. During a 2 day workshop in Barcelona, these questions were then synthesized by academic, business and government representatives to identify 22 priority research needs. This presentation provides an overview of major research themes from Europe. Following the workshop these research quesitons were sent to SETAC Europe members, who ranked questions of relative importance. Highly ranked questions ranged from research needed to understand consequences of multiple stressors and chemical mixtures, adverse outcomes across multiple levels of biological organization, and chemical emissions through space and time to development and selection of mechanistic toxicokinetic and toxicodynamic modeling tools and identification protection goals. It is anticipated that outputs from this effort will help increase the quality and relevance of environmental research, decrease scientific uncertainty in assessing and managing environmental risks, and increase the credibility of technical and policy responses to global environmental stressors. SETAC further anticipates these questions will support its Long Range Planning efforts.

618 Towards Sustainable Environmental Quality: Priority Research Questions for Australasia

V.J. Pettigrove, The Univ of Melbourne / Zoology

Authors: Pettigrove V, Sevicke-Jones G, Manning T, Gaw S, Ataria J, Cameron M, Coates G, Death C, Harford A, Hassell K, Hoak M, Gadd J, Jolley D, Karami A, Kotzakoulakis K, Lim R, McRae N, Metzeling L, Mooney T, Myers J, Pearson A, Sharley D, Sutherland O, Thomas O, Tremblay L, Wood W, Rudd M, Ankley G, Boxall A, Brooks B. The Global Horizon Scanning and Prioritization (GSHP) Project is a SETAC initiative that aims to collect and prioritize the most important future environmental quality research questions as recognized by scientists and engineers from around the globe. We report here the conclusions of the Australasia (AU) workshop held in Nelson, New Zealand in August 2015. Prior to the workshop, SETAC members and other scientists were invited to submit research questions, which in their view, were priority needs to address in the region. 76 questions were received. During the workshop, these questions were partitioned and the top 18 selected. A general question raised was how can ecotoxicology become more relevant to the protection of ecosystems, particularly in terms of making sure ecotoxicology and guidelines are relevant to local issues. Several priority questions deal woth the theme of how widely international ecotoxicological data and databases can be applied to regional ecosystems. It was noted that Australia and New Zealand have many endemic species and there is little information on their sensitivity to contaminants. Many challenges for the development of guidelines were identified. These include the need to develop guidelines for ephemeral water bodies, incorporating information on the effects of short-term exposures to contaminants, plus the use of biomarkers and other sub-lethal responses to stressors and how guidelines can be made to consider mixtures, especially pesticides and veterinary pharmaceuticals. More toxicological data on local species needs to be gathered and incorporated into regional guidelines. Climate change issues were also raised regarding their ecotoxicological implications. One example was considering the effect of predicted water temperature and ocean acidity changes on ecotoxicology of marine environments. An important question raised was how do we incorporate and protect cultural and social values to empowr citizen, especially indigenous engagement into research, management and legislation.

619 Towards Sustainable Environmental Quality: Priority Research Questions for Latin America (LA)

T. Furley, APLYSIA Environmental Research and Solutions; J. Brodeur, CONICET; H. Silva de Assis, UFPR / Pharmacology; P. Carriquiriborde, Centro de Investigaciones del Medio Ambiente, Universidad Nacional de la Plata – CONICET – Comisión Administradora del Río Uruguay / Centro de Investigaciones del Medio Ambiente CIMA; K. Chagas, Aplysia Soluções Ambientais / TÉCNICO; J. Corrales, Baylor Univ / Environmental Science; M. Denadai, Federal Univ of Sao Carlos; J. Fuchs, Universidad de Buenos Aires (UBA); R. Mascarenhas, Univ Estadual de Feira de Santana; K.S. Miglioranza, Univ of Mar Del Plata / Laboratorio de Ecotoxicología y Contaminación Ambiental ECoA; D. Miguez Caramés, Laboratorio Tecnológico del Uruguay (LATU); J. Navas, INIA – National Inst for Agricultural and Food Research and Technology / Environment; D. Nugegoda, RMIT Univ / School of Applied Sciences; E. Planes, Instituto Nacional de Tecnología Industrial (INTI); I.A. Rodriguez, Univ of Florida / Wildlife Ecology and Conservation; M.O. Medina, Univ of Guadalajara; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; A. Boxall, Univ of York / Environment Dept; M. Rudd, Emory Univ / Dept of Environmental Sciences; B.W. Brooks, Baylor Univ / Dept of Environmental Science

The Global Horizon Scanning and Prioritization (GSHP) Project is a SETAC initiative that aims to collect and prioritize the most important future environmental quality research questions as recognized by scientists and engineers from around the globe. We report here the conclusions of the Latin America (LA) GSHP Workshop held in Buenos Aires in September 2015. Prior to the workshop, SETAC members and other scientists from LA were asked to submit research questions which, in their view, were priority needs to address in the region. 100 questions were received. These were organized in 6 categories and ranked. The resulting top 20 questions were: Environmental Chemistry: -Adsorption/release of toxic compounds form plastic wastes, -Impacts of pharmaceuticals in aquatic ecosystems, -Quality criteria and limits for environmental legislation. -Quantification of contaminant metabolites and breakdown products in abiotic and biotic matrices. Ecotoxicology: -Climate change influence on fate and effects of pollutants, -Extrapolation of results from regulatory single species toxicity test to local taxa and scenarios, –Understanding the complexity of pesticide toxicology in ecosystems, -Laboratory and field methods and approaches to address ecological complexity. Health, CECs and Environment: -Impacts of nanomaterials on ecosystems and human health, -Algal toxins production and risk for human health. Risk Assessment: -Characterization of individual and combined risks of diffuse chemical contaminants. -Development and refinement of tools for sustainable production and use of chemicals. -Risks characterization of pulp mills effluents for human and the environment. Environmental Management and Policy: -Continuous improvement of the maximum limits of toxicity for agriculture, and domestic and industrial effluents, while maintaining ecosystem services. -Current environmental regulations effectiveness and its implementation and enforcement in LA. -Standardization and harmonization across LA countries. -Effectiveness of protected areas to safeguard biodiversity from pollutants. -Risk management improvement for solid wastes. Spotlight on LA: -Sensitivity information of regional species for better prediction of impacts on local ecosystems. -Impact evaluation of natural resources extraction. -Tools for characterizing and classifying industrial and residential effluents. These questions should be considered as part of a long-term strategic research plans in LA.

620 Towards Sustainable Environmental Quality: Priority Research Questions for Africa

V. Wepener, N. Smit, North-West Univ / Unit for Environmental Sciences and Management; R.M. Albertus, Sasol Technology Pty Limited / Environmental Science and Technology; N. Basopo, National Univ of Science & Technology / Applied Biology and Biochemistry; S. Bollmohr, ECO.Trac / Dept of Zoology; H. Ogunfowokan, Obafemi Awolowo Univ; O. Olorunfemi, Univ of Benin / Animal and Environmental Biology; C. Onwurah, Univ of Nigeria / Dept of Educational Foundation; B. Opeolu, Cape Peninsula Univ of Technology / Faculty of Applied Sciences; R. Pieters, North-West Univ / Unit for Environmental Sciences and Management; R.G. Snyman, Cape Peninsula Univ of Technology / Biodiversity and Conservation; V. Somerset, CSIR; M. Thwala, CSIR / Source Directed Measures Research Group; J.H. van Vuren, Univ of Johannesburg / Zoology; B. Ximba, Cape Peninsula Univ of Technology; B.W. Brooks, Baylor Univ / Dept of Environmental Science

The Global Horizon Scanning and Prioritization (GSHP) Project is a SETAC initiative that aims to collect and prioritize the most important future environmental quality research questions as recognized by scientists and engineers from around the globe. In this presentation the conclusions derived during the African GSHP Workshop held at Langebaan in October 2015 are presented. SETAC Africa and other scientists in the region were requested to submit the priority research questions. A total of 96 questions were received prior to the workshop. During the workshop these questions were refined and partitioned to select the top 24 questions from six categories: Capacity building in Environmental Toxicology and Chemistry in Africa, Mixtures and multiple stressors, Risk Assessment in the African Context: Policy and Regulations, Contaminants of Emerging Concern, Linking Science and Society and Environmental Chemistry: Analysis, fate and exposure. The prioritized questions included: overcoming the lack of and access to equipment, consumables and facilities to enhance African environmental research output, integrity and intercontinental cooperation; enhancing mentoring programs in increasing or building environmental science research and training capacity; developing innovative cross border collaboration with specialists in various environmental fields to fast track solutions to pressing environmental problems; develop capacity in environmental and health science education, communication and dissemination to raise awareness; cumulative effects of converging agricultural, mining and urbanization on ecosystem and human health; altered risk profiles due to climate change; the risks of multiple stressors to iconic African wildlife, emerging contaminants such as plastics, e-waste, genetically modified crops/organisms and fracking; identification and management of susceptible ecosystems; trans-boundary "superfund sites"; integration of disease and poverty into human health risk assessments following; human health as a result of changes in the chemical use and production patterns due to global changes; indigenous knowledge systems to develop sustainable environmental protection programs in Africa; the effect of trade, trans-boundary movement and quality of products, food and feedstuffs on human and environmental health. There is a realisation that the critical environmental questions need to be addressed in concordance with issues affecting human health.

621 Towards Sustainable Environmental Quality: Priority Research Questions for North America

Brooks, Baylor Univ / Environmental Health Science Program Dept of Environmental Science

The SETAC World Council launched the Global Horizon Scanning and Prioritization Project aimed at identifying geographically specific research needs to address stressor impacts on environmental quality. Priority research questions were solicited from SETAC North America members, members of the American Chemical Society's (ACS) Environmental Chemistry and Agrochemicals Divisions and other environmental professionals. A total of 310 questions were received, which were scientific in orientation, and covered diverse aspects of fields related to SETAC's mission to advance sustainable environmental quality. Research questions were initially partitioned among the following breakout themes: 1. Ecotoxicology and Applied Ecology: Multigeneration and Field; 2. Environmental Chemistry: Analysis, Fate and Exposure; 3. Regulatory Challenges and Societal Issues; 4. Predictive, Alternative and High-throughput Approaches; 5. Environmental Management: Restoration and Engineering Science; 6. Multiple Stressors (including Mixtures and Climate Change); 7. Eco- and Environmental Toxicology; 8. Sustainability Sciences (including Green Chemistry); and 9. Reducing Uncertainty in Hazard and Risk Assessment. During a 2 day workshop in Salt Lake City, these questions were then synthesized by academic, business and government representatives, including liaisons from the ACS divisions, to identify 40 priority research needs. This presentation provides an overview of major research themes from North America. It is anticipated that outputs from this effort will help increase the quality and relevance of environmental research, decrease scientific uncertainty in assessing and managing environmental risks, and increase the credibility of technical and policy responses to global environmental stressors. SETAC further anticipates these questions will support its Long Range Planning efforts.

622 Towards Sustainable Environmental Quality: Priority Research Needs for Asia

K.M. Leung, The Univ of Hong Kong; J. You, Jinan Univ / School of Environment; C.R. Arias-Barreiro, PETRONAS / Global Toxicology Health Safety Environment; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; A. Boxall, Univ of York / Environment Dept; M. Rudd, Emory Univ; B.W. Brooks, Baylor Univ / Environmental Health Science Program Dept of Environmental Science

The SETAC World Council launched the Global Horizon Scanning and Prioritization Project aimed at identifying geographically specific research needs to address stressor impacts on environmental quality. Priority research questions were solicited from SETAC Asia-Pacific (sans Australasia, which held a workshop in Nelson NZ) members and other environmental professionals. Quesitons were partitioned among six breakout groups during a 1 day workshop during the SETAC Asia-Pacific meeting in Singapore then synthesized by academic, business and government representatives to identify priority research needs. This presentation provides an overview of major research themes from Asia. It is anticipated that outputs from this effort will help increase the quality and relevance of environmental research, decrease scientific uncertainty in assessing and managing environmental risks, and increase the credibility of technical and policy responses to global environmental stressors. SETAC further anticipates these questions will support its Long Range Planning efforts.

623 Towards Sustainable Environmental Quality: Initial Synthesis of a Novel Effort to Identify Global Research Needs

B.W. Brooks, Baylor Univ / Environmental Health Science Program Dept of Environmental Science; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; A. Boxall, Univ of York / Environment Dept; M. Rudd, Emory Univ / Dept of Environmental Sciences

The SETAC World Council launched the Global Horizon Scanning and Prioritization Project aimed at identifying geographically specific research needs to address stressor impacts on environmental quality. Priority research questions were solicited from SETAC members and other environmental professionals within the five SETAC geographical units (GU), then synthesized by expert teams of academic, industry and government representatives to form lists of the top research questions that, if answered, would substantially advance our understanding of how a range of environmental stressors (chemical, physical, biological) impact environmental quality in different geographic regions. During 2015, workshops were held for SETAC Africa (in Langebaan, South Africa), SETAC Europe (in Barcelona, Spain), SETAC Latin America (in Buenos Aires, Argentina) and SETAC North America (in Salt Lake City, USA). For SETAC Asia-Pacific, an initial workshop in 2015 focused on Oceania (in Nelson, New Zealand) while a second workshop in Singapore during 2016 focuses on other parts of Asia-Pacific. Each workshop was chaired by SETAC members representing academic, business and government sectors. Questions received were scientific in orientation, and covered diverse aspects of fields related to SETAC's mission to advance sustainable environmental quality. This presentation provides a project overview and synthesis of major research themes emerging within and across SETAC Geographic Units. It is anticipated that outputs from this effort will help increase the quality and relevance of environmental research, decrease scientific uncertainty in assessing and managing environmental risks, and increase the credibility of technical and policy responses to global environmental stressors.

Alternative Approaches to Complex Environmental Challenges – Part 1

624 Assessing and Managing Aquatic Stressors In A Changing Global Environment

P.M. Chapman, Chapema Environmental Strategies Ltd

We are facing a dynamic future in the face of multiple stressors acting individually and in combination: climate change; habitat change/loss; overuse of resources (e.g., overfishing); invasive species; harmful algal blooms/eutrophication; and, chemical contaminants. Respective changes to aquatic environments will be discussed with a particular focus on climate change (e.g., decreased ocean pH), whose effects are expected to be greater in polar and tropical areas than in temperate areas. Risks from climate change and other stressors will be dynamic and changing; historic assessment and management approaches will be inadequate. Wicked problems (non-linear, complex, competing risks and benefits, not easily solvable), which will become increasingly common, will be discussed with examples. The importance of agreed protection goals and considering both the negatives (risks) and the positives (benefits) will be discussed. The talk will conclude with three key questions for researchers and managers will be outlined: determining tipping points; maintaining ecosystem services; and, managing competing ecosystem services.

625 Personal exposure to PAHs near natural gas extraction

L. Paulik, Oregon State Univ / Environmental and Molecular Toxicology; K. Hobbie, ICF / Health Science; D. Rohlman, Oregon State Univ / Environmental Health Sciences Center; R.P. Scott, B.W. Smith, Oregon State Univ / Dept of Environmental and Molecular Toxicology; L. Kincl, Oregon State Univ / College of Public Health and Human Sciences; E.N. Haynes, Univ of Cincinnati / Center for Environmental Genetics; K.A. Anderson, Oregon State Univ / Environmental and Molecular Toxicology

Natural gas extraction (NGE) has expanded rapidly in the United States in the last 15 years. Despite concern about environmental impacts, few studies have directly measured emissions coming from NGE. No study has directly measured personal exposures of people living near NGE. Recent research has suggested that NGE emits polycyclic aromatic hydrocarbons (PAHs) into air. This study used low-density polyethylene passive air samplers to measure PAHs near active NGE wells and sites permitted to host future wells in a rural Ohio community. At each site inner and outer rings of samplers were placed around the well pad or the proposed well pad location. This study also used silicone passive wristband samplers to measure personal PAH exposures of people living near these air sampling sites. Samples were analyzed for 62 PAHs using GC-MS/MS, and isomer ratios were used to identify sources of PAH mixtures. ∑PAH levels in air were significantly higher at sites with active NGE wells than at sites without wells (Wilcoxon rank sum test, $p < 0.01$). Isomer ratios indicated that PAH mixtures at sites with active NGE wells had more petrogenic signatures, while sites without wells had more pyrogenic signatures. This is consistent with NGE well sites being more heavily affected by emissions from within the earth. ∑PAH levels were significantly higher in wristbands from participants who had NGE wells on their home properties than from participants who did not (Wilcoxon rank sum test, $p < 0.005$). Specifically, median ∑PAH was 4.5 times higher in wristbands of participants living within 0.75 km of active NGE wells than in wristbands of participants living farther than 2.0 km from any active NGE wells. There was a significant positive correlation between ∑PAH in participants' wristbands and ∑PAH in air measured at the stationary sampling site nearest to each participant's home (simple linear regression, $p < 0.01$). This work provides further evidence affirming that NGE emits PAHs into air. These findings also suggest that living on a property with an active NGE well may increase personal exposure to PAHs.

626 Risk Communication Lessons from the Lower Duwamish Waterway Fishers Study – One Size Does Not Fit All

S. Replinger, K. Godtfredsen, Windward Environmental LLC; D. Williston, King County / Dept of Natural Resources and Parks; M. McNees, Windward Environmental LLC; K. Pace, Public Health Seattle & King County / Local Hazardous Waste Management Program; S. Reilly, ECOSS; J.H. Stern, Dept of Natural Resources and Parks / Dept of Natural Resources and Parks

As part of the Superfund cleanup process for the Lower Duwamish Waterway (LDW) in Seattle, WA, the Lower Duwamish Waterway Group conducted a fishers study to gather information from people who either harvest or consume seafood from the LDW. The objective of this study was to inform the development and improve the effectiveness of institutional controls (ICs) related to the consumption of resident seafood. ICs will be needed at the site both during and following cleanup. During cleanup, tissue concentrations are expected to be elevated relative to existing conditions as a result of dredging, and following cleanup, tissue concentrations are expected to re-equilibrate at concentrations above human health risk thresholds. The fishers study included two primary components: 400 quantitative surveys were completed in 7 languages with fishers of more than 20 ethnicities as part of a year-long effort to survey fishers along the river and 11 qualitative key informant interviews were completed with a total of 22 community members that allowed for more in-depth discussions with people who fish on the LDW and people who are preparers or consumers of LDW seafood. Among the key findings of the study is a better understanding of who is fishing on the river, who is consuming LDW resident seafood, and how fishers and consumers of LDW seafood prefer to receive health information about the Duwamish. In addition, the study provided insight into the risk models of Duwamish fishers. Specifically, risk associated with the consumption of resident seafood is primarily perceived through the fisher's perception of the cleanliness of the water, visual inspection of the seafood, experience (or lack thereof) of acute sickness, and word of mouth. This and other information learned over the course of the study will be used to shape future communication strategies about long-term health risks from eating contaminated seafood from the Superfund site. The results of the study show that differences in age, gender, cultural background, and other factors mean that a one-size-fits-all approach to risk communication will not be successful, but rather risk communication must include a variety of methods (e.g., interactive community-based outreach efforts) tailored to the needs of the community.

627 Evaluating Toxicity-Based Injury Thresholds for Contaminants at the Hanford Nuclear Site Using Multiple Empirical Approaches

T. Baker, NOAA / Office of Response Restoration; B. de Jourdan, Oregon State Univ / Environmental and Molecular Toxicology; S. James, US Fish and Wildlife Service

A group of eight State and Federal agencies and Tribes are participating in a Natural Resource Damage Assessment (NRDA) at the Hanford Nuclear Site in Eastern Washington. The Site has more than 40 contaminants of potential concern (COPCs) within a large pollution footprint, including portions of the Columbia River. Because of Hanford's size, complex place in U.S. history, current cleanup status, and long-term nature of contamination, information relevant to injury threshold-setting is voluminous and of highly variable quality and degree of completeness. Open access and transparency during the entire threshold evaluation was non-negotiable among Trustees. All of these factors and the legal overlay of the NRDA process made consensus-based decision-making in traditional ecotoxicity-based frameworks challenging. We successfully used an iterative, Workshop-based process to first frame the issue of injury thresholds to a large group of NRDA stakeholders, and then reach interim understandings about the range of injury threshold values in soils, surface waters, and sediments that should be considered for taking the next step in the injury assessment – quantifying injuries to resources and ecological services. Over several years, we collaboratively drafted technical memos focused on understanding ecological effects from a single contaminant and maintained all analyses as open access. For many COPCs, we used results from multiple empirical approaches to inform our NRDA evaluation, notably a soil Predicted No-Effect Concentrations (PNEC) calculator, Biotic Ligand Models, Consensus-Based Sediment Quality Guidelines, and Equilibrium Partitioning approaches. We also undertook an extensive evaluation of background contaminant concentrations, considered existing screening-level benchmarks and ecological injury thresholds, criteria, standards, and guidance values, reviewed peer-reviewed literature on sub-lethal endpoints and mixture toxicity, and cross-walked our preliminary findings to Site-specific ecological risk analyses and laboratory toxicity tests. At Hanford, an iterative and collaborative Workshop approach with completely open data access and well-developed memoranda has led to significant progress.

628 Hormone receptor bioanalytical assays as indicators of endocrine disrupting potential: Case studies from the field and laboratory

J.H. Bisesi, S. Robinson, Univ of Florida / Envirionmental and Global Health; L. Ferguson, Duke Univ / Dept of Civil and Environmental Engineering; N.D. Denslow, Univ of Florida / Physiological Sciences; T. Sabo-Attwood, Univ of Florida / Environmental Global Health

Aquatic environments are often inundated with complex mixtures of contaminates with endocrine active modes of action. Bioassays to assess the toxicity of point source outflows and surface waters can often be expensive and time consuming; often requiring follow up testing to determine specific mechanisms of toxicity. High throughput bioanalytical assays using hormone receptors have emerged as a technique to identify the cumulative impacts of complex mixtures on specific endocrine modes of action. Through collaborative efforts we have developed a fluorescence based estrogen receptor binding assay as well as a luciferase based estrogen receptor transactivation assay. Both assays are plate based, high throughput assays with great sensitivity. This presentation will focus on potential uses of such assays with examples from the lab and field including: (1) Identification of estrogenicity of emerging contaminants. As new chemicals are developed and released in our aquatic environments it is important to understand their mode of action in aquatic species. Using these assays we can quickly assess a chemicals ability to bind and activate or deactivate the estrogen receptor. (2) Assessing the estrogenic potential of contaminated field sites. Following the collection of water samples and subsequent extractions from field sites in the US as well as Haiti, we have successfully used these assays to identify sites of potential concern due to elevated estrogenic activity. (3) Determining how interactions of nanomaterials and estrogens impact downstream responses. Emerging contaminants like nanomaterials have the potential to interact with estrogenic compounds already present in our environment. Using these assays we have shown the single walled carbon nanotubes have the potential to sorb estrogens and decrease estrogen receptor binding and activation. These examples demonstrate the versatile nature of in vitro hormone receptor assays for assessing the impacts of complex mixtures of aquatic contaminants. Results from these assays can be used to prioritize sample testing, which has been recommended under the adverse outcome pathway paradigm.

629 The Differential Binding of New River Wastewater Effluent EDCs to the New TriFishER Assay for Measuring Estrogenicity

B. Tate, S. Tuberty, Appalachian State Univ / Biology; B. Hawkins, North Carolina State Univ / Dept of Biological Sciences

Endocrine disrupting compounds (EDCs) have been identified in aquatic environments, are known to mimic natural estrogens (e.g.17ß-estradiol), and disturb reproduction and development of aquatic wildlife. One important mechanism of EDC action is modulation of activation of estrogen receptors (ERs). The identification of specific EDCs that interact with ERs is a complex issue due to the vast diversity of endocrine disrupting chemicals found in the environment. Even more uncertain is the number of the ~70,000 chemicals not yet tested for EDC activity. Therefore, it remains unknown if these unidentified chemicals contribute to the combined effects of EDCs. Although vertebrates possess multiple ER subtypes with different ligand binding and transactivation properties, most screening is done using a single ER subtype, the human ERα. This approach may result in an underreporting of estrogenic contamination, particularly for non-mammalian aquatic species. Teleost fish express three ER subtypes (ERa, ERba, and ERbb), with ligand binding profiles distinct from each other and mammalian ERs (ERa and ERb). We report here a new validated assay called the TriFishER that applies all three fish estrogen receptors (α,β_a & β_b). In addition to being more environmentally relevant, the TrifishER assay is economical, more time efficient (~2 days), while maintaining sensitivity in the nanogram/liter range, making it an important tool in determining aquatic EDC binding potential. The Trifisher assay is a proven high throughput competitive binding assay that uses an E. coli expression vector transformed with each of the three acER (Atlantic Croaker estrogen receptor) ligand binding domains. Each class of compound binds differently to each receptor giving the compounds a unique binding profile (i.e. fingerprint), which can then be used identify EDC activity in the environment. To test this hypothesis the Trifisher assay has been used with environmental samples from communities that differ in their average population age along the New River corridor of NW NC. The TriFISHer assay is not able to detect what type of estrogenic compound is present in solution or the precise concentrations of individual estrogenic compounds present in the solution. The TriFISHer assay will also not be able to predict what genes are activated after EDCs bind to the receptors.

630 Riparian Spiders: A valuable tool in ecotoxicological studies

G. Beaubien, MTSU / Biology; C. Olson, Middle Tennessee State Univ; D. Walters, USGS / Fort Collins Science Center; M. Mills, USEPA / National Risk Management Research Laboratory; R.R. Otter, Middle Tennessee State Univ / Biology

A major first tier division for most environmental studies is whether exposure is occurring in the aquatic or terrestrial ecosystem. However, some of the most complex scenarios occur when contaminants and/or organisms are exchanged between linked aquatic-terrestrial systems (typically in the riparian zone). Historically, ecotoxicological studies operated under the assumption that once a contaminant enters the aquatic ecosystem it is rendered an aquatic concern only, and the export to the terrestrial ecosystem is insignificant. Early interchange studies highlighted the importance of cross-system subsidies and contaminant transport typically in the form of emerging aquatic insects or salmon. More recently, riparian spiders have gained traction as a valuable tool in this field of study. These abundant and widespread secondary/tertiary consumers feed on aquatic emergent insects and can act as a contaminant bridge to the terrestrial food-chain. They possess life history characteristics that make them attractive as potential model organisms (e.g., ubiquitous distribution, small home ranges, and short life spans). Progressively, more studies are using/studying riparian spiders to investigate a variety of research directions, including contaminant export, food chain dynamics, and contaminant monitoring. In this presentation a chronological overview of key studies utilizing riparian spiders as well as ongoing studies will be discussed.

631 Efficacy & residual toxicity of a NaOH-based ballast water treatment system for freshwater bulk freighters: shipboard trials

A.A. Elskus, USGS / Ecosystems; D.A. Wright, C.L. Mitchelmore, Environmental Research Services; N. Welschmeyer, Moss Landing Marine Laboratories; C.J. Flynn, Glosten Associates; J.W. Henquinet, Henquinet Consulting; P. Pelletreau, American Steamship Company; B.J. Watten, USGS / SO Conte Anadromous Fish Research Laboratory Leetown Science Center

The ballast water (BW) of freshwater freighters is an important pathway of secondary spread of nonnative species in the Great Lakes. However developing BW treatment systems (BWTS) that significantly reduce the viability of BW organisms yet retain little to no residual toxicity upon release pose a significant environmental challenge and there are currently no type-approved BW treatment systems (BWTS) for freshwater ships. The efficacy and residual toxicity of a novel sodium hydroxide (NaOH)-based BWTS were tested aboard the Great Lakes bulk carrier M/V American Spirit during 4 trials conducted in July & September 2015. BW was treated

by adding NaOH to elevate pH to 11.5 or 11.7 for 48 h, then reduced to pH < 9 before discharge by sparging with carbon dioxide gas. The density of organisms after treatment met the 2013 Vessel General Permit discharge standards for all 3 organism size classes (< 10 mm, ≥ 10 mm to < 50 mm, > 50 mm) in both September trials, and for all organism classes in July trials with one exception. To provide additional data, procedures not in the current regulatory standards were added. These included evaluation of total coliform and total heterotrophic bacteria (< 10 mm) which were reduced > 96% at both pH levels relative to intake densities. Additional tests for phytoplankton and protists using adenosine triphosphate concentrations and fluorescein diacetate tagging demonstrated dramatic reductions in the living biomass of these organisms (≥ 10 mm to < 50 mm) at both pH levels. A 7d whole effluent toxicity test indicated NaOH-BWTS discharge water at the highest level tested, pH 11.7, met the vessel general permit daily maximum for residual toxicity. In addition, testing with the 24 h, dinoflagellate-based QwikLite 200 Biosensor System detected no residual toxicity. This BWTS has the potential to become a successful method for treating large volumes of BW released into freshwater systems.

Canadian Oil Sands: Advancing Science in Chemical and Toxicological Characterization, Reclamation and Monitoring – Part 2

632 Thia-arenes and Aza-arenes in Samples from the Oil Sands Area of Alberta

C.A. Manzano, C.H. Marvin, D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; T. Harner, Environment and Climate Change Canada / Atmospheric Science Technology Directorate; J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Charland, M. Siu, Environment and Climate Change Canada / Air Quality Research Division; C. Teixeira, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J.W. Martin, Y. Zhang, Univ of Alberta / Laboratory Medicine and Pathology

The Athabasca Oil Sands (AOS) deposits located in Northern Alberta, Canada are considered the world's third largest oil reserve (OPEC, 2014). Long-term data sets on major contaminants, such as polycyclic aromatic compounds (PACs), have been gathered in the past few years as part of the Alberta-Canada Joint Oil Sands Monitoring (JOSM) program, initiated in April 2012. However, most efforts and monitoring plans have focused on a limited list of PACs, which are formed by the incomplete combustion of organic matter during both natural and anthropogenic processes. PACs in the AOS area can be emitted from a large list of potential sources that include natural erosion of geological formations, forest fires, bitumen upgrading, diesel combustion and airborne dust from mining operations. Therefore, samples collected in the AOS area can potentially contain a complex mixture of PACs, which can also include sulfur and nitrogen containing heterocyclic compounds (thia-arenes and aza-arenes). This study was designed to explore PAC isomers currently not being monitored in snowpack samples, lake sediment samples and passive air samples collected at varying distances from the main AOS developments during 2012-2013. All samples were analyzed using two-dimensional gas chromatography with time-of-flight mass spectrometry (GC×GC/ToF-MS), equipped with a liquid-crystalline column in the first dimension and a nano-stationary phase column in the second dimension. Thia-arenes and aza-arenes were identified in all samples collected and classified into isomeric groups, based on their mass spectra and their location in the 2D-chromatogram. Relative concentrations of thia-arenes and aza-arenes decreased with distance from the main developments, and with increasing depth of lake sediments. Additionally, a delayed petcoke sample from local sources, extracted with dichloromethane and methanol, was also analyzed. All thia-arenes and aza-arenes found in the snowpack, lake sediments and air samples, were also found in the delayed petcoke extract. The distribution of thia-arenes and aza-arenes in the petcoke extract was similar to those observed in samples collected within 20 km of the major developments. Therefore, thia-arenes and aza-arenes identified have the potential to be used as source indicators for future research in the area.

633 Developmental and reproductive effects of adult & larval wood frogs exposed to naphthenic acids from commercial sources & oil sands process water

M. Galus, Univ of Ottawa; L. Fieschi-Méric, D.M. Orihel, Univ of Ottawa / Dept of Biology; J.V. Headley, Environment and Climate Change Canada; K. Peru, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J. Gutierrez Villagomez, Univ of Ottawa / Dept of Biology; S.A. Hughes, Shell Health – Americas / Shell Health Risk Science Team; D.W. McMartin, Univ of Regina; J.M. Blais, Univ of Ottawa / Dept of Biology; V. Trudeau, Univ of Ottawa / Biology

Naphthenic acids (NAs) are naturally found in the bitumen deposits in Canada's oil sands region, and through the extraction process, can become concentrated in oil sands process-affected water (OSPW). OSPW is currently stored in tailings containment facilities on oil sands sites as they are not currently regulated for discharge. As part of the industry's reclamation plan, strategies are looking at whether or not OSPW can be treated and safely discharged back into the environment. Therefore, as a part of these efforts, it is important to understand the effects of NAs and OSPW on the health of amphibians at different stages of development. Adult Wood frogs (L. sylvaticus) were caught near Bishops Mills, Ontario, Canada and bred in lab. Egg masses were allowed to develop until Gosner stage 8-10 (embryonic) and 20-21 (hatchling) before tadpoles were exposed to commercial NAs (Merichem Co.; 0-196 mg L^{-1}) and NAs extracted from OSPW (0-190.5 mg L^{-1}). In both studies, tadpoles were photographed 96hr post exposure to determine morphometric parameters, abnormalities and survival rate. Embryonic wood frogs exposed to 8-12 mg L^{-1} of Merichem NAs were significantly smaller in size, had reduced pigmentation and showed compromised structural integrity of the gut; particularly uncoiling of the intestines and thickening of the intestinal lumen. Surprisingly, hatchlings exposed to the same NA concentrations exhibited few alterations until higher NA concentrations (48 mg L^{-1}), suggesting a critical window of exposure for this species. When exposed to NAs extracted from OSPW, hatchling wood frogs showed similar developmental impacts as with Merichem exposure, however not until concentrations approached 80 mg L^{-1}. Adult wood frogs were also exposed to NAs extracted from raw OSPW during spawning. Exposure to 3, 10 and 30 mg L^{-1} disrupted spawning behavior with reduced occurrence and time in amplexus. All eggs laid by frogs exposed to 3, 10 and 30 mg L^{-1} were abnormal in development, suggesting NAs from OSPW could be reducing fecundity. Efforts are still underway to find causative agents in the very complex mixture of NAs and to understand whether or not effects observed in the lab would occur with NAs exposures in the wild. Nevertheless, these results help further our understanding of the toxicological properties of NAs and their impact on a key bioindicator species.

634 Naphthenic acids derived from oil sands processed waters are respiratory uncouplers

K.I. Rundle, M. Sharaf, Univ of Prince Edward Island / Dept of Biomedical Sciences Atlantic Veterinary College; D. Stevens, Univ of Prince Edward Island / Biomed Sci; C. Kamunde, Univ of Prince Edward Island / Biomedical Sciences Atlantic Veterinary College; M.R. Van den Heuvel, Univ of Prince Edward Island / Dept of Biology Dept of Biomedical Sciences Atlantic Veterinary College

The extraction of bitumen from oil sands via the surface mining produces large volumes of waste water. Naphthenic acids, a complex mixture of carboxylic acids, are a dominant group of compounds present in the oil sands process affected water. Naphthenic acids have been shown to acutely lethal to fishes as well as cause a variety of sublethal effects, including: endocrine disruption, developmental abnormalities, and inhibition of growth. No over-arching mechanism of action for these acids has been found. It was hypothesized that naphthenic acids would act as respiratory inhibitors due to their carboxylic acid moiety, and based on observations from other carboxylic acids that have been observed to disrupt cellular energetics. It was predicted that NAs will inhibit the electron transport chain and uncouple oxidative phosphorylation and that these effects will be mediated by oxidative stress. To test this hypothesis, naphthenic acids were extracted from 17-year-old tailings from Syncrude Canada using acid precipitation followed by DEAE cellulose cleanup methods, DCM liquid-liquid extraction, and a subsequent precipitation under acidic conditions. The precipitate was washed with distilled water and freeze dried in order to generate a solid material. Naphthenic acids were characterized using HRMS and found to be greater than 95% pure based on the negative ion spectra. Mitochondria were isolated from rainbow trout liver cells using differential centrifugation and cellular respiration parameters were tested using an Oroboros respirometry system. Mitochondrial redox state and membrane potential were evaluated using real-time flow cytometry in combination with the fluorescent dyes, DCFDA and JC-1. Results have shown inhibition of cellular respiration following naphthenic acid exposure at concentrations above 120 mg/L. Naphthenic acids specifically caused a reduction in stage 4 respiration. Results will be discussed with regards to the environmental relevance of the dose-effect relationship observed here.

635 Effects of elevated salinity and dissolved organic matter in surface water from an oil sands end-pit lake on the toxicity of metals to zooplankton (Ceriodaphnia dubia)

K.B. White, K. Liber, Univ of Saskatchewan / Toxicology Centre

In order to manage growing inventories of fluid fine tailings (FFT) and oil sands process-affected water (OSPW), Alberta oil sands mine operators have proposed end-pit lakes (EPLs) as a method for the long-term storage and reclamation of tailings. In December of 2012, Syncrude began the industry's first large-scale demonstration of EPLs with the creation of Base Mine Lake (BML) – an artificial lake containing FFT capped with OSPW and fresh water. However, tailings contain a complex mixture of dissolved organics, salts and metals which have adverse effects on phytoplankton and zooplankton – aquatic organisms essential for early ecosystem development. The initial elevated salinity of BML decreased rapidly during 2013 and 2014, but has since slowed. The chloride concentration (410 mg/L) is now within a tolerable range for most freshwater organisms but will still cause stress. From October 2014 to August 2015, most dissolved metal concentrations decreased an average of 60%; Cu and Zn were the only metals which increased (>300% and >200%, respectively). As of August 2015, Cu and Hg are the only metals which still exceed Canadian Water Quality Guidelines, although As, Cd and Cr all exceeded in 2014. Despite these decreases, some metals remain highly elevated above natural background levels (Mo is 45x higher in BML than in the Athabasca River). Comparisons to chronic toxicity values for model phytoplankton and zooplankton species (Raphidocelis subcapitata and Ceriodaphnia dubia, respectively) yield hazard quotients >0.05 for Cu, Ni and U only. The vast majority of all other dissolved metals now have chronic toxicity hazard quotients < 0.01 for both species and are no longer of any concern. As a result, current work is focused on characterizing the potentially attenuating effects of the elevated BML salinity, alkalinity and dissolved organic carbon on the toxicity of Cu, Mo, Ni, and U to these initial aquatic colonizers. Our research will allow Syncrude to more adequately evaluate the efficacy and sustainability of EPLs as a method for long-term oil sands reclamation. This is crucial, as the results of the BML demonstration will have a profound impact on the future development of oil sands within Canada and around the world.

636 The impact of raw and ozonated oil sands process water exposure on prey capture and facial morphometrics in zebrafish larvae

D. Philibert, D. Lyons, Univ of Alberta / Biological Sciences; M. Meshref, R. Huang, N. Klamerth, Univ of Alberta / Civil and Environmental Engineering; J. Hughes, USGS / Columbia Environmental Research Center; M. Gamal El-Din, Univ of Alberta / Civil and Environmental Engineering; K. Tierney, Univ of Alberta / Biological Sciences

In the oil sands mining industry, oil sands process water (OSPW) is stored in tailings containment facilities to ensure it can be recycled for bitumen extraction, process cooling and hydro-transport of materials (e.g., tailings slurries). As part of the industry's reclamation plan, tailings containment facilities will eventually be developed into terrestrial or aquatic habitat that can sustain functions similar to natural habitat in the region. The effectiveness of ozone treatment in increasing OSPW quality is under study to determine the suitability of this treatment method. The impact of OSPW exposure on early developmental stages of fish has been well studied, however, the sublethal impacts of raw and ozonated OSPW exposure in later developmental stages have yet to be determined. During the growth and development of juvenile fish, feeding efficiency is ecologically important. Cardiac function and craniofacial structure can have a large impact on the success and speed of prey capture, which can translate into differences in larval growth, maturation and reproductive success. In this study we examined the effect of embryological exposure to raw and ozonated OSPW from two different mine sites on the craniofacial morphology, cardiac function and prey capture success of zebrafish larvae. The study of more ecologically relevant endpoints, such as prey capture and feeding behavior, on well characterized teleost model species, such as the zebrafish, will allow a better understanding of potential impacts of OSPW on fish species and the suitability of ozone for treatment of OSPW.

637 Long-term effects of oil sands process-affected water (OSPW) on growth, reproduction, and energy reserve of Daphnia magna

E. Lari, D. Steinkey, G.G. Pyle, Univ of Lethbridge / Biological Sciences

Determining the potential effects of oil sands process-affected water (OSPW) on aquatic ecosystems is of main concern to oil sands companies and legislators concerned about the reclamation of mining sites. In the present study, the effect of OSPW on energy reserve, growth, and reproduction of Daphnia magna was investigated. One-week old D. magna were exposed to 1 and 10% OSPW and culture water as control, for 10 days. The neonates produced were removed and counted throughout the exposure. The length and dry weight of both the adult and neonate daphniids was measured at the end of exposure. To investigate the energy reserve in exposed daphniids, total hydrocarbon, protein, and lipid was measured. The number and weight of neonates in 1% group was not different from the control, but the daphniids exposed to 10% OSPW produced fewer and smaller neonates. The weight of daphniids in 10% OSPW was lower than the control, but not different from control in the 1% group. Neither of the treatments had an effect on daphniid length. Energy reserves of daphniids exposed to OSPW is lower than the control group. The results of the present study suggest that exposure to OSPW reduces the fitness of individual D. magna that may impose ecological pressure on D. magna population.

638 Identification of chemical classes contributing to the toxicity of oil sands process affected water

G. Morandi, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre; K. Zhang, Univ of Alberta / Div of Analytical and Envionmental Toxicology Dept of Laboratory Medicine and Pathology; C. Sun, Univ of Alberta / Laboratory Medicine and Pathology; A. Pereira, Alberta Innovates Technology Futures; S. Wiseman, Univ of Lethbridge / Biology; J.W. Martin, Univ of Alberta / Laboratory Medicine and Pathology; J. Giesy, Univ of Saskatchewan / Dept of Veterinary and Biomedical Sciences and Toxicology Centre

Oil Sands process-affected water (OSPW) produced during extraction of bitumen in the surface-mining oil sands industry in Alberta, Canada, can be acutely and chronically toxic to aquatic organisms. It is known that organic compounds that are dissolved in OSPW are responsible for most toxic effects. Here, we present an overview of a four year project with the purpose of identifying chemical classes contributing to the toxicity of OSPW. By use of best available analytical technology, linear ion trap (orbitrap) ultrahigh resolution mass spectrometry operated in positive and negative electrospray ionization modes ($^{+/-}$), and an effects- directed analysis approach, three rounds of sequential fractionation and acute toxicity testing were completed. From this work, two refined fractions of dissolved organic chemicals in OSPW (F3-NE2a and F3-NE2b) were produced and were acutely toxic to exposed embryos of Fathead minnow (Pimephales promelas) and by use of the Microtox® test (Bacterium; Vibrio fisheri).

To support this work, an acute aquatic toxicity model was developed to predict the toxicity of samples of OSPW to embryos of Fathead minnow to further investigate the contribution of chemical classes in the mixture. For model development, a narcosis mode of action was assumed, and the target lipid model of Di Toro et al., (2000) was applied for toxicity predictions by use of measured bioaccumulation estimates of the individual accurate masses, either octanol-water (D_{OW}) or membrane-water (D_{MW}) partition coefficients measured at a pH of 7.4. This work highlighted the contribution of the chemical classes SO^+, SO_2^-, $O_2^{+/-}$ and NO^+ to the acute toxicity of OSPW and demonstrated that an explicit assessment of chemical accumulation into polar lipids by use of D_{MW} improves toxicity predictions. Chronic toxicity of the tertiary fractions (F3-NE2a and F3-NE2b) was investigated by use of the USEPA 21-day Fathead minnow reproduction bioassay to assess effects of dissolved organic chemicals in OSPW on the endocrine system of Fathead minnows exposed under laboratory conditions. Endocrine disrupting effects were assessed by use of various reproductive measurements and morphological, histopathological, and molecular/biochemical responses of males and females. This work has highlighted the contribution of novel chemical classes to the acute and chronic toxicity of OSPW and will aide in the development of reclamation and monitoring programs in the oil sands region of Alberta, Canada.

639 Bioassay-directed fractionation of bitumen-influenced groundwaters from the Athabasca oil sands region

R. Frank, A.J. Bartlett, P. Gillis, J. Parrott, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A. Bauer, Univ of Waterloo / Biology; R. Vanderveen, M. Rudy, Environment and Climate Change Canada; L.R. Brown, Environment and Climate Change Canada / Aquatic Contaminants Research Division; J.W. Roy, G. Bickerton, Environment and Climate Change Canada; D. Dixon, Univ of Waterloo / Dept of Biology; M. Hewitt, Environment and Climate Change Canada / National Water Research Inst

Much of the oil sand deposit in the area surrounding Ft. McMurray, AB is near-surface, enabling cost-effective surface mining operations in this region. Ground and surface waters can traverse the deposit, possibly mobilizing water-soluble bitumen derived chemicals into the Athabasca River watershed. In addition to this input, recent research has identified oil sands process-affected water (OSPW) contamination of groundwater systems surrounding tailings ponds. While chemical profiles are beginning to be described for these natural and anthropogenic bitumen-influenced groundwaters, little is known regarding their toxicity and the identities of the toxicologically relevant components. In the current study, a preparative fractionation protocol was applied to a sample set of four groundwaters (>100L each), previously identified as containing either natural bitumen or OSPW contamination mixed with natural bitumen. The fractionation method allowed for the isolation of individual mixtures of neutral organics, polar organics, and inorganics (metals and salts), generating five fractions in total. The resulting fractions were assessed using a suite of invertebrate bioassays (in complement to fish bioassays presented separately) for acute toxicity profiles. Assays with Hyalella sp., Daphnia sp., freshwater mussel glochidia and Microtox indicated differences in the observed toxicity between species, between different fractions of the same source and also between sources when comparing the same fractions and species. This work will guide more detailed fractionation studies designed to identify the compound classes of interest within the soluble organic mixtures of bitumen-influenced waters. This information is critical for the development of water monitoring programs in the oil sands region.

Epigenetics and Environmental Exposures: Mechanisms and Effects from Invertebrates to Fishes

640 Role of DNA methylation in AHR-mediated toxicity of PAHs in chicken embryo

J. Brandenburg, J. Head, McGill Univ / Natural Resource Sciences

DNA methylation is an epigenetic mark that plays an important role in regulating gene expression. As with other epigenetic marks, patterns of DNA methylation are sensitive to environmental stressors (e.g. contaminants) and have the potential to be heritable (i.e. faithfully copied as cells divide, persisting beyond initial exposure). Here, we assess the role of DNA methylation in aryl hydrocarbon receptor (AHR) mediated toxicity of polycyclic aromatic hydrocarbons (PAHs) in the developing chicken embryo. Graded concentrations of the PAH, benzo[k]fluoranthene (BkF), were injected into the air cell of fertilized unincubated chicken eggs on embryonic day 0 (ED0). Liver tissue was sampled at several timepoints throughout development – ED7, ED10, ED19, and two days post-hatch (D2) – in order to assess BkF-associated patterns of cytochrome P4501A (CYP1A) mRNA expression and DNA methylation. Induction of CYP1A mRNA isoforms CYP1A4 (23-fold) and CYP1A5 (15-fold) was first observed starting on ED10, several days after the start of organogenesis. The transcriptional response was transient. By ED19, the signal was no longer present, a finding that corresponds well with previously published data suggesting that the developing chicken embryo rapidly metabolizes PAHs. In contrast, BkF-associated increases in DNA methylation at key regulatory sequences within the CYP1A4/5 shared promoter persisted through ED19 and were also detected in the hatched chick. We investigate how these persistent epigenetic marks may affect subsequent exposures to AHR ligands using a chicken embryo hepatocyte model. This work begins to explore linkages between early-life experiences in the embryo and later-life responses to PAHs.

641 Multi generational effects of pharmaceutical exposure in zebrafish (Danio rerio)

S. Fraz, McMaster Univ / Biology; A. Lee, McMaster Univ; J. Wilson, McMaster Univ / Biology

Carbamazepine and gemfibrozil are two pharmaceutical contaminants frequently detected in wastewater effluent and surface waters. They are characterized by continual release, long half lives in water, and bioaccumulation with uncertain metabolism rates in fish. Carbamazepine and gemfibrozil are reported to negatively affect male reproduction in mammals and fish. This study investigated the hypothesis that carbamazepine and/or gemfibrozil act as endocrine disruptors via anti androgenic effects, that direct exposure to either contaminant can adversely affect parental male reproductive physiology, and these impacts may be transmitted to unexposed offspring. We exposed adult zebrafish to 10 μgL^{-1} of either carbamazepine or gemfibrozil for 6 weeks and analyzed a range of male reproductive indices, which were also investigated in unexposed F_1 and F_2 offspring to assess multi generational impacts. We observed that exposure to carbamazepine and gemfibrozil caused a decline in breeding success and mean embryo production in F_0 parents. Exposure also resulted in a reduction in whole body, plasma and testicular 11-ketotestosterone (11KT); and altered male courtship, aggression and sperm morphology. The F_1 offspring were raised in clean water from seven distinct lineages where only a single parent or both parents were exposed to either carbamazepine or gemfibrozil. F_1 offspring from exposed paternal lineages had reduced breeding success and mean embryo production as well as altered male courtship, sperm velocity, sperm morphology, and whole body 11KT. Similar findings were recorded for F_2 males. The F_3 offsprings are currently being reared. Our results indicate sub-lethal toxic effects are transferred to unexposed male offspring via parental exposure alone. Preliminary findings suggest carbamazepine and gemfibrozil may act as anti androgens in fish and that exposure to these pharmaceuticals may reduce male reproductive fitness.

642 Assessing benzo[a]pyrene-mediated effects on the zebrafish transcriptome and promoter methylation to explain developmental adverse outcomes

K.L. Willett, Univ of Mississippi / Pharmacology; X. Fang, Univ of Florida; J. Corrales, Baylor Univ / Environmental Science; C.E. Thornton, Univ of Mississippi / Pharmacology

Benzo[a]pyrene (BaP) is a well-known but mechanistically complicated carcinogen, reproductive and developmental toxicant. In zebrafish (Danio rerio), waterborne or dietary BaP/PAH exposure causes developmental adverse outcomes including growth reduction, neonatal death, cardiac dysfunction, skeletal abnormalities, craniofacial and fin deformities. In an effort to mechanistically explain these toxicities, we performed genome-wide transcriptional analysis and discovered differential gene expression and exon usage in zebrafish at two important developmental stages. Additionally, we measured both global and gene specific promoter methylation by multiplex deep sequencing of 21 genes known for their role in human diseases. Consistent with previous findings on the mechanisms of BaP toxicity, we found that BaP impaired canonical pathways including xenobiotic metabolism signaling, Nrf2-mediated oxidative stress response, glutathione-mediated detoxification, AHR signaling, and estrogen biosynthesis pathways. Novel differentially regulated and disease-related pathways included Notch, melatonin and ApoE pathways. Alternatively spliced myosin and collagen genes may be involved in BaP-induced growth deficits. In BaP-exposed 96 hr post fertilization larvae, global DNA methylation was significantly decreased, and ten genes (6 hyper- and 4 hypomethylated) showed >10% change in CG methylation. Collectively, these molecular changes can be used to predict immediate, long-term, and multigenerational adverse consequences and to develop an AOP for BaP-mediated developmental toxicity. Supported by NIEHS R21ES019940.

643 Differential DNA Methylation in F2 Generation Testicular Cells Caused by Embryonic Exposure to Bisphenol A at F0 Generation

R. Bhandari, Univ of North Carolina at Greensboro / Biology; F.S. vom Saal, Univ of Missouri Columbia / Biological Sciences; D.E. Tillitt, USGS / Columbia Environmental Research Center

Bisphenol A (BPA) is a compound used primarily to manufacture polycarbonate plastics and epoxy resins. It is also an additive in other products. Due to extensive use of BPA in commercial products, the threat to human and wildlife health posed by BPA-containing waste in the environment is a potential concern. We have previously observed transgenerational reproductive defects in unexposed F2 and F3 offspring of Japanese medaka (Oryzias latipes) caused by embryonic exposure of F0 offspring to BPA (Bhandari et al., 2015, Scientific Reports 4: 903). Here we report molecular changes, specifically transcript abundance and DNA methylation of select promoters, in the testis of F0 fish (directly exposed as embryos) as well as in the F2 fish that had transgenerational phenotypes of impaired fertilization capacity and increased embryo mortality. BPA induced subtle changes in DNA methyltransferase enzyme expression in germ cells of the F0 adults exposed during embryonic development, and expression of Dnmt genes (Dnmt1, Dnmt3aa, Dnmt3bb) increased 2- to 10-fold in germ cells of the F2 males, accompanied by 2.5-fold increase in global DNA methylation. DNA methylation of the estrogen receptor promoter was significantly reduced in germ cells of F0 but was not altered in F2 germ cells. Elevated DNA methylation levels were maintained at the CpG island of androgen receptor (AR) core promoter of both testicular germ cells and somatic cells in the F2 generation. As expected, the expression of the AR gene in testicular somatic cells was significantly decreased, which confirms an inverse relationship between DNA methylation and gene expression. Together, these findings provide insights into transgenerational inheritance of BPA-induced epigenetic marks by germ cells and soma at the F2 generation.

644 Epigenetic mechanisms mediating responses to Florida Red Tides in the Eastern oyster Crassostrea virginica

R. Gonzalez-Romero, V. Suarez-Ulloa, Florida International Univ; J.A. Rodriguez-Casariego, Florida International Univ / Southeast Environmental Research Center; D. Garcia-Souto, Univ of Vigo; G. Diaz, A. Smith, Florida International Univ; J. Pasantes, Univ of Vigo; G. Rand, Florida International Univ; J. Eirin-Lopez, Florida International Univ / Dept of Biological Sciences

The study of the epigenetic mechanisms mediating exposure-response relationships constitutes the basis for environmental epigenetic analyses, providing information about how different environmental factors influence phenotypic variation. Marine invertebrates are emerging model systems in such studies and, among them, molluscs are remarkable candidates due to their ubiquitous distribution, easy accessibility and diverse lifestyles. However, knowledge about epigenetic mechanisms and their role during environmental acclimatory and adaptative responses is still scarce in these organisms. One of the most important sources of stress in the oceans is the occurrence of Harmful Algal Blooms (HABs), massive algal proliferation episodes where large amounts of harmful biotoxins are produced. Among them, brevetoxins (PbTx) represent the most predominant neurotoxic shellfish poisoning biotoxins in the coasts of Florida. In the present work we have simulated HAB episodes in the lab in order to analyze the epigenetic responses elicited by PbTx exposure in Eastern oysters (Crasostrea virginica). For that purpose, oysters were exposed to increasing concentrations of the PbTx-producing dinoflagellate Karenia brevis. After the simulation, histone variant expression and post-translational modifications (PTMs), as well as DNA methylation were compared between different oysters at different time points. Quantitative gene expression analysis of different histone variant genes did not show any significant differences between different time points, however western blot analysis showed that the amount of PbTx does correlate with the phosphorylation levels of H2A.X, a histone variant known for its involvement in the repair of DNA double stranded breaks. Similarly, oysters exposed to higher concentrations of PbTx showed modifications in global DNA methylation patterns, which may favor genomic stability when they are exposed to the toxin. Overall, the dynamic changes observed in PTMs and global methylation levels are consistent with the role of epigenetic mechanisms in the responses of oysters to marine toxins. Such results set a framework for future studies aimed at developing new markers of marine pollution.

645 DNA methylation reprogramming during development in the self-fertilizing mangrove rivulus and its sensitivity to environmental pollutants

A. Fellous, URBE; L. Lescat, T. Labed-Veydert, A. Voisin, Univ of Namur; R.L. Earley, The Univ of Alabama; F. Silvestre, Université de Namur ASBL / Dept of Biology

The mangrove rivulus, Kryptolebias marmoratus, is a small fish native from the mangrove ecosystems of Florida, Bahamas and Central America. It presents a great capacity to withstand the constantly fluctuating environmental conditions that define mangrove ecosystems, and is characterized by a high level of phenotypic plasticity. In natural populations, hermaphrodites coexist with a low proportion of males (androdioecy) and it displays the unique ability for a vertebrate of self-fertilization. Selfing has resulted in populations composed of distinct isogenic strains with a variety of identifiable phenotypes. Using rivulus to study phenotypic plasticity permits the construction of "true" reaction norms by reducing genetic noise within lineages. As a new biological model, molecular mechanisms controlling the key transitions during its life history remain largely unknown. Among them, epigenetic modifications such as DNA methylation have important regulatory functions controlling gene expression, and thus the phenotype. Here, LUminometric Methylation Assay (LUMA) was used to explore the dynamic of global DNA methylation during development, in juveniles and in diverse adult tissues. Significant differences between hermaphrodite ovotestes and male testes were observed (87.2% and 79.6%, respectively). After fertilization, a decrease in DNA methylation occurred from 27.8% in fertilized eggs to 15.8% in gastrula, immediately followed

by an increase and re-establishment of the adult pattern by the stage 26 (liver formation) (70.0%). In addition, characterization of genes coding for DNA-methyltransferase enzymes (DNMT1, DNMT3A and DNMT3B) suggests evolutionary conservation of this gene family. Together these results provide evidence of an original reprogramming pattern of DNA methylation among vertebrates, with a long apparent zygotic transition. To determine how sensitive to environmental stress the reprogramming period is, impacts of different contaminants (EE2, Cu and oil-spill pollutants) on DNA methylation during the zygotic transition is being investigated. Altogether we hypothesize that DNA methylation, and more generally epigenetic mechanisms, may have a crucial role in adaptive evolution of rivulus. Epigenetic mechanisms might provide the plasticity required to deal with myriad environmental challenges, which makes mangrove rivulus a promising new vertebrate model in ecotoxicological epigenetics.

646 Multiple stressors over multiple generations: assessing the combined risk of endocrine disruptors and climate change in an estuarine fish

B. DeCourten, S.M. Brander, Univ of North Carolina, Wilmington / Dept of Biology Marine Biology

Understanding anthropogenic impacts such as climate change and pollution on aquatic ecosystems is critical for preserving biodiversity and maintaining water quality. The pyrethroid pesticide bifenthrin is a known endocrine disrupting compound (EDC) found in biologically active concentrations in estuaries affected by urban runoff. Little is known about how elevated temperatures associated with climate change may affect the estrogenic activity of bifenthrin, particularly in species that exhibit temperature-dependent sex determination (TSD), Menidia beryllina. This study investigated the effects of temperature and bifenthrin exposure on reproductive output in M. beryllina across multiple generations. Fish in the parental generation were exposed to bifenthrin, ethinylestradiol (EE2 – positive control) and methanol (solvent control) at 22°C and 28°C for 14 days prior to spawning. Embryos in the F1 generation were exposed to EDCs as larvae (until 21 dph) and then reared to adulthood (8 months) in clean water at experimental temperatures. In all F1 treatments, elevated temperature resulted in fewer viable offspring. At the time of maturity, the F1 generation underwent spawning trials to assess reproductive output and offspring viability following larval exposure. Sex ratios of the F1 generation were influenced by elevated temperature and EDCs, resulting in alteration of adaptive TSD. Fish exposed to bifenthrin during development exhibited developmental deformities. Tissues were collected from each generation to assess the effects of these stressors on the expression of genes involved in reproduction and growth. Findings from this study will be useful in determining how EDCs will impact organisms and community structure in the face of global climate change.

647 Rainbow trout exposed to benzo[a]pyrene yields conserved microRNA binding sites in DNA methyltransferases across 500 million years of evolution

P. Craig, C. Kuc, D.J. Richard, S. Johnson, L. Bragg, M.R. Servos, A.C. Doxey, Univ of Waterloo / Biology

Benzo[a]pyrene (B[a]P), a polycyclic aromatic hydrocarbon formed by the incomplete combustion of organic material found ubiquitously in the aquatic environment, is an established carcinogen and has been linked to multigenerational effects through alterations in DNA methylation patterns. The initial objective of this study was to examine the regulation of DNA methylation following acute (24 h) and prolonged (14 d) exposure to low (1 ng/L) and high (10 ng/L) B[a]P in rainbow trout. However, with the recent release of the rainbow trout genome, we were able to conduct a more detailed analysis regarding the regulation of the enzymes involved in DNA methylation; DNA methyltransferases (DNMTs). Specifically, we obtained the 3' untranslated region (3'UTR) of DNMT1 and DNMT3a, which are regulators of maintenance and de novo DNA methylation, respectively. Bioinformatic approaches were used to identify candidate microRNA (miRNA) that potentially bind to the DNMT1 and 3a 3'UTR, and would likely inhibit the transcript abundance. Following exposure, muscle and liver tissue was extracted and analyzed for global methylation, DNMT1 and 3a transcript abundance, DNA methyltransferase activity, and candidate miRNA abundance. Results indicated a significant decrease in the level of global methylation in both liver and muscle, with an associated decrease in total DNA methyltransferase activity and DNMT3a transcript abundance. Further, there was a significant increase in one specific candidate miRNA (miR29a) in both liver and muscle that was predicted to bind to DNMT3a. Taking a phylogenetic approach, the binding sites of miR29a to the DNMT3a 3'UTR was compared across numerous species, spanning fish to mammals, and results revealed a highly conserved binding motif which has been maintained since the vertebrate ancestor, approximately 500 million years ago. This research establishes that miRNA act as an essential mediator between the environment and DNA methylation patterns via DNMTs, which is further confirmed by a genomic regulatory mechanism that has been deeply conserved throughout evolution.

Fate and Effects of Metals: Regulatory and Risk Assessment Perspective

648 Relative Risk Approach: A methodology for the ecological risk classification of inorganic substances

J. Hill, Environment & Climate Change Canada / Ecological Assessment Division; M. Beking, R. Bouwhuis, V. Dorais, J. Gauthier, M. Lin, O. Marois, M. Sauvé, Environment and Climate Change Canada / Ecological Assessment Division

Under the Canadian Environmental Protection Act, 1999, Environment and Climate Change Canada (ECCC) and Health Canada assess and manage, where appropriate, risks of chemical substances to the environment and to human health. The Chemicals Management Plan (CMP) is a Government of Canada initiative that addresses approximately 4300 substances identified as priorities for assessment. In the next phase of the CMP (2016-2020), about 1550 substances remain to be addressed, including approximately 380 inorganic substances. Early activities to address inorganic substances include identifying assessment data needs, developing tailored strategies and approaches, and early stages of assessment drafting. In particular, a relative risk approach is under development for identifying and classifying the potential ecological risks of inorganic substances as lower or higher potential for ecological concern. Predicted environmental concentrations were derived through a modelling analysis and a monitoring data analysis. The modelling analysis considers the interpretation of key physical-chemical properties, the use of Domestic Substances List inventory update (DSL IU) volumes and National Pollutant Release Inventory (NPRI) data to model potential environmental releases. The monitoring data analysis considers surface water quality data from Canadian monitoring and surveillance programs. The relative ecological risk of individual inorganic substances and groups was determined through comparing the generated predicted environmental concentrations to selected predicted no-effects concentrations to determine an overall preliminary relative risk classification.

649 Northern Mines Need Marine Effluent Toxicity Tests for the First Time in Canada

L.N. Taylor, L.A. Van der Vliet, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; R. Hennessy, Environment and Climate Change Canada / Biological Assessment and Standarization Section; R.P. Scroggins, Environment and Climate Change Canada / Biological Methods

In 2002, the Metal Mining Effluent Regulations (MMER) came into force under the Canadian Fisheries Act. They applied to all mines (except diamond and coal) that release a freshwater effluent to either a marine or freshwater environment. Compliance testing for acute lethality utilized freshwater organisms in both cases as the effluent is regulated 'end-of-pipe' and not for reasons like determining effects of effluents mixed with the receiver or for predicting field effects. Currently, the fish Reference Method prescribed in the MMER is with rainbow trout (EPS 1/RM/13) and the invertebrate method prescribed is with Daphnia magna (EPS 1/RM/14). The invertebrate test is used now only for monitoring but will be elevated to a compliance test in the next regulation amendment. Until recently, there was no need to consider how to test the acute lethality of saline metal mining effluents in Canada. The development of Northern mining deposits with saline groundwater is creating a regulatory gap and now Environment and Climate Change Canada (ECCC) is developing compliance acute lethality tests for measuring saline effluent toxicity with marine species. Within a three year period, we are identifying appropriate test organisms, standardizing the test design, and validating the methods through an inter-laboratory study (or ring test). In choosing appropriate organisms, we have considered their range of salinity tolerance, their ability to be cultured under laboratory conditions, and their relevance to the Canadian environment, but most notably, the availability of existing methods. Work accomplished, and expertise developed, by other method standardization agencies will be leveraged to drastically reduce the time and cost necessary to develop standardized test methods. Working alongside the timeline for the MMER amendment, which will include these new test methods, Canadian toxicology laboratories will need training and accreditation for these tests.

650 Developing Copper and Zinc Standards for Ecosystem Health Protection in New Zealand's Freshwaters

C.W. Hickey, Natl. Inst of Water & Atmospheric Res. / NIWA; B. Williamson, G. Mills, Diffuse Sources Ltd; M. Cameron, N. Vigar, L. Buckthought, Auckland Council; J. Milne, Greater Wellington Regional Council; M. Stevenson, Environment Canterbury

New Zealand is shifting from an effects-based approach to a standards-based appraoch for freshwater management. The New Zealand National Policy Statement for Freshwater Management (NPS-FM) has recently legislated nitrate and ammonia standards for all river environments – incorporating a risk-based approach and a national 'bottom line' which all waters are expected to achieve. These standards use a two-number criteria and management framework derived from on the Australian and New Zealand (ANZECC) risk-based methodology. The legislation requires the compulsory application of this framework for water classification. New Zealand's Ministry for the Environment is investigating incorporating metals (copper and zinc) in a future regulatory round, especially because increasing urbanisation and associated runoff is increasing stresses on local aquatic environments. For example, Auckland (New Zealand's largest city) is expected to increase it's population by 50% over the next 20 years but has limited space for expansion. Significant exceedances of ANZECC guidelines for copper and zinc in urban Auckland, and other urban areas, indicate that metals may be key contributors to poor ecological health in these urban areas. The proposed two-number approach for metals will take an additive toxic units (TU) approach to incorporate multiple metals present in urban streams – based on using suitable acute and chronic criteria and dissolved metals measurement. Monitoring data for urban areas showed that baseflow median dissolved Zn and Cu were 54% and 57% of total metals respectively, with dissolved chronic TUs of 2.5 and 8.1 for median and 90th percentiles, indicating that management practices would need to target dissolved fractions of Zn and Cu for baseline conditions. Limited event-related data is available to characterise acute exposure metals concentrations during rainfall-runoff and practical approaches will be required to monitor acute exposures to develop appropriate criteria, with passive samplers and other approaches being investigated. As the NPS-FM legislation requires management responses to reduce contaminant loads should the 'bottom line' be exceeded, suitable guidance will be needed to support toxicity identification, incorporation of toxicity modifiers (e.g., DOC, pH, hardness) and the implementation of source control and load reduction approaches.

651 Regulatory dexterity – The key to naturally fluctuating selenium concentrations

D. Guth, GEI Consultants, Inc. / Ecology; S. Pargee, GEI Consultants, Inc.; S.P. Canton, GEI Consultants, Inc. / Ecological Division

Many watersheds in Colorado have naturally elevated selenium concentrations originating from geologic sources, but these elevated concentrations can be greatly influenced by other factors in the region. In a portion of the Cherry Creek watershed south of Denver measured selenium concentrations show strong seasonal variability and a reduction from upstream to downstream. Water samples collected throughout the watershed from 2013-2015 showed a reoccurring relationship with selenium concentrations decreasing as seasonal flows increased. In the winter, selenium concentrations exceed Colorado's acute water quality standards at the upstream sites. However, increased flows during the summer months – initially from spring runoff and runoff from lawn irrigation later in the summer – provide enough dilution to decrease selenium concentrations below the acute water quality standard. In addition, in months where the standards are being exceeded upstream standards at the downstream sites are attained as a result of selenium removal in a natural wetland. The fluctuation in selenium concentrations are of particular interest because there are no point source discharges contributing to selenium concentrations. Despite seasonally elevated selenium concentrations fish populations remain healthy; selenium related deformities were insignificant and reproduction appeared to be unaffected as multiple age classes (young-of-year, juveniles, and adults) for several species were observed throughout the study area. Data collected for this study were used to propose seasonally appropriate ambient-based site-specific standards during the Colorado basin hearing, which were approved by the Water Quality Control Commission. The seasonally appropriate site specific chronic standards range from 4.6 – 37.2 µg/L and acute standards range from 18.4 – 41.0 µg/L. There was less variability in fish tissue concentrations, with elevated levels even at sites with lower water column selenium. This has important implications with regard to implementation issues related to the release of the 2015 Draft Aquatic Life Ambient Water Quality Criteria for Selenium. Simply put, it is important to remember that no two systems are the same and while spatial variability is commonly observed, temporal variation must also be considered.

652 Understanding the behavior of Silver in surface and waste water systems: Evaluation of WHAM as a risk assessment tool

R. Nasir, D. Smith, Wilfrid Laurier Univ / Chemistry; C. Merrington, WCA Environment Limited; A. Peters, wca; S. Lofts, Centre for Ecology & Hydrology / Shore Section

Silver (Ag) is of particular interest due to its use in consumer products as an antimicrobial agent, leading to concerns over its unintended release into the environment. The release of Ag to natural environment through waste water treatment plants as well as direct inputs could result in increasing free metal ion concentrations causing toxicity. Understanding the behaviour of Ag, therefore, as is enters aquatic systems, is critical to evaluating its potential environmental risk. The aim of this research is to develop understanding of Ag interactions with strong ligands such as dissolved organic matter (DOM) and sulphide compounds present in water (fresh and wastewater). A wide range of DOM sources (ranging from reference material to sewage effluents) as a well as raw sewage were used to understand Ag complexation with DOM at different pHs (4-10). Ag ion-selective electrode was used for potentiometric titrations to determine Ag binding to DOM and the measured Ag^+ was then compared to WHAM predictions. In addition, DOM was characterized optically and sulphide (inorganic & organic) analysis was also conducted on the samples. WHAM predictions of the Ag binding to DOM sources agree well with experimental results at pH 8, with the exception of raw sewage, which exhibited much stronger binding. This very strong binding could be partly, but not completely, explained by binding to thiol– and amino–containing ligands. A conditional binding model, comprising five ligands and using a structured formulation of binding strengths and site densities, was successfully fitted to the raw sewage titration data. The model fitting suggested that the strongest Ag–binding sites were comparable in binding strength to thiol groups, but that the sample contained relatively weak ligands that nevertheless appeared to be stronger binders of Ag than either amino or carboxylate groups. This suggests that multi-dentate binding of Ag may be important in determining the overall binding strength in raw sewage. At pHs below 8, WHAM under predicts Ag binding for some samples, which suggests that incorporation of additional strong ligands could improve WHAM predictions of Ag speciation in the environment. This will allow for development of more accurate and robust predictive tools for Ag risk assessment and regulation in aquatic systems.

653 Comparison of Aluminum Aquatic Life Criteria Approaches

D.M. Eignor, USEPA / Office of Water; C. Voros, G.J. Smith, Great Lakes Environmental Center; K. Taulbee, Great Lakes Environmental Center

The effects of water chemistry on the aquatic toxicity of metals have been an area of research since the Environmental Protection Agency's (EPA) water quality criteria (WQC) were first developed. A partnership among industry, academia, and government utilized research advancements in the aquatic toxicity of metals to effectively develop EPA' national water quality criterion for freshwater copper to protect aquatic organisms. This effort used the Biotic Ligand Model (BLM) to address the bioavailability of metals in aquatic systems and their acute toxicity to fish. The BLM adjusts the water concentration that causes acute toxicity of metals to aquatic organisms by calculating the relative binding affinity of cations in the water to the biotic ligand (eg., gills or any other active site) based on the geochemical conditions of the site versus a single value for the criteria. Similarly, in developing updated aluminum criteria, EPA is comparing several approaches that reflect water quality condition impacts on toxicity including: (1) existing complete 10 parameter BLM(s), (2) a simplified BLM approach where pH, hardness, dissolved organic carbon, temperature values were entered and other parameters use default values, and (3) multi-linear regression equations using pH, hardness, and dissolved organic carbon parameters. Comparisons were conducted to facilitate evaluation of the various approaches for criteria development.

654 Is total recoverable aluminum relevant for water quality criteria?

A.C. Ryan, K.E. Croteau, D.K. DeForest, Windward Environmental LLC; S.A. Tobiason, Windward Environmental; R.C. Santore, Windward Environmental, LLC; W.J. Adams, Rio Tinto

The national recommended ambient aquatic life water quality criteria (WQC) for aluminum in the United States are dated and the aluminum form that they are expressed as is potentially not relevant from a toxicological perspective. The chronic criterion of 87 mg/L is based upon total recoverable aluminum and is applicable for waters with pH between 6.5 and 9.0. Numerous studies have demonstrated that the toxicity of aluminum to aquatic organisms is affected by the chemistry of the exposure water, with pH, dissolved organic carbon (DOC), and water hardness being important toxicity modifying factors. Water chemistry also influences aluminum solubility, and this can be especially relevant because toxicity studies have demonstrated that freshly precipitated aluminum hydroxides can contribute to toxicity. Therefore, toxicity cannot be explained on the basis of dissolved aluminum alone. The conundrum is that toxicity cannot necessarily be explained on the basis of total recoverable aluminum, either. In laboratory toxicity tests, total recoverable aluminum represents dissolved aluminum and potentially some forms of mineral precipitates. In natural settings, surface waters are likely to contain suspended solids, and because aluminum represents approximately 8 percent of the Earth's crust it is expected that solids in the water column (e.g., silt and clay) will contribute to total recoverable aluminum measurements. While the methodology for determination of total recoverable aluminum will not necessarily solubilize all solids, it is likely that solids will contribute to the total recoverable aluminum concentration. To evaluate situations where suspended solids, which are not likely to be bioavailable, may contribute to total recoverable aluminum measurements, monitoring data were compiled from the NWIS (USGS) database. The type of data compiled consisted of dissolved and total aluminum, pH, DOC, major ions, total suspended solids, and suspended sediment concentrations. These data were used to evaluate cases where aluminum exceeds mineral solubility and to identify situations where total recoverable aluminum measurements are likely to include contributions from suspended solids. Results of this analysis suggest that WQC based upon total recoverable aluminum are overly conservative because of the contribution from suspended solids in the water column. An alternative, toxicologically relevant approach to aluminum WQC is warranted.

655 Field study of coarse sample pre-filtration as a compliance tool to minimize false-positive criteria exceedances for aluminum

S. Pargee, GEI Consultants, Inc.; R. Gensemer, GEI Consultants / Ecological Division; N. Love, GEI Consultants, Inc.

Compliance with water quality standards for metals is typically evaluated using either dissolved or total recoverable metal concentrations. For most metals, dissolved fractions best represent biologically available fractions, and so dissolved measurements are typically preferred. Aluminum regulatory criteria generally are based on the total recoverable metal because some insoluble colloidal phases can contribute to toxicity. However, the heat and acid digestion used in a total recoverable assay also measures metals associated with non-toxic particulate mineral phases, and so will likely overestimate concentrations of metal that would be biologically available and potentially toxic to aquatic life. This overestimation may result in "false positive" exceedances of aluminum criteria when samples contain elevated suspended solids comprised of non-toxic particulate aluminum. To help address this issue, aluminum criteria in New Mexico include a coarse sample pre-filtration step, with a recommended filter size of 10 µm prior to measuring total recoverable metal to minimize the amount of bias potentially incorporated by measurement of non-toxic mineral phase metal. This study evaluated the effects of different pre-filter pore sizes on aluminum concentrations and to evaluate the potential for pre-filtration to affect any potential toxicity of the water samples collected from stormwater retention ponds in Colfax County, New Mexico. The acute toxicity of the unfiltered water was evaluated for all sites and no toxicity was detected at concentrations of total recoverable aluminum as high as 55.8 mg/L, which is well above the acute water quality criteria based on the hardness of each sample. However, pre-filtration using a 1 µm filter reduced the aluminum concentrations to below criteria concentrations. The coarser aluminum particulates retained by this pre-filtration step are likely to be predominantly mineral (i.e., from native soils) in nature and not present in a bioavailable form. In addition, the molar aluminum-to-silica ratios showed that mineral phase aluminum was still passing through the 5 and 10 µm filters while the 1 µm filter likely removed these particulate aluminum phases. We conclude that pre-filter pore sizes as small as 1 µm are an acceptable alternative for removing larger non-toxic aluminum particles that would otherwise represent a false-positive comparison against regulatory criteria.

Engineering, Toxicology and Risk Assessment Guidance for Sediment Evaluation at Dam Removal Sites

656 Dam removal analysis guidelines for sediment

J. Bountry, Bureau of Reclamation / Water Resources; T. Randle, Bureau of Reclamation; J. Rathbun, MDEQ Water Resources Division; M. Collins, NOAA

American Rivers reported in 2014 that 1,185 dams have been removed in the United States since 1912, and that the majority of the dams (971) were removed within the past 20 years. Dam removal may be a preferred alternative for sites where the original project benefits are no longer needed or can be replaced with a reasonable alternative. Examples include sites with aging or abandoned infrastructure with hazard issues or intakes no longer operational due to sedimentation. Removal can often accomplish increased environmental benefits that can in part be obtained by reconnecting the supply of sediment, wood, and nutrients to areas from the upstream watershed to the river downstream of the dam. Because dams are built on both small and large rivers with a wide range of sediment characteristics, dam removal can result in varying levels of impacts. While some sites have negligible sediment that does not warrant robust analysis, other sites may have potential contaminants or required staged removal to control the rate of sediment release. Stakeholders, regulating agencies, and technical staff may not agree on what constitutes significant sediment impacts, and what level of information is needed to make decisions regarding sediment management. Existing manuals do not provide a framework or guideline for determining the level of analysis needed, the significance of sedimentation issues, or certainty that can be attained with available analysis tools. The U.S. Subcommittee on Sedimentation has recognized the need for a technical guideline to address sediment analysis for dam removal investigations. The new guideline utilizes a risk-based concept to determine the level of sediment data collection, analysis, modeling, and management necessary to evaluate and plan dam removal projects. The risk is defined as the product of the probability (e.g. likelihood) of a sediment impact and the consequence of the impact should it occur. The probability is generated by physical data at the site, whereas the consequence list is developed through collaborative discussions with project partners and stakeholders. The greater the risk, the greater the recommended level of sediment data collection, analysis, modeling, and management. Based on the risk determination, the guideline provides users a pathway to identify types of analysis and monitoring strategies for a given dam removal project.

657 Analyses of fine sediment transport for a large dam removal project: an empirical approach

Y. Cui, D. Booth, J. Monschke, Stillwater Sciences; S. Gentzler, J. Roadifer, AECOM; B. Greimann, Bureau of Reclamation; B. Cluer, NOAA NMFS

Potential accumulation of pollutants in reservoirs is normally associated with fine sediment deposits. The first step to understand the potential impacts of the downstream release of these sediments following dam removal is to understand the physical and chemical composition, volume, and spatial distribution of the sediment deposit, and from there, to forecast the sediment transport dynamics if they are released downstream. Unfortunately there are currently no reliable numerical models to accurately simulate the dynamics of the release of these fine sediments, mostly because their release following dam removal is often driven by rapid erosional process not addressed by traditional sediment transport theory. However, precise quantification of fine sediment transport is rarely necessary to evaluate potential environmental impacts of alternative scenarios. Using the removal of Matilija Dam in southern California, USA as an example, we quantify the likely magnitude of suspended sediment concentration and the duration of associated downstream impacts, two important parameters in assessing alternatives. Using a two-phase conceptual model established based on our understanding of the physical process under such conditions, the analyses first estimate the general magnitude of suspended sediment concentration and duration of impacts based on field and experimental data; they then quantify the duration of impacts under both worst-case and reasonable assumptions according to the underlying physics. For rapid sediment release scenarios, initial suspended sediment concentrations are likely to approach one million mg/L, persisting for a few hours to no more than a couple of days. Suspended sediment concentrations are expected to decline approximately exponentially after the initial peak, reaching background levels in this naturally high-sediment yield watershed within a few hours to a few days, provided that sufficient flow is available. The general method used in the analyses should be useful for similar dam removal projects, allowing the stakeholders to conduct further impact analyses and/or choose amongst dam-removal alternatives for implementation.

658 Unleashing History: Understanding Dynamic Processes Affecting Sediment Toxicity During Dam Removal

J.A. Steevens, USGS / Environmental Laboratory

Assessment of sediment during dam removal requires a strong understanding of the dynamic processes that are often overlooked as part of a traditional sediment risk assessment. Historical deposition of sediment in reservoirs results in accumulation of a broad range of sediment types depending on hydraulic events (e.g., floods, overland flow, erosion) and contaminants based on regional activities. In addition the type of sediment deposited may contain a wide range of organic materials and the biogeochemical processes that can be affected by regional geology. This presentation will emphasize the need to consider complex dynamic processes that are perturbed during dam removal and mobilization of sediment. These processes include changes in redox status, microbial activity that can affect nutrient status and contaminant bioavailability. Laboratory studies can be conducted to provide information that can be used to assess risk of sediments during dam removal, however the studies must consider temporal trends so that data can be applied in a predictive manner. For example, speciation of metals in the Tennessee Valley Authority Fly Ash spill was critical for understanding risk to benthic invertebrates and to predict release of Se and As ions. Within laboratory studies the temporal trends related to redox potential and metal speciation must be evaluated to predict bioavailability of metals in the field. Capturing this information requires the use of methods including porewater passive samplers coupled to bioassay methods that generate kinetic information on uptake and chronic effects. Case studies discussed will include processes observed during release of sediment during accidental breaches of dams as well as dredging of sediments.

659 Best Practices to Inform Risk-based Decisions for the Management of Dam Impounded Sediments

D.W. Moore, USACE/ERDC/EL; T.S. Bridges, US Army Corps of Engineers ERDC; W.J. Berry, USEPA / Atlantic Ecology Division ORD NHEERL; G. Reub, Ramboll Environ; V.S. Magar, Ramboll Environ US Corporation

In recent years an increasing number of Dams have been identified for removal either as a consequence of concerns over safety, diminished economic viability, and/or a desire to improve river function, etc. Sediments trapped behind dams slated for removal must be evaluated to establish appropriate management alternatives. Typically sediments impounded behind dams are organically enriched silts and clays with a propensity to bind contaminants and are generally reflective of the history of upstream land use activities, including legacy contaminants associated with agricultural and or industrial practices. Establishing viable management alternatives for these sediments prior to dam removal requires an evaluation of the potential ecological and human health risk posed by the proposed management action. As with any risk based evaluation, development of a site conceptual model is a critical first step to identify potential receptors of concern and the nature and magnitude of potential exposure pathways. Once these elements are understood, appropriate conservative screening tools maybe applied to identify potential risks that might require further evaluation in a more detailed site-specific assessment. This presentation provides an overview of a tiered, risk-based approach to include considerations for development of a site conceptual model, collection of data for initial screening, application of conservative screening tools, as well as application of a more detailed site specific assessment (sediment toxicity and bioaccumulation studies) should it be required.

660 What are the potential contaminants in sediment trapped behind low head dams in the Midwest?

J. Frey, USGS

There are 1000's of low head dams in the Midwest that no longer are used for their original purpose, typically power supply for grist mills, slackwater canal systems, or water supply. These low head dams create recreational safety problems with multiple people killed or badly hurt each year. Additionally, low-head dams have several ecological impacts, including degraded biological communities, obstructed fish passage, and accumulation of contaminated sediments. There are calls for low head dam removals based on these safety and ecological impacts but, there are few published studies that assess the contaminants that could be found in the sediments trapped behind these dams. The USGS Midwest Stream Quality Assessment collected data from July and August 2013 on contaminant concentrations in water and sediment at 27 sites on small and wadable streams and rivers. Sediment samples were analyzed for a suite of wastewater-associated compounds, hormones, and halogenated compounds now or previously in commerce (e.g., chlorinated pesticides, brominated flame retardants, PCBs). The most frequently detected compounds in the 27 samples included indole and 3-methyl-1H-indole (100% detection with a maximum concentration of 1,960 and 236 ug/kg, respectively), dieldrin (85.1% detection with a maximum concentration of 2.26 ug/kg), beta-sitosterol (96.3% detection and a maximum concentration of 48,900 ug/kg), p-cresol (92.6% detection and a maximum concentration of 14,400 ug/kg), 2,6-dimethylnaphthalene (92.6% detection and a maximum concentration of 126 ug/kg), dieldrin (85.2% detection and a maximum concentration of 2.26 ug/kg), and beta-stigmastanol (81.5% detection and a maximum concentration of 4,080 ug/kg). Although these samples were not collected behind dams, these data indicate potential contaminants of sediment behind low head dams that could be displaced if the dams were removed. As such, the results help focus what if any additional work may be important at individual dam removal sites.

661 Screening-level evaluation of potential toxicity risks from release of sediments behind four dams on the Klamath River, Oregon and California

C.W. Anderson, USGS / Oregon Water Science Center; P. Zedonis, U.S. Bureau of Reclamation / Northern California Area Office; B. Ross, S. Keydel, USEPA / Water Division EPA Region; M. Singer, Stillwater Sciences; M. Wade, CDM Smith

One of the most common management concerns related to dam decommissioning is the release, transport, and ultimate fate of sediments stored behind the dams. Contaminants in reservoir sediment are a particular challenge because they are expensive to collect and analyze and therefore are often understudied; their effects on humans and biota are not well understood especially in mixtures; and societal pressures may amplify the perception of their risk and the importance of decision making regarding their ultimate disposition. This study describes a screening-level evaluation to assess possible risks from contaminants in sediment behind four hydroelectric dams on the Klamath River in southern Oregon and northern California that are proposed for removal. The study followed the tenets of the interagency Sediment Evaluation Framework and the Dredged Material Management Program that guide decision making for dredging and disposal of sediments in the Pacific Northwest. The study generated multiple lines of evidence that were compared to five relevant exposure pathways of biota and human receptors to identify potential adverse effects. Lines of evidence included analysis of existing data that informed subsequent sample design; an inclusive suite of chemical analyses from multiple cores from each reservoir and downstream receiving waters; comparison of chemical data with established benchmarks; laboratory bioassays of aquatic biota to sediment and elutriates; bioaccumulation studies, and analysis of tissues in resident fish from the reservoirs. Short term (< 1 yr) exposure pathways included humans and aquatic biota via contaminants flushed downstream. Long term (> 1 yr) exposure pathways included humans and biota via deposits in reservoir terraces and river banks, in river beds, and in marine near shore areas; and humans and biota under current conditions via consumption of resident fish from the reservoirs. Results demonstrated that, while a variety of contaminants were detected at low levels, there were no chemicals present at levels with potential for significant adverse effects or that would preclude their release into downstream or marine environments. In this case, employing multiple lines of evidence for chemical toxicity and multiple exposure pathways provided evidence that significant adverse effects would be avoided if the Klamath Dams are decommissioned and the sediments are allowed to flush downstream.

662 Milltown Dam Removal Case Study

D. Booth, Booth Consulting

Milltown Dam, located on the Clark Fork River upstream of Missoula, Montana, was originally constructed in 1907 to provide hydropower-generated electricity for a sawmill. During the past century, metals-impacted sediment washed down from historic mining and smelting operations in the Butte/Anaconda area filling Milltown Dam's reservoir and resulting in arsenic contamination of the local groundwater. In 2004, as part of remediation of the larger Clark Fork River Basin Superfund Site, the U.S. Environmental Protection Agency ordered the removal of Milltown Dam and approximately 3 million cubic yards of reservoir sediment. Design and implementation of the Milltown dam removal/reservoir restoration program required orchestration of many factors involving State, tribal and federal agencies, as well as numerous community stakeholders. Of particular importance was sediment management decision-making which required the integrated effort of specialists in hydrology, engineering, environmental assessment and management, toxicology, and risk assessment. The project, which was completed in 2011, represents one of the most complex and intensively studied dam removal efforts completed to date and therefore provides lessons learned and best practices for use in future projects and in development of Dam Removal Analysis Guidelines for Sediment.

663 Sediment Management: The Intersection of Policy and Practice at Dam Removal Sites

S. McClain, American Rivers

Dam removal is one of the fastest, most effective ways to restore a river. However, for natural resource managers, watershed organizations and others, determining how to remove a dam and navigate things like the regulatory process can seem daunting. One of the more challenging issues that can define a project's level of complexity is the manner in which sediment must be managed. Sediment is one of nature's building blocks, moving and shaping the earth as it weathers and erodes rocks. Yet, as it becomes trapped behind dams, we struggle with the question of how to re-establish the beautiful, chaotic function of rivers in a way that avoids unacceptable degradation. The answer is not often as simple as letting the data dictate a path forward. Federal and state regulatory processes can have significant influence over sediment management options through the varied application of regulations tied to Clean Water Act 404 permitting and 401 water quality certifications. Though several states (e.g., New Hampshire and Massachusetts) have developed guidance for managing sediment at dam removal sites, many still view these projects through the same regulatory lens as traditional development projects. New guidance from the EPA on Water Quality Standards and the Bureau of Reclamation and U.S. Subcommittee on Sedimentation guidelines are at the forefront of efforts to address these inconsistencies. During this talk, we will explore how the intersection of sediment science and policy have influenced the practice and how rollout of these guidelines will contribute to and influence the management of sediment at future dam removal sites.

Integrating Chemistry and Biology in a Landscape Context to Reveal Potential Causes of Endocrine Disruption

664 Endocrine disrupting compounds in the Chesapeake Bay Watershed – Where are we going? Where should we go?

P.J. Phillips, USGS / New York Water Science Center; D.W. Kolpin, USGS / Iowa Water Science Center; K.L. Smalling, USGS / NJ Water Science Center; V.S. Blazer, USGS; L.R. Iwanowicz, USGS / Leetown Science Center; M. Schall, Pennsylvania State Univ; R. Braham, C. Ladino, T. Scott, USGS

USGS Scientists form across teh countray are tasked with establishing a national frameowrk to evaluate endocrine disrupting compounds and their effect on fish. This framework was applied directly to ongoing efforts as part of the USGS Chesapeake Bay research on fish health. In addition to endocrine disruption, Fish health issues include increased incidence of infectious disease and parasite infestations, feminization of male fish, reduced reproductive success and recruitment, and liver and skin tumors. Identifying and quantifying the sources, fate, transport, and distribution of EDCs throughout the Chesapeake Bay Watershed are a necessary first step in assessing exposure to fish. Chemical data are being collected and compiled from strategically selected stream sites in the Chesapeake Bay Watershed to: 1) address the multiple factors affecting fish health by focusing on the complex interactions of pathogens/parasites, land use and chemical exposure and 2) define sources, pathways and timing of chemical exposure to various life stages of fish for chemicals identified as causing potential adverse effects on fish health. Water and bed sediment are being collected and analyzed for over 200 potential EDCs (including hormones, pesticides, personal care products, and legacy pollutants) and bioassays are being assessed for biological activity such as estrogenicity. Initial sampling is focused on routine data collection from six sites in the Chesapeake Bay watershed representing a wide range of agricultural land use conditions, during both baseflow and stormflow conditions. Future sampling will include assessments of urban areas. Chemical and bioassay sampling are coordinated with companion biologic assessments (including histopathology, plasma vitellogeninin, intersex and other measurements) in order to assess exposure of fish to chemical contaminants at different times during the year and during different flow conditions. In addition, chemical data are being compiled from existing sources (including previous studies of EDCs and pesticides) in order to expand the geographic and temporal coverage of chemical and biologic analysis. Results from this study will be used to help understand sources and exposure pathways of EDCs to fish, and to develop management strategies to improve fish health in the Chesapeake Bay watershed.

665 Contaminants in the Chesapeake Bay watershed: A synthesis of data from a decade of studies using passive samplers

D.A. Alvarez, USGS-CERC / Physiology and Biochemistry; V.S. Blazer, USGS

For more than a decade, adverse effects associated with exposure to endocrine disrupting chemicals (EDC) have been observed in the Chesapeake Bay watershed. These effects have included major fish kills in the Potomac River drainage and increased rates of intersex in male smallmouth bass. In response to these biological issues, studies were conducted using passive sampling devices to identify organic contaminants in the water that may be responsible for the biological effects. These findings have been reported as parts of numerous smaller independent studies with no linkage between studies. In an effort to gain a better understanding of the overall chemical profile in the watershed, a synthesis of chemical occurrence data collected at sites co-located with fish health studies has been conducted. The majority of the study sites have land-use characteristics ranging from largely agricultural to mixed agricultural/small urban centers. Due to the prevalence of agriculture, the herbicides atrazine and metolachlor were two of the most frequently detected chemicals in the watershed. Estrone, likely from livestock and manure application as fertilizer, was commonly detected. Polycyclic aromatic hydrocarbons (PAHs) had a ubiquitous presence and the legacy organochlorine pesticides were frequently detected; however, generally at low nanogram per liter concentrations.

666 A landscape-based approach to assess the effects of exposure to complex chemical mixtures in the Shenandoah River watershed

D. Bertolatus, Univ of Colorado Denver / Dept of Integrative Biology; C.J. Martyniuk, Univ of Florida / Physiological Sciences; L.B. Barber, USGS / National Research Program; A.M. Vajda, Univ of Colorado-Denver / Integrative Biology

Aquatic habitats are often contaminated with complex mixtures of legacy and emerging chemicals. Characterizing the biological effects of exposure to these mixtures is an ongoing challenge. Identifying landscape-specific contaminant profiles and measuring the effects of exposure to these mixtures may reveal patterns useful for chemical regulation and management of ecosystems. Here, we employed an integrated chemical and biological analysis to measure differences in chemical mixtures and associated biological effects in watersheds with different landuse patterning. Adult male fathead minnows (Pimephales promelas) were exposed to water from four different locations within the Shenandoah River watershed (VA, USA) using flow-through mobile laboratories. The exposure locations were chosen to capture unique landuse in surrounding watersheds, including agricultural, municipal, mixed-use, and forested sites. Endpoints from multiple levels of biological organization were measured following exposure, including condition factor, GSI, number of nuptial tubercles, plasma vitellogenin concentration, and hepatic genome-wide expression profiles. Water samples were taken every 7 days during the fish exposure and analyzed for 460 chemical constituents. Each location had a unique chemical profile that was generally consistent with landuse in the surrounding watershed. Whole-organism and molecular responses also differed between the locations. At the agricultural site, survivorship was significantly reduced. Fish exposed at both agricultural and WWTP impacted sites had a reduced number of nuptial tubercles and decreased GSI, indicative of reproductive endocrine disruption. However, transcript biomarkers of estrogen exposure, including er1, er2, ar, vtg1, and vtg3, showed little to no differential expression in exposed fish, suggesting these organisms did not experience estrogenic endocrine disruption. Transcriptomics followed by pathway analysis revealed that processes related to immune function, cholesterol synthesis, and metabolism were affected in fish exposed at agricultural and WWTP impacted sites. These data provide insightful hypotheses regarding the specific effects of exposure to different types of complex mixtures and demonstrate the value of our complex mixture/landscape research approach.

667 The reality of combining chemical analyses and common bioassays for effects-directed analysis of endocrine disrupting chemicals in environmental water

J.C. Brennan, USGS / Columbia Environmental Research Center; D.A. Alvarez, USGS-CERC / Physiology and Biochemistry; R.W. Gale, J.K. Leet, D.E. Tillitt, USGS / Columbia Environmental Research Center

Endocrine disrupting chemicals (EDCs) are known to negatively impact reproductive, immune, and other endocrine-related processes in fish and other animals. Unexpected die-offs, skin lesions, and intersex in fish may be due to exposure to EDCs. Effects-directed analysis (EDA) is a technique utilized to discover the identity of biologically-active chemicals such as EDCs from complex mixtures including waters. In addition to discerning if the endocrine disruption in a particular environment is plausibly chemically-induced (i.e. male fish displaying intersex in a watershed), EDA can guide the identification of the responsible EDCs and also help rule out candidates not responsible for the observed biological activity or effect(s). However, EDA can be a labor-intensive process with a high likelihood of bioactive compound loss. EDA also is sometimes not possible due to sample volume limitations or low concentrations of EDCs often found in environmental waters. We assessed the ability of several bioassays (the well-known transactivation chemically-activated luciferase expression (CALUX) and the bioluminescent yeast estrogen/androgen screening (BLYES/BLYAS) cell bioassays, and the relatively new transgenic (CYP19a1b)-GFP zebrafish bioassay) to guide isolation of different types of EDCs in a conceptual EDA of natural and wastewaters. An EDA framework (known as the “decision tree”) was developed and a literature review of EDC concentrations in U.S. freshwaters was conducted as a basis for the bioassays’ detection capabilities. We found that, when compared to the BLYES and zebrafish screening assays, the CALUX estrogen cell assay had the greatest rate of detection above half-maximal activity for the majority of estrogens in natural waters post-EDA but all three assays had high detection rates in wastewater sources. The CALUX cell androgen bioassay had the greatest rate of detection for the majority of androgens in both natural and waste waters. There was no difference between the CALUX and yeast cell assays for detection of progesterone whether in natural or waste waters with high detection rate for both assays. The majority of EDCs had a higher rate of detection in all bioassays in wastewater vs natural waters, but for one EDC (genistein), none of the bioassays were suitable for EDA. The CALUX cell bioassays, in particular, when utilized for EDA allow detection of certain EDCs in water sources, while detection of other chemicals offers more challenges.

668 Severe intersex in wild fish is reduced to background levels after municipal wastewater treatment plant upgrades

K. Hicks, M. Fuzzen, K. McCann, Univ of Waterloo / Biology; L. Bragg, Univ of Waterloo / Dept of Biology; G. Tetreault, Enviroment Canada / Water Science and Technology Directorate; M.E. McMaster, Environment and Climate Change Canada / Water and Science Technology Directorate Aquatic Contaminants Research Division; M.R. Servos, Univ of Waterloo / Dept of Biology

Impacts on fish exposed to effluent from municipal wastewater treatment plants (WWTP) are a concern globally, with endocrine disruption being one of the most prominent effects observed. The objective of this study was to assess whether major treatment upgrades at a WWTP would reduce endocrine disruption previously observed in wild fish. The WWTP located in Kitchener, Ontario, is a conventional activated sludge plant that discharges effluent into a heavily urbanized reach of the Grand River. Multiple years of data have been collected for a sentinel fish species, the rainbow darter (Etheostoma caeruleum), associated with the Kitchener WWTP outfall since 2007. Intersex in male fish has been the most consistent effect observed, and this has been associated with reduced reproductive success. In 2012, major upgrades took place to convert the WWTP from non-nitrifying to a fully nitrifying activated sludge treatment plant. Effluent quality improved with declines in contaminants such nutrients and select pharmaceuticals, which are also reflected in the river water downstream the WWTP. The effluent estrogenicity was measured as high as 17 ng/L total 17β-estradiol equivalents prior to treatment changes but has decreased with implementation of the upgrades. This improved effluent quality was also reflected in the food web with $\delta^{15}N$ values measured in fish tissue which are now similar to fish from upstream sites. Intersex was assessed in male rainbow darter downstream the Kitchener WWTP in three consecutive years post-upgrade. There was a reduction in intersex incidence by as much as 85%, suggesting that the rainbow darter is responding to process upgrades. This is one of few studies to document a recovery of a wild fish population after improved effluent quality from a municipal WWTP.

669 Causal Analysis for Gonadal Development in Wild Redeye Mullet (Liza hematocheila)

J. Hu, Peking Univ

Reproductive abnormalities (gonadal intersex) have been observed in wild fishes and attributed to endocrine disrupting chemicals, but the specific causes are still unclear. To unravel the mystery, a forensic analysis utilizing field and laboratory studies is necessary to determine the causative agent(s). Investigations of potential intersex incidences and reproductive effects by pollutants at environmentally relevant concentrations is challenging due to the fact that 1) large sample sizes are required to achieve results with statistical power at environmental concentration, and 2) conventional histopathological observations of intersex can be easily overlooked due to the limited observation area of the testes and time required in this process. Therefore, at first we developed pMOSP1-EGFP transgenic Japanese medaka, which is a specific and sensitive biosensor for indicating intersex occurrence in male medaka fish by green fluorescence protein (GFP). Then we used this transgenic Japanese medaka for screening the chemicals which can induce intersex at environmental relevant chemicals, and find a potential chemical which could be a causal agent to induce the intersex of wild fish from the Liaodong Bay. Our approach provided a methodology to well understand the adverse outcomes of ecological health, and emphasized the urgent need to control the causal agent to avert ecological consequences of wild fishes.

671 Equol Induces Gonadal Intersex in Japanese Medaka (Oryzias latipes) at Environmentally Relevant Concentrations: Comparison with 17β-Estradiol

C. Wang, Peking Univ

Equol is present in the aquatic environment via livestock waste and runoff discharge; however, it remains unclear whether it can induce gonadal intersex in fish at environmentally relevant concentrations. This study evaluated adverse effects of equol on gonadal development by exposing transgenic Japanese medaka (Oryzias latipes) from hatching for 100 days. Equol induced intersex incidence in male medaka in a dose-dependent manner, and the benchmark dose corresponding to 10% intersex incidence (BMD_{10}) was 11.5 ng/L (95% confidence interval (CI): 5.8 ng/L, 19.8 ng/L), which was comparable to the required dose of 17β-estradiol (E2β) (9.0 ng/L, 95% CI: 6.6 ng/L, 11.0 ng/L). Since the BMD_{10} of equol was analogous to concentrations found in the aquatic environment, equol contamination would likely induce intersex in wild fish. Equol exposure resulted in reduced plasma 11-ketotestosterone (11-KT) concentrations in male medaka at 1.3 ng/L, while reduced plasma 11-KT concentrations were observed at a relatively high concentration (6.4 ng/L) of E2β. Such anti-androgenic property could partly explain the comparable potency of equol with that of E2β to induce intersex at relatively low concentrations, although the binding affinity of equol to medaka estrogen receptor α (EC_{50} 939.4 nM) was 230-fold lower than that (4.07 nM) of E2β. Significantly lower fertilization (p = 0.016) and hatchability rates (p = 0.013) were observed in the moderate to severe intersex males exposed to equol. This study for the first time demonstrated that equol could induce intersex in medaka fish at environmentally relevant concentrations.

Use of Modeling Tools to Determine Environmental Concentrations from Environmental Passive Samplers

672 Multiple coating thicknesses for sampling of organic pollutants – linear regressions confirm equilibrium even in challenging environmental media

P. Mayer, S.N. Schmidt, Technical Univ of Denmark / Dept of Environmental Engineering; K. Knudsmark Sjøholm, Univ of Copenhagen / Dept of Plant and Environmental Sciences; J.H. Christensen, Univ of Copenhagen; P.T. Gidley, US Army Engineer Research and Development Center / Engineer Research and Development Center; K. Vorkamp, Aarhus Univ / Dept of Environmental Science; G. Witt, HAW Hamburg / Dept of Environmental Engineering; A. Jahnke, Helmholtz Centre for Environmental Research – UFZ / Cell Toxicology

Partitioning-based sampling methods are increasingly used within environmental analytical chemistry and environmental monitoring. Such methods can be designed and operated in many different ways and can then yield a large variety of measurement parameters including time integrative concentration, freely dissolved concentration, chemical activity and equilibrium partitioning concentration in lipid. The analyte transfer from the environmental matrix into the polymer has several analytical advantages, but also leads to the crucial question on how to convert the measured mass accumulated in the sampler to a meaningful environmental parameter? This presentation focuses on equilibrium sampling, which allows for simple conversions using partition coefficients – even when sampling very complicated matrices. Parallel sampling with coatings of the same polymer but varying coating thicknesses can be used to conduct and confirm valid equilibrium sampling. Proportionality between analyte and polymer masses will then indicate (1) equilibrium partitioning, (2) the absence of substantial surface artefacts such as adsorption rather than absorption or abrasion and (3) the absence of depletion. It can thus provide QA/QC, including validity of sampling assumptions, without using performance reference compounds. Equilibrium concentrations of the analytes in the polymer are determined as the slopes of the proportionality lines, which integrates all measurements and also provides error estimates. The working principle of this approach will be presented together with a number of examples that include (i) several sampler formats, (ii) challenging environmental media such as sediment, soil, tissue, sludge and air, (iii) ex situ and in situ equilibrium sampling and (iv) targeted instrumental analysis of legacy pollutants and non-targeted screening of complex environmental mixtures. The challenge of reaching equilibrium within a reasonable time span will be addressed for different compounds and media, together with the analytical performance of equilibrium sampling in terms of sensitivity, precision and accuracy.

673 Actively shaken in situ passive sampler for measuring pore water concentrations of hydrophobic organic compounds

M. Jalalizadeh, Univ of Maryland Baltimore County

Passive sampling for the measurement of freely dissolved concentrations of organic pollutants in sediment pore water has emerged as a very promising approach, but in situ measurements are complicated by slow mass transfer of strongly hydrophobic compounds. In this research, we addressed the challenge of slow mass transfer by disrupting the external aqueous boundary layer around an in-situ passive sampler using periodic mechanical vibration. Laboratory experiments were performed using PAH and PCB impacted field sediments in order to compare the approach to equilibrium in PE passive samplers under static, well-mixed, and differently shaken passive sampling modes. Low-cost vibrating motors were used to provide the mechanical vibration of passive samplers. Passive samplers were enclosed in stainless steel mesh and were attached to motors like radial fins. We also performed numerical modeling of the mass transfer process to mechanistically explain our observations and optimize the duration and periodicity of the vibration to minimize the need of power to drive the vibration motors. We demonstrate through laboratory experiments and numerical modeling that periodic shaking in-situ greatly enhances overall mass transfer and reduces the difference in the extent of equilibrium achieved between a well stirred laboratory equilibrium and in-situ periodically shaken passive sampler. Vibration also reduced the errors involved in corrections for non-equilibrium based on fractional loss of performance reference compounds. Thus, greatly improving the accuracy of pore water measurement of strongly hydrophobic compounds. The proposed platform presentation will present the experimental results and numerical modeling of PAH and PCB uptake by PE passive samplers under static, well-mixed, and periodically shaken passive sampling modes.

674 Evaluating the precision of passive sampling methods using PRCs in the water column

A. Joyce, National Research Council/ USEPA / Atlantic Ecology Division; R.M. Burgess, USEPA / Atlantic Ecology Division

Low-Density polyethylene (LDPE) sheets are often used as passive samplers for aquatic environmental monitoring to measure the dissolved concentrations of hydrophobic organic contaminants (HOCs). HOCs that are freely dissolved in water (C_{free}) will partition into the LDPE until a thermodynamic equilibrium is achieved; that is, the HOC's chemical potential in the passive sampler is the same as its potential in the surrounding environment. Unfortunately, achieving equilibrium for high molecular weight or highly hydrophobic compounds can take several months or even years. One way to evaluate equilibrium status or estimate the uptake kinetics is by using performance reference compounds (PRCs). PRCs are partitioned into the LDPE prior to deployment and based on the fraction of each PRC lost during deployment, a sampling rate (R_s) or a fractional equilibrium (f_{eq}) can be determined for the target HOCs. Assuming equilibrium or applying a model using PRC data to estimate C_{free} concentrations may affect the precision of the measurement. In this work, we investigate how using different PRC models in different states of equilibrium affects the measured C_{free} concentrations and their precision for a suite of PCBs. To assess these models, four different thicknesses of LDPE passive samplers were co-deployed for 28 days in the water column at three sites in New Bedford Harbor, MA, USA. Following the deployments, the percent of PRC lost ranged from 0-100%. Fractional equilibrium decreased with increasing PRC molecular weight as well as sampler thickness. These data allow C_{free} comparisons to be made in two ways: (1) comparing C_{free} derived from one thickness using different models and (2) comparing C_{free} derived from the same model using different thicknesses of LDPE. Overall, a total of 27 PCBs (log K_{OW} ranging from 5.07 – 8.09) were measured at C_{free} concentrations varying from 0.05 pg/L (PCB 206) to about 200 ng/L (PCB 28) on a single LDPE sampler. Relative standard deviations (RSDs) for total PCB measurements using the same thickness and varying model types range from 0.04-12% and increased with sampler thickness. Total PCB RSD for measurements using the same model and varying thickness ranged from: 6 – 30%. No RSD trends between models were observed but RSD did increase as C_{free} decreased. These findings indicate that existing models yield precise and reproducible results when using LDPE and PRCs to measure C_{free}.

675 Why kinetics matter: the use of a numerical diffusion model for determining fractional equilibrium in passive samplers at varying flow conditions

R. Adams, Loyola Marymount Univ / Civil Engineering Environmental Science; A. Joyce, National Research Council/ USEPA / Atlantic Ecology Division; L. Griffin, Loyola Marymount Univ / Civil Engineering Environmental Science; O. Slosser, N. Charista, N. Aver, Loyola Marymount Univ; S. Margulis, Univ of California Los Angeles / Civil Environmental Engineering

Passive samplers have been effectively used to measure the freely-dissolved concentrations of hydrophobic organic contaminants in natural waters. Because rates of chemical uptake vary due to molecular size and ambient water conditions, including water boundary layer (WBL) thickness and the ratio of sampler size-to-water volume, the time to equilibrium is both compound- and water condition-specific. The use of pre-added performance reference compounds (PRCs) can be used to correct for this disequilibrium allowing for more accurate estimates of in situ contaminant concentrations. A physically based, one-dimensional diffusion model can be used to estimate water boundary layer thickness and correct for disequilibrium for multiple chemicals. In situ field measurements typically allow for limited concentration measurements (beginning and end of sampler deployment). In this study, synchronous fluorescence was used in polyethylene passive sampler laboratory experiments to measure multiple (~30) absorption and desorption concentrations of phenanthrene over time in order to verify the isotropic nature of the diffusion process in polyethylene (PE). A numerical diffusion model was created and found to be in good agreement with the absorbing and desorbing phenanthrene concentrations. In subsequent laboratory experiments, PE was spun at varying speeds (0, 1, 30, 80 cm/s) in order to mimic a range of environmentally-relevant WBL thicknesses and the desorption rates for pre-added pyrene and absorption rates for phenanthrene and benzo(a) pyrene were measured using synchronous fluorescence. The pre-added pyrene concentrations and the numerical model were used to estimate the water boundary layer thickness so that the fractional equilibrium could be estimated. Using this fractional equilibrium and the diffusion coefficient for each analyte of interest, the numerically-modeled and measured concentrations for phenanthrene and benzo(a)pyrene were compared. This numerical model allows for the use of a small number of PRCs to be used to estimate boundary layer thickness so that the fractional equilibrium can be estimated for any analyte using appropriate diffusivity coefficients. The model demonstrates the large range of equilibrium times for chemicals measured in the laboratory in contrast to the longer times in the field. Finally, the importance of WBL thickness and molecular size on kinetics is demonstrated in both lab experiments and using the numerical model.

676 Kinetic passive sampling of nonpolar compounds in water: the effect of model choice on data quality

K. Booij, PaSOC

Passive sampling methods for nonpolar compounds are gaining maturity as routine tools for chemical monitoring in water. Equilibrium sampling is the most straightforward way to go, but when equilibrium cannot be attained on realistic time scales, kinetic sampling is the only option. Calibration of the in situ uptake kinetics is usually done by evaluating the dissipation of performance reference compounds (PRCs), using the PRC fractions that remain in the sampler after exposure, relative to unexposed samplers. Mechanistic models are available to calibrate the in situ uptake rates and to calculate aqueous concentrations. Next to these mechanistic models, some empirical models are being used. One of these empirical models is based on estimating the degree of equilibrium for all analytes of interest from a linear plot of retained PRC fractions versus log K_{ow}. With another empirical model, in situ sampling rates (R_s) are calculated for all individual PRCs, followed by evaluating the R_s of the target analytes from a linear regression of log R_s versus log K_{ow}. Using PRC data from field exposed samplers, it is illustrated that these empirical models may be acceptable in some cases, and in other cases may result in loss of trueness and/or precision, or even loss of data for some compounds.

677 Simulated sampling rates across the Global Atmospheric Passive Sampling (GAPS) Network

N.J. Herkert, The Univ of Iowa / Civil and Environmental Engineering; A. Smith, Univ of Iowa; S.N. Spak, Univ of Iowa / Civil Environmental Engineering; J. Schuster; T. Harner, Environment and Climate Change Canada / Atmospheric Science Technology Directorate; K.C. Hornbuckle, Univ of Iowa / Civil and Environmental Engineering IIHR Hydroscience and Engineering

Passive air samplers equipped with polyurethane foam media (PAS-PUF) are important tools for measuring atmospheric concentrations of persistent organic pollutants, but accurate and consistent determination of compound-specific effective sampling volumes for PAS-PUF deployments has been limited by the expense and uncertainty of sampler calibration and depuration approaches. Here, we evaluate global performance for compound-specific sampling volumes in a process-based hourly model using five semi-volatile depuration compounds and 82 samples collected by the Global Atmospheric Passive Sampling (GAPS) Network in 2006-2007. We apply the model using observed local meteorology from the Integrated Surface Database and calibrated for global use from the GAPS database. We evaluate the global spatial and seasonal distribution of depuration-based and simulated PAS-PUF sampling rates, quantify global predictive performance, and identify future research directions and operational approaches for refining estimates of PAS-PUF sampling rates. Results support the global operational use of simulated sampling rates specific to each site, deployment, and semi-volatile compound.

678 Gas-Particle Partitioning and Passive Sampler Calibration for an Expanded List of PAHs from Urban and Rural Ambient Air Sampling

K. Ellickson, Minnesota Pollution Control Agency / Environmental Analysis and Outcomes; M. Krause, Minnesota Dept of Health / Public Health Laboratory Organic Chemistry; C. McMahon, Minnesota Pollution Control Agency / Environmental Analysis and Outcomes Division; C. Herbrandson, Minnesota Dept of Health / Environmental Health; C. Schmitt, Minnesota Dept of Health / Public Health Laboratory Organic Chemistry; C. Lippert, Mille Lacs Band of Ojibwe Dept of Natural Resources and Environment / Air Quality; G. Pratt, Univ of Minnesota / School of Public Health Division of Environmental Health

The extent of intra-urban PAH concentration variability is poorly known in the Twin Cities metro area and elsewhere. Active ambient air sampling requires electricity, security, and is cost prohibitive for finer spatial scale monitoring. Passive air sampling allows a larger number of samplers to be deployed within an area of interest, as they can be attached to any tree or utility pole (avoiding treated wood because of potential treatment contamination). Passive air samplers, however, require calibration using either active air sampling or depuration compounds. Our study calibrated passive mass loadings to active air sampling results by the calculation of an air sampling rate (Armitage 2013, Zhang and Wani 2012, Motelay-Massei 2005). An analysis of gas-particle partitioning, results below detection limits, and a sensitivity analysis of the summarization groups for active samplers (season, study year, study location, specific sites) was required in order to calculate air sampling rates that were both reflective of seasonality and stable enough to be useful for the entire study. Gas-particle partitioning was in keeping with previous studies and theoretical considerations. PAHs up to a molecular weight (MW) of approximately 166g/mole were found in the gas phase, while PAHs with MW between 166g/mole and 253g/mole partitioned between the gas and particle phases depending on ambient temperature and the chemical and physical characteristics of the PAH. Higher MW PAHs were found mainly in the particle phase. Partitioning coefficients were related to sub-cooled vapor pressures and octanol-air partitioning coefficients. There were several PAHs detected on the passive samplers (e.g. Benzo[a]pyrene, Benzo[e]pyrene, Benzo[j+k]fluoranthene) that were found exclusively in the particle phase in the active samplers. This finding could imply that the passive samplers collected some particles. Based on this finding we chose to use total (gas plus particle phase) active concentrations to calibrate passive samples. The air sampling rates for most PAHs were between 0.5-2.5m^3/day, but Dibenzothiophene sulfone was a clear outlier with sampling rates around 10m^3/day. We did not see a consistent relationship for all PAHs between sampling rate and ambient temperature. We did see a decrease in sampling rates with increasing molecular weight, possibly due to lower particulate sampling efficiencies in these samplers.

679 The potential role of mechanistic models for interpreting passive air sampling data for semi-volatile organic chemicals

J.M. Armitage, Univ of Toronto – Scarborough / Physical and Environmental Sciences; M. Silva Barni, Ecotoxicología y Contaminación Ambiental (ECoA) / Ciencias Marinas; F. Wania, Univ of Toronto at Scarborough / Physical and Environmental Sciences

Passive air sampling is now well-established in the contaminant monitoring community and there are a variety of passive air sampler (PAS) designs described in the literature. Although PAS can differ with respect to sampler material (e.g., polyurethane foam, XAD resin, activated carbon felt, polyethylene, polydimethylsiloxane) and housing (e.g., none, 'flying saucer', cylindrical), the uptake and depuration kinetics are typically assumed to conform to the same theoretical model (Whitman Two-Film Theory). However, as the old aphorism goes, "All models are wrong but some are useful". Potential errors inherent to any modeling approach relate not only to the validity of the assumptions made (e.g., air-side resistance dominates exchange) but also the reliability of required input parameters (e.g., sampler-air partition coefficients and their temperature-dependence). The main objective of this presentation is to examine the underlying assumptions adopted in the PAS community with respect to uptake and depuration kinetics of semi-volatile organic chemicals (SVOCs) using the modeling tool developed within our research group (PAS-SIM). Insights from previous model evaluations using concurrent passive XAD-2 and active air sampling data are highlighted along with simulations of depuration compounds under different environmental conditions (e.g., temperature profiles and wind speeds). These model applications are used to discuss the advantages and disadvantages of applying mathematical tools to convert the mass of chemical accumulated on a PAS during deployment to air concentrations and also to identify key data gaps and research needs in this area.

Chemical and Microbial Environmental Health Threats Associated with Disasters

680 Regional Variability in Bed-sediment Concentrations of Wastewater Compounds, Hormones and PAHs for New York and New Jersey Impacted by Hurricane Sandy

P.J. Phillips, USGS / New York Water Science Center; C. Gibson, The Nature Conservancy; S. Fischer, I. Fisher, USGS; T. Reilly, USGS / New Jersey Water Science Center; K.L. Smalling, USGS / NJ Water Science Center; K. Romanok, USGS; W.T. Foreman, USGS / National Water Quality Laboratory; R. Rovello, USGS; M. Focazio, USGS / Environmental Health; D. Jones, USGS

Bed sediment samples from 79 coastal New York and New Jersey, USA sites were analyzed for 75 compounds including wastewater associated contaminants, PAHs, and other organic compounds to assess the post-Hurricane Sandy distribution of organic contaminants among six regions. These results provide the first assessment of wastewater compounds, hormones, and PAHs in bed sediment for this region. Concentrations of most wastewater contaminants and PAHs were highest in the most developed region (Upper Harbor/Newark Bay, UHNB) and reflected the wastewater inputs to this area. Although the lack of pre-Hurricane Sandy data for most of these compounds make it impossible to assess the effect of the storm on wastewater contaminant concentrations, PAH concentrations in the UHNB region reflect pre-Hurricane Sandy conditions in this region. Lower hormone concentrations than predicted by the total organic carbon relation occurred in UHNB samples, suggesting that hormones are being degraded in the UHNB region.

681 Assessing Sediment Toxicity Predicted on the Basis of Sediment Chemistry in Barnegat Bay, New Jersey, Pre- and Post-Hurricane Sandy

Z. Szabo, USGS / New Jersey Water Science Center; K. Romanok, USGS; T. Reilly, USGS / New Jersey Water Science Center; Z. Defne, N.K. Ganju, USGS / Woods Hole Coastal and Marine Science Center

Hurricane Sandy made landfall in Barnegat Bay, New Jersey, October, 29, 2012, damaging shorelines and infrastructure. Estuarine sediment chemistry and toxicity were investigated pre- and post-event using samples collected at the same locations to evaluate potential environmental health impacts and to establish post-event baseline sediment-quality conditions. Trace element concentrations increased throughout the Bay up to two orders of magnitude, consistent with a northward redistribution of silt based on sediment transport modeling results. Conversely, there was a loss of organic compounds, clay, and organic carbon, consistent with sediment winnowing and transport. The number of sites exceeding sediment quality guidance levels, developed by Long and Morgan (1990), for trace elements tripled post-Sandy (most frequent, mercury and arsenic), and at one site, concentration of zinc exceeded the Effects Range-Medium level at which adverse biological effects have been noted in 50 percent of cases. Criteria for assessing sediment contaminants by region used consistently with the U.S. Environmental Protection Agency's (EPA) 2010 National Coastal Conditions Assessment indicated a change in sediment quality from good to fair post-Sandy. Potential toxic effects based on concentrations of sediment-borne contaminants in the Bay collected pre- and post-Sandy were assessed with EPA's Logistic Regression Model (LRM) developed for the test marine amphipod Ampelisca abdita. Measured sediment toxicity pre- and post-Sandy was the same for most sites and did not show statistically significant difference (paired-t test). At the site with the greatest relative increase for a suite of trace elements, survival rate of the test estuarine amphipod (Leptocheirus plumulosus) decreased, but survival rate did not decrease at the site with the large increase in zinc concentration. Predicted amphipod survival was not statistically significantly different pre- and post-Sandy, though the maximum calculated LRM values (used in computing survival rates) showed statistically significant increase post-Sandy corresponding with the increase in trace element concentrations. This study was possible because of the comprehensive baseline data enabling the evaluation of storm-derived changes in sediment quality, which can allow for similar evaluations for future events. Uncertainty in predicting potential toxic effects indicates greater understanding of factors affecting sediment toxicity is needed.

682 The US Geological Survey's Sediment-bound Contaminant Resiliency and Response Strategy: A decision support tool for evaluating contaminant hazards

D.K. Jones, USGS / Eastern Geographic Science Center; T. Reilly, USGS / New Jersey Water Science Center; K. Aquino, C. Carbo, E. Kaufhold, E. Zinecker, USGS / Eastern Geographic Science Center; W.M. Benzel, USGS / Central Minerals and Environmental Science Center; S.C. Fisher, USGS-Water / New York Water Science Center; D.W. Griffin, USGS; L.R. Iwanowiicz, USGS / Leetown Science Center; K.A. Loftin, USGS

Coastal communities are uniquely vulnerable to sea-level rise and severe storms such as hurricanes. These events enhance the dispersion and concentration of natural and anthropogenic chemicals and pathogenic microorganisms, which could adversely impact the health and resilience of coastal communities and ecosystems in coming years. The U.S. Geological Survey (USGS) has developed the Sediment-bound Contaminant Resiliency and Response (SCoRR) strategy to define baseline and post-event sediment-bound environmental health stressors (see toxics.usgs.gov/scorr). A tiered, multi-metric approach will be used to: (a) identify and map contaminant sources and potential exposure pathways for human and ecological receptors, (b) define the baseline mixtures of environmental health stressors present in sediments and correlations of relevance, (c) document post-event changes in EH stressors present in sediments, and (d) establish and apply metrics to quantify changes in coastal resilience associated with sediment-bound contaminants. Integration of this information provides a means to better assess the baseline status of a complex system and the significance of changes in contaminant hazards due to storm-induced (episodic) and sea-level rise (incremental) disturbances. This talk describes the construction of a decision support tool to identify locations vulnerable to contaminants that may be mobilized by coastal storms. The support tool is designed to accommodate a broad array of geologic, land-use, and climatic variables and utilizes public, nationally available data sources to define contaminant sources and storm vulnerabilities. By employing a flexible and adaptable strategy built upon publically available data, the method can readily be applied to other site selection or landscape evaluation efforts. Examples from the SCoRR pilot study, key limitations, and future applications will be discussed in addition to ongoing method developments to accommodate non-coastal disaster scenarios and more refined contaminant definitions.

683 Organic Contaminant Screening and Storm-Derived Change: The US Geological Survey's Sediment-bound Contaminant Resiliency and Response Strategy

K. Loftin, USGS / OGRL; T. Reilly, USGS / New Jersey Water Science Center; Z.R. Laughrey, R.A. Femmer, USGS; W.M. Benzel, USGS / Central Minerals and Environmental Science Center; S.C. Fisher, USGS-Water / New York Water Science Center; D.W. Griffin, USGS; L.R. Iwanowiicz, USGS / Leetown Science Center; D.K. Jones, USGS / Eastern Geographic Science Center

With well over 100 million organic chemicals known, it is unfeasible to identify and quantitatively monitor all contaminants with potential environmental health implications. Traditional analytical approaches have proven to be expensive, time-intensive, and cumbersome. Adaptive management practices require timely data of sufficient quality to engage the policy and implementation process designed to guide restoration activities, assess environmental health changes, and support improvements in ecosystem services. In response, the U.S. Geological Survey is testing recently developed analytical methods for organic contaminants as part of the Sediment-bound Contaminant Resiliency and Response Strategy (SCoRR) project. SCoRR focuses on changes in sediment quality at targeted sights in northeastern U.S. coastal counties impacted by a 2015 storm. Screening measurements were conducted by protein phosphatase inhibition, fourier-transform infrared spectroscopy, and liquid chromatography with in-line ultraviolet/visible and fluorescence spectrometers and time-of-flight mass spectrometry. Converging lines of evidence approaches will be discussed using chemometrics to guide screening evaluation of results in the context of storm-derived change and environmental health.

684 Health risks in coastal flood of Río de la Plata

F. Granja, C. Collingwood, M.E. Garcia, S.O. Demichelis, National Univ of Lanus / Environmental Laboratory Urban Environmental Management Dept of Productive Development and Technology

Diseases are considered “epidemics” when the amount of affected exceeds the usual number of expected cases and an “outbreak” when an epidemic occurs in a small geographic area and for a short time. According to the Ministry of Health of the Nation among the phenomena associated with epidemics and outbreaks that have the greatest potential risk in our country they are: cholera, dengue, chikungunya fever and flu. In addition, “emerging diseases” occur when environmental changes favor the increase of pathogens and vectors, therefore increases the risk on the human population. Environmental factors that increase the risk of epidemic diseases may be mentioned environmental degradation (such as water pollution, garbage dumps and lack of hygiene), lack of potable water and sewage (favors pollution well water) and floods, situations that are associated with the increase in communicable diseases. In coastal areas affected by floods, the overflow of contaminated water, waterlogging and the backwaters favor migration of rodents (reservoirs of diseases) and breeding of mosquitoes and other vectors, provocateurs malaria, dengue and other vector-borne diseases . Furthermore contact with contaminated water, increasing cases of tetanus, hepatitis A, cholera, influenza, and pneumonia and other diseases caused by cold. This project addresses the health risks associated with exposure to flood events in coastal cities of River Plate, in order to provide guidelines for urban environmental management pollution. a selection of built-up coastal areas Quilmes, Berazategui, Ensenada, Berisso, Magdalena and Punta Indio was made and exposed to frequent occurrence of floods and overflows of wastewater. a characterization of the negative health effects on each selected site was made. Majoritarian diseases in the study area were: lung diseases or respiratory problems such as pneumonia, bronchitis, bronchiolitis, etc. and turn digestive system diseases such as gastritis, gastroenteritis, diarrhea, pain pelvic and certain diseases of infectious or parasitic origin.

685 Review of current literature of cardiotoxicity of oil to early life stages of fish for use in Natural Resource Damage Assessments

K.L. Yozzo, None / Environmental Health Sciences; J. Hauri, Assumption College / Natural Sciences Dept; S. Kane Driscoll, M.E. McArdle, Exponent, Inc.; A. Morrison, Exponent / EcoSciences

After a release of contaminants, a Natural Resource Damage Assessment (NRDA) may be conducted to estimate the magnitude of injuries to natural resources, as well as the best options for restoration. Assessments for oil spills in the aquatic environment typically consider aquatic injuries related to phototoxic and narcotic effects on aquatic organisms, such as fish. Cardiotoxicity has recently emerged as an additional, potentially important mode of toxicity for Polycyclic Aromatic Hydrocarbons (PAHs) in early life stage (ELS) of fish. Suspected cardiotoxic effects, such as gross malformations, including pericardial and yolk sac edema, cranial facial malformations, and dorsal curvature, have been reported in fish species after exposure to PAHs. However, the repercussion of cardiotoxic effects is uncertain, as the reversibility of effects is possible and the link between laboratory observations to service losses relative to field populations is unclear. Additionally, available studies have significant limitations for use in a NRDA, including limited available field data to verify the effect beyond the laboratory, uncertain extrapolation to species of interest, and a lack of accurate information on the duration, concentration, and chemical composition of oil exposure. Additional limitations include uncertainty in the developmental windows of exposure for various species, inconsistent approach for calculating exposure of cardiotoxic PAHs, incomplete dose-response relationships reported in the literature, and insufficient data on long-term effects from cardiotoxicity. Future studies should further refine the cardiotoxic potential for different PAHs, verify that effects observed in the laboratory are observed in the field following exposure, and determine whether cardiotoxicity results in demonstrable long-term effects to individual fish and populations.

686 Young of the year bluefish as a bioindicator of estuarine health: Establishing a new baseline for persistent organic pollutants after Hurricane Sandy

K.L. Smalling, USGS / NJ Water Science Center; A. Deshpande, USDOC-NOAA-NMFS-NEFSC / Sandy Hook Laboratory; V.S. Blazer, USGS; B. Dockum, USDOC-NOAA-NMFS-NEFSC / Sandy Hook Laboratory; D. Timmons, USDOC-NOAA-NMFS-NEFSC; B.L. Sharack, USDOC-NOAA-NMFS-NEFSC / Sandy Hook Laboratory; R.J. Baker, USGS; J. Samson, USDOC-NOAA-NMFS-NEFSC; T. Reilly, USGS / New Jersey Water Science Center

Atlantic coastal bays of the United States are essential habitat for young-of-year (YOY) bluefish (Pomatomus saltatrix). Their residence in these estuaries during critical-life stages, high lipid content, and piscivory make YOY bluefish an ideal bioindicator species for evaluating estuarine health. Hurricane Sandy made landfall in late October 2012, causing widespread physical, environmental, social and economic impacts to much of coastal New Jersey and New York. Individual whole YOY bluefish from four estuaries (2-3 sites/estuary) impacted by the storm were collected in August 2013, analyzed for a suite of persistent organic pollutants (POPs) including polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs) and organochlorine pesticides (OCPs) and evaluated using histological health metrics. Contaminant body burdens were similar between individuals collected from a single estuary and no site specific capture location differences were observed. The contaminant residue concentrations in the YOY bluefish reflected a broad-scale, integrated portrayal of the nursery ground in a given estuary, rather than a localized snapshot of the capture location (site), more commonly observed in resident species. Regionally, concentrations in YOY bluefish differed by estuary and concentrations for many POPs decreased or were similar to those observed prior to the hurricane. Prevalence of the ecto-parasitic gill isopod (Lironeca ovalis) on YOY bluefish varied by estuary and no relationships between contaminants and lesions were observed. The gill isopods removed from Jamaica Bay bluefish were preserved, homogenized and analyzed for PCBs, PBDEs and OCPs and this study was the first to report the presence of POPs in this common parasite. The co-existence of parasitic infections and contaminant exposure has various impacts on accumulation of hydrophobic contaminants in the host and in some instances the parasites are able to accumulate at a higher rate than their host making them potentially a better indicator of exposure. Contaminant information gained from bluefish and/or their parasitic isopods could be an effective way to examine an entire estuary rather than a single point location from multiple trophic levels. Fish health assessments in combination with contaminant analysis should also be included in regional monitoring programs to determine the potential consequences of residing and feeding in urbanized estuaries even for short periods of time.

687 Impact of Hurricane Sandy on PAH levels and oncogenes in Atlantic menhaden

C.S. Bentivegna, C.R. DeFelice, Seton Hall Univ / Biological Sciences

The impact of Hurricane Sandy (October 29, 2012) on PAH body burdens and genetic polymorphisms in oncogenes was investigated in adult Atlantic menhaden (Brevoortia tyrannus) collected along the NJ coast. Collections were made in August, September and/or October of 2011, 2012 and 2013. PAHs were monitored in raw fish oil using excitation-emission matrix spectroscopy (EEMs). Genetic polymorphisms were monitored using PCR primer sets designed to amplify V-Rel and C-Raf. The presence and absence of bands on agarose gels was used to determine the degree of polymorphisms. Primer sets were designed from an Atlantic menhaden transcriptome and verified by cloning. Results for

EEMS showed that raw fish oils had relatively high levels of high molecular weight, PAH-like compounds (173 to 24,421 ng/mL) compared to values reported for bile in other species. Concentrations and EEMs profiles varied by collection; however, collection ship, month, year and fish size did not account for the data. Preliminary data for oncogenes showed variation in polymorphisms by collection. Overall, Superstorm Sandy did not alter body burdens of PAHs in raw fish oil of menhaden.

Radionuclides in the Environment, Including Accumulation in Biota

688 Environmental radioactivity and public anxiety

N. Fisher, SoMAS @ Stony Brook Univ / SoMAS

The disaster that befell the Fukushima nuclear power plant in March 2011, including the record release of radionuclides into the ocean, resulted in the expected radioactive contamination of water, sediments, and biota. The highest levels of radionuclides released into the Pacific were found closest to the source, that is, within the Fukushima prefecture. Radioactivity levels decreased markedly with distance from the source and greatly over time, reflecting radioactive decay (especially for ^{131}I) and dilution and dispersion by currents in the Pacific Ocean. Nevertheless, detectable levels of radiocesium were clearly evident in diverse marine fauna, ranging from small zooplankton to large apex predators, and indeed can still be measured, particularly in benthic fauna. Further, bluefin tuna which spawn in the western Pacific concentrated Cs isotopes prior to their migration across the Pacific to the eastern Pacific where we measured tissue radioactivities above the natural background. Although radioactivity levels were orders of magnitude below levels known to elicit any known toxic effects in fish or in human seafood consumers, there was a remarkable public outcry and widespread anxiety. Part of this anxiety may be due to the fact that radioactivity was spreading far afield, being visited on US shores, and in popular seafood items, no less. This disconnect between actual and perceived risks often accompanies environmental releases of radionuclides, and reflects a broad-based fear and ignorance of radioactivity. This anxiety regarding environmental radioactivity may well be a legacy of cold war era anxieties, as depicted in lurid science fiction movies or even more serious films that displayed the potential consequences of nuclear releases. The anxiety is also attributable to the invisible nature of the threat, the terrible consequences of exposure to high radioactivity levels, and the considerable uncertainties of the impacts, if any, of exposures to very low radioactivity levels. A plea will be made to encourage renewed education and training involving environmental radioactivity so that the US can return to a position of leadership and competence it once had some fifty years ago in this field. A more informed citizenry would also be better able to soberly judge the risks involved in nuclear matters and voice rational opinions on future energy policies.

689 Are Sediments a Source of Fukushima Radiocesium for Marine Fauna in Coastal Japan?

C. Wang, Stony Brook Univ; N.S. Fisher, State Univ of New York Stony Brook / SoMAS

The Fukushima nuclear power plant accident in 2011 resulted in the largest accidental release of artificial radionuclides into the world's oceans. Among the fission products released in large quantities, ^{137}Cs has the greatest potential for long-term impacts on marine biota and human consumers of seafood. Marine animals, seawater and sediment near Fukushima, Japan have become contaminated with ^{137}Cs released from the damaged nuclear power plant. Radiocesium concentrations in some benthic fauna declined more slowly than in pelagic fish in the same region. A year after the accident, ^{137}Cs concentrations in both surface and bottom water declined sharply and remained very low; while ^{137}Cs concentrations in coastal sediment remained rather high and declined very gradually over time. We tested the hypothesis that benthic fish remained more contaminated due to the bioavailability of radiocesium in sediments. Desorption of Cs from sediments followed a concentration gradient from sediment surface to overlying seawater. We assessed the bioavailability of dissolved and sediment-bound Cs for deposit-feeding polychaetes, and its subsequent transfer to crabs and fish. Laboratory experiments demonstrated that the assimilation efficiency of ^{137}Cs was 16% in polychaetes ingesting Fukushima sediment, up to 54.5% in crabs ingesting polychaetes, and about 80% in fish ingesting worms. Thus, deposit feeding invertebrates and their predators may acquire Cs from contaminated sediment and introduce it into the benthic food chain. In addition, all animals acquired Cs from the aqueous phase, accounting for up to 65% of their total body burden. Loss rate constants following dietary uptake were 45% d^{-1}, 14% d^{-1}, and 5% d^{-1} for polychaetes, crabs, and fish; rate constants following aqueous uptake were 20% d^{-1} for polychaetes, 10% d^{-1} for crabs, and 6% d^{-1} for fish, respectively. A bioaccumulation model indicated that the transfer factors of Cs from sediments and the trophic transfer factors from worms to predators were about 1. Our results are consistent with the idea that sediments can be an important source of Cs for benthic food chains and help explain why bottom fish remained more contaminated than pelagic fish in Japanese coastal waters after the nuclear accident.

690 Environmental fate of radiocesium in an aquatic and semi-aquatic food web on the Savannah River Site

J.C. Leaphart, Univ of Georgia – Savannah River Ecology Laboratory / Warnell School of Forestry and Natural Resources; A.L. Bryan, Univ of Georgia / SREL; A.M. Korotasz, Univ of Georgia Savannah River Ecology Laboratory / SREL; J.C. Beasley, Univ of Georgia Savannah River Ecology Laboratory / Warnell School of Forestry and Natural Resources

Although biomagnification of radiocesium (^{137}Cs) has been reported in aquatic ecosystems, previous reserch has been limited to select trophic linkages and few studies have included a comprehensive survey of fauna associated with aquatic, semi-aquatic, and terrestrial habitats within a single study framework. Furthermore, few studies have examined the effect of ontogenetic shift in foraging strategy and diet on radionuclide burdens between juvenile and adult organisms. The objective of this study is to advance our understanding of the dynamics of ^{137}Cs accumulation within food webs by quantifying ^{137}Cs concentrations across a wide range of biota found within contaminated wetland ecosystems on the U.S. Department of Energy's Savannah River Site, and aims to determine if changes in life history, specifically in cottonmouths (Agkistrodon piscivorus) and bullfrogs (Lithobates catesbeianus), contribute to differences in ^{137}Cs burdens between juvenile and adult individuals. Specimens representing a range of different taxa, including invertebrates, fish, amphibians, reptiles, and mammals, were collected from the contaminated R-Canal and Pond A ecosystems on the Savannah River Site, and tested to quatify ^{137}Cs concentrations in their body tissues. Results show that ^{137}Cs concentrations are not always greater in organisms representing higher trophic positions within contaminated ecosystems. Additionally, the data shows significant variation in ^{137}Cs burdens between juvenile and adult life stages in cottonmouths and bullfrogs. This suggests that ^{137}Cs does not undergo biomagnification when examining trophic level increase in aquatic and semi-aquatic/terrestrial organisms, and that ontogenesis between juvenile and adult life stages can influence ^{137}Cs accumulation in exposed individuals.

691 Effects of chronic radiation exposure on carnivores from the Chernobyl Exclusion Zone

C. Love, Univ of Georgia / Savannah River Ecology Lab; S.C. Webster, Univ of Georgia / Warnell School of Forestry Natural Resources; J.C. Beasley, Univ of Georgia Savannah River Ecology Laboratory / Warnell School of Forestry and Natural Resources; T. Hinton, Fukushima Univ / Inst of Environmental Radioactivity; M.E. Byrne, Univ of Georgia / Warnell School of Forestry and Natural Resources; D. Shamovich, Krasny Bor Landscape Reserve; S.L. Lance, Univ of Georgia / Savannah River Ecology Laboratory

Nuclear energy production is increasing globally, yet long term ecological implications of radiation exposure from normal industry practices or accidents such as Chernobyl or Fukushima are unclear. Acute exposure to radiation is widely recognized to cause morbidity and mortality in wildlife as well as have sub-lethal influences such as effects on immune response, with low-dose stimulation and high-dose suppression of immunity. However, robust information is lacking regarding the impacts of chronic radiation exposure. The Chernobyl Exclusion Zone (CEZ, evacuated and excluded since 1986) offers an ideal model system to investigate these long-term chronic effects of radiation exposure on wildlife populations. The CEZ harbors a heterogeneous landscape of radiation levels (40 – >7,500 KBq/m^2) and several carnivore species. Carnivores are at higher risk for accumulation of contaminants due to their high trophic level and long life span, and thus provide a good model system. Our research provides the first comprehensive study examining carnivore density, distribution, genetic characterization, and prevalence of parasites and disease as a function of radiation exposure. During fall 2014 and spring of 2015, we collected data on carnivores within the CEZ. We found that radiation levels do not influence the distribution of any of the mammal species we investigated. However, our preliminary data show a trend of higher gastrointestinal parasite loads of Coccidia and Alaria species in individuals exposed to higher levels of radiation, which may be indicative of complex sub-lethal effects experienced by chronically exposed individuals. Disease prevalence is affected by population density and we are currently using genetic mark recapture methods to estimate densities of two of the most commonly occurring carnivores in the CEZ, the gray wolf (Canis lupus) and raccoon dog (Nyctereutes procyonoides. When complete we can investigate parasite and disease prevalence as a function of radiation exposure, radiocesium body burden counts, population density, and genetic characteristics. Addressing individual health through parasite and disease prevalence provides insight into mechanisms affecting health of chronically exposed carnivores in the CEZ. Further work will incorporate these and other results into population based analyses to provide insight into the population level implications of chronic radiation contamination exposure.

692 Sources of radioactive cesium to marine biota off Fukushima

Z. Baumann, Univ of Connecticut / Marine Sciences; N. Fisher, SoMAS @ Stony Brook Univ / SoMAS; D.J. Madigan, Harvard Univ; J. Nishikawa, Tokai Univ; O. Snodgrass, NOAA NMFS; W. Gilhooly, Indiana Univ-Purdue Univ Indianapolis

Following the radioactive spill from the damaged nuclear power plant in Fukushima Prefecture in Japan in March and April of 2011, the levels of ^{134}Cs and ^{137}Cs in seawater and various marine fish caught off Fukushima steadily declined. A year after the Fukushima disaster, radioactive Cs (i.e. ^{134}Cs + ^{13}7Cs) in most of these fish remained elevated above human advisory of 100 Bq kg^{-1} wet weight. Moreover, coastal sediments off Fukushima were found to contain higher levels of radioactive Cs than in other coastal regions off Japan, suggesting that these sediments acted as a repository for the Fukushima Cs. We hypothesized that these contaminated sediments could serve as a source of radiocesium to organisms that are part of the benthic food web in that area. To evaluate the relative importance of Cs sources Cs (i.e. sediment vs. seawater) for marine organisms from that region, we collected biota representative of the pelagic, benthic and coupled benthic-pelagic food webs and different trophic levels during 3 cruises aboard Japanese research vessels from May of 2013 to September of 2014. We measured levels of radioactive Cs for muscle tissues of individual fish species or for bulk biomass for planktonic organisms to assure sufficient mass for radioanalysis. The ratios of stable isotopes of C, N and S i.e. δ^{15}N, δ^{13}C and δ^{34}S were also measured to apply to Bayesian mixing modelling, which served to identify trophic linkages (i.e. benthic, pelagic or coupled) for these biota. Based on modelling, which was largely influenced by the δ^{34}S values (< 19‰ for benthic organisms) we confirmed that fish with the highest radiocesium activities relied mostly on benthic dietary sources. The data suggest that Cs accumulated by these fish was remobilized from sediments off Fukushima and was transferred from sediment to bottom dwelling invertebrates i.e. meiofauna and macrofauna, which were subsequently eaten by various benthic fish such as cod and flatfish species. Thus, sediments may serve as both a sink and a source for radionuclides released from Fukushima.

693 The Influence of Residence Time on Uptake of Radiocesium by Waterfowl on a Contaminated Reservoir on the Savannah River Site

R.A. Kennamer, R.E. Oldenkamp, Univ of Georgia / Savannah River Ecology Laboratory; A.L. Bryan, Univ of Georgia / SREL; J.C. Beasley, Univ of Georgia Savannah River Ecology Laboratory / Warnell School of Forestry and Natural Resources; J.C. Leaphart, Univ of Georgia / Savannah River Ecology Laboratory; J.D. King, Univ of South Carolina Aiken / Biology Dept

Former nuclear reactor cooling reservoirs on the U.S. Department of Energy's Savannah River Site (SRS) historically received relatively low releases of radiocesium in the mid- to late 1900s. Migratory waterfowl visiting these reservoirs present a special concern for potential exposure of offsite sport hunters to radiocesium by consumption of contaminated meat. Recent collections of free-ranging waterfowl suggested that the Pond B reservoir has higher radiocesium concentrations than other SRS reservoirs and that American coots (Fulica americana) had higher levels of radiocesium than diving ducks. Historical monitoring on SRS has generally incolved collections of free-ranging watefowl, with no knowledge of residence time on the contaminated reservoirs. To examine the influence of residence time on radiocesium uptake, we released wild-captured coots and ring-necked ducks (Aythya collaris), whose flight capabilities were restricted by scissoring flight feathers, on a radiocesium-contaminated reservoir (Pond B) and then made lethal collections of both species after known residence times ranging from 32 -173 days. Both species accumulated radiocesium, with ring-necks accumulating slightly higher concentrations, but acheived asymptotic levels of whole body radiocesium over different periods with coots taking ~30 days and ring-necks taking ~75 days. Radiocesium levels in a small sample of both species appeared to decline > 90 days post-release. Differences in radiocesium levels between species are likely due to dietary differences and the possible late-season decline may be due to seasonal differences in diet or radiocesium bioavailability.

694 Uptake and dosimetric modeling of Tc-99, Np-237, and U-238 in the grass species Andropogon Virginicus

N. Martinez, Clemson Univ / Environmental Engineering and Earth Sciences; D. Montgomery, N. Edayilam, N. Tharayil, B. Powell, Clemson Univ

The purpose of this work is to quantify the uptake of ^{99}Tc, ^{237}Np, ^{238}U into the grass speciesAndropogon Virginicus as well as to develop and compare associated dosimetric models. These risk driving radionuclides were chosen for their wide range of biogeochemical behaviors, and A. virginicus was selected as it is a common ground covering in the Southeastern United States. Hydroponic experiments in a laboratory setting were used to determine the potential for A. virginicus to physically take up the nuclides, giving insight into the mechanisms that may cause previously observed upward soil column migration at the Savannah River Site. The hydroponic studies consisted of growing established A. virginicus specimens in Hoagland nutrient solution containing the aforementioned nuclides under a 12 hour light cycle with plants being harvested in groups of four at three time points post exposure. The experiment was repeated at the seedling stage in to investigate the influence of plant life stage on uptake. Analysis of nutrient solution and plant material was conducted through inductively coupled plasma mass spectrometry, liquid scintillation counting and autoradiography to compare uptake and translocation between the three different exposure times. Shoot concentration ratios for ^{99}Tc ranged from 6 to 17 L kg^{-1}, for ^{237}Np ranged from0.2 to 0.9 L kg^{-1}, and for ^{238}U ranged from 1 to 7 L kg^{-1}. Dosimetric models were developed for A. virginicus utilizing stylized representation of plant organs (shoots and roots), with preliminary work in voxel modeling. Dose conversion factors (μGy d^{-1} per Bq kg^{-1}) were calculated using Monte Carlo transport codes. Results are compared to existing ellipsoidal models within the ERICA tool and RESRAD-BIOTA; ellipsoidal models provide a conservative estimate of dose rates to the whole plant, yet in many instances a plant's structure is not well-represented by an ellipsoid. Comparative absorbed dose rates, determined by combining the uptake results with the dosimetric model, are reported for the laboratory-grown A. virginicus. In general, the development of more comprehensive, yet practicable, dosimetric models of non-human biota allows for a greater ability to quantify potential dose-effect relationships and evaluate potential environmental radioecological impacts.

695 Monitoring elemental concentrations and radioactivity in biological samples at uranium mines in the Grand Canyon watershed: The Kanab North site

D. Cleveland, J. Hinck, USGS / Columbia Environmental Research Center

The U.S. Geological Survey and its cooperators are currently engaged in biological and chemical monitoring of reference and mining sites in pre-, post- and active-uranium ore production stages in the Grand Canyon watershed (Arizona, USA). The present paper describes the results of chemical (e.g., nickel, copper, zinc, arsenic, selenium, lead, thallium, uranium) and radiological analyses of animal (brush mice, deer mice) and plant (salt cedar, sage brush, needle and thread grass) tissues collected at the Kanab North Mine site. The Kanab North Mine was mined for uranium ore from 1988 to 1990, and then placed on standby in 1992. Reclamation of the site began in 2013, and is scheduled for completion in fall 2016. However, contamination, including elevated uranium concentrations in plants and dust, still exists at the Kanab North site; and the lengthy standby status of the mine likely contributed to low-level chronic exposures of the biota to weathered ore, radioactivity, and related chemical constituents. The results for Kanab North will be compared to data obtained for animal and plant tissues at the Canyon Mine, a pre-mining site currently undergoing shaft sinking, and at a nearby non-mineralized reference site; concentration results will be compared to literature-based toxicity thresholds. These comparisons will help inform on the ecological effects of uranium mining in the Grand Canyon watershed.

Methods and Applications of Non-targeted Mass Spectrometry for Environmental Characterization

696 High-resolution metabolomics for sequencing the human exposome

D.I. Walker, Emory Univ / Division of Pulmonary Allergy and Critical Care Medicine; D.P. Jones, Emory Univ / Clinical Biomarkers Laboratory

Over the course of a lifetime, humans are exposed to a wide range of chemicals from multiple sources. Surveys using targeted biomonitoring approaches have considerably advanced understanding of the distribution and occurrence of select exposure hazards; however, analytical targets are often limited and measure in large populations is not cost-effective. To better understand the role of environmental exposures in disease, there is a need for analytical methodologies that provide systematic measure of the human exposome. In an effort to accomplish this goal, we have developed a high-resolution metabolic phenotyping strategy utilizing complimentary measures by gas-chromatography (GC) and liquid-chromatography (LC) with ultra-high resolution mass spectrometer (MS) detection. Semi-volatile chemicals were measured by GC with detection by Orbitrap MS following sample preparation using a modified quick, easy, cheap, effective, rugged and safe (QuECHERS) method optimized for small (< 200 µL) volumes of plasma. Detected chemical classes included organochlorine pesticides, polychlorinated biphenyls and brominated flame retardants, in addition to unknown spectra exhibiting fragments consistent with other organohalogen compounds. Non-volatile species were measured in 65 µL of plasma using triplicate analysis with C_{18} and HILIC stationary phases interfaced to an Orbitrap MS. Plasma proteins were first precipitated by treating 65 µL of plasma with acetonitrile and the supernatant was analyzed in triplicate using C_{18} and HILIC column stationary phases. Following data extraction and alignment, over 10,000 mass-to-charge (m/z) ions were detected. Ions were annotated using isotopic pairing, accurate mass matches to chemical databases and comparison to authentic reference standards. Identified species included chemicals arising from commercial products, endogenous metabolism and dietary sources, with >50% of the m/z ions providing no matches in the chemical databases. Using the combined analytical capabilities of GC and LC with high-resolution MS and simplified sample preparation, it is possible to provide measures of a large number of environmental chemicals and endogenous metabolites in a relatively high-throughput and cost-effective manner. The resulting data can be used to estimate exposure in human populations, evaluate disease-exposure associations and provides systematic measures of environment and biological response for exposome research.

697 Development and Evaluation of Non-Targeted Screening Methods with the use of NIST Standard Reference Materials

B. Place, J. Murray, National Inst of Standards and Technology / Chemical Sciences Division

The creation of environment non-targeted screening protocols requires the development of multiple aspects of an analytical method, including sample preparation, instrumental analysis, and data analysis. The impact of each one of these steps can be significant to the outcome of a non-targeted screening analysis of an environmental material. For these reasons, environmental materials that are abundant, homogeneous, and long-term stable are extremely valuable as test materials to develop non-targeted screening methods and to evaluate the performance of the developed methods. Standard Reference Materials (SRMs), as developed by the National Institute of Standards and Technology (NIST), are excellent resources for the development and testing of non-targeted screening protocols. A general overview of NIST SRMs will be presented, in regards to the creation and testing procedures used to create stable, homogenous, and relevant environmental materials. In the past few years, multiple researchers within and outside of NIST have used NIST SRMs (such as SRM 2585 Organic Contaminants in House Dust) to test out newly developed non-targeted screening protocols. Some examples of the use of NIST SRMs for non-targeted screening method development will be discussed, including successful compound identifications made using GCxGC-MS and LC(xLC)-HRMS techniques. Using NIST SRMs, multidimensional chromatography paired with mass spectrometry provides enhanced identification of unknown compounds through "cleaner" mass spectra from better chromatographic resolution. Compounds including personal care products and flame retardants were successfully identified by newly-developed non-targeted screening methods. As reproducibility of LC-HRMS non-targeted screening methods can be a concern, new computational tools were developed to evaluate whole-method reproducibility and will be demonstrated as applied to SRM 2585. Finally, a new type of water reference material is in development for organic analysis of aqueous environmental samples using solid-phase media. Through the use of non-targeted screening methods, we were able to examine the nature of the new material and evaluate its use for targeted and non-targeted analysis.

698 Use of Chemometrics and Computational Chemistry in Non-Targeted and Targeted Analysis of PAH Transformation Products in Various Environmental Matrices

I. Titaley, Oregon State Univ / Dept of Chemistry; N. Jariyasopit, Environment and Climate Change Canada; K. Glaesemann, Pacific Northwest National Laboratory / Environmental Molecular Sciences Laboratory; P.H. Cheong, Oregon State Univ / Dept of Chemistry; S.L. Massey Simonich, Oregon State Univ / Dept of Environmental and Molecular Toxicology

Degradation of parent polycyclic aromatic hydrocarbons (PAHs) in the environment is well established and recently the transformation products formed have been shown to be more toxic than parent PAHs. The measurement of these transformation products is less frequent because, often, the identities of these products are unknown. Non-targeted approaches are increasingly used to measure PAH transformation products in various environmental matrices that were previously unidentified. In addition to that, previous research has shown that the formation of these transformation products can be predicted using computational chemistry, using the thermochemical properties of chemical compounds. For instance, using the density functional theory (DFT), the Gibbs free energy of the reaction pathway from a parent PAH to transformed products can be calculated. This unique capability can be a powerful tool that aids analytical chemists in determining the likeliest transformation products that will be formed in the environment. However, computational chemistry alone cannot differentiate which products will likely form when biological processes are involved in the degradation process, such as in the presence of microbial enzymes. Chemometrics can complement computational chemistry to help solve this issue. This technique uses statistical models and curated data in the literature to provide chemical information. The Pathway Prediction System (PPS) from the University of Minnesota and the Swiss Federal Institute of Aquatic Science and Technology, is an example of database that uses this approach and can provide the chemical structures formed from microbial biodegradation. Together, with analytical methods, both techniques may provide researchers with a priority list of transformation products that will likely to be formed based on their thermodynamic data, which is important in non-targeted analysis. Moreover, with the presence of open sourced computer programs, chemometrics and computational chemistry offer a unique perspective for non-targeted analysis that can be adopted by a variety of labs as the techniques are independent of specific analytical instrumentations.

699 Characterization of organic micropollutants in ballast water and their role in disinfection byproduct formation following oxidative treatment

N. DeStefano, Duke Univ; W. Gerhard, C. Gunsch, Duke Univ / Civil and Environmental Engineering; G. Drillet, H. Eikaas, DHI; B.C. Kelly, Barry C Kelly / Civil Environmental Engineering; L. Ferguson, Duke Univ / Dept of Civil and Environmental Engineering

More than 10 billion gallons of seawater are transported globally each year during shipping activities. Ballast water has been identified as a major vector for the translocation of aquatic marine species, contributing to the spread of invasive species and pathogens. In an effort to mitigate ballast water impacts on marine ecosystems, the International Maritime Organization (IMO) has established the Ballast Water Management Convention in 2004. Pending regulations will require the installation of type-approved Ballast Water Management Systems (BWMS) in approximately 57,000 merchant ships globally, replacing and supplementing existing standards dictating open ocean tank water exchange. The majority of treatment systems use oxidizing agents, particularly chlorine, ozone or UV to kill invasive species or pathogens, generating halogenated disinfection byproducts (DBPs). The composition of DBPs is dependent on organic substrates present in the seawater, as well as environmental characteristics such as pH, salinity, temperature and total organic carbon. To better understand the chemical microenvironment of ship ballast tanks and the potential for DBP formation after treatment, we sampled ballast water from ships in the USA (east and west coast) and Singapore. In addition, test-scale and bench-scale BWMS systems were tested with several water sources differing in salinity, temperature, and organic carbon content to examine DBP production. Treated and untreated ballast water was characterized by HPLC with Orbitrap high resolution tandem mass spectrometry for both targeted and non-targeted polar micropollutants and DBPs, as well as for known volatile/semivolatile DBPs using GC-MS. Results indicate that micropollutant burdens and identities vary considerably according to ship location and water source, with complex polyethoxylated surfactants identified as a ubiquitous contaminant class. These and other organic micropollutants may form potentially toxic transformation products upon chemical or UV treatment for disinfection. Results of our measurements will be presented in context of implications for ballast water management for global shipping.

700 Non-targeted identification of contaminants in Southern California sentinel marine mammals

N. Dodder, San Diego State Univ; J.M. Cossaboon, San Diego State Univ / Graduate School of Public Health; D.W. Weller, S.J. Chivers, K. Danil, National Oceanic and Atmospheric Administration / Southwest Fisheries Science Center; K.A. Maruya, SCCWRP; E. Hoh, San Diego State Univ / Graduate School of Public Health

Apex marine predators of the Southern California Bight face a complex combination of environmental stressors including exposure to anthropogenic contaminants. These animals also serve as effective indicators of marine pollution due to their high trophic position, longevity, and large blubber stores. We developed an innovative non-targeted analytical method to characterize known and unknown anthropogenic contaminants often missed by traditional targeted methods. Coincident with the identification of anthropogenic compounds was the identification of several classes of halogenated natural products. The analytical method utilized comprehensive two-dimensional gas chromatography coupled to time-of-flight mass spectrometry (GC×GC/TOF-MS) to generate a full inventory of halogenated organic compounds from archived blubber samples of five candidate marine mammal species: long-beaked common dolphins (Delphinus capensis), short-beaked common dolphins (Delphinus delphis), Risso's dolphins (Grampus griseus), California sea lions (Zalophus californianus), and harbor seals (Phoca vitulina). In addition to the instrumental method, data management was critical to establishing the contaminant inventory and required the development custom software. A software tool to automatically identify halogenated mass spectra improved the data processing efficiency and allowed for the relatively large sample set compared to previous projects. Additional software was used to assist with compound identificaiton, organize mass spectra and ancillary information, ensure the reproducibility of identifications, and provide a mechanism for sharing the data (a mass spectral library) with other researchers using a standard data format. Compound identifications were performed through manual interpretation of mass spectra, and automated searching of standard reference and custom mass spectral libraries. Identified chemicals were catalogued and exposure profiles for each species were generated based on contaminant abundance and frequency of occurrence. Optimal sentinel species for future environmental monitoring were identified based on the magnitude and multitude of accumulated compounds. This research ultimately aims to develop a streamlined and comprehensive approach for the discovery of emerging contaminants, investigate associations with health outcomes, and reinforce the importance of non-targeted analytical methods in informing environmental monitoring and assessment.

701 Chemical assessment of effects on invertebrates using high-resolution mass spectrometry

C. Moschet, Univ of California Davis / Civil and Environmental Engineering; S. Hasenbein, Univ of California Davis / School of Veterinary Medicine Anatomy Physiology and Cell Biology; B. Lew, Univ of California Davis / Civil and Environmental Engineering; D.P. Weston, Univ of California / Dept of Integrative Biology; R.E. Connon, Univ of California, Davis / School of Veterinary Medicine; H.C. Poynton, Univ of Massachusetts, Boston / School for the Environment; T. Anumol, Agilent Technologies Inc.; T.M. Young, Univ of California-Davis / Civil and Environmental Engineering

The Cache Slough complex is an area of tidal sloughs in the Sacramento–San Joaquin River Delta of California (USA) and is an important habitat for endangered fish species (e.g., the endemic Delta Smelt). Existing pesticide data are sufficient to demonstrate a risk to aquatic invertebrates upon which several fish species depend. This study involved deployment of a sensitive amphipod species, Hyalella azteca, an important fish prey in the study area, combined with a complete chemical screening of water samples during two storm events in winter 2015/2016. The use of high-resolution mass spectrometry thereby allowed the screening for unknown chemicals. Water samples were concentrated by solid phase extraction. Non-polar pesticides were analyzed on an Agilent GC-QTOF-MS/MS. Negative chemical ionization (NCI) mode was selected for the target screening of pyrethroids and fipronil due to its high sensitivity. To identify further suspected pesticides without a reference standard, samples were measured in electron impact (EI) mode using an accurate mass spectral database containing 750 pesticides (Agilent Technologies). Polar chemicals were analyzed on an Agilent LC-QTOF-MS/MS using electrospray ionization (ESI) in both positive and negative mode. 27 target chemicals were selected to validate the method. Data were acquired with an All-Ions fragmentation method in order to carry out suspect screening using an accurate mass MS/MS database consisting of 1700 pesticides and related compounds. In addition, the samples were screened for a list of 1300 transformation products which were predicted by a biochemical pathway predictor (EAWAG-PPS). Finally, molecular features of all chromatograms were extracted to look at true unknowns in the sample. Features with significant differences between affected and non-affected samples were prioritized using Agilent Mass Profiler Professional (MPP) software. Over 120 different pesticides and transformation products could be detected at least once; 90 of them were found by the suspect screening. Many of the detected compounds correlated with toxicity toward H. azteca. The study clearly showed that classical targeted approaches would have missed a large part of the exposure. Stujdy results provide crucial information about chemicals that were the cause of observed toxicity to deployed H. azteca, which will represent a valuable resource for future watershed management toward the protection of the fragile delta ecosystem.

702 Suspect and Non-Target Screening of Organic Contaminants In Urban Aquatic Environments

B. Du, J. Lofton, J.E. Baker, Univ of Washington / Center for Urban Waters; E.P. Kolodziej, Univ of Washington Tacoma / Center for Urban Waters Interdisciplinary Arts and Sciences Civil and Environmental Engineering

For issues of both ecosystem and human health, identifying toxicants and other important bioactive molecules in high priority samples that include complex mixtures of many different contaminants is a challenging analytical task. Here, we present the use of high resolution quadrupole time of flight mass spectrometry (QTOF LC-MS/MS) to characterize the occurrence and fate of otherwise uncharacterized trace organic contaminants in aquatic environments. To better understand and prioritize the contaminates of potentially high ecological risk, we have analyzed paired water-tissue samples from fish experiencing acute mortality when exposed to stormwater runoff to investigate contaminant uptake and metabolic processes, while isolating a subset of high interest detections for targeted investigation. Sample collection and processing, data reduction, quality assurance-quality control, and data analysis workflows are described. Additionally, we will describe the use of QTOF LC-MS/MS to understand contaminant transformations screening HRMS fragment and mass defect data to identify transformation products, focusing on the fate of endogenous and xenobiotic compounds in the wastewater effluent. For example, we tentatively identified adrenosterone, a chlorination product of glucocorticoid compound, in the wastewater influent with reference standard and MS/MS library. However, possible existence of adrenosterone isomers presents additional challenges in determination of adrenosterone in the wastewater especially when properties of isomers are similar. Such investigations clearly point to the importance of combining chemical analysis with biologically based tools that allow for a comprehensive and holistic analysis of contaminant occurrence and fate in aquatic systems, with particular emphasis on identifying contaminants with bioactive and pharmacological properties from a complex mixture.

703 Targeted Discovery of Disinfection Byproducts in Swimming Pools and Spas

J.D. Byer, LECO Corporation; J.E. Binkley, LECO Corporation / Separation Science Applications; S.D. Richardson, Univ of South Carolina; L. Fell, LECO Corporation

Swimming pools are treated with disinfectants to protect swimmers from pathogens and prevent illness. The water used to fill a swimming pool if from a municipal drinking water supply, is also often treated with disinfectants such as chlorine. Disinfectants will react with naturally occurring organic matter in water and, in the case of swimming pools, they can also react with chemicals introduced to the water by the swimmers themselves to produce byproducts that can be potentially harmful. It is important to treat water while minimizing the risk of disinfection byproducts (DBPs). One of the first steps is to chemically characterize the DBPs in swimming pools and hot tubs, very complex matrices, using discovery techniques since a lot of the contaminants are unknowns. Comprehensive two-dimensional gas chromatography high resolution time-of-flight mass spectrometry (GC×GC-HRTOFMS), was used for the tentative identification of “known unknowns” and “unknown unknowns” in swimming pool and hot tub water. The “known unknowns” were identified by library database searching deconvoluted spectra using LECO’s ChromaTOF software. The “unknown unknowns” were tentatively identified using a combination of EI and CI accurate mass data for chemical formulae determination and structural elucidation by leveraging the accurate mass fragments.

Mixtures: Exposure and Toxicity from Combinations of Stressors

704 Juvenile mite sensitivity and fitness reduction of successive mite generation after exposure to metals

K. Jegede, Univ of Saskatchewan / Toxicology Centre; B.A. Hale, Univ of Guelph / School of Environmental Sciences; S. Siciliano, Univ of Saskatchewan / Toxicology Group and Dept of Soil Science

Metals like many other pollutants usually exist as mixtures in reality and toxicity data should be based on metal mixtures. Metals in mixtures could interact and the interactions could influence the end toxicity (synergism or antagonism) different from addition of individual toxicities (concentration addition). Metals persist in soil and thus, exposure to metals can have a multi-generational effect on soil organisms. This study assessed single metal and metal mixture toxicity of five metals on juvenile survival and fitness reduction in generations of two species of mites, Oppia nitens and Hypoaspis aculeifer. For the single metal tests, mites will be exposed to eleven concentrations of each metals in soil. For the mixture tests, mites will be exposed to the five metals in ten fixed-ratio rays and eight dose levels. The fixed ratio rays will be chosen based on contaminated site ratios and regulatory ratios. Juvenile survival will be assessed after relevant duration period for each species and its sensitivity will be compared to that of adult reproduction. Adult species will be exposed to single and metal mixtures and the control experiment will be adults not exposed to metal. The progeny from the experiment will be kept unexposed till the F3 generation. The F3 generation of the exposed and non-exposed mites will then be exposed to single and metal mixtures. The fitness will be assessed through differences in reproduction after metal stress as well as the performance of progeny in avoidance tests.

705 Predicting Sediment Chemical Mixture Toxicity from Marine Amphipod Mortality Data

S. Hsieh, S.P. Eckel, K. Siegmund, Univ of Southern California / Preventive Medicine; K.A. Maruya, SCCWRP; S.M. Bay, Southern California Coastal Water Research Project / Toxicology Dept; M.O. Gribble, Emory Univ / Environmental Health

Sediment quality objectives in California are informed by multiple lines of evidence, including toxicological experiments exposing amphipods to dredged sediments containing mixtures of chemicals that are partly described from targeted chemical analysis. No individual sediment characteristic has been found to be strongly predictive of amphipod mortality, raising the possibility that toxicity arises from the joint effects of the mixture. In this analysis, we establish that interactions among sediment components can explain sediment mixture toxicity, and explore whether any subset of mixture components is especially predictive. Sediment toxicity data were provided by the Southern California Coastal Water Research Project. Grab samples were taken at 1322 locations in California bays and estuaries between 1995 and 2003 as part of multiple regional monitoring and sediment characterization studies. Toxicity assays were conducted using the estuarine amphipod Eohaustorius estuarius. Chemicals were measured by AAS, ICP-MS, CVAFS, GC-FID, GC-ECD, and GC-MS, LC/MS or GC/MS as appropriate. Canonical correlation analysis (CCA), exploring which vector of chemical predictors is most correlated with amphipod mortality, and gradient boosted models (GBM), a tree-based approach for exploring whether nonlinear conditional relationships hold additional predictive value for mortality (dichotomized at ≥60% of amphipods dead) were used to evaluate the mixture of chemicals in relation to amphipod mortality. The most informative sediment components were total organic carbon, lead, iron, cadmium, zinc, and 4,4 DDD from GBM, and zinc, 2-methynaphthalene, and 4,4 DDD from CCA. The canonical variate for sediment chemical mixture explained 30% of the variation in toxicity. The bootstrapped area-under-the-curve was 0.65 (95% CI=0.61, 0.68), indicating that the GBM was an informative classifier. The GBM suggested that a tree depth of 4 splits provided optimal prediction of amphipod mortality, implying that higher-order interactions between mixtures of chemicals hold additional predictive value. The toxicity of sediment mixtures appears to be partly explained by interactions between mixture components.

706 Inverse U-shape and non-monotonic dose-response for the toxicity of Bt biopesticide to D. magna

A. de Souza Machado, Leibniz Inst of Freshwater Ecology and Inland Fisheries / Ecophysiology and Aquaculture; C. Zarfl, Univ of Tuebingen / Center for Applied Geosciences; S. Rehse, Leibniz-Inst of Freshwater Ecology and Inland Fisheries / Ecophysiology and Aquaculture; W. Kloas, Liebniz Inst of Freshwater Ecology & Inland Fish.

Bacillus thuringiensis (BT) pesticides, such as DiPel ES, are amongst the worldwide most used to control caterpillars. BT, an entomopathogenic bacteria that produces endotoxins, causes effects described as highly specific to target insects and therefore it is used worldwide without environmental limits. The exposure of high concentrations of components of this biopesticide to non-target organisms results generally in negligible effects. This study investigated the toxic responses of the non-target organism Daphnia magna to waterborne DiPel ES, as the mixture used in the application (BT, its endotoxins, its exotoxins, its spores, formulation products, fermentation products) and in environmentally relevant levels (24 concentrations from 0.0025µL/L to 500µL/L). Neonates were 48h-exposed to DiPel ES for LC50 and EC50 estimation. D. magna 17-21 days old were similarly exposed for EC50 and biomarkers. The biomarkers evaluated (whole body) were body weight, global protein, chitobiase, catalase, glutathione reductase, glutathione S-transferase, and acetylcholinesterase. Particle size distribution in the exposure media was further determined by light scattering analyses.Dipel affected immobilisation and mortality of neonates ($p>0.001$, EC50=from 0.17 to 0.20µL/L, LC50=0.40 to 1.17µL/L). This toxicity is ~100,000 higher than announced by manufacturer. Similar sensibility was found for immobilisation of adult daphnids (EC50= from 0.17 to 0.29µL/L), without significant mortality. Mortality and immobilization endpoints displayed a biphasic and inverse U-shaped response. This clearly not monotonic exposure challenges the central assumption of ecotoxicology, i.e. that toxicity only increases with increases in the concentration of contaminants. All biomarkers but acetylcholinesterase were affected by DiPel ES exposure ($p< 0.05$), displaying multiphasic dose-responses. This suggests a mechanism of toxicity able to affect generally organs and systems of the whole organism. The main particle size in experimental media was compatible to bacteria spores, however a secondary particle size compatible to metabolic active BT, was observed when highest toxicity was occurring. Therefore, it is possible that chemical and physiological interactions resultant of different behavior of BT and DiPel ES components at various concentrations might be related to the observed non-monotonic effects. Further studies are required to isolate the cause of non-monotonicity of this BT biopesticide.

707 Mesocosm assessment of the effects of an organic ultraviolet filter mixture and elevated seawater temperature on corals

T. He, City Univ of Hong Kong; T. Mei Po Mirabelle, City Univ of Hong Kong / Biology and Chemistry; A.B. Mayfield, L. Wang, National Museum of Marine Biology and Aquarium; T. Chen, National Museum of Marine Biology and Aquarium / Dept of Planning and Research; P. Liu, C. Tang, T. Fan, National Museum of Marine Biology and Aquarium; M.B. Murphy, City Univ of Hong Kong

Organic ultraviolet (UV) filters, active ingredients added to personal care products to protect skin from harmful effect caused by UV radiation, have been detected in surface waters at concentrations ranging from ng/L to µg/L levels. Previous studies reported that organic UV filters caused coral bleaching at low concentrations. Coral reefs are known to be one of the most biodiverse and important ecosystems on Earth, but reefs in many areas are facing multiple threats, including thermal stress due to global climate change. Despite the potential negative effects of organic UV filters on the health of corals, information is lacking about their toxicities. In addition, the simultaneous effects of organic UV filter exposure and thermal stress on corals also should be of concern. A 60-day mesocosm study was performed to test the effects of an organic UV filter mixture under general environmental concentrations and elevated temperature on coral nubbins [Seriatopora caliendrum (SC), Pocillopora damicornis (PD) and Montipora aequituberculata (MA)]. The mixture contained 200 ng/L benzophenone-3, benzophenone-4, benzophenone-1, benzophenone-8, octinoxate, amiloxate, enzacamene, avobenzene, ethylhexylsalicylate, homosalate, octocrylene, and octyl dimethyl-p-aminobenzoic acid. Treatments including (A) solvent control, (B) organic UV filters mixture alone, and (C) organic UV filters mixture + elevated temperature (30°C) were applied. Growth (n=4, Day 14, 30, 60), mortality, bleaching and polyp retraction (n=8, daily) were measured. Nubbins in treatment A appeared healthy throughout the exposure. Bleaching (37.5%) and death (12.5%) of SC in treatment B were observed. In treatment C, 100% bleaching and mortality of SC and 100% bleaching and 50% mortality of PD were found. Bleaching (50%) and thorough polyp retraction (100%) of MA nubbins in treatment C were also observed. Growth of SC in treatment B and of all three species in treatment C were significantly reduced. These results indicate that organic UV filters at environmental concentrations caused bleaching and death of vulnerable coral species, e.g. SC, while the combination of two conditions caused lethal effects to SC and PD. MA was found to be the most tolerant species under these conditions in our study. Future work will include measurements of gene expression [e.g. cytochrome P450, vitellogenin, superoxide dismutase (SOD)] and enzyme activities (e.g. SOD), and chemical analysis of tissue samples.

708 Variation in species sensitivity distribution obtained from ecotoxicity data of mixtures

W.D. Di Marzio, CONICET-PRIET; T. Di Lorenzo, CNR; M. Cifoni, D. Galassi, l aquila universita; M. Saenz, National Scientific and Technical Research Council Ecotoxicology Research Program, Dept of Basic Sciences, National Univ of Luján.

Species sensitivity distributions (SSDs) are increasingly used in ecological risk assessment procedures and formulation of water quality guidelines. The usefulness of SSD analyses is likely to depend, at least in part, upon the quality of input data. Inclusion of poor data will compound the problems of interpreting ‘natural’ variance, and will probably generate bad predictions. In this work we try to explain how ecotoxicity data obtained in mixtures studies could change de SSD curves for chemical assayed as alone. As first approach we run mixtures of Imazamox-Ammonium on groundwater copepods. SSDs for ammonium considering freshwater Cladocerans, Copepods and Amphipods, EC50 data from single assays and using EC50 data for ammonium in the mixtures were constructed. The binary mixture IMA- NH_4^+ was more toxic when compared their toxicities as single chemicals. The latter was true for both species studied. On the other hand the differences in sensitivity between species of copepod epigean and hypogean, views for ammonium studied separately virtually disappear when compared its LC50 values of both species in the mix. The mixture was found to be synergistic with regard to the action of toxic evaluated separately. Data for E. serrulatus fitted for IA reference modelshowing the lower sum of squared residuals (SS) with respect the deviation patterns. Considering the CA approach data for E. serrulatus not fitted according this, on the contrary a synergistic and dose ratio dependent deviation were evidenced. In this regard the isobologram presented shows a clear synergist effect as a function of dose ratio between ammonium and IMA. In the case of D. belgicus neither CA nor IA reference models fitted at lower SS values. On the contrary a significant synergistic effect was registered when data were subjects to CA model. For the analysis under IA model also was verified a dose ratio effect. SSD obtained without consider EC50 for NH_4^+ in the mixture for both species with IMA underestimate the fraction of potentially affected species.

709 Comparative short-term, chronic and mixture toxicity of chemicals in bee species: The role of toxicokinetic and toxicodynamic traits

D. Spurgeon, Centre for Ecology & Hydrology

The toxicity of a range of insecticides, other pesticides and contaminants have been assessed in chronic feeding tests with three bee species: Apis mellifera, Bombus terrestris audax and Osmia bicornis. Based on the data derived from these time series exposures, we were able to fit dynamic energy budget toxicity (DEBtox) models. These parameterisations allowed species variations for a range of key toxicokinetic and toxicodynamic parameters for each chemicals to be identified. From fitted models, we were also able to establish the full time course of expected effects on apical endpoints. This analysis allowed us to consider the consequences of life-time exposures for summer and overwintering (worker) bee populations. The magnitude of difference between toxicity statistics calculated from typical short-term bioassay results (e.g. 48 or 96 h feeding studies) and the likely actual sensitivity of life-time exposed populations could be generated for each of the three bee species. Analysis showed that short-term test data may sometime provide an assessment of toxicity that is between 3 and 25 fold lower than expected from life-time exposure. To extend our analysis beyond single chemicals, similar chronic feeding studies were conducted for a range of realistic chemical mixtures. Mixture toxicity modelling approaches, including concentration addition and independent action, and also the mechanistic DEBtox models were used to analyse the nature of joint effect in each species. A number of the tested mixtures showed non-interactive (additive) toxicity. However, examples of both potentiation and antagonism were found. The occurred mainly in cases where there was a clear mechanistic basis for the observed effect, such as detoxification system inhibition of substrate competition. Where synergism or antagonism was found, the magnitude of such effects were generally small. However, in each case they were repeated in each of the three study species provide weight of evidence support for the repeatability of these interactive effects. Overall our analyses suggests that both mixture models, and particularly mechanistic models, such as DEBtox, can be valuable tools for improving risk assessment realism particularly if uncertainties associated with interactive effects are included for priority cases.

710 Ecological Risks of Pharmaceuticals and Personal Care Products in Sediments of an Urban Waterway

D.G. Gunster, J. Nuwer, NewFields; T. Ambrose, NewFields Environmental / Sediment Management Marine Sciences; R. Gensemer, GEI Consultants / Ecological Division; A. Kovach, R. Holem, GEI Consultants

Sediment risk assessments typically evaluate chemicals that represent legacy sources of industrial activities (e.g., metals, pesticides, polychlorinated biphenyls). However, in urban waterways subject to runoff from stormwater and combined sewer overflows (CSOs), additional chemical and biological stressors may need to be considered to more fully evaluate all potential ecological risks in sediments. In this study, ecological risks associated with pharmaceuticals and personal care products (collectively referred to as PPCPs) were investigated in surface sediments of Newtown Creek, an intertidal waterway separating the boroughs of Queens and Brooklyn, New York. This area has an extensive history of industrial activity since the 1800s, and the creek currently receives significant freshwater input from several CSO discharges and stormwater. The objective of this study was to evaluate the quantitative risks from sediment PPCPs relative to the risks of other more typical contaminants of concern. Many of the PPCP analytes proved to be suitable tracers for sewage-related CSO input to sediments. Surface sediment PPCP concentrations correlate with those of a number of human pathogen indicators (bacteria) that are recognized tracers for human fecal pollution. Spatial patterns of PPCPs consistently indicated that CSO-derived sediments deposit not only in close proximity to the major CSOs where coarse-grained sediments are found, but also further downstream in regions characterized by finer-grained sediment. Ecological risks from PPCPs in Newtown Creek sediments are driven by endocrine-disrupting alkylphenols and estrogen hormones. Concentrations of these PPCPs in sediment pore water often exceed aquatic chronic toxicity thresholds by more than a factor of 5. Over-the-counter pharmaceuticals pose relatively little potential risk, rarely exceeding toxicity thresholds. The greatest risks from PPCPs are associated with sediments deposited in tributaries to the creek which receive discharge from the largest CSOs. Additionally, within these CSO tributaries the PPCPs pose unacceptable risk at levels similar to or exceeding those of “traditional” contaminants of concern like PCBs, PAHs, and metals.

711 Ecological Risk Assessment Crossroads between an NJDEP LSRP-led and EPA-Led Cleanup

S. Weatherwax, Langan Engineering & Environmental Services, Inc.; K. Czajkowski, Hudson Delaware Regional Chapter; S. Ueland, Langan Engineering & Environmental Services, Inc.

Langan was tasked with a implementing a multi-phased ecological risk assessment (ERA) investigation of a wetland and surface water drainage system associated with a former gas production facility located in northwestern New Jersey. Investigation activities were completed to characterize and evaluate the ecological risk associated with site-related contaminants of potential ecological concern (COPEC), including polychlorinated biphenyls (PCBs) and metals. Multiple lines of evidence were used to differentiate and understand the sources and risks of impacts to the wetland and surface water drainage system. During the investigation off-site contributions were identified from an adjacent Superfund. The Superfund site contributions changed a seemingly straight forward ERA into a complicated investigation of a mixture of impacts from the former gas production facility and the neighboring Superfund site. Additionally, a sense of urgency and potential complexity was added to this project as a result of a proposed county roadway development project within the vicinity of both sites. Using the established lines of evidence, Langan was able to identify and quantify the ecological risk associated with site-related sediment impacts and initiate development of a remedial approach to address site-related impacts.

Ecological Effect Models for Assessing the Risks of Pesticides: Ongoing Developments in the US and EU

712 How population models can help to assess the risks of pesticides to threatened and endangered species

V. Forbes, Univ of Minnesota / Ecology Evolution Behavior; N. Galic, Univ of Minnesota / School of Biological Sciences; A. Schmolke, Waterborne Environmental, Inc. / College of Biological Sciences; J. Vavra, UNL-Lincoln / School of Biological Sciences; R.A. Pastorok, Integral Consulting, Inc.; P. Thorbek, Syngenta / Environmetal Safety

This presentation will demonstrate why and how population models are needed to assess the risks of pesticides to species listed under the US Endangered Species Act (ESA). Despite a long history of population models used in conservation biology and resource management, application of population models for pesticide risk assessments under the ESA has been minimal. We conducted a literature review to explore the availability of appropriate population models and to quantify the extent to which they have been used in listed species risk assessments compared to other applications. In addition, we categorized the reviewed models in terms of their structure, taxonomic coverage, purpose, inputs and outputs, and whether they included density dependence, stochasticity, or risk estimates, or were spatially explicit. Our review covered 403 studies that used population models to inform species conservation and management, however only two of these published studies used population models to assess the risks of pesticides to listed species (both were models of salmon). We conclude that there is an untapped potential to adapt existing models for pesticide risk assessments under the ESA, but also that there are some challenges to do so for listed species. Species-specific life histories and ecology have an important influence on population risk resulting in no direct proportionality between organism- level toxic responses and their population-level impacts. We argue that species- or group-specific population models, in combination with toxicity data for non-listed species, provide an effective approach that can inform both screening-level and more species-specific assessments of risks to threatened or endangered populations and species.

713 Application of a population model for a threatened plant species in herbicide risk assessment

A. Schmolke, Waterborne Environmental, Inc. / College of Biological Sciences; R. Brain, Syngenta Crop Protection, Inc. / Dept of Environmental Risk Characterization; P. Thorbek, Syngenta / Environmetal Safety; D. Perkins, A. Ritter, D. Desmarteau, Waterborne Environmental, Inc.; V. Forbes, Univ of Minnesota / Ecology Evolution Behavior

Extrapolating from organism-level endpoints, as generated from standard pesticide toxicity tests, to populations is an important step in threatened and endangered species risk assessments. Population modeling approaches can be used as tools to estimate potential risk from pesticides to sensitive populations by integrating multiple sub-lethal and lethal effects simultaneously and by accounting for differences in species' life histories. We apply a population model for a threatened herbaceous plant species, Boltonia decurrens, to estimate the potential population-level impacts of different herbicides. We combine conservative in-habitat exposure scenarios with dose-response curves for growth and survival of standard test species, and apply those in the species-specific model. In the model, a yearly herbicide exposure from drift is linked to dose-response curves derived from vegetative vigor tests and affects established plants. Dose-response curves derived from seedling emergence tests are applied to model the effects of exposure from herbicides transported via runoff to emerging seedlings. Exposures are distributed across the simulated habitat applying the RegDISP model for spray drift, and a combination of the Pesticide Root Zone Model (PRZM) and the Vegetative Filter Strip Model (VFSMOD) for runoff. The distributed exposure modeling approach makes it possible to assess potential effects of herbicides on plant populations growing in habitats that border chemical use areas/fields and can be used to assess the effectiveness of mitigation measures such as in-field spray buffer zones. We show that responses of organism-level endpoints are not proportional to modeled population-level effects of pesticides. Specifically, comparison of dose-response curves from standard toxicity test species with the output of the population model demonstrates that the most sensitive organism-level endpoint is not predictive of population-level impacts. In addition, the model results suggest that in-field spray buffer zones can considerably reduce potential effects on populations of B. decurrens growing at the edge of a field. Our case study presents how species-specific population models can be applied in pesticide risk assessment bringing organism-level endpoints, exposure assumptions and species characteristics together in an ecologically relevant context.

714 Population-level risk assessment for an endangered butterfly species exposed to chlorpyrifos

K.V. Garber, USEPA / Office of Pesticide Programs Environmental Fate and Effects Division; N. Golden, US Fish & Wildlife Service / Ecological Services; S. Warner, US Fish and Wildlife Service / Environmental Contaminants Program

The United States Environmental Protection Agency, US Fish and Wildlife Service and National Marine Fisheries Service are currently working to develop methods for assessing population-level risks of pesticides to listed species. The draft biological evaluations, released in April 2016, are focused on three organophosphate insecticides, one of which is chlorpyrifos. As these pesticides kill a broad spectrum of insect pests, including several in the order Lepidoptera, there is particular concern for the 34 listed butterfly species. Many of these populations are experiencing significant declines due to dwindling habitat and other stressors. One such species, the Poweshiek skipperling (Oarisma poweshiek) is obligate to remnant prairies, which co-occur with major crops where chlorpyrifos is applied (e.g., corn, wheat, soybeans). This presentation considers methods to assess the percent of habitat and proportion of individuals of this species potentially exposed to chlorpyrifos over a 15 year period of use, and the magnitude of effects at predicted exposure concentrations. At the landscape scale relevant to this population, we examine how exposure may vary by comparing maximum allowable chlorpyrifos use with that predicted when considering factors such as annual variability in crop rotation through different years of land cover data from the US Department of Agriculture's cropland data layer, relevant application timing based on known pest pressure, and historical estimates of percent crop treated with chlorpyrifos in different regions. Contact exposures to larvae or adult butterflies and dietary exposure to larvae consuming grass or adults consuming nectar are considered the dominant routes of concern. Exposure is the result of spray drift transport from adjacent treated fields to prairie habitats inhabited by this listed species. Dose-response curves representing mortality for larvae and adult butterflies are used with spray drift deposition estimates to derive the magnitude of mortality in the exposed portion of the population. This presentation focuses on population-level methods for assessing direct effects of an insecticide, using chlorpyrifos and the Poweshiek Skipperling as an illustration. We will also discuss the applicability of these approaches to Lepidopteran species in general, based on our knowledge of the current status of these listed species and considering species that may be experiencing severe decline.

715 An aquatic food web and ecosystem model for estimating direct and indirect effects of pesticides

S.M. Bartell, Cardno Entrix; S. Nair, Idaho National Eng Environ Laboratory; R. Brain, Syngenta Crop Protection, Inc. / Dept of Environmental Risk Characterization

The Comprehensive Aquatic Systems Model (CASM) has been adapted to three models that estimate the direct and indirect toxic effects of pesticides on populations of aquatic plants and consumer organisms representative of Midwestern US lower-order streams, farm ponds, and emergent wetlands. The CASM computes the daily biomass of modeled populations for baseline (no pesticides) conditions and for exposure scenarios defined by daily concentrations of pesticide for 365 days. Baseline population dynamics reflect daily changes in environmental conditions characteristic of the modeled aquatic systems. The CASM provides alternative formulations (e.g., probit, triangular, piece-wise linear) of population-specific exposure-response functions that alter baseline bioenergetics-based growth and mortality parameters as a function of dissolved or bioaccumulated pesticide concentration for each day of exposure. The CASM estimates population, community, and ecosystem-level effects of pesticide exposure based on time-integrated differences between baseline and exposure scenario simulations. The CASM provides a capability to examine the lethal and sublethal, direct and indirect effects (e.g., alterations in within-guild competition, trophic cascades, and nutrient cycling) of time-varying pesticide exposures. The CASM has been developed within a Monte Carlo framework to permit probabilistic risk estimation and to facilitate model sensitivity and uncertainty analysis. The presentation describes the overall modeling approach and presents results for selected pesticides and exposure scenarios in the Midwestern US.

716 An ecotoxicological module for BEEHAVE to link standard laboratory tests to honeybee colony dynamics

P. Thorbek, Syngenta / Environmetal Safety; T. Preuss, Bayer CropScience / Environmental Modelling

The honeybee colony model BEEHAVE was developed by Becher et al. (2014) to assess the effects and interactions of multiple stressors on honeybee colony dynamics, e.g. varroa mites and the viruses they vector, forage shortage and potentially pesticides. Since then it has been evaluated by the European Food Safety Agency (EFSA) who concluded that it could form a sound basis for both setting of protection goals and, with further development, for risk assessment for honeybees. However, EFSA highlighted the absence of a specific ecotox (pesticide) module as a shortcoming. Here we present an ecotox module for BEEHAVE that can use the results from standard tests (e.g. honeybee acute oral, honeybee larval toxicity test) as inputs and predict impacts and, if any, time to recovery for the colony. Small modifications were made to BEEHAVE to allow for co-occurrence of varroa mites and pesticides, the use of dose-response relationships to predict initial effects, exposure via different routes and of different life stages. The BEEHAVE ecotox module will be validated against the results of tunnel (semi-field) studies to assess its ability to predict the initial effects that were observed in the studies.

717 Why Point Estimates of Mortality May Result in Inaccurate Population Modeling and Pesticide Risk Assessment

J.D. Stark, Washington State Univ / Dept of Entomology; W.G. Landis, Western Washington Univ / Inst of Environmental Toxicology; K. von Stackelberg, NEK Associates LTD / Dept of Environmental Health

Historically, point estimates such as the median lethal concentration (LC50) have been instrumental in assessing risks associated with toxicants to rare or economically important species. In recent years, growing awareness of the shortcomings of this approach has led to an increased focus on analyses using population endpoints and modeling. However, risk assessment of pesticides still relies heavily on point estimates of effect, especially the LC/LD50. However, the LC50 is an estimate, not an absolute number and it has an associated probability and therefore lies within a 95% confidence limit. In this presentation, we will show several examples of matrix population models that have been adjusted with only the LC50 and with the tails of the 95% CL. The results show that population-level outcomes can vary greatly when the tails of the 95%CL are considered ranging from extinction to full recovery. The implications of these results and the need to incorporate variability and uncertainty in point estimates for use in risk assessment will be discussed.

718 Quantifying uncertainty in toxicokinetic-toxicodynamic model predictions

R. Ashauer, Univ of York / Environment; N. Cedergreen, Univ of Copenhagen / Plant and Environmental Sciences; V. Ducrot, Bayer CropScience AG / Environmental Safety Ecotoxicology; F. Gabsi, Rifcon GmbH; T. Jager, DEBtox Research / Dept of Theoretical Biology; N. Kramer, Utrecht Univ / Inst for Risk Assessment Sciences; S. Reichenberger, DR. KNOELL CONSULT GmbH / FOOTWAYS SAS; R. Schaefer, Univ Koblenz Landau / Inst for Environmental Sciences; A. Focks, Alterra Wageningen Univ and Research Centre / Environmental Risk Assessment Team

Toxicokinetic-toxicodynamic (TK/TD) models quantify the expected chemically-induced mortality from any time-variable, environmentally relevant exposure profile, leading to more realistic predictions of individual and population level effects on sensitive species. The flexibility of TK/TD models enables their use for different extrapolation purposes of relevance in risk assessment, for example the evaluation of potential toxic effects from the modelled or measured exposure time series surface water bodies. TK/TD models allow directly relating exposure patterns to expected effects, thereby increasing accuracy and decreasing method-associated uncertainty of risk estimates. In addition, TKTD model predictions provide a means for quantifying uncertainty that is associated to biological variability as captured in the TK/TD model parameters. This study shows how information collected during model parameter estimation can be used to analyse uncertainty of model predictions in a probabilistic way. Model parameters were estimated from observed survival data for a set of four pesticides (carbendazim, cypermethrin, dimethoateand malathion), by maximizing the likelihood estimation. To approximate the joint confidence regions of all parameters, those parameter sets from the optimisation procedure that were not rejected in a likelihood ratio test were selected and subsequently used to generate forward predictions. The minimum and maximum of all predictions at each time point can be interpreted as a 95% uncertainty interval on the model predictions (reflecting parameter uncertainty). Model results for the four selected pesticides indicate that the sample size, the quality of data used for model calibration and the properties of the chemical-species interactions (e.g., the speed of the toxicokinetic and toxicodynamic recovery processes) have a direct impact on the parameter estimates, in particular uncertainties, and hence on the precision of model predictions as reflected by the size of the uncertainty bands of survival dynamics plots of and dose-response curves. Deterministic model predictions using best-fit parameters are in this way augmented with information about uncertainty of model predictions. This supports the evaluation of such model predictions for consideration in the regulatory environmental risk assessment of chemicals.

719 Optimizing experimental designs for calibration of TK-TD models

S. Charles, Univ Lyon 1 / Laboratory of Biometry and Evolutionnary Biology; C. Albert, Eawag Swiss Federal Inst of Aquatic Science and Technology; B. Goussen, Univ of York / Environment Dept; T. Jager, DEBtox Research / Dept of Theoretical Biology; S. Vogel, Eawag Swiss Federal Inst of Aquatic Science and Technology; R. Ashauer, Univ of York / Environment

The General Unified Threshold model of Survival (GUTS) provides a theoretical framework for analyzing stressor effects on survival over time through consistent model equations based on different assumptions about the stressor quantification, the compensatory processes and the nature of the death process. In ecotoxicology, stressors are toxicants characterized by a dose metric, e.g. the concentration in the medium surrounding an organism or inside the organism, or by the damage quantity they cause. The key GUTS feature is that mortality is estimated when the dose metric exceeds a certain threshold. Several GUTS flavors can be derived according to the assumption underlying the death process: (i) the threshold is distributed within a population, and when exceeded, the individual dies (individual tolerance, IT); (ii) there is one common threshold for all individuals, and when exceeded, the probability to die increases (stochastic death, SD); (iii) a unification of both previous assumptions (GUTS proper). While more realistic, GUTS proper requires the estimation of one additional parameter. Because environmental risk assessment of chemicals depends on robust estimates of GUTS parameters, we investigated parameter identification for GUTS proper, in relation to the experimental design of 'short-term' laboratory bioassays. In practice, standard survival datasets generally do not contain enough information to estimate all parameters of GUTS proper with sufficient precision. This is because a large number of individuals is required to provide strong information on probabilistic events. Hence, based on simulated datasets we identify appropriate experimental designs suitable to estimate all parameters of GUTS proper with the best possible precision. We show that datasets with a high number of animals per treatment allow for parameter estimation of GUTS proper with reasonable accuracy and precision. Moreover, increasing the number of animals or the duration of the experiment substantially reduce the uncertainty around the median value of the threshold. Nevertheless, general statements about optimisation for any chemical, any species, any test duration and/or any exposure concentration profile remain difficult. As take-home message, to the extent possible, we recommend not to use fixed experimental set-up for GUTS analyses, but rather tailor dedicated designs according to the chemical, the species and/or the research/regulatory question at hand.

Recovery of Pelagic Fishery Populations Following Oil Exposures

720 Assessing impacts of crude oil exposure across multiple levels of biological organization in a pelagic marine teleost, the mahi-mahi

M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology; G. Xu, Univ of California Riverside; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences; G. Galli, H. Shiels, Univ of Manchester; L. Fieber, RSMAS Univ of Miami; R.M. Heuer, D. Nelson, Univ of North Texas; D. Crossley, Univ of North Texas / Dept of Biology; C. Pasparakis, Univ of Miami; Y. Wang, L. Schlenker, RSMAS Univ of Miami; P. Perrichon, Univ of North Texas

The Deepwater Horizon oil spill in 2010, the largest marine oil spill in US history, resulted in exposure of early life stages (ELS) from spawning pelagic fish species including mahi-mahi (Coryphaena hippurus) over a period of several months. Observations of impaired swimming performance in young adult mahi following only 24 hours of exposure to water accommodated fractions (WAF) of surface slick oil obtained from the Gulf of Mexico during the spill (< 10 µg ∑PAH/l) was paralleled by reduced maximal metabolic rate (MMR), suggesting impaired cardiac function in WAF exposed fish. Subsequent studies demonstrated reduced in situ cardiac output in WAF exposed adult as well as larval mahi-mahi, an effect driven mainly by reductions in stroke volume rather than heart rate. The reduced cardiac output probably explains observations of reduced MMR and swim performance. Isolated cardiomyocytes, when exposed acutely to WAF, show reduced sarcomere shortening and reduced maximal current through L-type Ca^{2+} channels. Furthermore, WAF exposure results in alterations of action potential duration in myocytes, likely explained by observed alterations in inward rectifier and delayed rectifier K^+ currents. The observations of reduced sarcomere shortening and altered ion currents through Ca^{2+} and K^+ channels likely explains, in part, observations of reduced cardiac output. RNAseq experiments on WAF exposed larval mahi displayed altered expression of a number of genes involved in cardiac muscle and Ca^{2+} homeostasis following 24-96 hours of exposure, confirming cardiotoxicity also at the molecular level. Ongoing satellite tagging efforts of adult mahi-mahi aim to test the impacts of WAF exposure on fish in the wild. The expectation is that altered ion currents in isolated myocytes, which leads to reduced contractility and thereby cardiac output and swim performance will result in reduced overall performance expressed as growth, reproduction and survival rates of mahi-mahi in the wild. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Data are publicly available through the Gulf of Mexico Research Initiative Information & Data Cooperative (GRIIDC) at https://data.gulfresearchinitiative.org.

721 Eco-physiological implications of acute embryonic and juvenile oil exposure in marine fish

A. Esbaugh, Univ of Texas Marine Science Inst / Dept of Marine Science

Oil exposure has a well catalogued suite of effects on early life stage fishes. These effects are largely caused by the polycyclic aromatic hydrocarbon (PAH) compounds within oil, and include pericardial edema, craniofacial deformities, spinal curvature and mortality. Pericardial edema has been repeatedly demonstrated as the most sensitive measure of PAH exposure in fishes, and ostensibly leads to reduction in cardiorespiratory performance. Similar inhibition is also thought to occur in older life stages by interfering with cardiac excitation-contraction pathways. Cardiorespiratory performance governs the ability of vertebrates to transport oxygen from the environment to the tissues; a process even more limiting in aquatic organisms due to the proportionally low amount of oxygen in water. As such, a comprised cardiorespiratory system can result in a suite of sub-lethal eco-physiological complications for fishes. Here we will discuss the impacts of environmentally relevant (≤ 40 µg l^{-1} $SPAH_{50}$) sub-lethal oil exposure, both embryonic and juvenile life stage exposure, on a variety of ecologically relevant performance measures on a fast growing marine species, the red drum. This will include direct measures of ecological performance such as swimming and aerobic scope, as well as predator-prey and routine foraging dynamics. We will also examine additional measures of ecological performance that manifest through competitive scenarios, including direct dyadic social interactions, group social behavior, individual behavioral syndromes and long-term growth and survival. This research was made possible by a grant from The Gulf of Mexico Research Initiative. Data are publicly available through the Gulf of Mexico Research Initiative Information & Data Cooperative (GRIIDC) at https://data.gulfresearchinitiative.org.

722 Shaken, stirred, neat, or on the rocks: crude oil developmental cardiotoxicity in fish is independent of exposure regimen

J. Incardona, NOAA Fisheries / Env Fisheries Division; M.L. Gielazyn, NOAA / co USEPA Region IV; J.M. Morris, Abt Associates; T. Linbo, R. Edmunds, NOAA Fisheries; J.S. Labenia, NOAA Fisheries / Northwest Fisheries Science Center; B. French, T. Gill, NOAA Fisheries; L. Hernandez, NOAA; T. Linbo, Univ of Washington; C. Brown, Louisiana State Univ; R. Takeshita, Abt Associates; M. Krasnec, Stratus Consulting Inc./ Abt Associates; M. Carney, Stratus Consulting – Abt Associates; C.R. Lay, Abt Associates; H. Forth; N. Scholz, NOAA Fisheries

Most laboratory studies on the developmental toxicity of crude oil to fish have been based on scenarios derived from the 1989 Exxon Valdez oil spill. That spill produced a large surface slick that was subjected to high wave energy from storms, followed by the shoreline deposition of mousse on cobble beaches. Methods developed to mimic these habitat conditions included, respectively, high-energy dispersion of oil droplets into seawater with a specialized apparatus (paint stirrer/fan motor) and the now well-known oiled-gravel generator column. Several groups have criticized these exposure methods as too variable or too difficult to control, and advocated instead for standardized methods that avoid mechanical dispersion of droplets into the water column (e.g., the CROSERF method). The subsequent 2010 Deepwater Horizon incident was characterized by the mechanical and chemical dispersion of oil into small droplets under high pressure at the sea floor. In addition, highly weathered material became stranded in nearshore bays and marshes characterized by low surface wave energy. To address the former conditions, we previously developed a simple, easily standardized and reproducible method to mechanically disperse crude oils into seawater using a commercial blender, generating high-energy water accommodated fractions (HEWAFs). Using red drum (Sciaenops ocellatus), a nearshore species of the Gulf of Mexico that produces pelagic embryos and yolk sac larvae, we compared the HEWAF method to low-energy WAFs prepared by the CROSERF method. Using a variety of functional and morphological endpoints for developmental cardiotoxicity, we show the impacts of oil exposure are practically identical for both high- and low-energy methods. In comparison to other Gulf species (e.g., tunas, mahi), red drum embryos are intermediate in sensitivity, showing both relatively severe impacts on heart function and development, as well as secondary abnormal morphology phenotypes. In conjunction with data obtained from other marine and freshwater fish species, and other geologically distinct crude oils, we demonstrate that teleost embryos display a highly consistent and conserved cardiotoxic response to crude oil, irrespective of how it enters the aquatic environment.

723 Fleshing out crude oil cardiotoxicity adverse outcome pathways with transcriptomics in Atlantic haddock embryos

E. Sorhus, Inst of Marine Research / Reproduction and Developmental Biology; J. Incardona, NOAA Fisheries / Env Fisheries Division; . Karlsen, Inst of Marine Research; T. Linbo, NOAA Fisheries; L. SÃrensen, Inst of Marine Research; T. Nordtug, SINTEF Materials and Chemistry / Environmental Technology; T. van der Meeren, A. Thorsen, Inst of Marine Research; S. Jentoft, Univ of Oslo; R. Edvardsen, Inst of Marine Research; S. Meier, Environmental Chemistry

A major movement to improve risk assessments includes the development and use of adverse outcome pathways (AOPs). AOPs are derived from detailed toxicological cause and effect relationships that span multiple levels of biological organization, ideally from molecular initiating events to ecosystem scale responses. For more than a decade, zebrafish have been the primary experimental platform for mechanistic work on crude oil developmental toxicity in fish. While the zebrafish model has provided the initial cardiotoxicity AOP framework, it is a tropical freshwater species, while the worldÌ_s most valuable fisheries generally spawn in marine and estuarine habitats. Therefore, cross-species extrapolations remain a source of uncertainty for ecological risk assessments. Atlantic haddock (Melanogrammus aeglefinus) provides a number of pertinent features that make it an ideal subject for fully developing crude oil AOPs for marine fish with pelagic early life history stages, including large translucent embryos that provide sufficient mass for chemical analyses, a developmental rate that allows greater resolution between time points, and a sequenced genome. Atlantic haddock thus makes an excellent bridge between zebrafish and other non-model fish with less readily available embryos. The pelagic embryos and larvae of haddock were exposed to Norwegian Sea crude oil using a sophisticated continuous flow system providing controlled delivery of mechanically dispersed oil microdroplets and corresponding water accommodated fraction. We characterized visible cardiac function and morphological phenotypes and obtained corresponding RNASeq data from 6 developmental stages from embryonic exposures, and 5 stages during larval exposure. Cardiac function defects were dose-dependent and included bradycardia and ventricular asystole in embryos and atrioventricular conduction block in larvae. Embryos displayed dose-dependent failure of cardiac looping and reduced ventricular outgrowth. Gene expression data identified changes in key genes encoding specific components regulating cardiac action potentials and excitation-contraction coupling, and identified a clear cause-effect chain linking disruption of intracellular calcium handling to signaling molecules and transcription factors regulating cardiac morphogenesis. These findings thus provide major advances in delineating key molecular events in the developmental cardiotoxicity AOP from crude oil exposure.

724 Time- and oil-dependent genomic and physiological responses to Deepwater Horizon oil in mahi-mahi (Coryphaena hippurus) embryos

G. Xu, UC Riverside / Dept of Environmental Sciences; E. Mager, Univ of North Texas / Dept of Biological Sciences; M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology; C. Pasparakis, L. Schlenker, Univ of Miami; J. Stieglitz, Univ of Miami – RSMAS / Division of Marine Biology and Fisheries; D.D. Benetti, Univ of Miami / Dept of Marine Ecosystems and Society; E.S. Hazard, S. Courtney, Medical Univ of South Carolina; G. Diamante, Univ of California, Riverside / Environmental Toxicology; J.S. Freitas, UNESP / IBILCE / Sao Jose do Rio Preto / Dept of Environmental Chemistry; G. Hardiman, Medical Univ of South Carolina; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences

The Deepwater Horizon (DWH) oil spill contaminated the spawning habitats for numerous commercially and ecologically important fishes. Exposure to the water accommodated fraction (WAF) of oil from the spill has been shown to cause cardiac toxicity during early developmental stages across fishes. To better understand the molecular initiation events and explore new pathways responsible for toxicity, RNA sequencing was performed in conjunction with physiological and morphological assessments to analyze the time-course (24, 48 and 96 hour post fertilization (hpf)) of transcriptional and developmental responses in embryos/larvae of mahi-mahi exposed to WAF of weathered (slick) and source DWH oils. Slick oil exposure induced more pronounced changes in gene expression over time than did source oil exposure. Predominant transcriptomic responses included alteration of EIF2 signaling, steroid biosynthesis, ribosome biogenesis and activation of the cytochrome P450 pathway. At 96 hpf, slick oil exposure resulted in significant perturbations in in eye development and peripheral nervous system, suggesting novel targets in addition to the heart may be involved in the developmental toxicity of DHW oil. Comparisons of changes of cardiac genes with phenotypic responses were consistent with reduced heart rate and increased pericardial edema in larvae exposed to slick oil but not source oil.

725 The effects of photoproducts generated from irradiated crude oil exposures on pelagic and estuarine fish species

L.E. Sweet, Univ of North Texas / Biological Sciences; E. Barnes, Univ of North Texas; J.T. Magnuson, Univ of North Texas / Biology; C. Pasparakis, Rosenstiel School of Marine Sciences / Marine Biology and Fisheries; P. Perrichon, Univ of North Texas; J. Stieglitz, Univ of Miami – RSMAS / Division of Marine Biology and Fisheries; J. Strzelecki, CSIRO Oceans and Atmosphere; D.D. Benetti, Univ of Miami / Dept of Marine Ecosystems and Society; A. Esbaugh, Univ of Texas Marine Science Inst / Dept of Marine Science; M. Grosell, Univ of Miami / Deaprtment of Marine Biology and Ecology; S.E. Hook, CSIRO Centre for Environmental Contaminants Resear / Oceans and Atmosphere; K.A. Maruya, SCCWRP; J.M. Morris, Abt Associates; A. Revill, CSIRO Oceans and Atmosphere; D. Schlenk, Univ of California-Riverside / Dept of Environmental Sciences; A.P. Roberts, Univ of North Texas / Dept of Biological Sciences Inst of Applied Science

Photo-induced toxicity occurs when ultraviolet (UV) radiation excites photoactive polycyclic aromatic hydrocarbons (PAHs) to produce reactive oxygen species (ROS) and modified PAH photoproducts, resulting in increased mortality. Several studies following the Deepwater Horizon (DWH) oil spill have shown that co-exposure of UV radiation and crude oil to aquatic organisms significantly enhances toxicity. However, the effects of photoproducts generated during a crude oil spill have not been studied on pelagic or estuarine fish species. In this study, high energy water accommodated fractions (HEWAFs) of Australian Northwest Shelf (NWS), DWH oil from the surface (OFS), and DWH source oil b (SOB) were diluted and irradiated by ambient UV sunlight for 4-6 h to generate modified PAH photo-products. Two pelagic species, mahi mahi (Coryphaena hippurus) and yellowtail kingfish (Seriola lalandi), and two estuarine species, black bream (Acanthopagrus butcheri) and red drum (Sciaenops ocellatus) were exposed to dilutions of the irradiated HEWAFs. The effects on survival and cardiotoxicity were quantified in all fish species. Preliminary chemical analysis of the irradiated HEWAFs indicated that the UV radiation generated modified PAH photoproducts that were associated with cardiotoxicity in these studies. Further, the irradiated HEWAFs enhanced toxicity as high as six fold in the black bream and mahi mahi, compared to the non-irradiated counterpart. This research provides evidence that photoproduct formation during UV exposure contributes to the photo-enhanced toxicity of crude oil to pelagic and estuarine fish species. This research was made possible in part by a grant from The Gulf of Mexico Research Initiative, and in part by CSIRO Oceans and Atmosphere. Data are publicly available through the Gulf of Mexico Research Initiative Information & Data Cooperative (GRIIDC) at https://data.gulfresearchinitiative.org.

726 Phototoxic Target Lipid Model (PTLM) of Single PAHs and Mixtures

D.M. Di Toro, S. Marzooghi, Univ of Delaware / Civil and Environmental Engineering; B. Finch, B.A. Stubblefield, Oregon State Univ / Environmental and Molecular Toxicology; O. Dmytrenko, S.L. Neal, Univ of Delaware / Dept of Chemistry and Biochemistry

A model of PAH acute phototoxicity (PTLM) will be presented that is based on the target lipid model (TLM) of PAHs and other narcotic chemicals. It can predict either the LC50 concentration measured at a fixed duration of irradiance exposure, or the LT50, the time required to achieve 50% mortality at a fixed concentration. The inputs to the model are the molar adsorption spectra of the PAH of concern, the spectra of the light irradiance, and the duration of exposure to light. These are used to compute the energy absorbed by the PAH, P_{abs}, with units moles of photons absorbed per mole of PAH. The only species dependent parameter in the model is the critical target lipid body burden (CTLBB), which is obtained from the TLM. It is the organism lipid normalized body burden that produces 50% mortality. They apply to any narcotic chemical and are currently available for 47 aquatic animals and five algal species. The model has two parameters that are fit by calibration to a data set compiled from the literature comprising 20 individual PAHs and 15 test species. They are (1) the ratio of organism critical body burden for reactive phototoxic species, formed by the energy absorbed by the organism's PAH body burden, to the CTLBB; and (2) an exponent, a, that quantifies the nonlinear response of mortality to energy absorbed $(P_{abs})^a$. The model is validated by application to 12 alkylated PAHs and other phototoxic chemicals in oil. It is applied to mixtures of PAHs by assuming additivity of the toxic units computed for each of the PAHs in the mixture. The results of the calibration, its application to mixtures of PAHs, and to water accommodated fractions from various neat and weathered petroleum samples, will be presented.

727 DWH Oil Spill: Field evaluation of biological responses in Gulf sturgeon and laboratory exposure of shovelnose sturgeon to artificially-weathered oil

D.E. Tillitt, USGS / Columbia Environmental Research Center; J.A. Jenkins, USGS / National Wetlands Research Center; S. Hartley, USGS / Wetland and Aquatic Research Center; H.M. Olivier, USGS / National Wetlands Research Center; R. Draugelis-Dale, USGS / Wetland and Aquatic Research Center; D.A. Alvarez, USGS-CERC / Physiology and Biochemistry; R.W. Gale, USGS / Columbia Environmental Research Center; C. Lavelle, Univ of Florida / Physiological Sciences; A.C. Mehinto, Southern California Coastal Water Research Project / Dept of Toxicology; N.D. Denslow, Univ of Florida / Physiological Sciences

The Deepwater Horizon (DWH) oil spill began in April 2010 and ultimately released 3.19 million barrels of oil into the Gulf of Mexico (Gulf). Natural resources impacted by this disaster included numerous species of fish and wildlife of economic and ecological value, including the threatened Gulf sturgeon (Acipenser oxyrinchus desotoi). Gulf sturgeon are anadromous and were in freshwater tributaries spawning while the spill occurred and they returned to the Gulf in the fall. The objective of our study was to evaluate the potential influence of oil exposure on the health of Gulf sturgeon from all northern Gulf populations. Over 500 Gulf sturgeon were geospatially tracked by acoustic telemetry to evaluate extent and duration of oil exposure. Molecular and physiological indicators of fish health including whole blood DNA fragmentation, DNA repair protein, cell cycle, histochemistry, and gene expression profiles were evaluated in Gulf sturgeon from three genotypic populations. Additionally, shovelnose sturgeon (Scaphirhynchus platorynchus), were exposed to artificially weathered DWH oil through a high energy water accommodated fraction (HEWAF) at an ecologically-relevant concentration of 0.005 – 0.020% for 30d. Organ weights and hepatic CYP1A induction were measured in lab exposed sturgeon in addition to the blood-based health indicators. Gene expression profiles indicated alterations in pathways associated with immune system function, blood flow, neutrophil processes, T and B cell processes, wound healing, and DNA replication in lab exposed sturgeon, consistent with organ changes in the spleen, liver, and CYP1A induction. Whole blood DNA fragmentation and repair in Gulf sturgeon populations were not different prior to entry into the Gulf in 2010, consistent with predicted exposure to DWH oil when returning to freshwater tributaries, and exhibiting more DNA repair capability in the second year. Pathway analysis of gene expression in Gulf sturgeon indicated alterations in immune processes as well as DNA repair. Indications of oil-induced stress were evident in both the laboratory-exposed shovelnose sturgeon and field populations of Gulf sturgeon.

Alternative Approaches to Complex Environmental Challenges – Part 2

728 Integrated Management of Water Resources using Fractal Analysis

S. Mohapatra, IIT Bombay / CESE

Kumbhmela, the most popular festival in India where Hindu devotees take the bath in the waters of Sangam, the confluence of the holy rivers Ganges, Yamuna and (mythical) Saraswati, is famous worldwide for its sacredness. During such festival, a lot of devotees across the world take the holy dip in the water leading to serious water pollution decreasing aesthetic value of rivers. An attempt has been made in order to determine the spatial distribution of river water quality parameters and to identify places with the best quality for the different purpose within the study area based on (1) use of Geographical Information System and (2) Water Quality Index (WQI) calculation, and (3) fractal analysis. Using GIS contouring methods with ArcGIS 10.0, spatial distribution maps of pH, turbidity, TDS, BOD, DO and total coliform were analysed. The spatial distribution map shows that a majority of the river water samples falls in the very poor category. WQI was used to assess the suitability of river water from the study area for human consumption. From the WQI assessment, over 90% of the water samples fall within the ''Poor'' and ''Very poor'' categories, suggesting that river water from these unsuitable for drinking purposes. Whereas fractal analysis was applied by using year-long water quality data to predict the water quality data for subsequent festive years. A correlation was drawn with the number of people attending such events with that of the water quality. This tool can be applied to any river for the prediction of water quality across the globe during festive seasons when river water is being widely exploited.

729 FAA's Environmental Toxicology and Emissions Assessment of Alternative Piston Aviation Fuels

G.M. Huddleston, SynTerra Corporation; S. Gollamudi, A. Aceti, Crown Consulting, Inc. / Propulsion and Fuels Section; H. Schlickenmaier, Crown Consulting, Inc.; S. Eser, Penn State Univ / Earth and Mineral Sciences Energy Inst; M. Rodgers, C. Huang, Federal Aviation Administration / Propulsion and Fuels Section

The Federal Aviation Administration (FAA) shares the Environmental Protection Agency's (EPA) concerns about lead emissions from small aircraft. Owners and operators of more than 200,000 piston-engine aircraft operating in the United States rely on leaded aviation gasoline (avgas) to power their aircraft. Because of lead toxicity and environmental persistence, the FAA and EPA and industry are partnering to remove lead from avgas. Avgas emissions have become the largest contributor to the relatively low levels of lead emissions produced in the U.S. As a result, the Piston Aviation Fuel Initiative (PAFI) was established at the request of a broad cross section of the aviation and petroleum industries and consumer representatives to develop a path forward for the identification, evaluation and deployment of the most promising unleaded replacements for avgas. The mission of PAFI is to evaluate candidate unleaded replacement fuels and identify those fuels best able to technically satisfy the needs of the existing aircraft fleet while also considering the production, distribution, cost, availability, environmental and health impacts of those fuels. The FAA selected four unleaded fuels to undergo Phase I testing at the agency's William J. Hughes Technical Center. Phase I included environmental toxicology, emissions, engine and rig performance, and materials compatibility. This presentation focuses on the assessment framework for environmental toxicology and engine exhaust emissions. A risk-based approach was followed based largely on published toxicological data and physical/chemical properties of fuel components, comparing potential human health and ecological risks of the unleaded fuels to those of avgas. Engine exhaust emissions tests included analysis of total hydrocarbons, carbon monoxide, carbon dioxide, nitrogen oxides (NO, NO_2, and NO_x), methane, sulfur dioxide, acetaldehyde, formaldehyde, and particulate matter. Based on Phase I test results, two fuels were down selected to enter more comprehensive Phase II testing, with the eventual replacement of leaded avgas in 2018.

730 Sediment homogenization and aging alters the toxicity of metal-amended sediments

D. Costello, Kent State Univ / Biological Sciences; C.E. Schlekat, E.R. Garman, NiPERA; C.R. Hammerschmidt, Wright State Univ / Dept of Earth Environmental Sciences; A. Burton, Univ of Michigan / School of Natural Resources Environment

Metal-amended sediment is commonly used in laboratory studies to establish and verify sediment quality guidelines; however, the similarity between lab-prepared sediment and naturally contaminated sediment may be limited by experimental conditions (e.g., water renewal, pH buffering, equilibration time). A series of laboratory experiments explored how the existence of vertical heterogeneity in redox (i.e., oxic surface sediment overlying anoxic sediment) could modify sediment toxicity to Hyalella azteca. Geochemically distinct sediments were amended with Ni, Cu, and Zn in separate experiments, and toxicity thresholds were calculated using standard 28-day H. azteca bioassays. Metal amended sediment was then added to a flow-through flume to age for >100 days. During aging of the Cu and Ni amended sediments, caged H. azteca were placed on the sediment surface to monitor toxicity (7-day growth). During aging, metal concentrations were stable, but aged sediment was less toxic to H. azteca than freshly amended sediment. Spatially resolved sediment geochemistry revealed that the change in toxicity during aging was related to changes in metal speciation during the oxidation of surface sediment. Aged sediment was removed from the flume, homogenized, and placed in beakers for standard 28-d H. azteca bioassays. Surprisingly, the toxicity of aged sediment was more similar to results observed during initial beaker tests when compared to toxicity of intact aged sediment. Most notably, one sediment from each of the Cu and Ni tests elicited no toxicity at all concentrations tested following >100 days of aging flume, but when homogenized and placed in beakers the toxicity returned. Homogenization of sediments prior to 28-d bioassays likely eliminated redox and associated geochemical gradients in surface sediments that developed during aging, thus counteracting any effects of aging observed in mesocosm experiments with intact sediments. This study demonstrates the importance of properly designed sediment preparation methods for accurate concentration–response thresholds, but aging prior to standard 28-d bioassays does not seem to alter sediment toxicity when homogenization is required. However, we advocate more study of intact sediment cores to elucidate how homogenization of sediments prior to testing may modify metal geochemistry and toxicity to epibenthic invertebrates.

731 Extending a Toxic-Unit Model from Insect Prey to Bats: Pitfalls and Potential

L. Heiker, R.A. Adams, Univ of Northern Colorado / Biological Sciences; C. Ramos, Colorado State Univ, Pueblo / Biology

Metal contamination in freshwater ecosystems is a widespread consequence of mining activities, but effects on nearby riparian insectivores are poorly understood. In this study we attempted to extend a toxic-unit model of mixed metal bioavailability to predict bat habitat use. We hypothesized that more contaminated stream reaches (>3,000 m) in the Colorado Mineral Belt would have lower proximate bat activity due to reduced densities of adult aquatic emergent insect prey. From July to October 2014, we sampled twelve sites for bat activity, stream heavy metal concentrations, and aquatic emergent insect densities. There was no relationship between total bat activity and aqueous metal concentration, despite a confirmed negative correlation between metal concentration and aquatic emergent insect biomass. However, there was a trend toward streams with lower metal concentrations having more bat prey capture attempts (as measured by feeding buzzes) than streams with higher metal concentrations. These data suggest that although bats are passing over streams of all contamination levels at a similar rate, they may be encountering prey more often over cleaner streams. While this study highlights difficulties in determining sub-lethal effects on bats, the model may yet be a useful tool for assessing risk in higher-productivity habitats.

732 Assessing and Managing Multiple Risks in a Changing World – the Roskilde Recommendations

W.R. Munns, USEPA Atlantic Ecology Division / Atlantic Ecology Division; H. Selck, Roskilde Univ / Dept Science and Environment; A. Burton, Univ of Michigan / School of Natural Resources Environment; P.M. Chapman, Chapema Environmental Strategies Ltd; G. Banta, Roskilde Univ / Dept of Environmental Social and Spatial Change; A. Palmqvist, Roskilde Univ / Dept of Science and Environment; A. Thit Jensen, Roskilde Univ / ENSPAC

Roskilde University hosted a November 2015 workshop on "Environmental Risk – Assessing and Managing Multiple Risks in a Changing World". Thirty attendees from 9 countries developed consensus recommendations regarding: implementation of a common currency (ecosystem services) for holistic environmental risk assessment and management; improvements to risk assessment and management in a complex, human-modified, and changing world; appropriate development of protection goals in a 2-stage process involving development of a) universal, and b) site-, region-, or problem-specific protection goals; addressing societal issues; risk management information needs; conducting risk assessment of risk management; and development of adaptive and flexible regulatory systems. We encourage both cross- and inter-disciplinary approaches to address 10 recommendations: 1) adopt ecosystem services as a common currency for risk assessment and management; 2) consider cumulative stressors (chemical and non-chemical) and determine which dominate to best manage and restore ecosystem services; 3) fully integrate risk managers and communities of interest into the risk assessment process; 4) fully integrate risk assessors and communities of interest into the risk management process; 5) consider socio-economics and increase transparency in both risk assessment and risk management; 6) recognize the ethical rights of humans and ecosystems to an adequate level of protection; 7) determine relevant reference conditions and the proper ecological context for assessments in human-modified systems; 8) assess risks and benefits to humans and ecosystems, and consider unanticipated consequences of management actions; 9) avoid excessive conservatism or possible under-protection resulting from sole reliance on binary, numerical benchmarks; and 10) develop adaptive risk management and regulatory goals based on ranges of uncertainty.

733 Viability of Precision-cut Organotypic Cultures of Marine Mammal Skin: Applicability to in Vitro Toxicology

M. Hayden, Texas Tech Univ/TIEHH / Environmental Toxicology; K. Campasino, Texas Tech Univ / Dept of Environmental Toxicology; P.A. Fair, NOAA National Ocean Service; D. Klein, Texas Tech / Environmental Toxicology; G. Bossart, Georgia Aquarium; C. Godard-Codding, Texas Tech Univ / Dept of Environmental Toxicology The Inst of Environmental and Human Health

Organotypic culture refers to the culture of precision-cut organ slices. This in vitro methodology is amenable to many downstream applications including pharmacological and toxicological studies. Benefits of organotypic culture include the preservation and culture of the entire tissue structure, as opposed to cell culture where a single cell type is cultured. While this methodology is well established in pharmacology and mammalian toxicology studies and validated as closely modeling in vivo processes, it is relatively novel with regards to marine mammal toxicology. In vivo toxicological studies are precluded legally and ethically in marine mammals, thus in vitro studies are needed to understand the mechanisms and processes these animals undergo upon exposure to contaminants. One matrix that can be used for such in vitro studies is the skin and blubber matrix. While a few studies of this nature have been conducted with this matrix, they utilized manually cut organ slices as opposed to the precision-cut methodology reported here. To validate this methodology, we tested the viability of precision-cut bottlenose dolphin (Tursiops truncatus) skin and blubber sustained in culture after 24, 48, and 72h of incubation. We examined three endpoints to assess viability after each incubation time point: (1) cell growth from the cultured organ slices, (2) internal potassium (K^+) concentrations in the cultured organ slices as measured by a flame atomic absorption spectrometer, and (3) lactate dehydrogenase (LDH) activity in media collected from the cultures. Immediately following each time point, 20 mg of cultured tissue was saved for internal K^+ analysis with the remainder of the tissue used to create cell culture explants. Media from each culture was saved for LDH analysis. Fibroblast cell cultures were successfully grown from all organotypic cultures which demonstrated viability of this tissue type sustained in culture up to 72h. Internal K^+ analyses are underway to establish a threshold of viability with this type of analyses as with LDH analysis of the culture media. This data indicate organotypic culture of these precision-cut tissues as a valid methodology, opening the avenue of research to conduct non-lethal, minimally invasive toxicological studies in protected marine mammals. Analyses of bottlenose dolphin skin and blubber biopsies exposed to common marine contaminants are underway.

734 Using blubber to examine steroid hormone homeostasis in bottlenose dolphins exposed to dichlorodiphenyltrichloroethane (DDT)

T. Galligan, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences; L.H. Schwacke, NOAA / National Ocean Service; A.S. Boggs, NIST / Environmental Chemical Sciences Group

Dichlorodiphenyltrichloroethane (DDT) and its metabolites (ΣDDT) are known to impact steroid hormone homeostasis in mammals, but there has been minimal investigation in this area in cetaceans, likely due to the legal and logistical factors that limit use of marine mammals for toxicological studies. The purpose of this study is to examine the impacts of ΣDDT exposure on steroid hormone homeostasis in the bottlenose dolphin (Tursiops truncatus) using alternative analytical methods to overcome these limitations. Blood is the most commonly used tissue for endocrine status assessments, but collection of blood from wild cetaceans is stressful for the animal and logistically difficult for researchers. Conversely, blubber biopsies can be collected remotely by non-lethal projectile and steroid hormones have previously been measured in cetacean blubber, but the relevance of blubber hormone concentrations to the wider endocrine system is poorly understood. In order to contextualize blubber steroid hormone concentrations, we will build a generalized linear model for the calculation of circulating steroid hormone concentrations from blubber hormone measurements in T. truncatus. A liquid chromatography-tandem mass spectrometry (LC-MS/MS) assay will be used to simultaneously assay 17 steroid hormones in matched blood and blubber samples collected from a reference population of T. truncatus. To build the model, these measurements will be incorporated with demographic (sex, age, pregnancy status) and sampling (season, time to capture, and time to sample collection) variables that are known to impact steroid hormone homeostasis. We will use this model and blubber biopsies to assess endocrine status in bottlenose dolphins localized to a site with high environmental concentrations of DDT. Blubber organic contaminant burden will be analyzed by GC-MS. We hypothesize that ΣDDT burden will be negatively associated with steroid hormone concentrations in blubber (measured) and blood (model-predicted). This study will advance our understanding of the effects of DDT exposure on endocrine status in T. truncatus, and could facilitate use of blubber for future studies in other cetaceans.

735 Estimates of Community Exposure and Health Risk to Sulfur Dioxide from Power Plant Emissions Using Short-Term Ambient Air Monitoring

M. Shepherd, XBiotech / Environmental Agricultural and Occupational Health; C. Achutan, College of Public Health, Univ of Nebraska Medical Center / Dept of Environmental Agricultural and Occupational Health; R. Rautiainen, College of Public Health, Univ of Nebraska Medical Center / Dept of Environmental Agricultural Occupational Health; G. Haynatzki, College of Public Health, Univ of Nebraska Medical Center / Dept of Biostatistics

To estimate plausible health effects associated with peak SO_2 levels from three coal-fired power plants in the Baltimore Maryland area, air monitoring was conducted between June and September 2013. Historically, the summer months are periods when emissions are highest. Monitoring included a 5-d mobile and a subsequent 61-d stationary monitoring study. In the stationary monitoring study, equipment was set up at four sites where models predicted and mobile monitoring data measured the highest average concentrations of SO_2. Continuous monitors recorded ambient concentrations each minute. the 1-min data were used to calculate 5-min and 1-h moving averages for comparison with concentrations from clinical studies that elicit lung function decrement and respiratory symptoms among asthmatics. Maximum daily 5-min moving average concentrations from the mobile monitoring study ranged from 70 to 84 ppb(183-220 ug/m3) and maximum daily 1-h moving average concentrations from the mobile monitoring study ranged from 15 to 24 ppb (39-63 ug/m3). Maximum 5-min moving average concentrations from stationary monitoring ranged from 39 to 229 ppb (102-600 ug/m3), and maximum daily 1-h average concentrations ranged from 15-134 ppb (40-351 ug/m3). Estimated exposure concentrations measured in the vicinity of monitors were below the lowest levels that have demonstrated respiratory symptoms in human clinical studies for healthy exercising asthmatics. Based on 5-min and 1-h monitoring, the exposure levels to SO2 in the vicinity of the C.P. Crane, Brandon Shores and H.A. Wagner power plants were not likely to elicit respiratory symptoms in healthy asthmatics. Implications: Mobile and stationary air monitoring for SO_2 were conducted to quantify short-term exposure risk, to the surrounding community, from peak emissions of three coal-fired power plants in the Baltimore area. Concentrations were typically low, with only a few 5-min averages higher than levels indicated during clinical trials to induce changes in lung capacity for healthy asthmatics engaged in exercise outdoors.

"One Health": Opportunities for SETAC Leadership in Integrating Environmental, Human and Animal Health

736 History and Evolution of One Health: Integrating Human, Animal and Environmental Health

A. Aguirre, George Mason Univ / Environmental Science and Policy

One Health is an evolving, interdisciplinary way of approaching complex health issues by recognizing the interconnectedness of human health, animal health and the environment. It integrates human, veterinary, wildlife, and environmental health disciplines at multiple levels to face increasing challenges to health, nutrition, security, and economic growth worldwide. One Health seeks to increase communication and collaboration across disciplines in order to promote, improve, and defend the health of all species on the planet. One Health is a framework concept needed to encourage and expand transdisciplinary collaborations in research, practice, policy, and communications for the benefit of people, plants, animals, and ecosystems. Although the term "One Health" is fairly new (~2004), the concept has a long history, both nationally and globally. From ancient Greece and Rome through the Renaissance and into the current era, taxonomic linkages, similarities, and differences among humans and other animals have formed the heart of comparative medicine. In recent years, through the support of key individuals and vital events, the One Health concept has gained explicit recognition. It is increasingly common to see One Health included by name in inter-institutional research partnerships, conferences, communications, and organizational frameworks–particularly those championed by the human health and veterinary medical communities. To date, however, environmental quality contributions to health and wellbeing remain the least developed components of recent collaborations organized under the One Health concept. The One Health approach represents a great opportunity to toxicologists and chemists to reach out for new collaborations by offering their environmental quality expertise to partnerships focused on solutions that work for humans, plants, animals, and the environment.

737 Continuint the One Health Dialogue in SETAC

L. Kapustka, LK Consultancy

SETAC engagement of One Health began at the Salt Lake City SETAC Meeting. There is a tension at the heart of this concept that divides along lines of reductionism and holistic, systems approaches. Instead of either or, these complementary ways understand complex environmental issues that exist in ecological-sociological landscapes. Quantifying substances in complex media has advanced to amazing degrees of precision and accuracy. Despite the ability to analyze situations in great detail, important determinants of environmental conditions including health of humans and ecological entities remain elusive. While we learn more and more about a situation, we miss the connections that really matter. Humans seem predisposed to become specialists and become increasingly isolated from things going on around them – the siloization phenomenon. John Maynard Keynes observed "It is better to be roughly right, than precisely wrong." Ecological-sociological landscapes are regulated by nested feedback loops that defy simple linear causal explanations. There is awareness that instead of a single determinant of health, multiple factors interact in unexpected ways. Poverty and the stresses that come with it make humans more susceptible to illness. Changes in climate in Eastern Africa is one of many contributing factors to the spread of malaria. Similarly, multiple stressors to plants and wildlife, including fragmentation of landscapes can make insults from chemical pollutants more potent. One Health arose from veterinary sciences with the recognition that some diseases are shared by livestock and humans and that livestock and wildlife can give early warning signals of impending problems for humans. The Center for Disease Control and the World Health Organization have adopted One Health programs promoting collaboration among physicians, veterinarians, and ecologists. Combatting the Zika virus will require reliance on the tenets of One Health to be successful. Management of environmental contamination has been dominated by reductionist approaches. Establishing effective policy and programs to deal with the contamination has proven challenging, even before consideration of changing climate conditions. The complexity of futures scenarios demands a holistic systematic approach. To do this, there will be a need for multi- and transdisciplinary collaboration that should be embraced by SETAC. In this overview, I will highlight opportunities and challenges available to SETACers.

738 Multilateral Environmental Agreements on Chemicals and Waste: How can we improve the link between human and ecosystem health?

R.O. Barra, Universidad de concepcion / Aquatic systems; C. Wellington-Moore, UNEP GEF/STAP

There are five key Multilateral Environmental Agreements (MEAs), and a global policy framework (Strategic Approach to International Chemicals Management (SAICM) which aim to reduce the toxic chemical load to our environment. However, of the more than 103 million chemicals registered by the Chemicals Abstracts Service to date, the chemicals listed in the annexes of the MEAs, indicates that only about 130 chemicals are actually covered, with a focus on a limited number of industrial chemicals, persistent organic pollutants ozone depleting substances, a range of non-POPs pesticides, mercury, and some chemical-related wastes. Monitoring data for the last decade indicates that there have been successes using the current a posteriori approach of the MEAs, which have led to reductions in the risk derived from persistent chemicals. The current SAICM (2006) has also contributed by raising concern on chemicals of emerging concern such as nanomaterials, endocrine disruptors etc. But does the current approach respond to the need of sustainable development goals?. Taking a global solution perspective, the aim is to enhance sustainable chemicals management practices throughout the chemical life cycle, minimizing the negative impacts to human health and ecosystems. In the different MEAs the inclusion of human and ecosystem health concepts have been differently applied. For instance, in the POPs Review Committee of the Stockholm Convention,in the listing of new chemicals added to the Convention, there are considerations on human health and ecosystem impacts. The consideration of these elements are based on (eco) toxicological thresholds and a risk profile is elaborated with all the available scientific information. Another example, is the mercury platform work that STAP is developing together SETAC to provide a model of interaction between scientists, and any data owners and data users, capable of contributing to knowledge on global mercury emissions, and impacts on human health and ecosystems. Starting with a pilot of fish mercury data, the intent in practice is to build a body of evidence to assess pollution levels, to improve understanding of fate and transport of mercury in the environment, how communities may be affected, and elaborate the best specific control measures. In the face of a growing list of chemical formulations, we need to increase integrated evidence for the global governance of chemicals, and the One Health concept may be instrumental in that direction.

739 Benefits of a Safer Chemical Ingredient List

E.T. Lavoie, USEPA / Office of Pollution Prevention and Toxics; C. Menasche, ORISE with USEPA / Safer Choice Program; J.L. Tunkel, C. Rudisill, SRC, Inc. / Environmental Health Analysis

Safer products minimize risk through the selection of the least hazardous ingredients for a particular functional use and product type. The USEPA Safer Choice program has labeled more than 2,000 products, indicating to consumers and other purchasers that a product meets EPA's rigorous Safer Choice Standard. EPA evaluates intentionally added ingredients and residuals against published safer chemical criteria. The Safer Choice Safer Chemical Ingredient List (SCIL) assists product manufacturers in their search for safer chemicals. SCIL currently includes over 750 chemicals that have met the program's criteria, including: surfactants, solvents, preservatives and chelants. Providing transparency from 15 years of identification and assessment of formulated wet chemistry products, SCIL offers product formulators, retailers, researchers, advocates and activists insights on and means to achieve informed substitution and advance green chemistry principles. Chemicals are distinguished using simple color codes that quickly communicate toxicological information for a diverse audience. Criteria for listing were developed in multi-stakeholder public processes and are available to be used for any application. Unlike restricted substance lists and regulatory lists, SCIL empowers formulators to lead in safer chemistry (and avoid tomorrow's "chemical of the week") and suppliers to highlight their green chemistry successes. Even with the successes highlighted in this presentation, additional work on developing safer chemicals needs to be done; for example, several categories-including preservatives and colorants-have limited numbers of chemicals that pass all hazard criteria. Where substances are initially reviewed one at a time or in the context of a small category, the growing SCIL will allow for the re-review of large categories of substances, and improvement in criteria for defining 'safer' chemicals. Part of the EPA strategy for this work is to engage external audiences and expand the list. As the number of restricted substances, or chemicals with negative public attention increase, formulators and the public need a resource to define chemicals unlikely to be restricted. SCIL serves as a guide for safer chemistry grounded in science and 'one health'.

740 One Health: An Organizing Framework for Global Engagement on Coupled Human-Ecological Training and Research?

B.W. Brooks, Baylor Univ / Environmental Health Science Program Dept of Environmental Science

SETAC launched the Global Horizon Scanning and Prioritization Project to identify geographically specific research needs aimed at advancing sustainable environmental quality. Priority research questions were solicited from SETAC members and other environmental professionals within the five SETAC geographical units (GU), then synthesized by teams of academic, business and government representatives to develop lists of the top research questions that, if answered, would substantially advance our understanding of how a range of environmental stressors (chemical, physical, biological) impact environmental quality in different geographic regions. During 2015, workshops were held for Africa (in Langebaan, South Africa), Australasia (in Nelson, New Zealand), Latin America (in Buenos Aires, Argentina) and SETAC North America (in Salt Lake City, USA). An Asia Pacific workshop is planned during the Singapore meeting in September. Whereas several consistent patterns of research needs are emerging among GUs, coupled human health and ecological consequences of stressors and research and training capacity emerge from GUs with a number of developing countries. Such observations are critical because global population concentration is increasingly occurring in megacities of countries in transition, where landscape modification and access to diverse chemicals, including consumer products, pesticides and medicines, are increasing more rapidly than waste management infrastructure and other public health intervention strategies are implemented. SETAC's noble mission, multidisciplinary and tripartite membership, and global organization structure is uniquely positioned to contribute to transdisciplinary One Health teams. Timely opportunities, including collaboration with environmental public health professionals and organizations, will be presented as potential opportunities for SETAC members to develop training and collaborative research frameworks across GUs.

741 Assessing Ecosystem and Human Health Effects from Natural and Man-Made Disasters

G.I. Scott, Univ of South Carolina / Env Health Sciences; D.E. Porter, A.L. Jones, J.V. Miglarese, Univ of South Carolina / Dept of Environmental Health Sciences Arnold School of Public Health; P.A. Sandifer, College of Charleston / School of Sciences Mathematics; L.C. Knapp, College of Charleston / Graduate School Environmental Studies; T.K. Collier, Oceans and Human Health Program; A.E. Sutton-Grier, Univesity of MD and NOAA / Earth System Science Interdisciplinary Center

Since 1990, natural disasters have globally impacted about 217 million people each year. Recent evidence suggests a substantial increase in such disasters since 1989, increasing from 50- >100 annually from 1950-1970's followed by a rapid to ~275-350/year during 2000-2009. Coupled with this have been the concomitant interactions of increasing urbanization, deforestation, environmental degradation, and climate change. This recent history of disasters in the U.S. underscores a trend of increasing frequency and level of economic damages and effects on ecosystem and human health. In 2005, Hurricane Katrina caused > $85 billion in disaster damages and 1,833 deaths; in 2010 the Deepwater Horizon oil spill was directly responsible for 11 deaths and the release of some 5 million barrels of oil to the Gulf of Mexico ecosystem and in 2012, in there were 11 weather disasters in the U.S. that resulted in 377 deaths and >$110 billion in damages, including Hurricane Sandy which accounted for >$70billion in damages. Most disaster response efforts focus on immediate and near-term injury and exposures (e.g., to infectious disease, toxic substances, or toxins), with relatively little attention to long-term effects on ecosystem and human health. Conceptual models have been widely utilized in many fields of scientific research to organize and visualize information so as to reveal associations, connections, and sometimes even cause-and-effect relationships among elements in complex environments, including ecosystems. These tools may be additionally employed to increase understanding, develop testable hypotheses, and identify appropriate and effective environmental management steps to minimize risks. Despite their long and widespread use, there has been relatively little prior effort to develop conceptual models that relate disaster- or other stressor-caused environmental damage to ecosystem and human health and well-being. Data will be presented on a conceptual model that evaluated ecosystem and human health effects both during and after natural (hurricanes) and man-made (oil spills) disasters. This model provides a framework to improve and better connect both pre-disaster preparation and post-disaster responses in ways that lead to increased understanding of significantly important associations between environmental condition and human health and well-being by assessing both direct and indirect health effects associated with stress directly caused by disasters.

742 Plasma chemistry & persistent organic pollutants in loggerhead sea turtles with & without fibropapillomatosis from Florida Bay & Indian River Lagoon

J. Lynch, National Inst of Standards and Technology / Chemical Sciences Division; D.A. Bagley, Univ of Central Florida / Dept of Biology; R.D. Day, NIST / Chemical Sciences Division Hollings Marine Laboratory; L.M. Ehrhart, Univ of Central Florida / Dept of Biology; A.M. Foley, Florida Fish and Wildlife Conservation Commission / Fish and Wildlife Research Inst; C.A. Harms, North Carolina State Univ / Center for Marine Sciences and Technology and College of Veterinary Medicine; J. Trevillian, NIST / Chemical Sciences Division Hollings Marine Laboratory; B.A. Schroeder, National Marine Fisheries Service / Office of Protected Resources; N.I. Stacy, Univ of Florida / College of Veterinary Medicine

Florida Bay and the Indian River Lagoon (IRL) are semi-enclosed coastal ecosystems that have suffered the consequences of anthropogenic alterations. Development and agriculture in Florida have increased runoff of chemical pollutants in both bays, and freshwater diversion has resulted in annual events of hypersalinity in Florida Bay. Some of the sea turtles inhabiting these bays exhibit the tumor-forming disease, fibropapillomatosis (FP). We evaluated plasma chemistry panels and persistent organic pollutants (POPs) in a total of 37 juvenile loggerhead sea turtles (Caretta caretta) at these sites. None of the turtles had moderate or severe FP tumors; only low severity FP was observed in 18 % and 20 % of the sampled Florida Bay and IRL turtles, respectively. POP concentrations did not differ between tumored and non-tumored turtles and were lower in the Florida turtles than loggerheads foraging farther north where FP is rare or absent. These findings support recent conclusions that POPs are not a primary co-factor for the initiation of FP. Florida Bay turtles had significantly higher plasma sodium, chloride, calculated osmolality, and aspartate aminotransferase (AST), and lower albumin, potassium, and POP concentrations, than the IRL turtles. Compared to reference ranges we developed from a meta-analysis of loggerhead plasma chemistry data, Florida Bay turtles, which were sampled over only one week in June 2009, had mildly elevated plasma sodium, chloride, and AST. Using clinical judgement and results from the meta-analysis, we developed criteria for health conditions and categorized 82 % of the sampled Florida Bay turtles with osmoregulatory imbalance, 68 % with AST exceeding those indicative of tissue damage, and 23 % with possible renal insufficiency. IRL turtles were affected to a lesser degree (40 %, 7 %, and 0 %, respectively). We speculate that hypersaline conditions (>40 practical salinity units) that occurred approximately six weeks prior to the sampling event in Florida Bay may have caused the osmoregulatory imbalance, and may make the turtles more susceptible to other health stressors. While loggerhead turtles in the IRL and Florida Bay are exposed to POPs, the toxicological risks appear to be lower relative to other environmental stressors, such as hypersalinity in Florida Bay. Future research should assess the osmoregulation and health of marine organisms across seasons and years in relation to salinity in Florida Bay.

743 One Health Approach Towards Addressing Pollution at the Pole – Integrating Evidence Across Inuit, Wildlife, and Ecosystems

N. Basu, McGill Univ / Dept of Environmental Health Sciences

Many are surprised to learn that Inuit populations, Arctic wildlife, and northern ecosystems are amongst the most contaminated groups worldwide. Here I will outline how One Health principles underlie key aspects of the pollution at the pole discourse. First, traditional belief systems of Inuit are grounded in the notion that everything is connected. Contamination of ecosystems, wildlife, and people are inter-related, and together this has profound and well-documented impacts on socio-cultural systems, economic well being, and total health. Second, Arctic contamination has been of societal concern and scientific interest since the early 1970s, and have been the focus of a number of initiatives such as the Northern Contaminants Program (NCP) initiated in 1991 by the Canadian government and the Arctic Monitoring and Assessment Programme (AMAP), a circumpolar multi-country program established to assess the state of multiple compartments in the Arctic ecosystem. These programs have followed One Health principles, and enabled detailed investigations into the source, fate, and transport of contaminants into the Arctic ecosystem, as well as human health and wildlife risk assessments. Finally, international agreements, including the Stockholm Convention and the Minamata Convention, put important value on evidence from humans, wildlife, and ecosystems, especially as they pertain to the Arctic. Taken together, One Health principles are omnipresent in the global discourse of contamination at the pole, and here I will highlight key examples that emphasize the importance of such an approach in helping translate knowledge into action.

PAHs in the Real World: Sources, Sinks, Bioavailability and Toxicity

744 Assessing PAHs in the Real World

A. LeHuray, Chemical Management Associates LLC; B. Magee, ARCADIS

For the past 4 decades, broad spectrum chemical analysis of environmental samples has typically included the “EPA 16” individual polycyclic aromatic hydrocarbons (PAHs). The data remain useful for such purposes as geographic or historical comparisons, preliminary investigations of legacy sites, or initial forensic evaluations of undifferentiated petrogenic versus pyrogenic sources. PAHs occur in the environment as complex mixtures, however, rather than as individual chemicals, and concentrations of a limited list of individual PAHs is insufficient either to make use of sophisticated methods of PAH evaluation or to advance understanding risks associated with PAHs in the environment. Assessing environmental mixtures of PAHs involves recognition of complicated processes that can vary from location to location and differ in different media (air, soil, sediment, biota). One approach to unraveling the complexity is to analyze for a longer list of individual PAHs and including heterocyclic compounds or alkylated or substituted PAHs. Adding to the list of analytes furthers precautionary risk assessments based on assumptions of additive toxicity. Expanded lists of individual analytes, however, does not alter the actual toxicity of PAH-containing materials. Indeed, including more compounds when using an additive approach may exacerbate overestimation of risks. Use of a longer list of compounds may, in some cases, add confidence to identification of PAH sources. Almost two decades ago, recognition that PAH concentrations in sediments often do not correlate with ecological toxicity resulted in replacing “consensus standards” based on concentrations alone with equilibrium partitioning approaches, with the emphasis on exposure to bioavailable or bioaccessible PAHs. At the same time, measurement of bioavailability of specific PAH-containing materials has become a accepted adjustment to human health risk assessments. The recommendation of EPA’s Science Advisory Board to conduct toxicity testing on a variety of PAH-containing mixtures with an eye towards replacing the additive “Relative Potency Factor” approach reflects recognition that antagonism as well as bioavailability likely are important mediators of potential PAH risks. Recent work demonstrating the dominating importance of PAH source materials on partitioning indicates that properties in addition to individual PAH concentrations of different mixtures hold the key to assessing PAH bioavailability and risk.

745 PAHs in urban sediments of the Lower Rouge River “Old Channel”: fingerprinting, source characterization, robust statistical methods

A. Craig, AAAS/ USEPA / Analytical Services Branch; C.G. Appleby, AAAS USEPA / OLEMOSRTIAnalytical Services Branch

The global prevalence of polycyclic aromatic hydrocarbons (PAHs) in urban environments holds significant implications for contemporary public health and environmental remediation efforts. Various statistical methodologies are used in modern approaches to characterization of PAH contamination sources. The continued evaluation and improvement of these methods represents a central, enduring project in environmental forensics. From 2008 to 2014, hundreds of sediment samples were collected from the “Old Channel” segment of the Lower Rouge River (Detroit, MI) on behalf of the U.S. Environmental Protection Agency (EPA). Select samples were analyzed for 38 parent and alkylated PAHs via a modified EPA Method 8270. In this study, conventional ‘fingerprinting’ source characterization methodology, classical principal component analysis, and robust principal component analysis are used to describe the mixture, type, and magnitude of PAH contamination indicated by the analytical data. The advantages and limitations associated with each approach to PAH source characterization are explored through a discussion of the results generated by each method. Synthesis of PAH distribution analyses and interpretation of quantitative results contextualize the complex of PAH contamination sources observed within PAH forensics literature and contemporary data science and chemometric techniques.

746 Using PAH Compositional Analysis to Evaluate Dissolved-Phase Groundwater Discharge to Surface Water from Local Soil/Sediment Influence

H. Costa, L. McWilliams, Haley & Aldrich, Inc.

Groundwater discharge to surface water is a pathway of growing concern in evaluating the potential toxicity and/or bioavailability of polycyclic aromatic hydrocarbons (PAHs) from upland sources to aquatic resources. This potential pathway for surface water impairment is particularly relevant at former manufactured gas plant (MGP) sites, where coal tar dense nonaqueous-phase liquid (DNAPL) and high-concentration residuals can occur within close proximity (both upland and offshore) of shorelines where product and wastes were historically handled and transported. Because groundwater typically discharges to surface water close to the shoreline, nearshore sediment remediation may require mitigation of not only contaminant conditions in sediments but also in discharging groundwater. To design a remedy that addresses the groundwater pathway, it is essential to distinguish PAH loading via groundwater discharge from elevated PAH concentrations in pore water resulting from contact with contaminated sediments. PAHs from both pyrogenic (e.g., coal tar or creosote) and petrogenic sources contain compositional features that enable distinguishing dissolved-phase PAHs from either particles or NAPL entrained in a groundwater sample. Because pyrogenic NAPL compositions are very similar to dissolved-phase compositions, some prediction of phase-partitioning should also be used to support the interpretation. This case study from a former MGP site remedial investigation illustrates how PAH compositional analysis and predictive phase partitioning were used to identify PAH sources in groundwater and in pore water along a field-delineated groundwater discharge flowpath. Various compositional features were considered and compared with equilibrium partitioning predictions. The key features proved to be a combination of comparing concentrations and compositions in the groundwater/pore water with predictions, and comparing compositions (but not concentrations) with DNAPL and co-located sediments. Pore water PAH concentrations and compositions indicate that the PAHs are primarily influenced by the contamination of the sediments with which the pore water is in direct contact, rather than a dissolved-phase plume transported along a groundwater flowpath. The results were used to preclude the need for upland groundwater treatment or remediation, and to inform the reactive cap design for contaminated nearshore sediments.

747 Challenges in Analysis of Hydroxy PAHs in Urine

M. Woudneh, SGS AXYS; J. Benskin, Stockholm Univ / Environmental Science and Analytical Chemistry; R.D. Grace, SGS AXYS; M.C. Hamilton, SGS AXYS / Biosciences; B.H. Magee, ARCADIS; G. Hoeger, ARCADIS / IEST; N.D. Forsberg, Arcadis US, Inc. / Environmental and Molecular Toxicology; J. Cosgrove, SGS AXYS

Monohydroxy polycyclic aromatic hydrocarbons (OH-PAHs) are the major metabolites of PAHs. Despite their importance as biomarkers of PAH exposure, OH-PAHs are notoriously unstable. Consequently, countless studies have reported difficulties in the analysis of OH-PAHs. The present work sought to identify and remedy issues related to OH-PAH instability, in order to enhance analyte recoveries and obtain a robust method for elucidating PAH exposure in the general population. Stability experiments involving spiked water stored for 14 days at 20°C, in the presence of direct sun light, revealed >98% loss for all analytes. Solvent type, but not temperature played a significant role in analyte stability. The source of instability was identified as photo-induced oxidation. Analysis of urine samples obtained from mice fed with a PAH-contaminated diet revealed that >94% of each analyte was present in conjugated (glucuronated and sulfated) form. An investigation into the stability of the conjugated and free forms revealed the latter species to be the most stable. Overall, analyte instability was minimized by reducing exposure to light and through the use of an antioxidant and nitrogen atmosphere. The findings summarized in this work are relevant for those involved in biomonitoring of PAHs.

748 Review of Bioaccumulation and Bioconcentration Factors Used by USEPA in Derivation of 2015 Human Health Water Quality Criteria

P.D. Anderson, Arcadis US, Inc.; J. Iannuzzi, M. Buonanduci, C. Hassinger, ARCADIS

In July 2015 EPA released updated human health ambient water quality criteria (HHWQC). As part of that update EPA revised its approach to estimating bioaccumulation of substances into fish employing bioaccumulation factors (BAFs) in place of bioconcentration factors (BCFs) when supported by existing data and methodology. In January 2016 EPA released additional guidance providing more detail on the process followed to update bioaccumulation factors. This presentation has two goals. First, a review of that process to determine if it was applied correctly by EPA when developing HHWQC for PAHs and other highly metabolized compounds. Second, to the extent the process was not followed and alternative BAFs (or BCFs) should or could have been derived, the paper presents those alternative BAFs (or BCFs) and associated revised HHWQC for PAHs. This paper also provides a general overview of the process developed by EPA, evaluates its application on a national basis, and as necessary, recommends modifications that would improve the process.

749 Assessing PAH-related toxicity by spiking field-collected sediments with a site-specific contaminant mixture

S.E. Hartzell, Univ of Maryland, College Park; M.A. Unger, G.G. Vadas, M. Vogelbein, Virginia Inst of Marine Science / Aquatic Health Sciences; L.T. Yonkos, Univ of Maryland / Environmental Science and Technology

The sediments of Bear Creek near Baltimore, Maryland contain a complex mixture of organic and inorganic contaminants, including polycyclic aromatic hydrocarbons (PAHs). PAH concentrations measured in both whole sediment and sediment pore water have shown positive correlations with amphipod mortality during laboratory assessments of field-collected sediment. However, numerous other constituents, including heavy metals, have also shown positive correlations with toxicity at the site, making it difficult to determine whether PAHs are a driver of observed adverse biological effects within Bear Creek. To further examine the relationship between PAHs and observed toxicity within Bear Creek sediments, and to determine whether PAHs are a likely driver of toxicity at the site, a spiked sediment test was conducted using a subset of the suite of PAH compounds found at the site. Sediments were collected from two control sites that represent a similar sediment matrix to previously assessed contaminated samples from Bear Creek. Sediments were spiked with a mixture of 18 PAH compounds detected at the Bear Creek site, as determined by previous analysis of PAHs in total sediments and sediment pore water. Spike total PAH concentrations were selected based on observed concentrations of PAHs in site sediments that yielded toxicity results ranging from complete mortality to complete survival. Pore water from spiked sediments was analyzed by an antibody-based PAH biosensor that is sensitive to 3-5 ring PAHs, and sediments were used to conduct a ten-day acute toxicity test using the benthic amphipod Leptocheirus plumulosus. Results provide insight into the relationship between PAHs and sediment toxicity to benthic organisms at a specific site, while the study demonstrates the application of site-specific spiking experiments to sediments containing complex mixtures of multiple contaminant classes.

750 Individual PAH metabolites in English sole (Parophrys ventulus) bile from Puget Sound, WA, USA from the past 10+ years

D. da Silva, National Oceanic and Atmospheric Administration; C. Sloan, National Oceanic and Atmospheric Administration / National Marine Fisheries Service / Northwest Fisheries Science Center; S. O'Neill, J. West, Washington Dept of Fish and Wildlife / Fish Program; J. Herman, National Oceanic and Atmospheric Administration / National Marine Fisheries Service / Northwest Fisheries Science Center; C. Gallagher, Wellesley College; G.M. Ylitalo, NOAA Fisheries / National Marine Fisheries Service / Northwest Fisheries Science Center

Polycyclic aromatic hydrocarbons (PAHs) are commonly found in the environment, particularly in urbanized areas or in regions with petroleum-related activities. PAHs pose risks to marine life, as these compounds are known to be carcinogenic and toxic, affecting survival, growth and reproduction of several species. Due to the ability of fish to quickly metabolize PAHs, it is crucial to assess the presence of metabolized PAHs in fish, in addition to the conventional parent (non-metabolized) PAH analysis, for a better understanding of the exposure to PAHs and their fate in fish. Biliary PAH metabolites can be found at relatively high levels in fish from areas where very low levels of parent PAHs are detected in abiotic samples or fish muscle, due to the fast metabolism and accumulation in bile prior to excretion. Moreover, during the excretion process, the PAH metabolites can be reabsorbed by fish and become more toxic than the parent PAH. Unfortunately, there are limited data on environmental levels of PAH metabolites in marine species, particularly from urbanized areas such as Puget Sound, WA. We recently developed a rapid method for accurately quantifying 27 individual hydroxylated PAH metabolites (OH-PAHs) in fish bile. The method consists of removing polar lipids and protein, hydrolyzing phase II conjugated OH-PAHs, solid-phase extraction, and analysis by LC-MS/MS. The method was validated using pre-spiked (efficiency) and post-spiked (matrix effect) tests and reference and control materials. Recoveries of spiked samples ranged from 60 – 129% (mean 97%, SD 15%). Using this method, we determined PAH metabolite concentrations in bile of English sole (Parophrys ventulus) from 3 urban sites of Puget Sound collected from 1997 – 2015. Several OH-PAHs were detected in 100% of the samples, except control site, with dihydroxydihydro forms of both low- and high-molecular weight PAHs being the most abundant metabolites. This distribution suggests of multiple sources of PAHs in to Puget Sound, with summed metabolite levels reaching over 5,000 ng/mL of bile. Our findings indicate that English sole, and potentially many other marine species, from Puget Sound are exposed to elevated levels of toxic and carcinogenic PAHs.

751 Toxicity in zebrafish of complex polycyclic aromatic hydrocarbon mixtures exposed to terrestrially-appropriate UV-irradiation

P. Hoffman, Oregon State Univ / Environmental and Molecular Toxicology; J. Minick, Oregon State Universtity / Environmental and Molecular Toxicology; K.A. Anderson, Oregon State Univ / Environmental and Molecular Toxicology

Previously, we determined degradation kinetics for a mixture of environmentally-relevant polycyclic aromatic hydrocarbons (PAHs) derived from an EPA-designated Superfund site and denoted Supermix 10, when irradiated with accurate solar-emulating Ultraviolet light (UV). That initial study has been expanded to double the time scale and as well as examine the role of spectral perturbation in determinations of half-life and product formation. By manipulating filters on a xenon-arc source, three differing spectral compositions were established. They were characterized by UVA to UVB ratios of 20:1 (approximating solar flux), 10:1 (excess UVB) and 4:1 (excess UVB and UVC). Pairwise comparisons of the three spectral compositions show statistically significant differences in kinetics of degradation for all analytes within the mix between 20:1 and 4:1 ratio sources, for a constant UV flux. As predicted, only phenanthrene, an analyte whose absorbance spectrum drops precipitously near the border of UVA and UVB, showed a statistically significant increase in degradation rate between the 20:1 and 10:1 UV sources. Pairwise examination of four analytes irradiated to a defined dose individually as well as irradiated within the complex mixture showed consistent, but relatively small differences and demonstrated artifacts likely common to individual low-concentration irradiations. Source comparisons were extended to differential product formation by direct comparison of total ion chromatograms from 20:1 and 4:1 UV sources. To examine the toxicological implications of this UV-modified complex mixture, embryonic zebrafish were exposed to unirradiated Supermix 10 and Supermix 10 exposed to a series of UV doses corresponding to 2, 4 and 8 hrs of exposure. Unirradiated Supermix 10 toxicity is driven by benz(a)anthracene, pyrene and retene, three chemicals with relatively short half-lives of 29.4, 77.0 and 346 minutes respectively within our irradiation system. Our working hypothesis is that the relatively rapid degradation of these three drivers of toxicity will reduce toxicity of Supermix 10 relative to its unirradiated counterpart.

Soil and Water Contaminants: Evaluation, Biomonitoring and Abatement Bioindicators for Effective Management

752 Metal Concentrations in Urban Soils of Kumasi Metropolis, Ghana

M. Dodd, Royal Roads Univ / School of Environment Sustainability; G. Darko, Kwame Nkrumah Univ of Science and Technology / Dept of Chemistry; M. Nkansah, Y. Aduse-Poku, E. Ansah, Kwame Nkrumah Univ of Science and Technology, Kumasi / Dept of Chemistry

Ninety-six surface soil samples were collected using a 0.5 km x 0.5 km grid in areas where most of the commercial activities were concentrated in Kumasi, the second most populated urban area in Ghana, West Africa. The samples were analyzed for total metals using a field portable X-ray fluorescence analyser (FPXRF). A subset of the samples (38) was also analyzed by aqua-regia/ICP-MS. A comparison of the FPXRF data to the ICP-MS results indicated a strong linear correlation between the two methods for the majority of the metals (e.g., the Pearson Correlation coefficients ($p < 0.001$) for As, Cu, Pb, and Zn were 0.985, 0.894, 0.879 and 0.985, respectively. This indicated that the FPXRF is a useful tool for screening a large number of samples for potential human health risk assessment of metal exposure. Multivariate and geostatistical analyses of the data suggested that Cr, Cu, Fe, Ni, Pb and Zn in the soils were mainly derived from anthropogenic origin whereas As, Cd, Hg, Mn, V, and Sn were attributable to soil parent materials and atmospheric deposition. The concentrations of As, Cr, Cu, Pb and Zn in some of the samples exceeded environmental quality guidelines for residential land use such as the Canadian Council of Ministers of the Environment soil quality guidelines. The use of geo-accumulation, enrichment factor and pollution load indices indicated high contamination in some of the soil samples. To assess the potential health effects associated with ingestion of the metal contaminants in the soils an in vitro physiologically based extraction test was used to determine metal bioaccessibility. The mean metal bioaccessibility were As (14%), Cr (2.8%) Cu (47%), Pb (62%), Ni (24%) and Zn (73%). Based on the total metal concentrations, soil properties and bioaccessibility data the risk associated with exposure to metals (e.g., Pb, Cu and Zn) at some of the sampling locations were deemed high. Ongoing work includes detailed risk characterization and the development of a strategy for effectively communicating the identified risk and recommendations for limiting exposure to the identified metal contaminants.

753 Fates of some phenylurea herbicides in tropical soils: trends and correlations

B. Agbaogun, Univ of Ibadan / Dept of Analytical and Ecological Chemistry; B.I. Olu-Owolabi, Univ of Ibadan / Dept of Chemistry; K. Fischer, Univ of Trier / Dept of Analytical and Ecological Chemistry

Fates of xenobiotics in tropical soils have received considerably little attention, despite the fact that approximately one half of the earth's population and roughly one third of its land mass are found in the tropics. In this work, adsorption and mobility of three phenylurea herbicides (Diuron, Linuron and Monuron) were studied in typical Nigerian soils. Eighteen top soils (majorly of Alfisol, Inceptisol and Entisol orders on the USDA taxonomy) were collected at different locations in the Southwestern Nigeria. Samples were comprehensively characterised for their physical-chemical properties, using standard methods, and soil mineralogy (powder and texture preparations) was determined with XRD. Eight of the samples were later selected for adsorption test, using batch equilibrium method. Effects of solution pH, temperature, concentration, and contact time were investigated; and also were sorption kinetics and isotherms. The samples were analysed for equilibrium concentration with HPLC-DAD at 250nm, and multivariate analysis of the data was carried out with R. Results indicated that the pH ranged from 5.37 – 7.54, the %SOM ranged from 0.92-6.97. %N ranged from 0.1 – 0.9, and CEC_{effec} ranged from 21.5 – 112 mmolc/Kg. Dithionate extractable oxides- Fe_d, Al_d and Mn_d ranged from 2.02-14.62, 0.11-0.64 and 0.16-3.13g/Kg respectively, while oxalate extractables- Fe_o, Al_o and Mn_o ranged from 0.20-1.86, 0.13 – 1.42 and 0.14- 2.32g/Kg respectively. Granulometry results showed that %sand ranged from 66-92, while silt+clay proportion ranged from 8-34%. XRD analysis of the powder samples revealed the presence of albite, microcline and quartz in all samples. Some samples contained sodalite and dolomite in addition. The semi-quantitative XRD analysis of the clay fraction revealed the dominance of kaolinite (41-93%), followed by illite (7-60%), with only three samples containing smectite (3-12%). Batch tests- though still ongoing, revealed strong positive correlations between sorption parameters and soil properties such as SOM, Mn_o, Fe_o, CEC, Mn_d, soil pH, Fe_d, and Al_d (in decreasing order of magnitude of r). K_d, K_{oc} and K_f ranged from 0.03-0.10, 2.29-5.34 and 0.07-0.19 respectively. Adsorption parameters decreased with increase in temperature while test solution pH showed no significant effect. The K_{oc} got in this study and the $t_{1/2}$ reported in literature will be used to assess the leachability of the pesticides in the soils, using the Gustafson Ubiquity Score (GUS).

754 Polychlorinated Biphenyls (PCBs) in Fish Fillet Tissue: Nationally/Regionally Representative Statistical Surveys of US Waters

J. Wathen, L. Stahl, USEPA / Office of Water Office of Science and Technology; B.D. Snyder, Tetra Tech, Inc; T. Olsen, USEPA / ORD NHEERL Western Ecology Division; T. Kincaid, USEPA / ORD NHEERL WED; H.B. McCarty, CSC Government Solutions LLC, a CSRA Company

As of 2015, the USEPA has conducted probabilistic, nationally-representative assessments of polychlorinated biphenyls (PCBs) in fish tissue in U.S. lakes (2000-2003), twice in rivers 5^{th} order and greater (2008-2009 and 2013-2014) as part of National Rivers and Streams Assessments (NRSAs), and in nearshore waters in the Great Lakes as part of the National Coastal Condition Assessments (2010 completed, 2015 in progress). Not manufactured in the U.S. since 1979, PCBs are an extremely persistent group of organo-chlorine compounds that are toxic and carcinogenic, and readily bioaccumulate in fish, especially predatory species. PCBs are highly pervasive in fish, with the highest mean concentrations in the U.S. occurring in the Great Lakes; intermediate concentrations occurring in U.S. rivers, with those concentrations being significantly elevated in the Eastern Highlands eco-region relative to the rest of the country; and relatively lower concentrations occurring in non-Great Lake U.S. lakes. Availability of analytical results from the 2013-2014 NRSA allows us to compare PCB concentrations in fish tissue in these three sets of waterbodies (U.S. rivers 5th order and greater, Great Lakes, other U.S. Lakes), the extent to which observed concentrations of summed data for all 209 PCB congeners in fish tissue exceed relevant human health and ecologic thresholds in these waterbodies and in each of three eco-regions of the U.S., which also include the Plains & Lowlands and West & Mountains eco-regions.

755 Risk Assessment of Constant Use of Detergent in Fermentation Processing of Cassava in Southeastern Nigeria

P. Abara, Federal Univ of Technology Owerri / Dept of Biological Sciences; U.A. Ibiam, Ebonyi State Univ / Dept of Biochemistry; A.C. Udebuani, Federal Univ of Technology / Dept of Biotechnology; C.O. Ezea, Federal Univ of Technology Owerri / Biological Science

The study investigated, the risk associated with the use of detergents to speed up the processing of cassava which is a staple food in Southeastern Nigeria. Due to effects of climate related variables on the production and processing of cassava, rural dwellers have adopted the practice of using detergent to help the process of fermentation of cassava. First of all, field survey of the use of this crude processing method was carried out to establish the percentage distribution of rural dwellers practicing it. Cassava tubers were harvested in an unpolluted farm, carefully peeled, soaked in detergent water and allowed to ferment. The amount of detergent residue accumulated in the processed cassava was evaluated using the titrimetric method. Thereafter 24 albino Wistar rats were fed with the paste for 28 days to determine the toxicological effects of detergent residue on the organism. Catalase, superoxide dismutase, lipid peroxidation, ascorbic acid and glutathione were assayed. Liver and kidney parameters were also assayed. Results obtained showed that more than 70% of the rural dwellers (cassava processors) use detergent in fermenting cassava, 15% of them use other chemical substances to ferment it while only 5% of them do not add any chemical or additive to it. The dried cassava paste was found to contain between 0.019 to 0.177 mg/g anionic surfactant residue and between 0.058 to 0.177 mg/g cationic surfactant residue. Result of the enzyme assay showed that catalase, superoxide dismutase, alanine aminotranferase, aspartate aminotransferase and alkaline phosphatase were not significantly affected ($P < 0.001$); lipid peroxidation, ascorbic acid glutathione total protein, albumin, bilirubin, urea, uric acid, and creatinine showed no significant difference ($P < 0.001$). Care should be taken by rural dwellers, cassava processors should be educated on the risk associated with the use of chemicals to ferment cassava.

756 Use of nano iron (III) oxide (nFe3O4) for the remediation of organotin – TPT in Marine Wastewater System

O. Fatoki, Cape Peninsula Univ of Technology / Chemistry; O.S. Ayanda, Cape Peninsula Univ of Technology; F. Adekola, Univ of Ilorin Nigeria / Chemistry; B.J. Ximba, Cape Peninsula Univ of Technology / Chemistry

Triphenyl tin is present in antifouling paints where it is used to prevent the growth of fouling organisms on marine structures and vessels. TPT is a classified endocrine disruptor and can cause imposex in marine organisms. Thus it has the potential to affect the biodiversity of the marine environment. The potential effects stress the need to control its presence in the environment. Iron nano particle has generated some interest in recent years because of their unique characteristics which made them suitable for a number of applications including remediation of recalcitrant environmental pollutants. The removal of triphenyltin (TPT) from artificial seawater using nano iron (III) oxide (nFe_3O_4) was studied. The adsorption was investigated, including both equilibrium and kinetics. Equilibrium adsorption data were analyzed using Langmuir, Freundlich, Temkin and Dubinin–Radushkevich (D-R) isotherm models. Pseudo first- and second-order, Elovich, fractional power and intra-particle diffusion models were applied to test the kinetic data and $\Delta G°$, $\Delta S°$ and $\Delta H°$ were also calculated. The effects of adsorbent dose, contact time, pH, stirring speed and initial concentration of TPT were also studied to establish optimal conditions for the removal of TPT using the nano material. The optimal conditions established were applied to TPT removal from TPT – contaminated natural shipyard wastewater. The result showed that 95.37 % TPT was removed by the nFe_3O_4 which showed the use of nano iron as a possible route for the remediation of TPT contaminated wastewater before being discharge into the environment.

757 In vitro image-based phenotypic analysis with Liquid chromatography–mass spectrometry for evaluation of wastewater and river water quality

W. Wenlong, Kyoto Univ; T. Mitsuru, National Inst for Environmental Studies / Environmental Biology Division; N. Daisuke, National Inst for Environmental Studies / Center for Environmental Risk Research; Y. Minoru, Kyoto Univ / Dept of Environmental Engineering; S. Hideko, National Inst for Environmental Studies / Center for Environmental Risk Research

Image-based phenotypic profiling was well applied for drug discovery through measurement of cellular phenotype that related on toxicity mechanism, which exhibit potential for toxicity identification evaluation. We developed an image-based phenotypic phenotypic analysis with human breast cancer MCF-7 cells to evaluate the impacts of whole wastewater and river water, and compared with conventional bioassay (e.g. cytotoxicity test) and non-target chemical analysis (UPLC-qTOF-MS) to evaluate the potential target chemicals. We used 13 cellular parameters (nuclear intensity, nuclear area, nuclear perimeter, nuclear major, nuclear minor, nuclear minor/major, nuclear form factor, cell intensity, cell area, cell major, cell minor, cell minor/major, cell form factor) to characterized cellular morphology, while defined "distance score" in PCA score plot to evaluate phenotypic variation. The "distance score" exhibited dose-dependently relation after 17β-estradiol (E2) exposure, which indicated the sensitivity of image-based phenotypic analysis. Whole water induced various effects of phenotypic variation such as cell body and nuclear shrink; synapse on the cell membrane; rhombus shape; enlarged cell body and nuclear that was well characterized with image-based phenotypic analysis. Compared with cytotoxicity of whole water, the "distance score" showed reduction from wastewater treatment influent to effluent benefited from the multiple toxicity-based parameters, which indicated the capability for toxicity reduction evaluation of image-based phenotypic analysis. To investigate the correlation between potential toxicant in water and cellular phenotype, cell morphology combining non-target chemical analysis (UPLC-qTOF-MS) were correlated using optimized potentials for liquid simulations (OPLS) analysis. We selected 10 phenotype-active chemicals which exhibited high potential as target chemicals in image-based phenotypic analysis. In image-based phenotypic analysis, multiple parameters exhibited information-rich, while phenotypic parameters provided toxicity-related and higher throughput endpoint for Toxicity identification evaluation. We believe that this method is a promising approach for environmental toxicant screening along with toxicity-phenotype-chemicals relations clarification and cell morphology database construction of environmental contaminants.

758 Risk assessment of continous discharge of mixtures of chemical subatances into an urban watershed in Owerri Southeastern Nigeria

A.C. Udebuani, Federal Univ of Technology / Dept of Biotechnology; P. Abara, Federal Univ of Technology Owerri / Dept of Biological Sciences; I.N. Onwurah, Univ of Nigeria / Dept of Biochemistry; J.N. Dike-Ndudim, Imo State Univ Owerri / Medical Laboratory Sciences

Abstract In this study, we used an efficient and economic science-based risk assessment approach to evaluate the impact of mixtures of unquantified concentrations of chemical substances being discharged into an urban watershed inOwerri, Imo State, Nigeria. Water samples were collected from the Nworie River, Owerri in South Eastern Nigeria. Physico-chemical characterization of water samples from upstream, midstream and downstream of the river was carried out using standard methods. Parameters studied included turbidity, colour, pH, phosphate, nitrate, BOD, COD, amongst others. Levels of selected heavy metals were also determined in the samples using atomic absorption spectrophotometry (AAS). In the static bioassay tests, five (5) batches of juvenile tilapia fishes, each having seven (7) fishes were exposed to the raw polluted water and filtered polluted water from the watershed as well as uncontaminated water (control) for twelve (12) to twenty-four (24) hours. The exposed juvenile fishes were observed for mortality after 12 h and 24 h exposure periods. Most of the physic-chemical parameters including heavy metals exceeded the WHO guidelines for surface water quality with zinc having the highest concentration in all the sampling locations, followed by lead and arsenic. In the bioassay, 60 – 73% of the juvenile fish died from the raw polluted water, and 15-20% for the filtered polluted water. No death was recorded in control. There is therefore, need for the mitigation and control of influx of chemical substances into this river ensure human and environmental health.

759 Assessment of the prevalence of Chromobacterium violaceum, in Domestic water sources in Imo State, Nigeria

J. Dike-Ndudim, Imo State Univ, Owerri / Medical Lab Science; L.N. Egbuobi, Public Health Laboratory; H.M. Okorie, Imo State Univ Owerri / Medical Lab Science

Chromobacterium violaceum, as opportunistic pathogen of extreme virulence, infects human through soil, contaminated – puncture wounds, food and water. It is a less common water-borne pathogen, but due to its high virulent nature, it becomes a great concern to public health and environmental scientists. Hence this research primarily aimed at monitoring and ascertaining the prevalence of this organism "Chromobacterium violaceum" in domestic water sources in a tropical environment and determining its antimicrobial susceptibility was embarked on. Twenty-four (24) water samples were aseptically collected from five water sources in Owerri (Otamiri River, Nworie River, Borehole, Tap and sachet water) into sterile bottles for this analysis. The water samples were transported to the Microbiology laboratory of the department of Medical Laboratory Science, Imo State University, Owerri within six (6) hours of collection and analyzed bacteriologically by pour plate method on Nutrient Agar for viable heterotrophic counts. Typical colonies of C. vidaceum were isolated and purified, on fresh sterile Nutrient agar medium. Thereafter, the antibiotic susceptibility test was performed using disc diffusion technique on sterile nutrient agar. Otamiri river source recorded the highest viable heterotrophic bacterial count ($7.4x10^5$cfu/ml), while Borehole water source recorded the least viable heterotrophic count ($1.5x10^5$cfu/ml). The prevalence of Chromobacterium violaceum in domestic water sources is 5(25%) and was isolated only from Otamiri River, sachet and borehole, among other sources. The antimicrobial profile showed that Chromobacterium violaceum is highly resistant to antibiotics. Hence, it is recommended that enlightenment campaign to educate the masses of the health risk associated with the use of water contaminated with this organism, while Government should vote more money into water ministry to fight this bug.

Mercury Fate and Biogeochemistry

MP001 Predicting methylmercury (bio)availability at the base of the aquatic food web

S. Klapstein, Acadia Univ / Earth Environmental Science; D.A. Risk, St Francis Xavier Univ / Earth Sciences; S.E. Ziegler, Memorial Univ of Newfoundland / Earth Science; N.J. O'Driscoll, Acadia Univ / Dept of Earth and Enviromental Science

Methylmercury (MeHg) toxicity is of particular interest in remote environments, far from point sources of contamination, where high levels of MeHg are accumulating in top predators. The ecosystem variables that control this sensitivity of food webs are not well known. MeHg concentration in water and uptake into the base of the food web is one key factor controlling mercury entry into food webs. To date, few studies have directly considered photodemethylation reactions in combination with physical attributes of aquatic ecosystems to predict where and when dissolved MeHg may be available. To address this research gap we have used numerous controlled and semi-controlled experiments that focused primarily on the quantification of the relationships between solar radiation exposures, dissolved organic matter (DOM), and MeHg within six freshwater lake systems. DOM photoreactivity measured through photobleaching of lake water within our study system was primarily driven by DOM concentration (quantified as dissolved organic carbon (DOC); R^2=0.94). A DOM photoreactivity manipulation experiment that used water from one lake did not show consistent prediction of photodemethylation rate constants. Photodemethylation rates tended to be higher in water collected during early summer, when in-situ DOM concentration was lower, than in water collected in late-summer or fall ($p < 0.05$). DOM concentration could explain 76% of variation in photodemethylation rates in an inter-lake comparison semi-controlled natural solar radiation experiments conducted over 1 week periods in summer and fall. By quantifying the photoreactivity of DOM and the interplay between DOM and MeHg photoreactions, we have developed a model for predicting photodemethylation potential and efficiency within the top 1 m^3 in oligotrophic dystrophic temperate lakes. These outcomes were then scaled up and used to calculate the overall photodemethylation potential in each of our six study lakes for comparison with MeHg concentrations in the corresponding food webs. This model may be appropriate for other aquatic ecosystems by simple standardization techniques depending on water quality characteristics such as DOM photoreactivity (structure), pH, and dissolved ionic species. Overall, this compiled body of work yielded a method for predicting mercury availability to food webs depending on environmental and physicochemical factors.

MP002 Does amino acid content explain methyl mercury concentrations in aquatic invertebrates?

J.C. Thera, K.A. Kidd, Univ of New Brunswick; R.F. Bertolo, Memorial Univ of Newfoundland; N.J. O'Driscoll, Acadia Univ / Dept of Earth and Enviromental Science

Methylmercury (MeHg) concentrations in aquatic invertebrates are known to be highly variable within and among systems. For example, in Kejimkujik National Park, Nova Scotia, Canada, Aeshnidae dragonflies showed a 3-fold difference in MeHg among lakes. Though the concentrations of MeHg in invertebrates are important predictors of MeHg in fish, the factors driving MeHg variability in invertebrates are less understood. In biota, MeHg is stored in proteins bound to the sulphur-containing amino acid cysteine. Our objective was to determine if the cysteine content of organisms varies within and between aquatic food webs and may be used to model MeHg variability among taxa and systems. Benthic macroinvertebrates from different functional feeding groups and zooplankton (bulk) were collected from six lakes in Kejimkujik National Park that are known to vary in physical and chemical characteristics and biotic MeHg. MeHg concentrations were measured and compared to protein bound cysteine (as cysteic acid) and 14 other amino acids (ultra performance liquid chromatography; UPLC). Multiple discriminant analysis revealed significant differences in the amino acid composition of taxa (Wilk's lambda, $p < 0.0001$) with cysteine as one of the primary discriminating variables. Cysteine content (per mg total protein) differed among invertebrate taxa, with the lowest concentrations in Limnephilidae caddisflies and the highest concentrations in zooplankton. Preliminary results also indicated that log MeHg (mg/kg dw) was significantly and positively related to cysteine within three of the four taxa ($p \leq 0.01$). These results suggest that cysteine content explains some of the among-taxa differences in MeHg concentrations and will improve our understanding of the factors that drive MeHg variability in aquatic food webs.

MP003 Interaction of Mercury with Thiols: Complexation and Enhanced Dissolution of Mercury Sulfide

G. Liu, P. Jiang, S. Chen, Y. Cai, Florida International Univ / Dept of Chemistry Biochemistry and Southeast Environmental Research Center

The biogeochemical cycling of mercury (Hg), a notoriously toxic contaminant of worldwide health concern, includes complicated transport and transformation processes that are regulated by a variety of environmental factors. The presence of thiol (-SH) containing substances in the environment, including low molecular weight (LMW) amino acids and natural organic matter (OM), has profound effects on the mercury speciation, mobility, and reactivity. The effect of thiol-containing substances on environmental behavior of mercury sulfide (HgS) has recently drawn much attention. Although often being regarded as one of the largest sinks for Hg in sediments, soils, and sulfuric waters due to its extremely low solubility, mercury sulfide can undergo enhanced dissolution in the presence of thiol-containing substances, which could act as an important process in controlling mercury transport, transformation, and bioaccumulation. In the presence of different thiol-containing substances, including cysteine, glutathione, and humic substances, the dissolution of mercury sulfide was investigated. It was found that thiol-containing substances could promote the dissolution of mercury sulfide, with varying enhancing effects depending on type of thiol-containing substances. The enhancing effect of thiol-containing substances on mercury sulfide dissolution was related to complexation of mercury with thiols. After dissolved mercury is released into the solution from mercury sulfide dissolution, the complexation of mercury with thiols could hinder the dissolved mercury being re-adsorbed back to the surface of mercury sulfide solids and thus enhance the dissolution.

MP004 The Influence of Avian Biovectors on Mercury Speciation in a Coastal Wetland

J. Kickbush, Acadia Univ / Biology; M. Mallory, J. Rand, J. Murimboh, Acadia Univ; N.J. O'Driscoll, Acadia Univ / Dept of Earth and Enviromental Science

Mercury is a persistent and bioaccumulative chemical that is present in many remote environments due to its ability to be transported long distances in the atmosphere, and to be deposited far from the original source (Sunderland and Chmura 2000). Wetland ecosystems are important "hot spots" for mercury in eastern Canada, providing anoxic environmental conditions that promote the bacterial methylation of mercury. Methylmercury is the most biologically available form of mercury and the form which biomagnifies in food webs (Gochfeld 2003). Seabird guano is a well-documented biovector for metals – including mercury – and nutrients, which may indirectly affect metal speciation (Choy et al. 2010). The site for this study, Big Meadow Bog (Brier Island, Nova Scotia, Canada) has a history of ditching in the 1950s, which changed hydrology significantly, resulting in colonization by 3000 pairs of herring gulls (Larus argentatus) in the 1980s. To quantify changes in mercury mobilization and speciation in response to this biovector, groundwater samples were collected from this site as well as a reference bog with similar geological and hydrological characteristics. The filtered samples were analyzed for total mercury, methylmercury, and water chemistry (pH, conductivity, anions, cations, and dissolved organic and inorganic carbon). Preliminary results show higher nutrients (nitrate, phosphate, and sulfate), total mercury, and methylmercury concentration when compared to the reference bog that is minimally impacted by avian biovectors. This elevated

availability of methylmercury could potentially pose a threat to the local ecosystem and wildlife population due to methylmercury's toxicity to living organisms (Akearok et al. 2010, Singh et al. 2011).

MP005 A mechanistic investigation of mercury reduction and volatilisation in soil

E. Mann, R. Khusial, A. Carpi, John Jay College of Criminal Justice CUNY / Dept of Sciences

Mercury (Hg) is a ubiquitous, toxic and bioaccumulative environmental contaminant that undergoes reaction to change speciation and environmental fate. Some areas, like the Oakridge National Laboratory Y-12 National Security Complex (TN, USA), have experienced historical contamination of surrounding soils with Hg, and remediation of such sites has been complicated by poor mechanistic understanding of Hg reactions. Specifically, non-volatile Hg species in soil can undergo reduction to form volatile Hg(0), which can then be lost to the atmosphere; however, the mechanism of this reaction is not known. This work used a computational study, coupled with laboratory experiments to propose one mechanism for reduction of one environmentally relevant Hg species, mercury (II) chloride ($HgCl_2$), in soil-like environments. Computational modelling using Gaussian software suggests that $HgCl_2$ reduction might include a unimolecular dissociation driven by scissoring of the chlorine bonds to form Hg(0). Based on the energy of excitation suggested in these computational results, we hypothesized that UVB radiation would provide the energy necessary to reduce $HgCl_2$ to Hg(0) via photolysis, without requiring a secondary electron donor. To test this, clean silica sand was spiked with an aqueous solution of $HgCl_2$, and exposed to full spectrum radiation, while the flux of Hg(0) from this sand was quantified over time. Laboratory flux results show some unexpected variability that may indicate factors in addition to radiation (eg/atmospheric composition) could be affecting $HgCl_2$ reduction in these sand samples; as a result, experiments are ongoing in an attempt to discern the nature of these effects.

MP006 The influence of chloride concentration on Hg photochemical reduction in melted Arctic snow

E. Mann, John Jay College of Criminal Justice CUNY / Dept of Sciences; S.E. Ziegler, Memorial Univ of Newfoundland / Earth Science; A. Steffen, Environment and Climate Change Canada / Science and Technology Branch / Air Quality Research Division; N.J. O'Driscoll, Acadia Univ / Dept of Earth and Enviromental Science

Mercury contamination in Arctic snow is a cause for concern due to springtime deposition and melt that may transport mercury to local aquatic environments. Chloride (Cl^-) content has been linked to snowpack Hg concentrations in the Canadian high Arctic, where higher Cl^- snow has higher Hg concentrations, which may mean greater Hg movement to aquatic environments with spring snow melt. Hg in frozen or melted snow may also undergo photoreaction, which will alter the Hg load in the snow/snow melt; however, the effects of Cl^- concentration on photoreactions of Hg in Arctic snow/snow melt have not been determined. A laboratory study was undertaken to quantify the effects of Cl^- concentration on Hg photoreduction kinetics in Arctic snow, with the goal of providing predictive equations that could be implemented into Hg fate and transport models. Snow was collected from Alert, NU, Canada from 9 to 11 May 2014 into 2.2L Teflon bottles, and melted before being re-frozen and shipped south for analysis. Samples were thawed and spiked with 0 – 10 ppm added Cl^- (as NaCl). Samples at each Cl^- concentration were irradiated in triplicate at 4°C, with UV (280 – 400 nm) radiation from 1.26 – 5.78 $W \cdot m^{-2}$ for 24 – 48h in a LuzChem photoreactor. Photoproduced Hg(0) was quantified using a Tekran 2537, and pseudo-first order kinetic parameters, photoreduction rate constants (k) and total photoreduced Hg amounts ($Hg(II)_{red}$), were determined for each UV/Cl^- treatment. Relationships between Hg photoreduction kinetics, Cl^- concentration and UV intensity were derived. With such relationships, existing Hg fate and transport models can better predict Hg reduction dynamics in the Arctic where snowpack Cl^- concentrations can be very spatially variable, and Cl^- loadings to snow are predicted to increase as changing climate conditions continue to influence Arctic sea ice cover duration and extent.

MP007 Evaluation of Fish Length to Methyl Mercury and PCB Relationships--Teasing Out Interactions to Support Risk Management

H. Summers, Integral Consulting Inc. / Inst of Environmental Toxicology and Chemistry; K. Whitehead, J.L. Durda, Integral Consulting Inc

Methyl mercury (MeHg) and polychlorinated biphenyls (PCBs) are being monitored in fish tissue at the Berry's Creek Study Area (BCSA), a Superfund site located in a side embayment of the Hackensack River in the Meadowlands, New Jersey. Mummichog (Fundulus heteroclitus) and white perch (Morone americana) have been monitored since 2009 for tissue concentrations of MeHg, PCBs, and other chemicals of potential concern. Levels of MeHg in fish are affected by a number of variables such as environmental methylation rates, bioaccumulation in prey, fish movement and growth rates, and fish population age structure, all of which can change annually. In systems where exposure is variable because of environmental chemical concentration gradients and fish movement, control for species size and understanding of other biotic factors is important for establishing a baseline data set for long-term monitoring. At large, contaminated sites, spatial refinement of bioaccumulation and risk patterns is critical to the success and cost effectiveness of risk management strategies. The objectives of this analysis are to quantitatively characterize the relationships between white perch and mummichog MeHg and PCB concentrations as a function of fish length/weight and to evaluate interactions among environmental compartments in order to establish a baseline data set for risk characterization. A correlation analysis was conducted for white perch and mummichog length/weight and MeHg and PCB concentrations; significant bivariate relationships were further evaluated to develop regressions using general linear models that included co-variables of sampling year, geographic reach, lipid content, tissue type, and sex. Correlations were found between mummichog length and MeHg tissue concentrations, but linear fits and r2 values were poor. Correlations were also found between white perch length and MeHg and PCB tissue concentrations. However, white perch lengths varied significantly among sampling years and thereby confounded interpretation of trends in MeHg and PCB tissue concentrations, preventing the development of meaningful regression relationships for the site. Therefore, to support long-term monitoring needs, sampling strategies were altered to focus on the most prevalent size class of white perch in the BCSA, not on only the largest white perch.

MP008 Numerical Water Quality Criteria Derivation to Protect the Florida Panther Using the Everglades Mercury Example

L.E. Fink, Waterwise Consulting, LLC / Owner and Principal

The Florida panther (Puma concolor coryi) is listed as an endangered species under the Federal Endangered Species Act (ESA) and is Florida equivalent statute. This requires that the responsible agencies restore and protect the quantity an quality of the habitat and connecting corridors using a srategy set forth in the ESA-mandated Florida Panther Recovery Plan (FPRP). Unfortunately, some portions of South Florida considered by the U.S. Fish and Wildlife Service and its Florida counterpart to be suitable Florida panther habitats have a methylmercury (MeHg) contamination problem. This represents a toxic chemical barrier to full utilization of otherwise suitable habitat by Florida panthers that forage on prey linked to the aquatic food chain. The FPRP fails to take this toxicological barrier into account, beyond mention of a need to continue monitoring Florida panther blood and fur for toxic substances. This is a fatal flaw in the FPRP. It has been compounded by the failure of the U.S. Environmental Protection Agency to promulgate a MeHg Water Quality Criterion (WQC) and related Total Maximum Daily Load (TMDL) under the Clean Water Act to ensure Florida panther protection in the absence of timely promulgation by the State of Florida. Instead, EPA Region 4 approved a Florida Statewide Mercury TMDL Plan that sacrifices the human use of the Everglades as a sport fishery, let alone fish-eating wildlife that consume large fish at higher rates in proportion to their body weight than humans. This is also true of their opportunistic predators. The Florida panther is linked to the aquatic food chain via its consumption of raccoons, otter and juvenile alligators when its preferred prey species are scarce or inaccessible as a consequence of unsuccessful competition with the fitter or a physical barrier such as high water levels. A fish-equivalent WQC protective of the Florida panther can be derived using a series of linked steady-state bioaccumulation models, reasonable assumptions about predation preferences for raccoon, otter and juvenile alligator, their predation preferences for various fish, amphibian, and shellfish species, and reasonable values for representative bioaccumulation factors in the Everglades aquatic food chain. When that is done, Florida's TMDL Water Quality Target of 0.3 ppm in fish flesh cannot be demonstrated to be fully protective of the cognitive function of Florida panthers forced to forage on prey linked to the Everglades aquatic food chain.

MP009 Effects of Coastal Managed Retreat on Mercury Biogeochemistry

T. Sizmur, Univ of Reading / Geography and Environmental Science; A. Godfrey; N.J. O'Driscoll, Acadia Univ / Dept of Earth and Enviromental Science

We investigated the impact of managed retreat on mercury (Hg) biogeochemistry in the Bay of Fundy, which is subject to diffuse contamination with Hg. We visited Beaubassin Research Station on the Chignecto Isthmus between Nova Scotia and New Brunswick and collected sediment cores from an area of land that was due to be inundated with seawater after a failing dyke was intentionally breached. We returned two years later, re-sampled the dyke cell and also collected sediment cores from an adjacent mudflat and a salt marsh. We analysed the total mercury (THg) and methylmercury (MeHg) concentrations of the sediments in the cores. We discovered that the concentration of THg in the sediment doubled after the dyke was breached due to the deposition of fresh sediment that had a smaller particle size, and higher pH. The concentration of MeHg was 27% lower in the sediments after the dyke was breached. Because we found greater concentrations of THg and lower concentrations of MeHg after the sediments were inundated we can conclude that the reduction in MeHg was due to a low bioavailability of Hg to the sulphate reducing bacteria capable of methylating Hg. This may have occurred due to higher organic matter levels, greater sediment pH, and higher ionic strength. Overall we did not find any evidence to suggest that coastal managed retreat resulted in an elevated risk of Hg methylation during the first year after inundation. As the sediment becomes vegetated, increased activity of Hg-methylating bacteria may accelerate Hg-methylation rate.

MP010 The effect of solid phase sorbent materials on the leachability of mercury from contaminated soils

C. Miller, Troy Univ / Biology and Environmental Sciences; S. Lukjan, Troy Univ / Chemistry; J. McCurdy, Troy Univ / Biology and Environmental Sciences; A. Johs, Oak Ridge National Laboratory; B. Robertson, Alabama State Univ / Biological Sciences

Streambank soils within the East Fork Poplar Creek (EFPC) watershed have elevated concentrations of mercury (Hg) as a result of historic use and discharge of Hg into the system associated with activities at the Y-12 National Security Complex. Mercury can leach from these soils as a result of water level fluctuations and erosion of stream banks resulting in the soils acting as a source of Hg to the creek. Laboratory experiments were conducted to examine the amount of Hg leaching from two soil samples collected from EFPC and a soil sample collected from Hinds Creek, an uncontaminated creek used as a reference site. For these batch laboratory studies the amount of mercury leaching from the soils when exposed to artificial creek water, consisting of a calcium nitrate solution, or actual creek water was examined for two weeks with samples collected every 3-4 days. After two weeks, solid phase sorbents were added to some of the samples and the amount of Hg leaching from the soils with and without sorbent addition was examined for an additional two weeks. The concentration of Hg in the reference soil was 0.028 µg/g and the two soils from EFPC had Hg concentrations 100 and 10,000 times greater than the reference soil. After the two week leaching period with artificial creek water, the concentration of Hg in the aqueous solution was 7 ng/L for the reference site. The aqueous phase concentration from the treatments containing EFPC soils were 100 and 1,000 times greater than the reference soil treatments. The solid phase sorbents that were tested include Thiol-SAMMS®, Organoclay™ PM-199, Organoclay™ MRM, SediMite™ and a biochar. The results from this laboratory study will help evaluate the usefulness of solid phase sorbent materials as a remedial option for reducing the amount of Hg leaching from soils into EFPC.

MP011 Developing a Centralized Mercury Knowledge Sharing Platform Using Emissions, Fate and Exposure Data

R.O. Barra, Universidad de concepcion / Aquatic systems; B.W. Vigon, SETAC; C. Wellington-Moore, UNEP GEF/STAP; D.C. Evers, Biodiversity Research Inst; M.S. Bank, Univ of Massachusetts / Dept of Environmental Conservation

The global agreement reached in 2013 regarding Mercury is a milestone in the chemicals management of pollutants. The so-called Minamata Convention has been signed, and is now being ratified by many countries (27 at the time of writing). Critical to achieving the goal of protecting human health and the environment from mercury, is the grounding of action in evidence, which in turn relies on sound scientific information about emissions, fate and impacts, typically captured in scientific journals and other literature often not accessible to other stakeholders. To develop regional and local knowledge bases for management and evidence based decision-making requires, in part, the ability to capture, synthesize, analyze and visualize data at varying scales and timeframes. It is also essential to facilitate understanding among global governance mechanisms, financiers, regulators and other stakeholders on how mercury emission reductions and site–specific projects, associated with implementing provisions of the Convention, affect the broader exposure and risk profiles of human populations and ecosystems. This initiative to develop a centralized Mercury Platform, which is in its first phase, attempts to create and manage an interoperable platform, deployed via UNEP Live, for data upload and download as well as knowledge sharing through information synthesis and facilitation of Communities of Practice comprising expert and critical stakeholder groups. A potential user survey was conducted in early 2016, targeting scientists, Minamata Convention focal points, stakeholders and SETAC members and drew responses from >400 individuals from different geographic regions throughout the globe. The term "knowledge sharing" is a deliberate attempt to move beyond traditional web-based delivery of quantitative but un-interpreted information. This will be achieved through user--mediated requests for data synthesis and visualization as well as implementation of standardized data protocols and delivery of meta-data as a component of shared output. This is being done through a demonstration pilot hosted at the UNEP Live platform, using the Biodiversity Research Institute's Global Biotic Mercury Syntheses database on selected biota. A key element of knowledge creation is the incorporation of pre-set or user-defined ways to provide insights and answers, not just data. The foreseen critical elements of a more full scale deployment of the platform will also be presented.

MP012 A Mercury Impacted Aquatic Food Web Based on Empirical Data

C. Mancini, AECOM / Environmental Services; S. Thakali, J. Collins, AECOM; R.G. Stahl, E.I. DuPont de Nemours and Company / Corp Remediation

Historical mercury (Hg) releases occurred at a textile manufacturing facility on the South River, Virginia, resulting in increased Hg concentrations in biotic and abiotic media, which have not declined over the past thirty years, as originally expected. Effective remediation of the Hg contamination requires a clear understanding of both migration, and complete exposure pathways. This model is further complicated by the unique nature of the biogeochemical fate of mercury in the environment, along with the relationships of discrete linkages among abiotic and biotic endpoints. In addition, the remedy must include a robust monitoring program, informed by these pathways. As such, good quality empirical data are essential to ensure primary and secondary sources are being remediated. This presentation will summarize the characterization and assessment of the aquatic food web associated with a portion of the South River watershed based on comprehensive empirical data collected over more than a decade. These data sets formed the basis for the development of the monitoring scheme that will provide input to an adaptive management framework to assess the effectiveness of the proposed remedy.

MP013 Survey of mercury in the fur of Bats (Chiroptera) of Coastal South Carolina

N. Roach, Florida Gulf Coast Univ; D.G. Rumbold, Florida Gulf Coast Univ / Depart of Marine and Ecological Sciences

Exposure to methylmercury (MeHg) has been widely overlooked in insectivorous organisms due to the perception, which has been shown repeatedly to be incorrect, of reduced exposure by low trophic level organisms. Bats may be at risk of MeHg exposure due to their high metabolic rates, relatively low caloric content of their prey, link to aquatic food webs, and their long lifespan, of up to twenty years. Bats eat a wide variety of insects, some of which have aquatic larval stages which gain MeHg from their environment before becoming a flying adult insect. Accordingly, fur was collected from bats during a "Bat Blitz" in Beaufort County, South Carolina over three days in July 2015. This area of South Carolina is colloquially called the "low country" and characterized by the small elevation gradient, large tracts of marshlands, and meandering streams. Total-Hg in fur ranged from 1.5 mg/kg to 34.8 mg/kg in the Seminole Bat (Lasiurus seminolus, n=117) and from 3.5 mg/kg to 78.0 mg/kg in the Big Brown Bat (Eptesicus fuscus,n=40). Patterns in fur-Hg related to sex, maturity, forearm length and location will be presented and discussed in the context of results of surveys of bats from other areas reported in the published literature. To our knowledge, this is the first survey of Hg in bats in the United States south of Virginia.

MP014 Mapping gaseous mercury concentrations around an abandoned mine in Italy using passive air samplers

D. McLagan, Univ of Toronto Scarborough / Chemistry; F. Monaci, Univ of Siena; H. Huang, Y.D. Lei, C.P. Mitchell, Univ of Toronto Scarborough / Dept of Physical and Environmental Sciences; F. Wania, Univ of Toronto at Scarborough / Physical and Environmental Sciences

The Abbadia San Salvatore mercury (Hg) mine (Central Italy) was the largest mine of the Mount Amiata Hg ore district and the third largest site of Hg production during the 20th century. Despite the cessation of operations in 1983 and recent remediation work, the mine remains a major source of Hg to the environment, especially the atmosphere. To map the atmospheric dispersion of gaseous Hg in the region we employed our recently calibrated passive air sampler for gaseous Hg. Sampling has been completed across two 7-by-7 sampling grids: a fine-spatial scale (~1km^2 total area) around the mine itself (week long deployments in October 2015 and June 2016) and a coarser grid (~50km^2 total area) across the western slope of Mt. Amiata (four 3-month deployments in 2015/16). The vertical concentration gradient of gaseous Hg was assessed by placing samplers at 2-4 m intervals above the ground on several taller structures within the mine site. Finally, uptake experiments were conducted in the Pacific Furnace and Carpentry buildings, both known to have very high gaseous Hg concentrations, to ascertain the maximum amount of Hg that the samplers can take up and provide increased temporal resolution data at the two sites. The new passive samplers provide the first time-averaged, highly spatially-resolved, and spatially concurrent mapping of gaseous Hg in and around a Hg mine. During the October fine-scale deployment, a strong concentric pattern was observed, with concentrations declining rapidly from the centrally located Pacific Furnace building. Concentrations of gaseous Hg at the Pacific Furnace (up to 7000 ng m^{-3}) and other locations across the mine were in good agreement with other studies that have conducted instantaneous, but non-concurrent gaseous Hg measurements at the site. The vertical gaseous Hg profiles just outside the Pacific Furnace site showed a very strong, decreasing logarithmic relationship with height above the ground, suggesting substantial evasion from an elevated surface source. Samplers did not reach equilibrium at the high-concentration sites despite accumulating up to 3100 ng of Hg over a week of sampling. The temporal variation in this data also correlated well with temperature and a high rainfall event that occurred during the deployment. Analysis of coarse-grid samples is ongoing and results should provide a clear picture of the mine's impact on atmospheric Hg in the region.

MP015 Analysing Nova Scotia lichens for mercury content

C.H. Saunders, A. Walker, Acadia Univ / Biology Dept; R. Cameron, Nova Scotia Provincial Government / Dept of Enviroment; N.J. O'Driscoll, Acadia Univ / Dept of Earth and Enviromental Science

Many lichens (a symbiosis of green algae or cyanobacteria and fungi), being epiphytic upon plant substrates, are known to be excellent air pollution indicators. A variety of lichen species are known to sequester airborne chemicals, including heavy metals such as mercury and are thus ideal biological indicators of such pollutant levels in the natural environment. Currently the spatial patterns of mercury associated with the lichens of Nova Scotia is largely unknown. This study will quantify spatial relationships in mercury adsorbed to lichens across Nova Scotia. Lichens in the genera Usnea and Hypogynmia were collected from sitesacross the province, including from long-term lichen monitoring plots. Samples were dried at air temperature, cryoground and analysed for total mercury by thermal degradation, gold amalgamation- atomic absorbance using a Nippon Mercury Analysis System (MA-2000). Geographic Information Systems will be used to produce mercury concentration gradient contour maps for the province in order to identify areas of high mercury contamination. Additionally, lichens of Nova Scotia are poorly represented in GenBank, and DNA barcoding of select specimens will be conducted, and the findings made available to the scientific community.

MP016 Mercury Concentrations in Apple Snails and Endangered Snail Kites Located in Florida, USA

C. Ortega-Rodriguez, Texas Christian Univ / Dept of Biological SciencesInst of Applied Science; B. Soulen, Univ of North Texas; R. Fletcher, E. Robertson, Univ of Florida IFAS; A.D. Sowers, US Fish and Wildlife Service; A.P. Roberts, Univ of North Texas / Dept of Biology Inst of Applied Science

Metals contamination in a freshwater gastropod, the apple snail (Pomacea sp.), poses a risk to surrounding terrestrial consumers who rely upon them as a food source, such as the endangered snail kite (Rostrahamus sociabilis). Mercury (Hg) is a metal contaminant found in nearly all aquatic systems. However, concentrations of Hg in apple snails and snail kites have not been extensively studied. Here, we determined concentrations of Hg (total Hg, Hg2+, and MeHg) in the native Florida apple snail (P. paludosa), the invasive island apple snail (P. maculata) and juvenile snail kite feathers to examine the relationship between Hg contamination in apple snails and juvenile snail kites. Apple snails and kite feathers were collected from central and southern Florida. Whole body total Hg concentrations for native apple snails was 47.67 to 205.11 ng/g dw, and ranged from 16.71 to 355.99 ng/g dw in invasive apple snails. Most of the total Hg in native and invasive apple snails was MeHg, which accounted for 70-99% of total Hg. Mean feather total Hg concentrations in snail kites ranged from 178.8 to 411.6 ng/g across sites. There was a positive correlation (r^2 = 0.83) between mean total Hg concentrations in apple snails and snail kite feathers across sampling sites. This study is the first to examine the relationship between Hg contamination in apple snails and snail kites and suggests that apple snails may provide a significant route of dietary exposure to MeHg in kites.

MP017 Dried Blood Spots as a novel tool for methylmercury exposure assessment

A. Santa, McGill Univ / Natural Resource Sciences; N. Basu, McGill Univ / Dept of Environmental Health Sciences

Methylmercury is a global contaminant of concern that is being addressed worldwide via the UNEP Minamata Convention. Dietary exposure to methylmercury primarily affects the central nervous system, while prenatal exposure may result in developmental deficits. Mercury levels in blood is a key biomarker for methylmercury exposure in humans and wildlife. However, the use of whole blood as a biomarker possess technical and logistical challenges such as the need for trained personal, adequate sample volume, and cold-chain transport and storage. Some of these challenges may be overcome with dried blood spots (DBS), which have been incorporated into major international data collection efforts (e.g., newborn screening) for over 50 years. The aim of this study was to develop a method to measure MeHg in DBS. DBS were created using human blood MeHg standard reference material (SRM) from the Institut National de Santé Publique du Québec. Three SRMs were used to encompass a range of MeHg concentrations: low 3.28+/- 0.11 parts per billion (ppb), medium 8.68+/- 0.26 ppb, and high 37.21+/- 0.02 ppb. Two, 3 mm sub-samples (6.5 microliters of blood) were digested using alkaline digestion and analyzed with a Tekran 2700. Preliminary results indicate that concentrations of MeHg fall between the expected ranges. Application of this method to wildlife surveillance programs and human biomonitoring endeavours are yielding fruitful results, which will be summarized in the presentation. Taken together, these studies are showing that DBS can be used as a tool to assess MeHg exposure with high accuracy and precision.

MP018 Nutrients and Hg cycling in Long Island Sound embayments

Z. Baumann, Univ of Connecticut / Marine Sciences; N. Mazrui, X. Shi, W. Huffman, R.P. Mason, Univ of Connecticut

The concentration of nutrients in estuarine waters has been hypothesized to influence the magnitude of methylmercury (MeHg) bioaccumulation. A conceptual model developed by Driscoll et al. 2012 suggests changes in nutrient loadings can alter MeHg bioaccumulation in resident biota through several pathways. Data to support the model is, however, yet to be published. This study covers sampling, during the spring and summer of 2016, of water, sediment and biota including shellfish, zooplankton and small forage fish from 5 embayments, known to receive different nutrient concentrations within Long Island Sound. The concentration of total mercury (HgT) and MeHg were measured in water, sediment and biota samples. Concentration of nitrate, nitrite, ammonia and phosphate in the water and pore water collected from these locations were also measured. In addition, we measured dissolved sulfide in pore water as sulfide substanially impacts Hg geochemistry. This presentation will focus on the gradient in nutrient concentrations in seawater and sulfide in pore water and how they influence mercury (Hg) biogeochemistry, especially the production of MeHg in sediments and MeHg bioaccumulation into resident biota. Thus far, our findings show differences in the fraction of HgT occurring as MeHg (% MeHg) in porewater collected from surface sediments, which ranges from 1 to 14%.

MP019 Mercury in Fishes from Yosemite (CA), Mount Rainier (WA), and Rocky Mountain (CO) National Parks: Potential Drivers and Ecological Risk

C. Flanagan Pritz, National Park Service / Air Resources Division; C. Eagles-Smith, USGS / FRESC; J.J. Willacker, USGS / FRESC; M. Lutz, USGS-WRD / Water Resources Division; M. Tate, USGS

The National Park Service (NPS) safeguards over 400 special places for the protection of unique natural resources and scenic beauty. Although celebrated as some of the most pristine ecosystems, recent studies have documented the presence of mercury in fish from NPS units across the western United States, including Mount Rainier (MORA; WA), Rocky Mountain (ROMO; CO), and Yosemite (YOSE; CA) national parks. Even protected areas, such as national parks, are subjected to mercury contamination because it is delivered through atmospheric deposition, often after long-range transport. Approximately 1,200 fish (primarily Salmonidae) were sampled from 52 subalpine lakes and rivers between 2003–2012 in MORA, ROMO, and YOSE, and analyzed for total mercury concentrations. Preliminary results indicate that mercury concentrations in fish varied substantially among and within parks, suggesting that landscape factors may be particularly important determinants of mercury risk in the parks. Basin delineations and landscape models were utilized to determine significant drivers in fish mercury concentrations, such as atmospheric deposition and dissolved organic carbon (DOC). Although mercury concentrations in most fish were low, at some sites they exceeded health thresholds for potential impacts to fish, birds, wildlife, and humans. Ongoing studies aim to further characterize mercury in fish from eastern national parks, evaluate the utility of dragonfly larvae as a biosentinel for mercury in aquatic food webs, and assess mercury source attribution via mercury stable isotope markers. With a strong foundation in research, the NPS strives to understand how best to minimize air pollutants in park ecosystems, including airborne contaminants like mercury where concentrations in fish challenge the very mission of the national parks to leave resources and wildlife unimpaired for future generations.

MP020 Mercury and metals deposition in Flin Flon Manitoba and the Experimental Lakes Area Ontario (Canada): a multi-lake sediment core reconstruction

J. Wiklund, Environment and Climate Change Canada; J.L. Kirk, D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; D.C. Muir, M. Evans, F. Yang, J. Keating, M. Parsons, Environment and Climate Change Canada

Metal ore smelting and refining has historically been a major source of Hg globally, accounting for ~76% of atmospheric anthropogenic Hg emissions between 1850-2008. However, there is a great deal of uncertainty surrounding current and historical Hg deposition and re-emission rates associated with this source. We will present a landscape-scale multi-lake approach to reconstruct the history of Hg deposition sourced from human activities in two remote regions of Canada: the Experimental Lakes Area (ELA), Ontario and Flin Flon, Manitoba, which has been a copper and zinc mining and processing centre since the 1930s and Canada's largest Hg emitter until 2010, when the smelter was closed. 14 high fidelity lake sediment cores were collected from the ELA and Flin Flon regions in 2009-2010. Cores were dated using ^{210}Pb methods, then analyzed for concentrations of Hg. Results show that records of anthropogenic Hg flux and inventory were remarkably consistent among the 5 ELA lakes, but varied by 2 orders of magnitude among the 9 Flin Flon lakes. For the Flin Flon region, we integrated the strong exponential relation between anthropogenic Hg inventory (μg/m^2) and distance from point source to estimate changes in Hg deposition over 5-year time steps within 50 km of the smelter. We estimate that 64±16 tonnes of locally sourced anthropogenic Hg were deposited on the landscape over the ~80 years of smelter operations, which is ~20 times greater than the quantity that has accumulated within 50 km of the ELA since ~1860. Deposition to the Flin Flon landscape accounted for ~11% of estimated emissions until the 2000s, when smelter releases were reduced >10-fold and observed deposition exceeded smelter releases. These results suggest that landscape re-emission of legacy Hg will remain a local and global Hg source for unknown time-scales. Analyses of 45 elements in these same sediment cores demonstrates enrichment of numerous metals/metalloidsover the pre-~1860 baseline in both the ELA and Flin Flon regions. For example, we estimate that 99749.24 Tonnes of metals composed of Ag, As, Bi, Cd, Cu, Ga, Pb, Sb, Se, Tl, Zn, and Te was deposited to the landscape within 50 km of the Flin Flon smelter over its operative career. This represents ~55% of estimated dust releases to air for roughly the same period, highlighting the differences in transport/deposition pathways among Hg and other metals.

Status and Trends of the Landscape-Scale Mercury Problem in South Florida and the Everglades

MP021 Mercury Concentrations in Feathers of Adult and Nestling Osprey (Pandion haliaetus) from Coastal and Freshwater Environments of Florida

D.G. Rumbold, Florida Gulf Coast Univ / Depart of Marine and Ecological Sciences; K. Miller, T. Dellinger, Florida Fish and Wildlife Conservation Commission; N. Haas, Florida Gulf Coast Univ

We determined mercury (Hg) concentrations in feathers of osprey (Pandion haliaetus), both nestlings (n=95) and adults (n=110), across peninsular Florida and the Florida Keys during February-August 2014. Feathers plucked from nestlings, aged 3 to 7 weeks, contained Hg concentrations that ranged from 0.338 mg/kg to 45.79 mg/kg and averaged 6.92 ± 7.58 mg/kg (mean ±1SD). Feathers shed from adults contained significantly higher concentrations ranging from 0.375 mg/kg to 93.65 mg/kg, with an average of 17.8 ± 16.1 mg/kg. These levels were in the upper range of previously reported feather Hg concentrations of osprey and clearly show that Florida continues to have Hg hotspots that are elevated compared to many other regions. While these concentrations did not exceed levels previously reported in osprey from heavily Hg contaminated areas that showed no evidence of reproductive impairments, we cannot rule out potential individual-level effects to highly exposed nestlings after fledging.

MP022 Recreating the Everglades: laboratory modeling of in ovo mercury exposure in the American alligator

F. Nilsen, National Inst of Standards and Technology / Environmental Chemical Sciences Division; A.M. Brunell, Florida Fish & Wildlife Commission; T.R. Rainwater, Clemson Univ; S.E. Long, National Inst of Standards and Technology / Analytical Chemistry Division; L.J. Guillette, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences OBYGYN

The Florida Everglades are one of the most unique and biologically diverse ecosystems on the planet, and home to a variety of endangered animals. The Everglades are also known to accumulate mercury at much faster rates than similar environments in other locations, due to a 'perfect storm' of environmental parameters. These factors make the Everglades an ideal place to study many species-specific responses to mercury exposure; however routine sampling in the Everglades is difficult due to the system's remote location, challenging landscape and required resources. In this study, we utilized the American alligator, a reptilian sentinel with an extensive range throughout the southeastern United States to model mercury exposure in ovo in an Everglades apex predator. Using a routinely monitored population of alligators in coastal South Carolina, we calculated total mercury concentrations in adult blood, egg yolk, and embryos and generated a formula to model this relationship in alligator populations at other locations using an adult female blood sample. We then conducted a laboratory dosing study that reflected the expected egg yolk and embryonic concentrations of total mercury for American alligators in the Everglades. This study utilized two clutches of live eggs collected from a site northern Florida where low concentrations of mercury have been previously measured in adult alligators. Total mercury was measured in a sample of eggs (n = 3) from both clutches prior to dosing, taking into account intra-nest variation observed in previous studies. Eggs from both clutches were combined and then randomly divided into three groups (control/natural dose, low dose, high dose) and dosed by topical application with methylmercury-cysteine at stage 12 of embryonic development. Eggs from each group were analyzed for total mercury at 24hr, 48hr, 7d and 14d after dosing to determine the rate of mercury transmission through the eggshell. The remaining eggs were incubated until stage 27, and then embryonic blood samples were collected and analyzed for total mercury (THg). The samples from 24hr, 48hr, 7d and 14d after dosing suggest that much less than the published 33% of topically applied chemicals transfer through the eggshell. This study demonstrates the utility of modeling for lab-based environmental contaminant research, high intra-clutch variation in THg, and the limitations of topical application as a chemical administration technique in egg dosing studies.

MP023 Assessment of total mercury in sentinel estuarine fishes of the Florida Everglades and adjacent coastal ecosystems

D. Tremain, Florida Fish and Wildlife Conservation Commission / Fish and Wildlife Research Inst; D. Adams, Florida Fish & Wildlife Commission / Fish and Wildlife Research Inst; D.W. Evans, NOAA Center for Coastal Habitat and Fisheries Research

Mercury is a persistent toxicant of concern in south Florida that can bioaccumulate in aquatic food webs to levels that are harmful to human and ecosystem health. Proposed efforts to restore hydrological flow in the Florida Everglades may alter the spatial distribution and temporal trends in mercury bioaccumulation in south Florida fish populations. Monitoring of mercury concentrations in sentinel fish species permits an assessment of changing conditions, natural or anthropogenic impacts on upstream watersheds, and of potential regional influences on human and wildlife consumers of these fish species. Crevalle jack (Caranx hippos) and Gray snapper (Lutjanus griseus) are two common and widely distributed Florida estuarine fishes that are known to accumulate mercury. From 2006-2008, we assessed total mercury concentrations in these two species from 13 broad south Florida estuarine regions situated downstream of proposed Everglades restoration activities. Mean mercury concentrations in jacks and snappers from Florida Bay and Card/Barnes Sound estuaries adjacent to the Taylor Slough watershed were significantly higher than concentrations recorded in neighboring south Florida estuaries, and were as much as 2.0 and 2.7 times higher than concentrations measured in jacks and snappers, respectively, from central Florida Atlantic coast estuaries (i.e., Loxahatchee estuary, St. Lucie estuary, and Indian River Lagoon). Mean mercury concentrations in snappers from many southwest Florida Gulf coast estuaries (0.13—0.28 mg/kg) also exceeded mercury concentrations in snappers collected from neighboring offshore Gulf waters during the same time period (0.14 mg/kg in 2007-2008) and more recently (0.15 mg/kg in 2014-2015). These results provide a comprehensive landscape-scale baseline that can be used to identify mercury hotspots in south Florida, guide future research efforts in the region, and to monitor temporal and spatial changes in estuarine and coastal mercury concentrations as future Everglades restoration activities are implemented.

MP024 A Summary of the Scientific, Administrative and Legal Deficiencies in Florida's Statewide Mercury Total Maximum Daily Load Plan

L.E. Fink, Waterwise Consulting, LLC / Owner and Principal

The U.S. Environmental Protection Agency (EPA) protects the water quality of the nation's waters by reviewing and approving or rejecting and issuing a Total Maximum Daily Load (TMDL) for each water quality-impaired water body that cannot attain each of its duly promulgated Water Quality Standard (WQS) to protect aquatic life and human health after all point sources are in compliance with their technology-based effluent limits. The TMDL is the mass assimilation capacity under seasonally appropriate infrequent design conditions with an explicit or implicit ample margin of safety. The Waste Load Allocation is then divided fairly among all permitted point and nonpoint sources after subtracting the uncontrollable nonpoint source loads. For the WQS to be fully protective of human health, humans must be able to consume fish and shellfish from those waters at rates that do not present an unreasonable risk of diminution of the quantity or quality of life otherwise granted to each citizen by its creator. EPA calculated the methylmercury (MeHg) reference does (RfD) by dividing the lowest observable adverse effect level from an epidemiological study by an appropriate margin of safety. EPA ten translated the RfD into the equivalent total mercury (THg) concentration in fish flesh,by subtracting the national daily average MeHg background dose rate from the MeHg RfD multiplied by the national average woman's body weight and then divided that difference by the national average fish consumption rate multiplied by the trophic level

1, 2 and 3 diet weighted-average bioaccumulation factor for freshwater fish. When this is done using the higher Florida average fish consumption rates and marine fish THg levels, the THg WQC in fish flesh is 0. To avoid this conundrum, Florida adopted a probabilistic risk assessment approach with probability distributions functions for some but not all factors used by EPA in calculating the national MeHg as THg WQC. This resulted in an underestimate of health risks posed to the representative most susceptible fetus when its mother consumes fresh and salt water fish with Florida average THg levels during her pregnancy, let alone at subsistence rates from the most popular fisheries like the Everglades and Florida Bay, both contaminated above Florida's statewide 90th percentile cut-off. It is in this context that I summarize the scientific, administrative and legal deficiencies in Florida's Statewide Mercury TMDL Plan approved by EPA Region 4.

MP025 A contrast in mercury methylating populations and processes at high (U3 in WCA-2A) and low (DB-15 in WCA-3A) sulfate locations in the Everglades

H. Bae, Univ of Florida IFAS / Dept of Soil and Water Science; A. Ogram, Univ of Florida / IFAS / Soil and Water Sciences; F. Dierberg, DB Environmental, Inc.

Methylation of inorganic mercury is the first step leading to bioaccumulation and transfer of mercury across trophic levels. It is generally assumed that sulfate reduction is dominant process controlling mercury methylation in most environments; however, recent studies have shown that the microbial ecology of methylation may be much more complex than previously thought. In this study, we compared the dominant microbial groups responsible for mercury methylation in detritus (surficial floc) in areas of the Everglades with relatively high (U3) and low (DB-15) sulfate concentrations. Somewhat surprisingly, concentrations of methyl mercury (MeHg) were significantly higher in detritus at DB-15 than in U3. This observation is consistent with the relative concentrations of genes linked to mercury methylation (hcaAB), which were ten-fold greater at DB-15 than U3. In addition, genes characteristic of sulfate reducers (SRB) and syntrophs (dsrB) and methanogens (mcrA) were ten-fold higher in DB-15 than in U3 detritus. Note that concentrations of genes do not necessarily represent actual metabolic activities, but rather the potential for activity. Significantly, hgcAB sequences from DB-15 soil and periphyton were also dominated by methanogens; in contrast, most hgcAB sequences in U3 were associated with SRB. We suggest that mercury methylation in DB-15 is controlled in part by methanogens, and that the relatively high dsrB numbers in DB-15 represent syntrophs that also contribute to mercury methylation. This is consistent with the much higher ratios of the concentrations of dissolved organic carbon: sulfate, and lower pore water sulfide concentrations in DB-15 than in U3. The relatively low concentrations of MeHg at U3 may be the result of methylation by SRB, coupled with potentially higher rates of mercury demethylation at this site. Previous studies have demonstrated that demethylation rates are increased with increased sulfate concentrations in the Everglades (Marvin-DiPasquale and Oremland, 1998. ES&T. 32:2556-2563). In conclusion, controls on MeHg concentrations in the Everglades are complex and include methylation by different functional groups of microorganisms whose activities and physiologies are controlled by an array of environmental factors. At U3 and DB-15, the interplay between methanogens and SRB, and between the competing processes of mercury methylation and MeHg demethylation, may explain differences in MeHg concentrations in detritus.

MP026 Removal of Mercury from Surface Water by Constructed Wetlands in South Florida, USA

B. Gu, South Florida Water Mgmt District / Water Resources; N. Niemeyer, South Florida Water Management District / Water Quality Bureau; P. Julian, Florida Dept of Environmental Protection / Office of Ecosystem Projects

Stormwater Treatment Areas (STAs) in south Florida are constructed wetlands designed to remove phosphorus from stormwater runoff originating from upstream agricultural areas, Lake Okeechobee discharge and other upstream land uses. Studies have shown that wetlands can be a significant site of mercury methylation. Concerns were being raised that attempts to reduce downstream eutrophication could inadvertently exacerbate the mercury problem known to be present in the Everglades. As a result, South Florida Water Management District implemented a mercury monitoring program which includes the quarterly collection of inflow and outflow water samples in each STA for analyses of total mercury (THg) and methylmercury (MeHg) during the first three years of operation. Mercury loads and load reductions were calculated using the annual average concentration and hydrological flow data for each STA. Results indicate that STAs displayed net reduction of THg and MeHg with an overall average of 54% for THg and 48% for MeHg. The highest reduction (80%) for THg is found in STA-3/4 and the lowest (7%) is found in Taylor Creek STA. The highest MeHg reduction is found in Taylor Creek STA (67%) and the lowest (19%) in STA-2. During the monitoring period, a total of 3,924 grams and 114 grams of THg and MeHg, respectively, were removed annually from STA inflows. Removal efficiency is thought to be related to mercury load, wetland biogeochemistry and hydrology. Significant insights can be gained by additional studies of the mechanisms of MeHg production and reduction in constructed wetlands.

Particle- or Pollen-Bound Pesticides in the Environment

MP027 Neonicotinoid and phenylpyrazole insecticides and their metabolites: Presence in WWTP effluents and surface water samples

M. Woudneh, R.D. Grace, M.C. Hamilton, J. Cosgrove, SGS AXYS

Neonicotonid and phenylpyrazole insecticides have received significant attention mainly due to their toxicity to aquatic and terrestrial insects. Current analytical methods for these analytes do not measure insecticide metabolites, which are also toxic, and do not include the concentration of synergists, whose presence magnify the toxicity several times, producing under estimated toxicity data for water samples. In the present work, we have developed isotope dilution LC-MS/MS method for the quantitative measurement of 8 neonicotinoids and 6 metabolites, as well as the phenylpyrazole fipronil and 4 of its degradation products. To help with better estimation of water toxicity data the method's analyte list also included three most commonly used synergists; piperonil butoxide, piperonil sulfoxide and MGK 264. The developed method was used for analysis of WWTP effluents and aqueous samples from agricultural areas. Distribution of the insecticides/metabolites dissolved in the aqueous phase and adsorbed to the solid phase was measured and their relative partitioning will be discussed. Ultimately these data contribute to our understanding of the fate and behaviour of some of the most widely used insecticides in the world.

MP028 Neonicotinoid Insecticides and Other Particle Bound Pesticides in the Atmosphere at Agricultural Impacted Sites

R.J. Raina-Fulton, Univ of Regina / Dept of Chemistry Biochemistry

Neonicotinoid insecticides partition between the gas and particle phase in the atmosphere and have a significant particle phase fraction. Fungicides including strobilurin fungicides also partition in the particle phase in the atmosphere. Neonicotinoids and a variety of fungicides have been used on a wide range of crops and particularly for neonicotinoid insecticides have varied application methods including foliar sprays, soil and seed treatments. This study investigates the seasonal atmospheric concentrations of neonicotinoids insecticides and selected fungicides in the particle phase in the atmosphere under field conditions within agricultural regions impacted by applications on varied crops with different schedules to give a real life seasonal trend on the occurrence of these insecticides and fungicides in the particle phase of the atmosphere. The air sampling is completed with a particle/vapour high-volume air sampler with a PM2.5 cyclone attached to the sampling head at most sampling sites. Study area includes Canadian sites within Okanagan Valley, Lower Fraser Valley, and Prairies and US sites within Yakima Valley, Okanogan County, and Prairies. In addition sampling took place at Glacier and Mt. Rainier National Park. These regions were also selected to allow for determination of long-range atmospheric transport events. The initial method development took place at sites in the Canadian Okanagan Valley where there are orchards and vineyards and extended into similar agricultural regions in Okanogan County and Yakima Valley of the United States. Detected neonicotinoids in the particle include imidaclopyrid, clothianidin, and acetamiprid with the highest concentration of 360.0 pg/m^3 for imidacloprid in 2013. Strobilurin fungicides detected included pyraclostrobin, trifloxystrobin, fluoxastrobin, and fluoxastrobin with pyrastrobin concentrations reaching 656 pg/m^3 in 2013. These analysis in 2013 did not include the full seasonal trends so new analysis of samples collected in 2014 or 2015 will be presented to provide a more complete picture of the seasonal variation. The LC/MS/MS method developed in 2015 included 7 neonicotinoid insecticides and 6 strobilurin fungicides in the particle phase and an updated method will be presented with consideration of inclusion of degradation products and other particle associated insecticides and fungicides. Data on other particle bound pesticides will also be presented which utilize GC/MS methods.

Plastic Debris: From the Continent to the Sea

MP029 Quantifying a source of microplastics: Shedding of synthetic microfibers from textiles

B. Carney Almroth, L. Åström, Univ of Gothenburg / Biology and Environmental Sciences; S. Roslund, H. Petersson, N. Persson, The Swedish School of Textiles

Sources, occurrence and fate of microplastics in the environment are a subject of intense research, and they pose a potential threat to aquatic and marine organisms. Plastic fibers, presumably from textiles, have been indicated as a major source of this type of microplastic pollutant. These fibers have been identified in the majority of samples tested, ranging from freshwater to marine systems, surface and deep waters, sediment as well as biota from numerous trophic levels. These fibers are thought to be entering the oceans via washing machines and wastewater treatment plants, as well as house hold dust. In this study, the amount of microfibers shedding from synthetic textile fabrics was quantified for three different materials; acrylic, polyamide and polyester. All synthetic textile fabrics in the study were found to shed, but fleece and microfleece fabrics shed by far the greatest amount of fibers, up to 7360 fibers per m^2 in one wash. Tests showed a higher fiber loss when washing fabrics with detergent rather than without (as has been done in previous reports estimating fiber loss). A greater fiber loss was found among the fabrics that had been repolished to simulate wear, indicating that older garments might shed more as they age and become worn. However, the greatest number of fibers are lost during initial washing of new textile samples. The authors therefore propose that prewashing of all fabrics and garments at factory sites, followed by careful contaimnent of lost fibers at this pre-consumer stage, could be a means of reducing fiber loss to the environment. This study has also applied and optimized industrial standardized washing test, normally used in coloring tests.

MP030 Quantifying and characterizing plastic debris in a south Texas wastewater treatment system

J.L. Conkle, Texas A&M Univ Corpus Christi / Physical and Environmental Sciencees; E. Waddell, Texas A&M Univ Corpus Christi

It is often stated the wastewater treatment plant (WWTP) effluent is one of the major ways in which plastic enters the environment. While this may be true, only a handful of studies have actually examined WWTPs to quantify and examine the characteristics of plastics from this source. In those studies, the WWTPs removed the majority of plastic particles. However, there has been less work on plastic fibers in these systems. In this study, the influent, effluent and biosolids of a wastewater treatment plant with a capacity of 8 million gallons per day was sampled. The objectives of this study were to quantify and characterize plastic entering the WWTP and assess its fate. To accomplish this, samples were taken bi-weekly at a Corpus Christi, TX WWTP for 3 months. Samples were then sieved for plastic particles and fibers at 50 and 300 mm. This research is ongoing, but the expectation is that both plastic particles and fibers will be found in the system, with fibers outnumbered the particles.

MP031 New Methods for Recovery of Microplastics from Digestive and Respiratory Tissue

E.N. Waddell, Texas A&M Univ-Corpus Christi / Environmental Science

Plastic materials are nearly ubiquitous throughout the marine environment, where they negatively impact some marine organisms. Once in the environment they can be consumed actively/deliberately or passively (by filter feeding or when associated with other food materials) in addition to becoming entangled in gills. This uptake of microplastics can result in the bioaccumulation of plastics, necessitating research to quantify microplastics in lower trophic level marine organisms. Extraction and identification of microplastics can be challenging due to their small size and the complexity of the organismal structures in which they accumulate. Some existing extraction methods use concentrated nitric acid and hypochlorous acid to breakdown organismal tissue. However, these chemicals rapidly dissolve nylon, which is commonly used for fishing line, fabrics, ropes, etc. and therefore prevalent in the environment. Due to this presence, it is important to utilize methods that account for nylon when quantifying plastic loads in marine organisms. To quantify microplastic loads in blue crabs (Callinectes sapidus), a new method has been developed where the soft tissues of the digestive system are dissolved using 40% hydrogen peroxide, followed by hot filtration, while microplastics associated with the the non-dissolvable gills are removed using sonication and density separation.

MP032 Microscopic anthropogenic litter in terrestrial birds from Shanghai, China: Not only plastics but also natural fibers

S. Zhao, D. Li, East China Normal Univ

The level of contamination by microscopic anthropogenic litter (0.5–5 mm) in terrestrial ecosystems is not well understood. After chemical digestion in 10% KOH, microscopic anthropogenic litter from the gastrointestinal tracts of 17 terrestrial birds was identified and categorized under a stereomicroscope based on its physical properties and melting tests. In total, 364 items from 16 birds were identified as microscopic anthropogenic litter, ranging in size from 0.5 to 8.5 mm. No relationship between plastic load and body condition was found. Natural fibers, plasticfibers and fragmented plastics represented, respectively, 37.4% (136 items), 54.9% (200 items) and 7.7% (28 items) of total litter items. Small sample sizes limited our ability to draw strong conclusions about the metabolism of naturalfibers, but the decline in the proportion of naturalfibers from the esophagus to stomach to intestine suggested that they may be digestible. Particles smaller than 5 mm represented more than 90% of the total number of pollutant items. Particles with colors in the mid-tones andfibrous shapes were overwhelmingly common particles. The results reflect pollution by microscopic anthropogenic litter in the terrestrial ecosystem of the study area. Microscopic naturalfibers, which may disperse and adsorb chemical pollutants differently from microplastic and may pose an even greater risk, are in urgent need of further research.

MP033 Consequences of environmentally relevant concentrations of microplastic with and without PCBs in a freshwater food chain

C.M. Rochman, UC Davis / Ecology and Evolutionary Biology; S. Teh, Univ of California – Davis; S. Serrato, UC Davis; E.J. Reiner, Ontario Ministry of Environment / Laboratory Services Branch; M. Robson, Brock Univ / Chemistry

Plastic debris has now been documented in several freshwater habitats and animals. Much of this material is microplastic (< 5 mm in size) and is associated with a cocktail of chemicals added during manufacturing that are persistent, bioaccumulative and toxic (PBT). This combination of microplastic and PBTs are likely ingested by freshwater organisms at various trophic levels in nature. Ingestion of microplastic provides another pathway for sorbed chemicals and those already associated with microplastic to transfer to animals with uncertain health effects. Furthermore, there is little information on the extent to which ingesting microplastics may enhance biomagnification in aquatic foodwebs. To provide a better understanding of how microplastic affects chemical transfer and how different types of microplastic affects the health of freshwater organisms we designed an experiment using Asian clams (Corbicula fluminea) and white sturgeon (Acipenser transmontanus). We quantified the pathway for microplastics to transfer sorbed PCBs to prey, measured the chemical transfer of PCBs from prey to a predator and determined how the ingestion of various polymers, with and without PCBs, affects organismal health. Asian clams were exposed for 30 days to separate treatments of microplastic (polyethylene terephthalate, polyethylene, polyvinyl chloride and polystyrene) with and without sorbed PCBs. Next, diets were formulated using purified ingredients and clams from the first exposure and fed to their predators (sturgeon) for 30 days. Chemical analyses using GC/MS were used to analyze concentrations of PCB congeners from microsplastic in animal tissues, allowing us to measure any bioaccumulation and biomagnification. Several toxicological assays, including histophathology and immunohistochemistry were used to measure effects related to exposure to various types of microplastic with and without PCBs. Results of these experiments will be presented.

History and Role of SETAC in the Advancements in Environmental Chemistry and Aquatic Toxicology

MP034 Linking academic training to the 'real world': Adventures in an internship with industry

D.M. Saunders, Univ of Saskatchewan / Toxicology; J.E. Naile, Shell Oil Company / Ecosystems Research Division; J. Hughes, USGS / Columbia Environmental Research Center; D. Lyon, Shell Oil Co. / Shell Health Risk Science Team; C.L. Meyer, Shell Oil Company / Ecotoxicology

We as scientists interpret data from precise observations to inform logical hypotheses and experienced choices, yet when we graduate we are meant to decide upon a career path in one of several fields including academia, industry, and government, without prior experience to inform our decisions. Graduate studies are inherently niche experiences as students are experts in a specific realm of toxicology, generally in the context of academia. In the field of toxicology, which can be viewed as an applied science, it is particularly important to create well informed and experienced individuals who understand the context of their science in the 'real-world'. One method with which to gain experience in different sectors is through internships. For example, some institutions including the Toxicology Centre at the University of Saskatchewan (U of S) and the Ecotoxicology Group at Shell have recently made strides to improve the breadth of experience of graduate students. Students at the U of S who participate in the NSERC funded Human and Ecological Risk Assessment (HERA) program are mandated to complete internships within government, academia, or industry, while Shell has recently initiated a graduate level internship program. These programs help students to understand the context of their science and develop a more informed individual who is better prepared for the challenges following completion of their degree. These programs are unique in that they allow students to apply concepts learned in their studies to real scenarios, effectively demonstrating the value of their training. Further, experience gained from an internship can help to identify gaps in marketable skills and encourage greater thought into ideas of environmental significance and applicability of data, which are not always present in an academic setting. The industry sponsor benefits from having enhanced academic connections, insight into current training methods, a pipeline of talent, and a fresh perspective on their issues. Internship programs such as those initiated at the U of S and the Ecotoxicology group at Shell are unique opportunities for students to gain experience in a diversity of fields and were formed in the tripartite spirit of the Society for Environmental Toxicology and Chemistry. In this presentation we will outline some of the projects and educational experiences of the first generation of Shell interns and discuss the benefits for both the student and the industrial sponsor.

Exposure, Effects and Fate of New Organic Contaminants in Aquatic Ecosystems

MP035 Polyhalogenated Carbazoles in Aquatic Sediments from the United States and China

Y. Wu, D. Chen, Southern Illinois Univ Carbondale / Cooperative Wildlife Research Laboratory and Dept of Zoology; R. Sutton, San Francisco Estuary Inst; K. Xu, Louisiana State Univ / Dept of Oceanography and Coastal Sciences; J. Moore, US Fish and Wildlife Service / Interior; K. Grasman, Calvin College / Dept of Biology; Y. Qiu, Tongi Univ

The present study reports the discovery of a suite of polyhalogenated carbazoles (PHCZs) in aquatic sediments collected from five watersheds located in United States and China, including the Saginaw River system (Michigan, USA), Gulf of Mexico (USA), San Francisco Bay (USA), Lake Tai (China), and Lake Dianshan (China). While halogenated carbazoles have recently been reported in sediments from the Great Lakes of North America and a few other aquatic systems in Europe, data on their occurrence remain overall limited worldwide. In this study, 11 halogenated carbazoles, including 3-chloro, 3,6-dichloro-, 1,3,6,8-tetrachloro-, 2,3,6,7-tetrachloro-, 3-bromo-, 2,7-dibromo-, 3,6-dibromo-, 1,3,6-tribromo-, 1,3,6,8-tetrabromo-, 1-bromo-3,6-dichloro-, and 1,8-dibromo-3,6-dichloro-carbazole were screened. Halogenated carbazoles were detected in 98.7% of the sediment samples, with concentrations ranging from below method limits of quantification to 51.5 ng/g dry weight. In most of these sediment samples, PHCZ concentrations exceeded those of polybrominated flame retardants (PBDEs). The latter group of chemicals has been demonstrated to be persistent and globally distributed. In general, 3,6-dichlorocarbazole was consistently the dominant congener, followed by 3-chlorocarbazole, in the studied watersheds, except for the Lake Tai sediments, where. 3,6-dibromocarbzole rivaled 3,6-dichlorocarbazole in concentrations. Additionally, 1,3,6-tribromo-, 1,3,6,8-tetrabromo, 1-bromo-3,6-dichloro-, and 1,8-dibromo-3,6-dichloro-carbazole were also frequently detected. These findings demonstrated that polyhalogenated carbazoles are widely distributed in marine and freshwater systems in the USA and China. They may represent another group of persistent organic pollutants with global distribution and dioxin-like effects. Future investigations are needed to elucidate their sources and fate, as well as ecological risks, in global aquatic environments.

MP036 Chemicals of Emerging Concern (CECs) in the Saginaw River System

Y. Wu, H. Tan, Southern Illinois Univ Carbondale / Cooperative Wildlife Research Laboratory and Dept of Zoology; J. Moore, US Fish and Wildlife Service / Interior; K. Grasman, Calvin College / Dept of Biology; L.L. Williams, US Fish & Wildlife Service; D. Chen, Southern Illinois Univ Carbondale / Cooperative Wildlife Research Laboratory and Dept of Zoology

The present study investigated a variety of chemicals of emerging concern (CECs), including flame retardants and polyhalogenated carbazoles (PHCZs), in the Saginaw River System (Michigan, USA) and the Saginaw Bay of Lake Huron. Surface water samples were collected from 14 representative sites in the watershed in the spring and summer of 2014 and 2015, and surficial sediments were collected from the same sites in 2014. After sample cleanup by gel permeation chromatography and solid phase extraction, target compounds were quantitatively determined on gas chromatography coupled to a single quadrupole mass spectrometer. In sediments, concentrations of organophosphate flame retardants (OPFRs) ranged from 2 to 151 ng/g dry weight (dw), significantly greater than the levels (0.11 – 42 ng/g dw) of polybrominated flame retardants (PBDEs). Additional flame retardants, such as bis(2-ethylhexyl)-3,4,5,6-tetrabromophthalate (BEH-TBP), bis(2,4,6-tribromophenoxy)ethane (BTBPE), tetrabromo-o-chlorotoluene (TBCT), and 1,2,5,6-tetrabromocyclooctane (TBCO) were also frequently detected in sediments. The total concentrations of non-PBDE, alternative flame retardants (excluding OPFRs) ranged from 0.1 to 22.9 ng/g dw. In surface water, concentrations of OPFRs (16.6 – 418 ng/L) far exceeded those of PBDEs (non-detection to 1.0 ng/L) and other flame retardants (generally no detection). In addition to flame retardants, PHCZs were also widely distributed in the watershed, with concentrations in sediments of 1.4 – 68.6 ng/g dw. PHCZs are an emerging group of persistent organic pollutants possessing dioxin-like effects. Overall, our findings suggest that emerging flame retardants are widely distributed in the Saginaw River system. Use of some of them has been increasing as replacements for PBDEs in a variety of applications. Therefore, environmental monitoring is needed to track the concentrations of these flame retardants and other CECs over time in the Saginaw River watershed and assess whether they may be posing risks to biota.

MP037 Source and Risk Assessment of Persistent Organic Pollutants (POPs) in Water and Sediments from the Bosten Lake, Northwest of China

W. Chen, Lancaster Univ / School of Environmental Studies; F. Peng, S. Qi, C. Qu, X. Xing, China Univ of Geosciences / School of Environmental Studies

The Bosten Lake is the largest inland freshwater lake in China and among the most important water sources in the arid region of Northwest China. To study the distribution and source of the pollutants in this region is essential for protection of the fragile ecosystem and further assessment of potential risk to ecosystem and human health. Water and sediments samples were collected from the Bosten Lake and analysed for persistent organic pollutants (POPs). Our previous study (Chen et al, 2011) showed that the all the organochlorine pesticides (OCPs) except o,p'-DDT were detected in sediments from the Peacock River which supplied by the Bosten Lake, indicating that Bosten Lake and/or agricultural tailing water returned directly into the Peacock River could be a possible source of OCPs. The results from the Bosten Lake showed that the OCPs were also widely detected in both water and sediments. The distribution characteristics of OCPs are impacted by the human activities around. The input accompanied with water and suspended particulate matters from the Kaidu River, atmospheric transport and human activities could be the main sources of the POPs in the Bosten Lake. As the important source of the water supply, the potential risk to the ecosystem and human health for POPs couldn't be disregard in the Bosten Lake region.

MP038 Chronic and multigenerational toxicity evaluation of the flame retardant tris (2-butoxyethyl) phosphate (TBOEP) using Daphnia magna

M. Lépine, M. Giraudo, M. Houde, Environment and Climate Change Canada; M. Houde, Environment and Climate Change Canada / St Lawrence Center

Tris (2-butoxyethyl) phosphate (TBOEP) is an organophosphorus flame retardant of high production volume used in floor waxes and as plasticizers in a wide range of applications. The use of TBOEP containing products has resulted in its release and ubiquitous occurrence in the aquatic environment. In this study, three life-history endpoints (survival, growth, and reproduction) were evaluated in Daphnia magna to investigate sublethal effects of TBOEP. Chronic exposure (21 days) to an environmentally relevant concentration of TBOEP (10 µg/L) was carried out over three successive generations. Exposures to TBEOP did not impact survival and reproduction but altered the growth of zooplankton. The mean number of molts was found to be significantly lower in D. magna exposed to TBEOP compared to controls for a given generation, however no differences were observed among generations. Results also indicated potential negative effects over generations on the size of exposed organisms. Complementary epigenetic (i.e., DNA methylation) and transcriptomic analyses will help to better understand these results and to study the impact of TBOEP on the molecular level. Results highlight the relevance of chronic and multigenerational biological evaluation for environmental risk assessments for emerging chemicals.

MP039 Transcriptomic response of Daphnia magna exposed to benzotriazoles: endocrine-disrupting potential and molting effects

M. Giraudo, M. Douville, Environment and Climate Change Canada; G. Cottin, Universite Paris Descartes; M. Houde, Environment and Climate Change Canada

Benzotriazoles (BZTs) are ubiquitous aquatic contaminants used in a wide range of industrial and domestic applications from aircraft deicers to dishwasher tablets. Acute toxicity has been reported in aquatic organisms for some of the BZTs but their mode of action remains unknown. The objectives of this study were to evaluate the transcriptomic response of D. magna exposed to sublethal doses of 1H-benzotriazole (BTR), 5-methyl-1H-benzotriazole (5MeBTR) and 5-chloro-1H-benzotriazole (5ClBTR) using RNA-sequencing and quantitative real-time PCR. Cellular and life-history endpoints (survival, reproduction, growth) were also investigated. Significant effects on the molting frequency were observed after 21-d exposure to 5MeBTR and 5ClBTR. Molting in cladocerans is closely intertwined with growth and reproduction and is actively controlled by ecdysteroid hormones. No effects on molting frequency were observed for BTR but RNA-seq results indicated that this BZT induced the up-regulation of genes coding for cuticular proteins which could have compensated the molting disruption. Complementary short-term temporal analysis (4- and 8-d exposure) of the transcription of genes related to molting and hormone-mediated processes indicated that both BTR and 5ClBTR induced an over-transcription of cyp18a1 with time, which is a negative regulator of the ecdysteroid receptors EcR and USP. Cyp18a1 induction could have resulted in the observed reduction in molt frequency in 5ClBTR-exposed animals, further explained by the concomitant decrease of cuticle genes transcription. On the other hand, the increased number of molts measured in response to 5MeBTR could have been induced by the decreased transcription of cyp18a1 and ecr/usp and the over-transcription of cuticular genes measured in exposed-organism. Measurement of the activity of the molting enzyme chitinase is presently being conducted in order to better understand the effects of BZT on the growth of D. magna. Overall, results suggested that molting effects observed at the physiological level could be linked to endocrine regulation impacts of BZTs at the molecular level.

MP040 Oxygen-functional Groups & Ready Biodegradability of Flavor and Fragrance Molecules

Y. Su, Symrise AG / ToxicityTeam; S. Gebhardt, E. Singer, Symrise AG; M. Matthies, Univ of Osnabruck

For the environmental fate of organic chemicals, their biodegradation potential is an essential intrinsic property. A key factor effecting biodegradability of chemicals might be their functional groups and their molecular structures. Therefore, the aim of this work was to investigate the influence of oxygen functional groups and the molecular structure on the biodegradation potential of a numerous flavor and fragrance molecules. The results showed that different oxygen functional groups contained in the molecules have variably effects on the biodegradation potential of the chemicals. For instance, ester-, formate-, hydroxyl- and carboxylic groups have a significant enhancing effect, whereas ether-, acetale-, epoxide groups show remarkable inhibiting effects on the biodegradation potential of the molecule. Furthermore, for some functional groups such as ketones and aldehydes, the biodegradation potential depends on their position in the molecule (e.g. direct or indirect binding to a ring system). Based on these results it might be possible to modify the biodegradation potential of chemicals by introducing certain oxygen function groups into the molecules or by modifying their molecular structures. These outcomes provide a perspective for the development of environment friendly "green chemicals".

MP041 Pharmaceutical and personal care product residues in wastewater treatment plant samples from Kentucky and Georgia, USA

K.S. Sajwan, Savannah State Univ / Dept of Marine and Environmental Sciences; H. Mowery, D. Benningfield, S. Peng, Murray State Univ / Dept of Chemistry and Watershed Studies Inst; B.G. Loganathan, Murray State Univ / Dept of Chemistry Watershed Studies Inst

The occurrence of pharmaceutical and personal care product (PPCP) residues in the environment has received considerable attention in the recent years as these compounds have been implicated for negative effect on biota and the ecosystem. PPCPs are considered emerging environmental pollutants, and have been detected in groundwater, surface water and municipal wastewater, fish and biosolids. The present study was aimed at determining baseline levels of pharmaceutical chemicals such as macrolide antibiotics, carbamazepine, personal care products namely triclosan, polycyclic musks in influent and effluent samples from wastewater treatment plants in Murray, Kentucky and Savannah, Georgia, USA. Influent, effluent, return activated sludge, pre-chlorination, post-chlorination, upstream from the WWTP, and downstream samples were analyzed following the approved procedures. Detectable levels of pharmaceutical chemicals as well as personal care products were found in most of the samples analyzed. In general, influents contained higher concentrations of the analytes than the effluents. Presence of azithromycin, carbamazepine, triclosan and polycyclic musks in the effluents indicated that these compounds are persistent and are not degraded/or lost during the wastewater treatment processes and contaminate the receiving water bodies such as streams and rivers.

MP042 Temporal trends of volatile methylsiloxanes in Tokyo Bay sediment core, Japan

Y. Horii, T. Yamazaki, Center for Environmental Science in Saitama; C. Lam, City Univ of Hong Kong; N. Yamashita, National Inst of Advanced Industrial Science and Technology / Environmental Management Research Inst

Methylsiloxanes have been widely used in personal-care and house hold products because methylsiloxanes have low surface tension, high thermal and chemical stabilities. However, a part of volatile methylsiloxanes (VMSs) have recently been identified as priority chemicals for environmental risk assessment due to their persistence in the environment and bioaccumulative potency. To reveal temporal trends of VMS accumulation into the aquatic environment, in this study, we investigated the vertical concentrations of cyclic and linear VMSs (7 VMSs including D3, D4, D5, D6, L3, L4, and L5) in a sediment core collected from Tokyo Bay, Japan. The sediment core was collected in July 2013 from the inner bay (N35°35'00", E139°55'00"), using an acrylic tube. The sediment core (86 cm length), sliced at 2-cm increment was analyzed. The time interval of each slice were estimated based on sedimentation rate (1 cm/y, the data from previous study) and sedimentation depth. Cyclic VMSs were found throughout the sediment core upper 38 cm sections, at ΣVMS ranging from 10 to 700 ng/g dry wt. The highest concentration of ΣVMS was found in the 10-12 cm section of the core. The concentrations of ΣVMS increased with decreasing depth of upto 10-12 cm, corresponding to the year 2001-2003, then slightly decreased (almost constant) upto the surface layer to the year 2013 (630 ng/g dry wt). Interestingly, the vertical profiles of D4 concentrations were different from other cyclic VMSs; the highest concentration of D4 was found in the 14-16 cm section (the mid-1990s), then D4 concentrations decreased upto the surface layer. In general, the vertical profiles of organic compounds in a sediment core reflect production and usage trends and industrial activities. Replacement D4 to D5 in personal-care products such as shampoo and cosmetics in the mid-1990s appear to have been effective in reducing the input of D4 to the aquatic environment, whereas ΣVMS concentrations were found to be almost constant in last decade. The annual flux of VMSs into the Tokyo Bay sediments in 2004-2013 (in average) was calculated to be 2.4 ng/cm^2 for D4, 90 ng/cm^2 for D5, 16 ng/cm^2 for D6, and 110 ng/cm^2 for ΣVMS. Based on the surface area of Tokyo Bay (922 km^2), annual deposition of ΣVMS into Tokyo Bay sediment were roughly estimated at 1000 kg.

MP043 Glyphosate-induced toxicity in African catfish (Clarias gariepinus, Burchell) following a sub-lethal exposure

M.M. Salman, O.T. Aladesanmi, Obafemi Awolowo Univ / Inst of Ecology and Environmental studies

Glyphosate is a non-selective herbicide which has been severally used to control weeds. The present study aimed to examine the cytotoxic and haematological effects of glyphosate on Clarias gariepinus. Sixty fishes were exposed to acute concentrations of 54, 108, 162, 216 and 270 mg/l of glyphosate with two replicates and two controls for 96 hrs. Thereafter, the median lethal concentration (LC_{50}) was calculated using probit analysis. Subsequently, 21 days bioassay was employed where one hundred and eight fishes were exposed to sub-lethal concentrations of 0, 9, 18, 27, 36 and 45 mg/l in two replicates. Blood samples were further collected through caudal severance and analysed using an auto-analyzer machine. In addition, the chromosome spreads were prepared and the photomicrographs were taken. The dividing cells were counted with respect to the total number of cells in the slides in order to determine the mitotic index. Behavioural responses such as vertical swimming, flaring of operculae and gasping were observed. The LC_{50} obtained was 167.76 mg/l while a dose-dependent increase in chromosomal stickiness and decrease in mitotic index was observed. Similarly, the erythrocyte, leucocyte, haemoglobin, and haematocrit decreased dose-dependently while the mean corpuscular volume and mean corpuscular haemoglobin increased dose-dependently. Fluctuating pattern was however recorded for the mean corpuscular haemoglobin concentration. Behavioural responses such as surface swimming and mouth opening denotes respiratory impairment in the fishes. Also, the reduced erythrocyte, haematocrit and haemoglobin recorded denote anaemic condition in exposed fishes. The decreased leucocyte predisposes the fishes to high risk of disease infection while the sticky chromosome depicts respiratory impairment. In addition, the dose-dependent decrease in mitotic index indicates impairment of cell division in the exposed fishes. Considering the abnormal effects revealed, glyphosate herbicide is toxic to Clarias gariepinus. Therefore, its use on/near aquatic environment should be highly restricted, if not prohibited.

MP044 Developmental Toxicity and Mechanistic Investigations of Nitrated and Heterocyclic PAHs

A.C. Chlebowski, G. Garcia, J.K. La Du, W.H. Bisson, Oregon State Univ / Dept of Environmental and Molecular Toxicology; S. Simonich, Oregon State Univ / Depts of Chemistry and Environmental Molecular Toxicology; R.L. Tanguay, Oregon State Univ / Environmental Molecular Toxicology

Nitrated polycyclic aromatic hydrocarbons (NPAHs) and heterocyclic PAHs (HPAHs) are recognized environmental pollutants, with sources including petroleum-based products, combustion, in particular diesel, and formation by atmospheric reactions with unsubstituted PAHs. However, the health risks of NPAHs and HPAHs to humans and environmental systems are not well-studied. The developmental zebrafish (Danio rerio) model was used to evaluate the toxicity of a structurally diverse set of 27 NPAHs and 10 HPAHs. Their individual activities towards the aryl hydrocarbon receptor (AHR), including the role of the AHR in observed toxicity, and genetic markers of oxidative stress and cardiac toxicity were evaluated. All 25 commercially-available NPAHs were assessed, as well as two NPAHs synthesized in-house, which are not commercially available, in addition to 10 commercially available HPAHs. Zebrafish embryos were exposed from 6 to 120 hours post fertilization (hpf) to a dilution series of individual compounds and evaluated for 22 developmental endpoints. The potential role of AHR was determined via CYP1A immunohistochemistry (IHC), as well as a GFP/CYP1A reporter zebrafish line. All compounds were screened computationally through molecular docking into previously developed AHR models of zebrafish isoforms 1A, 1B, and 2. The docking scores, representing AHR binding and activation, predicted the in vivo CYP1A response with a success rate of 69%. Some compounds did not induce observable developmental toxic responses, while others produced statistically significant concentration-dependent toxicity. The tested compounds also exhibited a range of AHR binding

and CYP1A induction patterns, including CYP1A expression in the liver, vasculature, skin, and yolk, which we determined to be due to distinct isoforms of the AHR using morpholino oligonucleotide knockdown. Furthermore, we investigated mRNA expression of oxidative and cardiac stress genes at 48 and 120 hpf, investigating potential mechanisms-of-action for NPAHs. We also compared the developmental toxicity of two amino PAHs (metabolites of NPAHs) to the corresponding NPAHs, and observed equal or increased toxicity in the amino PAHs compared to the corresponding NPAHs. This indicates the need for further experimental and in silico studies of NPAHs and HPAHs as environmental contaminants with the potential for adverse human health effects, including further investigation into the mechanisms-of-action and metabolism.

MP045 Contaminants of Emerging Concern in Herring Gull and Caspian Tern Eggs From United States Colony Sites in the Great Lakes of North America

G. Su, Carleton Univ; R.J. Letcher, Environment and Climate Change Canada / Ecotoxicology and Wildlife Health Division; L.L. Williams, US Fish & Wildlife Service; J. Moore, US Fish and Wildlife Service / Interior; K. Grasman, Calvin College / Dept of Biology

Numerous chemicals have been designed, synthesized and widely used to various manufactured materials such as plastics, foams, textiles, furniture, paper coating and many others materials. These chemicals include various organic flame retardants (OFRs) and per- and polyfluoroalkyl substances (PFASs). Both FRs and PFASs have been reported in the environment in fish, wildlife and humans, and including in birds from the Laurentian Great Lakes of North America with a focus on the eggs of herring gulls (Larus argentatus). The Canada-U.S. International Joint Commission (IJC) renewed the U.S.-Canada Great Lakes Water Quality Agreement (GLWQA) on September 2012, which specifically calls for the identification and monitoring of chemicals of emerging (environmental) concern (CECs) in various matrices, i.e. animal species and especially in fish-eating birds. However, other than the herring gull (which is not a totally aquatic fish consumer), there is presently limited information on CECs in other bird species such as the purely fish-eating Caspian tern (Hydroprogne caspia). The Caspian tern is also currently a state-threatened species in Michigan. In the present study, a broad suit of CECs, including 26 polybrominated diphenyl ethers (PBDEs), 23 non-PBDEs halogenated FRs (NPHFRs), 16 organophosphate esters (OPEs), 4 perfluorinated sulfonates (PFSAs), 13 perfluorinated carboxylic acids (PFCAs) and 5 emerging perfluoroalkyl acids (PFAAs) or precursors, were determined and compared in 30 individual Caspian tern eggs and 10 herring gull eggs collected in 2013 and 2014 from U.S. / Michigan nesting sites on Two Tree Island (St, Marys River), Charity Reef (Saginaw Bay) and Channel-Shelter Island (a Confined Disposal Facility in Saginaw Bay). The general order of concentration levels in Caspian tern eggs was as follows: ΣPFSA (mean: 793 ng/g wet weight (ww); range:116-4690 ng/g ww) > ΣPFCAs (131; 30.4-506 ng/g ww) ≈ ΣPBDEs (86.7; 32.4-189 ng/g ww) >> ΣNPHFRs (0.67; ND-4.3 ng/g ww) ≈ ΣOPEs (0.46; ND-2.89 ng/g ww). Compared to gull eggs, tern eggs contained significantly lower concentrations of ΣPBDE and ΣNPHFR, but with up to 10 times greater mean concentrations of ΣPFSAs and ΣPFCAs. This indicates that terns are exposed to and bioaccumulate greater amounts of ΣPFSAs and ΣPFCAs than gulls as reflected in their respective egg concentrations, which is likely due to differences in the respective dietary consumption of these two species.

MP046 Temporal and spatial behavior of pharmaceuticals in Narragansett Bay, Rhode Island, United States

M.G. Cantwell, USEPA; D.R. Katz, USEPA / Atlantic Ecology Division; J.C. Sullivan, ORISE at USEPA / AED; K.T. Ho, R.M. Burgess, USEPA / Atlantic Ecology Division

The behavior of active pharmaceutical ingredients (APIs) in urban estuaries is not well understood. In this study, 15 high volume usage APIs were measured over a one year period throughout Narragansett Bay, RI, USA to determine factors controlling their concentrations and distribution. Dissolved APIs ranged in concentration from not detected to 310 ng/L, with numerous APIs present at all sites and sampling periods. Eight APIs were present in suspended particulate material, ranging in concentration from < 1 ng/g to 44 ng/g. Partitioning coefficients (K_ds) were determined for APIs present in both the dissolved and particulate phases, with their range and variability remaining relatively constant during the study. Organic carbon normalization reduced the observed variability of several APIs to a small extent; however, other factors appear to play a role in controlling partitioning behavior. The continuous discharge of wastewater treatment plant effluents into upper Narragansett Bay resulted in sustained levels of APIs, resulting in a zone of "pseudo-persistence". For most of the APIs, there was a strong relationship with salinity, indicating conservative behavior within the estuary. Short flushing times in Narragansett Bay coupled with APIs present primarily in the dissolved phase suggests that most APIs will be diluted and transported out of the estuary, with only small amounts of several compounds removed to and sequestered in sediments. This study identifies factors controlling the temporal and spatial dynamics of dissolved and particulate APIs, whose partitioning behaviors provide an increased understanding of their fate, including bioavailability, in an urban estuary.

MP047 Effect of substituted phenylamine antioxidants on three life stages of freshwater mussel Lampsilis siliquoidea

R.S. Prosser, Environment and Climate Change Canada / Canada Centre for Inland Waters; P. Gillis, Environment and Climate Change Canada / Aquatic Contaminants Research Division; E. Holman, J. Toito, Environment and Climate Change Canada / Aquatic Contaminants Research Division; D. Milani, Environment and Climate Change Canada / Watershed Hydrology and Ecology Resarch Division; A. Bartlett, J. Parrott, V. Balakrishnan, Environment and Climate Change Canada / Aquatic Contaminants Research Division

Substituted phenylamine antioxidants (SPAs) are produced in relatively large volumes and incorporated into a variety of consumer products, e.g., polymers, lubricants, dyes, and adhesives. Based on their physical and chemical properties, SPAs could be potentially persistent, bioaccumulative and/or toxic, consequently, the Government of Canada is assessing this class of compounds under the Chemicals Management Plan for potential risks to the environment. The current study assessed the toxicity of four SPAs, chosen from a list of twelve, (diphenylamine (SPA 2), N-phenyl-1-naphthylamine (SPA 6), N-(1,3-dimethylbutyl)-N'-phenyl-1,4-phenylenediamine (SPA 8), and 4,4'-methylene-bis[N-sec-butylaniline] (SPA 12)) to three life stages of the freshwater mussel, Lampsilis siliquoidea. Acute sensitivity was determined by exposing the larval stage of mussels (glochidia) to SPAs for 48 h in water. A negative relationship between the toxicity of SPAs and their solubility in water was observed. The 48-h EC50s for glochidia viability using measured concentrations were 5951, 606, 439, and 258 µg/L for SPA 2, 6, 8, and 10, respectively. Juvenile (~ 1 cm in length) and adult Lampsilis siliquoidea were exposed to sediments spiked with individual SPAs for 28 days in aerated (static) vessels with a 3.5:1 water-to-sediment ratio. Mortality was assessed along with rate of feeding of juvenile mussels. In addition, reactive oxygen species, total glutathione, and lipid peroxidation in gill, digestive gland, and gonad of SPA-exposed adult mussels were measured to determine whether exposure to SPAs caused oxidative stress; bioaccumulation was also assessed in these tissues. Preliminary data analysis based on nominal concentrations showed that LC/EC50 values for the juvenile and adult mussels were >100 µg/g sediment dry weight for all four SPAs examined. Analysis of tissue and sediment is ongoing; calculation of biota-sediment accumulation factors will provide information on the bioavailability of SPAs to freshwater mussels. The results of this study will support environmental risk assessment activities to determine if SPAs could impact freshwater ecosystems.

Everglades and Wetlands Science Part 1: Ecology and Contaminants in Ever-Changing Ecosystems

MP048 Geospatial analysis of Perfluoroalkyl Acids in American Alligators (Alligator mississippiensis) in Florida and South Carolina

J.T. Bangma, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences; J. Reiner, National Inst of Standards and Technology / Chemical Sciences Division; J.A. Bowden, National Inst of Standards and Technology; R. Lowers, NASA / Environmental Sciences; A.M. Brunell, Florida Fish & Wildlife Commission; B. Finnell, Medical Univ of South Carolina; F. Nilsen, National Inst of Standards and Technology / Environmental Chemical Sciences Division; T.R. Rainwater, Clemson Univ; P.M. Wilkinson, South Carolina Dept of Natural Resources; I. Christie, Medical Univ of South Carolina; J. Martin, College of Charleston; M. Guillette, Medical Univ of South Carolina / obgyn; L.J. Guillette, Medical Univ of South Carolina / Marine Biomedicine and Environmental Sciences OBYGYN

This study aimed to geospatially assess Perfluoroalkyl acid (PFAA) plasma levels in the American alligator (Alligator mississippiensis) both across Florida and South Carolina (n = 125) and specifically at Merritt Island National Wildlife Refuge (MINWR) at Kennedy Space Center in Titusville, FL (n = 229). We investigate potential seasonal and spatial trends. This study provides a solid baseline for PFAA levels in a wetlands keystone species within the southeastern United States, and develops a more thorough understanding of crocodillian PFAA sex-based differences on a regional and local scale as well as PFAAs and snout to vent length (SVL) relationships.

MP049 The Combined Effects of Coal Combustion Waste and Pond Drying Regime on the Southern Toad (Anaxyrus terrestris)

R.W. Flynn, Univ of Georgia – Savannah River Ecology Laboratory / Savannah River Ecology Laboratory; S.L. Lance, Univ of Georgia / Savannah River Ecology Laboratory

Energy production is one of the largest drivers of environmental change. Despite shifting towards an energy security model that embraces diversity in energy sources, coal still represents the single largest source of energy in the United States. The combustion of coal for energy results in the production of large amounts of solid waste in the form of coal combustion waste (CCW), which contains a number of potentially toxic trace elements. Nearly half of CCWs produced are stored in the environment, in landfills and surface retention basins. While these practices limit the amount of area impacted by this waste, they can create highly contaminated localized habitats where wildlife can come in direct contact with the CCW. Retention ponds that contain CCWs mixed with water often fail resulting in the surrounding landscape receiving large volumes of waste. CCWs have lethal and sub-lethal effects on a variety of aquatic life, including amphibians; however the influence of wetland drying regime on CCW toxicity has not yet been explored. Wetland drying can influence CCW toxicity by increasing the levels of trace elements and/or by stressing amphibian larvae that must accelerate development. We used simulated ponds (mesocosms) to examine how wetland drying regime and the presence of CCWs in sediments separately and interactively affect the growth, development, and survival of the southern toad (Anaxyrus terrestris). The presence of CCW sediments led to reduced mass and snout-vent-length at metamorphosis ($p < 0.05$), but did not delay development. We found no effect of drying regime on development or size at metamorphosis and no interaction between sediment type (with or without CCW) and drying regime. We used a Cox proportional hazard model, with mesocosm ID as a clustering term, to examine the effects of the treatments on probability of metamorphosis and found no consistent effects of the applied treatments. These data suggest that for southern toads, the effects of CCWs are consistent regardless of drying regime. We will be following up with analyses of initial size distributions of larvae for each tank, actual concentrations of trace elements in each tank over time, and body burdens acquired by individuals across tanks to attempt to better explain the among tank variation we observed in the study.

Advancing -Omics into Regulatory Frameworks: Case Studies and Perspectives

MP050 Bringing the fathead minnow (Pimephales promelas) into the genomic era

T. Saari, USEPA / ORD, NHEERL; D.L. Villeneuve, G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; F. Burns, L. Cogburn, S. Deschamps, R. Jackson, DuPont de Nemours; R. Hoke, E.I. DuPont de Nemours and Company / Haskell Global Centers for Health and Environmental Sciences; A. Schroeder, Univ of Minnesota Crookston

The fathead minnow (Pimephales promelas)is a well-established ecotoxicological model organism that has been widely used for regulatory ecotoxicity testing and research for over a half century. Throughout this time, a lot of knowledge has been gained about the fathead minnow's biological responses to various xenobiotics. However, despite its importance as a model organism, the fathead minnow still has few publicly available gene sequences. Recently, Burns et al. (2015; Environ. Toxicol. Chem. 35:212) described the sequencing and de-novo assembly of the fathead minnow genome. Two draft genome assemblies are now publicly available on the GenBank database. However, on their own the draft assemblies remain of limited use to researchers who are primarily interested in the functional units of the genome, i.e. the genes. In the present study, an annotation pipeline, consisting of gene prediction, evidence alignment, and data synthesis, was applied to the fathead minnow SOAPdenovo assembly. Ab initio gene prediction was performed using AUGUSTUS, which provided a starting point of 43,345 gene predictions. Fathead minnow Expressed Sequence Tags (ESTs) and zebrafish protein-coding sequences (CDSs) were then aligned to the assembly using the corresponding spliced alignment methods of the program Exonerate. Of the over 240,000 EST alignments, 73% were successfully aligned with 90% or greater sequence identity and query coverage. Similarly, 39% of nearly 45,000 zebrafish coding sequences were successfully aligned with 70% or greater sequence identity and 50% or greater query coverage. The alignments and gene predictions were then passed into the program MAKER, which combined the weighted evidence from various sources into individual gene structures. Together, these data will provide a valuable annotated genome resource to the community and lay a foundation for future studies which make use of and build upon fathead minnow molecular sequence information. The contents of this abstract neither constitute nor necessarily reflect official USEPA policy.

MP051 Examining the effects of endocrine disruption on innate immunity in Rana (Lithobates) catesbeiana tadpoles

S. Partovi, Univ of Victoria / Dept of Biochemistry and Microbiology; N. Veldhoen, Univ of Victoria / Biochemistry and Microbiology; R.C. Miliano, Environment and Climate Change Canada / Pacific Environmental Science Center; L. Li, Univ of Waterloo / Dept of Civil and Environmental Engineering; X. Zheng, A. Khojasteh, E.R. Hall, Univ of British Columbia / Civil Engineering; W.J. Parker, Univ of Waterloo / Dept of Civil and Environmental Engineering; G. van Aggelen, Environment and Climate Change Canada / Pacific Environmental Science Center; C.C. Helbing, Univ of Victoria / Dept of Biochemistry Microbiology

Thyroid hormone (TH) facilitates a number of crucial processes in vertebrates, including growth, metabolism, and development. In frog tadpoles, TH is responsible for the metamorphosis of aquatic larvae into terrestrial frogs. During this process, the body of the animal undergoes extensive internal and external changes in preparation for a terrestrial life. The innate immune system, in particular, is significantly altered by TH modulation during metamorphosis, and is fundamental to the survival of the tadpole during this energetically demanding process. Tadpole liver and tail fin are heavily involved in the innate immune response and are valuable organs to study during metamorphosis as well as during disease challenge. Disruptions to vital TH pathways have negative implications for the intricate process of tadpole development, which presents the opportunity to use frogs as sentinels for research on TH disruption. A wide variety of endocrine disrupting chemicals (EDCs) have been shown to interfere with hormone signaling in vertebrates, including amphibians. These include chemicals from sources such as pharmaceuticals, herbicides, pesticides, and personal care products. Conventional wastewater treatment methods do not fully remove EDCs, allowing low concentrations to persist in treated wastewater effluent. These low level EDCs may remain biologically active and disruptive to the endocrine system of developing tadpoles. Disruptions to TH pathways that affect the development of innate immunity in tadpoles may result in increased susceptibility to disease and infection. In the present study, we exposed American Bullfrog (Rana (Lithobates) catesbeiana) pre-metamorphic tadpoles to the THs 3,5,3'-triiodothyronine (T3) and thyroxine (T4), the sex-hormone 17 beta-estradiol (E2), as a non-TH control, a cocktail of known EDCs, and treated municipal wastewater effluent. Gene expression was evaluated in the tail fin and liver using RNA-seq and targeted qPCR assays to determine the impact of these chemicals on various genes and pathways, including those relating to the innate immune system. It has been empirically demonstrated that the innate immune system of bullfrog tadpoles is affected by exposure to TH. The presented work will further our understanding of the connection between EDCs and innate immune system perturbation.

MP052 Gene Expression Responses in Freshwater and Marine Fish Exposed to Wastewater Effluents

D. Vidal-Dorsch, VDA LCS / Toxicology; C.J. Martyniuk, Univ of Florida / Physiological Sciences

Laboratory exposures were conducted to determine the transcriptome response between freshwater and marine fish species after exposure to wastewater effluent. We performed microarray and gene network analyses in sexually mature male fathead minnows (Pimephales promelas) and marine, field caught, male hornyhead turbot (Pleuronichthys verticalis). Agilent 8 x 15K, one color arrays were used to determine gene expression. Fish were exposed to negative controls, estradiol (E2), and 5% concentrations of municipal wastewater effluents. Secondary and advanced primary treated effluents were used. Fathead minnow (FHM) liver gene expression showed differences among fish exposed to estradiol and effluent. There was no pronounced differentiation among fish exposed to the different effluent types; although, several fish exposed to advanced primary treated effluent clearly grouped together. Gene network analysis revealed that some genes differentially expressed in FHM exposed to advanced primary treated effluent were involved in specific processes. For example, FHM had cholesterol and drug metabolism pathways that were down-regulated after exposure to advance primary treated effluent. Furthermore, there was a significant relationship between subnetworks regulated by E2 and fish exposed to primary treated effluent. Marine hornyhead turbot fish exposed to effluent were mapped to the FHM pathways to compare responses in both species. After mapping the turbot genes to the FHM pathways the results suggested that the marine fish may have responded on a similar manner to the freshwater species after effluent exposure. For example, estrogenic, cholesterol and drug metabolism pathways were also affected by exposure to both effluents, but a different magnitude of effects was found in the livers of turbot exposed to advance primary treated effluent. The present study demonstrates that some of the responses observed after exposure to environmental contaminant mixtures (e.g., effluents) were conserved in both marine and freshwater species.

MP053 Hepatic proteome to account for the molecular mechanism underlying dioxin susceptibility in C3H/lpr and MRL/lpr mouse strains

T. Nguyen, Center for Marine Environmental Studies (CMES) / Center for Marine Environmental Studies CMES; C.M. Lauan, Ehime Univ / Center for Marine Environmental Studies CMES; J. Yoo, Ehime Univ / Center for Marine Environmental Studies CMES; M. Iida, Graduate School of Computer Science and System Engineering / Kyushu Inst of Technology; T. Agusa, Ehime Univ / Center for Marine Environmental Studies CMES; E. Kim, Kyung Hee Univ / Dept of Life and Nanopharmaceutical Science and Dept of Biology; H. Iwata, CMES, Ehime Univ / Center for Marine Environmental Studies

Dioxins cause various toxic effects through aryl hydrocarbon receptor (AhR) in animals with inter-species and strain differences in susceptibility. C3H/lpr and MRL/lpr are inbred mouse strains that are a dioxin-sensitive and -resistant type, respectively. However, the molecular mechanism underlying the different susceptibility still remains unclear. Here, we adopted a proteomic approach using two-dimensional electrophoresis coupled with matrix-assisted laser desorption/ionization time-of-flight/ time-of-flight (MALDI-TOF/TOF) mass spectrometry to clarify the difference in effects of 2,3,7,8-tetrabromodibenzo-p-dioxin (TBDD) exposure on the hepatic proteome between C3H/lpr and MRL/lpr mice. To confirm the induction of cytochrome P450 isozymes (CYPs) by TBDD treatment in each strain, we initially measured CYP1A1 and 1A2 protein levels and their catalytic activities. Results showed that at the dose of 10 µg/kg body weight, TBDD treatment increased CYP1A1 and 1A2 levels in both strains, but a more prominent induction was observed in C3H/lpr than MRL/lpr. This supports that C3H/lpr was more sensitive to dioxins than MRL/lpr. We successfully identified 40 up- and 17 down-regulated proteins in C3H/lpr and 7 up- and 10 down-regulated proteins in MRL/lpr by TBDD treatment. Interestingly, the proteins induced in C3H/lpr were involved in the metabolism of tryptophan and its metabolites as endogenous AhR ligands, suggesting that AhR is more activated by accelerated production of endogenous AhR ligands in TBDD-treated C3H/lpr than MRL/lpr. We also identified that proteins responsible for reducing the oxidative stress such as superoxide dismutase and peroxiredoxins were up-regulated in C3H/lpr mice by TBDD treatment. The present study reveals that the high dioxin-susceptibility of C3H/lpr strain may be associated with more activation of AhR signaling by endogenous AhR ligands and more efficient elimination of oxidative stress.

MP054 Next generation sequencing analysis to assess the effects of prenatal bisphenol A exposure on developing chicken embryos

S. Itoh, Center for Marine Environmental Studies (CMES) / Center for Marine Environmental Studies CMES; T. Agusa, M. Hirano, M. Ochiai, Ehime Univ / Center for Marine Environmental Studies CMES; E. Kim, Kyung Hee Univ / Dept of Life and Nanopharmaceutical Science and Dept of Biology; H. Iwata, CMES, Ehime Univ / Center for Marine Environmental Studies

Bisphenol A (BPA) is an estrogenic chemical that has been used in various products. Large amount of its usage has resulted in the contamination of BPA in wild animals including birds. There is growing concern about the toxic effects of BPA in developing organisms, because the early life stage is highly sensitive to endocrine disrupters. However, there is less information regarding the effects of BPA on avian embryos. In particular, the effect on gene expression profile has not yet been clarified. We thus performed an in ovo injection test using chicken eggs and investigated the effect of BPA on the developing embryos by analyzing their hepatic transcriptome by next generation sequencing (NGS). Seventy five chicken (Gallus gallus domesticus) eggs were divided into five groups (n=15 per group); vehicle (corn oil) control, low (10 ng/g egg), moderate (1,000 ng/g egg), and high (100,000 ng/g egg) doses of BPA- and 17 β-estradiol (E_2)-treated (10 ng/g egg) groups. On the 2nd day post egg-laying, test chemicals were injected into the air sac. On the 21st day post egg-laying, the embryos were dissected and each of organs was collected and weighed. RNA solutions extracted from liver samples were used for NGS analysis. To identify differentially expressed genes, transcriptome data obtained from the NGS was analyzed by cuffdiff. Pathway and network analysis of the genes differentially expressed by BPA or E_2 treatment were carried out by KEGG pathway and STRING, respectively. Measurement of the liver weight showed an increasing trend in BPA- and E2-treated groups compared with the control group. Data analyses of NGS indicated that mRNA levels of 204, 4078, 1766, and 3006 genes were significantly changed by the treatment with the low, moderate, and high doses of BPA, and E_2, respectively. This indicates that more effects on the transcriptome were induced in the groups treated with moderate and high doses of BPA and E_2 than in the group treated with low dose of BPA. Pathway analysis revealed that BPA affected the DNA replication, cell cycle, and nucleotide metabolism in the embryo livers. Network analysis indicated that cyclin-dependent kinase 1, serine/threonine-protein kinase PLK1, peroxisome proliferator-activated receptor alpha, and angiotensinogen were identified as hub genes in moderate and high doses of BPA- and E_2-treated groups, implying that these genes may play central roles in the effects of BPA on developing chicken embryos.

MP055 Sex-dependent effects of prenatal bisphenol A exposure on liver transcriptome of rat offspring

T. Nguyen, Center for Marine Environmental Studies (CMES) / Center for Marine Environmental Studies CMES; K. Yamamoto, T. Agusa, M. Hirano, M. Ochiai, Ehime Univ / Center for Marine Environmental Studies CMES; E. Kim, Kyung Hee Univ / Dept of Life and Nanopharmaceutical Science and Dept of Biology; H. Iwata, CMES, Ehime Univ / Center for Marine Environmental Studies

Bisphenol A (BPA) is one of ubiquitous endocrine disruptors in the environment. Many studies have shown that BPA causes multiple effects such as alteration of mammary gland development, sexual maturation, immune system function, behaviors, and detrimental effects on glucose homeostasis and insulin sensitivity. However, knowledge is still limited on the mechanism of transgenerational actions of BPA. In this study, we treated pregnant Wistar rats with low (50 ng/kg bw/day) and high (5000 ng/kg bw/day) doses of BPA on embryonic day 4-18 and investigated the effects on the liver transcriptome of postnatal day 0 pups. Hepatic mRNA levels of pups were analyzed by a paired-end sequencing with Illumina HiSeq 2500. The genes which had significantly different FPKM (fragments per kilobase of transcripts per million mapped reads) in BPA-treated groups from those in the control group (FDR < 0.05) were used for further analysis. Network and pathway enrichment analyses were performed by using Cytoscape and its plug-in. Results showed that prenatal exposure to BPA altered mRNA expression levels of genes involved in the metabolic pathways, peroxisome proliferator-activated receptor (PPAR) signaling pathway, cell cycle, and DNA replication in both male and female pups. BPA exposure suppressed the genes related to the fatty acid metabolism in females at low and high doses, but only high dose of BPA caused the effect in males. This sex-dependent transcriptome effect was supported by phenotypic alteration, showing a similar pattern in the increase of offspring's body weight. Interestingly, BPA exposure may decrease glucose uptake and increase insulin resistance in females, but increase glucose uptake and insulin sensitivity in males through the sex-dependent effects on mRNA expression of glucose transporter type 4, insulin receptor and its downstream gene, phosphatidylinositol-4,5-bisphosphate 3-kinase. Moreover, the up-regulation of sterol regulatory element-binding protein 1cmRNA and the down-regulation of PPARα mRNA and its target gene, carnitine palmitoyltransferase 1 in females may lead to the induction of lipogenesis and inhibition of beta oxidation by BPA exposure. These results suggest different modes of action of prenatal exposure to BPA between male and female offspring. Further analysis including biochemical assays and quantitative PCR as well as the expression at the protein level of these genes will be performed to confirm the results.

MP056 Sex-specific molecular responses in the hypothalamus may underlie differences in behavior following exposure to Phenanthrene in the fathead minnow

J.R. Loughery, Univ of New Brunswick / Biological Sciences; E. Crowley, Univ of New Brunswick Saint John; A. Mercer, UNBSJ; K.A. Kidd, Univ of New Brunswick; C.J. Martyniuk, Univ of Florida / Physiological Sciences

Phenanthrene (PHE), a three-ring polycyclic aromatic hydrocarbon, is a common environmental contaminant. Most often formed through incomplete combustion, PHE can be created both naturally and anthropogenically. PHE concentrations can be elevated in aquatic environments through oil spills, atmospheric deposition and industrial wastewaters. PHE has been described to have a narcotic mode of action and the objective of this study was to determine if sub-chronic exposure would affect behavior. The second objective was to potentially determine the molecular basis for this response in the hypothalamus. Fathead minnow (Pimephales promelas; FHM) were exposed to 201.8 µg/L average measured waterborne concentration of PHE in a static-renewal bioassay over 7 wks. After exposure, individual behavior in a novel aquarium test was measured. Following this, fish were sacrificed, body measurements taken, and hypothalamic tissues excised for transcriptomic analyses. Condition factor of both sexes were decreased after PHE exposure, and gonadosomatic index was decreased in exposed females but not males. Behavioral tests indicated that male fish exposed to PHE were more active than reference fish; however, there was no difference between female control and treated fish. Microarray analyses identified that there were 1126 and 1105 probes differentially expressed in males and females, respectively. Sub-network enrichment analyses identified 160 and 94 pathways, in male and female hypothalamus, respectively. Thirty-one pathways were common to both sexes. These included swallowing and cardiovascular reflex. Of the 129 unique pathways altered in male hypothalamus, forward locomotion, pineal gland function, and grooming behavior were down-regulated 18 – 39%. Pathways unique to the female hypothalamus included estrogen receptor signalling pathway and dopaminergic system. This study supports a narcotic mode of action for PHE and highlights some of the pathways in the central nervous system that may explain, in part, differences in the behavioral response to PHE.

MP057 Using the molecular basis of olfaction in metamorphosing frog tadpoles as an indicator of thyroid hormone disruption in aquatic systems

K. Jackman, N. Veldhoen, Univ of Victoria / Biochemistry and Microbiology; R.C. Miliano, Environment and Climate Change Canada / Pacific Environmental Science Center; L. Li, Univ of Waterloo / Dept of Civil and Environmental Engineering; X. Zheng, A. Khojasteh, E.R. Hall, Univ of British Columbia / Civil Engineering; W.J. Parker, Univ of Waterloo / Dept of Civil and Environmental Engineering; G. van Aggelen, Environment and Climate Change Canada / Pacific Environmental Science Center; C.C. Helbing, Univ of Victoria / Dept of Biochemistry Microbiology

The American bullfrog, Rana (Lithobates) catesbeiana, is a model organism for studying thyroid hormone action in vertebrate species. Metamorphosis from an aquatic tadpole to a terrestrial frog involves reconstruction of nearly every tissue in the amphibian's body and is entirely dependent on the action of thyroid hormones, L-thyroxine (T4) and 3,5,3'-triiodothyronine (T3). Premetamorphic R. catesbeiana tadpoles lack any measurable circulating thyroid hormone and exogenous TH exposure results in a precocious induction of metamorphosis. Olfaction is a critical component of tadpole survival, facilitating food location and predator avoidance. Olfaction requirements change during metamorphosis as the herbivorous tadpole transitions from aquatic to terrestrial environments and becomes a carnivorous frog. Little is known about the influence of thyroid hormones or endocrine disrupting compounds (EDCs) found in household and industrial products on the olfactory system. In the present study, the olfactory impact of exposure to various hormones and known EDCs was investigated. Premetamorphic tadpoles were separately exposed to environmentally-and physiologically-relevant concentrations of T3, T4, 17 beta-estradiol (E2), and multiple concentrations of a chemical cocktail of known EDCs typically found in municipal wastewater. Further, municipal wastewater was spiked with this chemical cocktail and subjected to either anaerobic membrane bioreactor (AnMBR) or membrane enhanced biological phosphorus removal (MEBPR) processes. A parallel treatment train was operated for each with vehicle spiked into the wastewater influent. The olfactory bulb (OB) from the brain and the olfactory epithelium (OE) from the rostrum were dissected from tadpoles after 48 hours of exposure. RNA was extracted from the tissues and transcript levels were evaluated using RNA-seq and targeted qPCR. Gene expression data indicate that both tissues are responsive to thyroid hormones. The results will be compared with parallel studies performed on behavioral and neurophysiological endpoints to uncover important aspects of thyroid hormone-dependent processes in the olfactory system and the effects of disruption by anthropogenic EDCs.

MP058 Shotgun Proteomics of Hexagenia spp. exposed to Surface waters and Effluents from Toronto and Hamilton Harbour, ON

D. Simmons, Univ of Waterloo / Biology; B. Duncker, Univ of Waterloo / Dept of Biology; J. Sherry, Environment and Climate Change Canada / Water Science Technology Directorate; P.A. Helm, Ontario Ministry of the Environment & Climate Change / Environmental Monitoring and Reporting Branch; T. Watson-Leung, Ontario Ministry of the Environment / Aquatic Toxicology Unit; R. Chong-Kit, Ontario Ministry of the Environment & Climate Change; M. Nowierski, S. Kleywegt, Ontario Ministry of the Environment & Climate Change / Standards Development Branch

Hexagenia are an ecologically and widespread group of mayflies belonging to the order Ephemeroptera. There is growing interest in the development of a standardized test protocol using Hexagenia for use in ecotoxicological assessments. Both Hamilton and Toronto Harbours were designated by the International Joint Commission as being Great Lakes Areas of Concern due to contaminated sediments from Industrial activity and excess nutrients from wastewater effluents. Our goal was to characterize the effects of exposure to surface water and effluents from these two areas on the Hexagenia spp. proteome. Surface water samples were collected from three locations in Hamilton Harbour and two locations in Toronto Harbour. Effluents were also collected from wastewater treatment plants (WWTPs) discharging into the Harbours. Mayflies were exposed to all effluent and surface waters for 48hrs, with 10 replicates per exposure. Each animal was analyzed individually. Shotgun proteomics is a method where the proteome is first digested into peptide mixtures and then characterized by LC-MS/MS. The largest number of protein matches were found in the Diptera (Flies) database, while the greatest relative number of species matches were found in the Odonata (Dragonflies& Damselflies) & Ephemeroptera (Mayflies) databases. Significant differential expression of common proteins among all exposure and control groups suggest that there were effects on the proteome of Hexegenia spp. by effluents. The discussion will identify potential ways that data from this study could inform regulatory frameworks.

Chemical, Biological and Instrumental Methods for Detecting Harmful Algae and Their Natural Toxins

MP059 Overview of USEPA Office of Research and Development's planned research on Analysis and monitoring in fresh and coastal/ estuarine environments

J.M. Lazorchak, USEPA / Office of Research and Development; H. Mash, T. Sanan, USEPA Office of Research and Development / NRMRL; T. Jones-Lepp, USEPA; M. Elovitz, USEPA / Water Supply and Water Resources Division; J. Allen, USEPA / Office of Research and Development; J. Lu, USEPA ORD Cincinnati; J.W. Santo Domingo, USEPA / Cincinnati; R. Zucker, USEPA ORD RTP

Several factors are contributing to the development of the "perfect" Harmful algal Bloom (HAB) storm. For example, climate change associated with elevated temperatures over prolonged time periods, changes in population demographics, agricultural land use linked to nitrogen loading increases, chronic economic stress and an aging water treatment infrastructure all combine to increase the probability of toxins breaking through to consumers' taps. In August of 2014 the State of Ohio issued a "Do Not Drink" notice after a harmful bloom event when elevated levels of microcystin (≥1 μg/L) were detected in the finished water of a treatment system serving approximately 1,900 customers. This system drew raw water from a location in Lake Erie close to the intakes of the City of Toledo, which provides water to about 500,000 residents. Increases in salinity are also having adverse ecosystem impacts stemming from freshwater HABs and invasive toxic algae. In addition, high biomass blooms are known to have adverse ecosystem impacts such as reduction of the photic zone impacting sensitive trophic interaction and reduction of oxygen levels that kill fish and bottom dwelling organisms. Some non-cyanobacterial freshwater HABs also produce toxins that can kill fish. The most problematic of these is the marine invasive Prymnesium parvum (i.e., "golden algae") which has caused fish kills in Texas annually since 2001 and has been documented in at least 10 other states. As a result of the human, ecological, and economic impacts of HABs, the USEPA's Office of Research and Development has established a research program to address issues related to the detection, quantification and monitoring of algal blooms and the organisms that produced them. This research plan has several objectives: develop new or refine existing chemical, instrument and biological methods for the detection of cyanobacteria and their toxins; test such methods in field studies in both HAB and non HAB environments; determine the method(s) that can be best uses as early warning (pre bloom conditions within days to weeks) systems for the detection of cyanobacteria and their toxins. We will discuss ongoing efforts on research projects that include chemical detection of toxins, use of molecular, flow cytometry, mass spectrometric, and microscopic approaches for phyto/ zooplankton identification, Phone apps for HABs early warning, and advanced instrumental and hyperspectral image analysis approaches.

MP060 Analysis of total microcystins in water at low part-per-trillion levels by on-line solid phase extraction coupled to UHPLC-MS/ MS

G. Munoz, S. VO DUY, Universite de Montreal / Chemistry; B. Husk, BlueLeaf; S. Sauve, Universite de Montreal

Anthropogenically-induced eutrophication of aquatic ecosystems, in conjunction with rising water temperatures worldwide, have been linked with increased frequency and magnitude of harmful algal bloom events. The proliferation of waterborne cyanobacteria may result in blue-green or red layers to form intermittently on freshwater or marine habitats, a harbinger of further risks to come when the bacteria release endotoxins upon dying. Among the wide panel of naturally-occurring cyanotoxins, microcystins are the most frequently monitored. In recent years, exceedances of the World Health Organization (WHO) drinking water guideline for microcystins (1 μg L^{-1}) have led to temporary "do not drink" notices, including in Northern America. A standard method for microcystin surveillance in drinking water facilities is the enzyme-linked immunosorbent assay (ELISA) that may achieve detection limits as low as 40 ng L^{-1}. Despite many acknowledgeable benefits, the ELISA approach has been reported to produce false positives, a potentially contentious issue for water managers who need to correctly and readily identify risks before taking the appropriate measures. In this context, a fast and reliable method is proposed for the quantitative determination of total microcystins in drinking water. After a Lemieux-von Rudloff oxidation step to yield the 2-methyl-3-methoxy-4-phenylbutyric acid (MMPB) moiety, samples were directly analyzed by solid phase extraction coupled online to liquid chromatography electrospray ionization triple quadrupole mass spectrometry. Particular care was devoted to method optimization, addressed through experimental designs to incorporate potential interactions between factors. Hence, the choice of on-line solid phase extraction settings was conducted using a multi-criteria desirability approach (Derringer's functions). This allowed for the ultrasensitive determination of total microcystins in water at sub part-per-trillion levels (method limit of quantification ~ 0.4 ng L^{-1} total microcystins, 2500 times lower than the current WHO threshold). Excellent determination coefficients were observed on the linearity range tested which covered > 4 orders of magnitude. Accuracy, recovery and precision were also evaluated and proved idoneous, independently of the spike level. Total microcystins are now amenable to ultra-trace analysis in drinking water resources.

MP061 Use of Membrane Filtration as an Alternative Method in the Extraction of Microcystin Cyanotoxins Produced by Harmful Algal Blooms

H. Mash, USEPA / ORDNRMRL

The frequency and intensity of harmful algal blooms (HABs) is increasing for a variety of reasons, with implications for human/animal health and water use. The development of analytical tools to measure and monitor individual microcystin cyanotoxins produced by HABs is complicated by several factors, including a limited availability of commercial standards and uncertainty about the variability and toxicity of the diverse microcystin congeners. Current methods invariably require sample concentration, typically solid-phase extraction, so as to be amendable for measurement at ambient concentration levels. Such methods (i.e. EPA Method 544) are only validated for a limited number of the known variants where standards are available. However, the efficiency and validity in the use of solid-phase extraction cannot be adequately confirmed for other variants. This research investigates the use of membrane filtration as an alternative methodology for extraction and concentration of various microcystins.

MP062 Acute and chronic toxicity testing of algal toxins using a suite of aquatic test organisms

N.E. Kemble, K. Feltz, K.R. Echols, USGS – Biological Resources Division / Columbia Environmental Research Center; J.M. Besser, USGS – Columbia Environmental Research Center / Columbia Environmental Research Center

Cyanobacteria, or blue-green algae, produce toxins that act as defense against grazers and competitors and that can also adversely affect aquatic and terrestrial animals as well as humans. Toxicity associated with fresh water cyanobacterial blooms was first described in 1878 and is now an issue worldwide. Cyanobacterial blooms have been increasing in frequency and intensity and have been linked to increased eutrophication from urbanization, agriculture and industrial nutrient enrichment. Microcystin and cylindrospermopsin are two of the most common classes of algal toxins found in waters of the United States. The objective of this study is to evaluate the toxicity of these two algal toxins to a diverse set of commonly tested aquatic invertebrates, fish, and amphibians. Species tested include the amphipod Hyalella azteca; the midge Chironomus dilutus; the mussel Lampsilis siliquoidea; the cladocerans Ceriodaphnia dubia and Daphnia magna; the fathead minnow Pimephales promelas; the rainbow trout Oncorhynchus mykiss; and the gray tree frog Hyla versicolor. Acute toxicity screens were conducted at nominal concentrations of 1 mg/L for microcystin-LR and 0.025 mg/L for cylindrospermopsin which exceeded the 90th percentile of ambient concentrations in U.S. surface waters. In addition, four species (H. azteca, C. dilutus, D. magna and P. promelas) were retested at four-fold higher concentrations (4.0 and 0.1 mg/L, respectively). Concentrations of algal toxins measured with Enzyme-linked immunosorbent assays (ELISA) averaged 98% of the nominal microcystin-LR concentration and 152% of the nominal cylindrospermopsin concentration. Survival in the first acute toxicity screen was ≥80% for both algal toxins and survival was 100% for the species retested at higher concentrations. Chronic 35-d exposures are being conducted with fathead minnows exposed to nominal concentrations up to 0.01 mg/L microcystin-LR and 0.0025 mg/L cylindrospermopsin. Results of acute toxicity screens indicates that concentrations of microcystin-LR and cylindrospermopsin reported for lakes and streams in the U.S. are unlikely to pose substantial risks of acute toxicity to aquatic organisms.

MP063 Cardiotoxicity of the blue-green algae Microcystis aeruginosa on developing Japanese medaka (Oryzias latipes)

S. Saraf, J. Jankowiak, B. Kramer, C. Gobler, A.E. McElroy, Stony Brook Univ / School of Marine and Atmospheric Sciences

Microcystis aeruginosa (M. aeruginosa) is a freshwater cyanobacterium that is associated with harmful algal blooms worldwide. M. aeruginosa blooms are of particular concern due to the higher temperature optimum and nutrient source flexibility of cells, along with their increasing distribution and secretion of heptotoxins, microcystins, by toxic strains. Blooms are toxic to a wide range of organisms, including humans, but are potentially more detrimental to aquatic individuals due to their chronic exposures and multiple routes of entry for microcystins. Effects of M. aeruginosa have mainly been examined in adult and juvenile fish, although early life stages (ELSs) are possibly more susceptible to the toxic effects. Survival and growth of ELS fish may represent a bottleneck for sustaining healthy populations, making effects at this level have elevated ecological significance. We have been examining the toxicity of natural blooms and pure cultures of M. aeruginosa in addition to the pure toxin, microcystin-LR, on embryos of Japanese medaka (Oryzias latipes). Decreased heart rate was found to be the most sensitive endpoint assessed, as compared to survival, time to hatch, body length, and gross developmental abnormalities. Continuing work examines whether the observed bradycardia is due to structural changes or temporary depression of heart rate, and if observed effects translate to changes in respiratory capacity and bioenergetics of developing fish, which could have long term ecological implications.

MP064 Microcystin-LR in Mouse Liver Tissue: Extraction and Analysis

C. Rosal, USEPA / EMMD / ORD / NERL / EMMD / ECB; N. Chernoff, USEPA; D. Hill, USEPA / ORD / NHEERL / TAD / DTB; R. Borjas, USEPA / Student Services Contract

Microcystins (MCs) are common global cyanobacterial toxins found in marine and freshwater environments. The adverse health effects they produce are primarily due to protein phosphatase inhibition in the liver. An important factor in assessing potential MC mammalian toxicity is the relationship of environmental exposure to hepatic toxicity and tissue levels in the liver of affected animals. With these data, environmental exposures can be directly compared to actual levels in the target organ, and these data increase the ability to evaluate comparative inter-species toxicity as well as MC levels in other human samples that may be available for epidemiology studies. This presentation covers only a fraction of the entire study and focuses on the method development on the extraction and analysis of liver tissues from mice dosed with known amounts of microcystin-LR (MCLR) as the representative congener. Several extraction approaches are currently being explored for best recoveries of free and extractable MCLR and other MCs as well as extraction approaches for total, free and bound MCs. Extracts are analyzed using an ultra-high performance liquid chromatography (UPLC) – quadrupole time-of-flight mass spectrometry (QToFMS) and a triple quad MS (MSMS) systems. Preliminary data show very low recovery of free and extractable MCs based on the amounts spiked to non-dosed liver tissues prior to extraction. These results imply two things: 1) the extraction method needs further optimization, and/or 2) most of the MCs are bound to tissues. These results are inconclusive at this point since the total MCs extraction method development is still underway. More conclusive data should be available during the time of this presentation.

Environmental Application of Cell-Based and High-Content Screening Assays for Monitoring Program and Risk Assessment

MP065 Using reporter gene assays to evaluate endocrine disruption in the rivers of three agricultural areas in South Africa

R. Pieters, North West Univ / Unit for Environmental Sciences and Management; N. Aneck-Hahn, M.C. Van Zijl, Univ of Pretoria / Urology; C. De Jager, Univ of Pretoria / School of Health Systems and Public Health; J. Dabrowski, CSIR South Africa

South Africa is the largest user of pesticides in sub-Saharan Africa. Here we report on the endocrine disrupting effects agricultural chemicals may have on the aquatic environment. Three regions with different crops were selected. The Letsitele site grows a variety of tropical and citrus fruits, Viljoenskroon area is dominated by maize and the Lomati region is known for its sugar cane. Water and sediment samples were collected bi-annually from the rivers from 2011 to 2013. Water samples were acidified to a pH of 2–3 and stored at 4°C. Filtered water samples were extracted with a C18 solid phase extraction cartridge and eluted with methanol. Dried and ground composite sediment samples underwent pressurised liquid extraction with a 3:1 mixture of dichloromethane:acetone. Clean-up steps included solid phase extraction, and size exclusion chromatography. Oestrogen activity was determined by the recombinant yeast screen (YES) and the T47D-KBluc cells. The androgen activity was investigated with the MDA-KB2 cell line. All the assays use the principle of a reporter gene being expressed when a ligand successfully binds to the respective hormonal receptor however the YES is a colorimetric assay, and both mammalian cell assays are luminescent. The mammalian cell assays were used for evidence of both activation and inhibition induced by environmental extracts. Stimulation of the hormonal receptor in the cells causes expression of the firefly luciferase and an extract's response is expressed in terms of the relative response by the positive controls: oestradiol equivalents (EEq) or testosterone equivalents (TEq). Inhibition was compared to the control cells slightly stimulated with positive control. Viability assays were run concurrently with all endocrine assays. The T47D-KBluc assay was more sensitive than the YES. Oestrogenic and androgenic activities were detected in water and sediment samples from all three agricultural areas. Oestrogenic activity in the water from across all sites and seasons ranged from < DL–6.78±2.28 ng EEq/L and in the sediment between < DL–254.95±69.2 ng EEq/kg with the highest for both matrices from the maize farming area. No androgenic activity was quantifiable for the water samples from the maize district however one of its sediment samples also had the highest activation of the androgen receptor. When comparing the levels of the commonly used pesticides in each area to the bio-assay results, no discernible pattern was found.

MP066 PROTECT (Puerto Rico Testsite for Exploring Contamination Threats) – Mixture Toxicity Assessment and Identification in Groundwater from Puerto Rico

X. Wen, Northeastern Univ / Dept of Civil and Environmental Engineering; G. Shao, Northeastern Univ / Dept of Pharmaceutical Sciences; I. Cotto, Univ of Puerto Rico at Mayaguez / Dept of Civil Engineering; N.I. Torres Torres, Univ of Puerto Rico at Mayaguez / Civil Engineering and Surveying; S. Rahman, Northeastern Univ / Dept of Civil and Environmental Engineering; I.Y. Padilla, Univ of Puerto Rico at Mayaguez / Civil Engineering and Surveying; A.N. Gu, Northeastern Univ / Dept of Civil and Env Engineering

Complex mixtures of chemicals that may pose a risk to ecosystem and human health are often present in aquatic environments. Feasible tools are needed to monitor aquatic environments and help identify chemicals that may cause adverse effects. As part of the NIEHS research center—PROTECT program, this study aimed to provide a fast, initial screening and assessment of the potential ecological and health impacts of Puerto Rico groundwater samples to reveal environmental contaminants and their potential contribution to health impacts. For the first sampling event, 15 samples were collected from selected wells and springs on the north coast of Puerto Rico. Organic substances in these samples were enriched via liquid-liquid extraction (LLE) and polar solid phase extraction (SPE). The LLE extracts were subjected to chemical analysis of phthalates on GC-ECD and chlorinated volatile organic compounds on GC-MS. The SPE extracts were subjected to both untargeted chemical screening on GC-MS and quantitative toxicogenomics assays that measured molecular toxicity based on endpoints—Protein Effect Level Index (PELI)—derived from temporal altered protein expression levels for 148 biomarkers targeting all known cellular stress response pathways including general, chemical, oxidative, protein and DNA stress responses. The resulting proteomics toxicity profiles/fingerprints allowed for multivariate statistical analysis to reveal the similarities and distances among these samples. Different molecular toxicity levels (overall average and stress pathway-specific PELI values) and distinct 3-D toxicity profiles were revealed among the samples. For example, the highest PELI value in protein stress was observed with the MIT well water, where the the highest number of chemicals were detected, including pesticides, anesthesia and phthalates. The POL well water showed the highest general and oxidative stresses. Correlation analysis between chemical analysis results and different toxicity endpoints showed that the occurrence of pesticides such as terbacil, atrazine and aldrin was significantly correlated with protein stress ($R > 0.8$, $p < 0.01$). This study demonstrated that this new toxicogenomics in vitro assay scheme and methodology platform can be an effective tool for groundwater monitoring, which can help identify chemicals that may have adverse health impacts and provide insights into potential toxicity mechanisms associated with complex mixtures of chemicals in aquatic environments.

MP067 Passive Polyethylene Samplers and in vitro Bioassays to Investigate Biological Effects of Complex Mixtures of Gaseous Hydrophobic Organic Contaminants

C.A. McDonough, Univ of Rhode Island / Graduate School of Oceanography; D. Franks, Woods Hole Oceanographic Institution / Biology; M.E. Hahn, Woods Hole Oceanographic Institution / Biology Dept; R. Lohmann, Univ of Rhode Island / Graduate School of Oceanography

Extensive research has established that particle-bound hydrophobic organic contaminants (HOCs) in air pose a serious health risk to humans but the biological relevance of the gaseous fraction, which is freely available to diffuse into biological tissue, is poorly characterized. Humans are exposed to gaseous air pollutants every day via respiration, dermal uptake, and dietary uptake from crops into which HOCs partition. In this study, passive polyethylene samplers (PEs), which accumulate truly gaseous HOCs over time via diffusion, were deployed in air throughout the greater Cleveland area for about 2 months. 9 sites, representative of urban, residential, and rural locations, were monitored. Extracts were analyzed by gas chromatography with mass spectrometry (GC/MS) for a suite of target compounds including polycyclic aromatic hydrocarbons (PAHs) and organic flame retardants (OFRs). Total polybrominated diphenyl ethers (PBDEs) were greatest at a site in downtown Cleveland, while total PAHs were greatest at a suburban, residential site east of the city. Aliquots of each extract were used to investigate biological effects of the extracted mixture via in vitro bioassays. To measure relative potency in activating the aryl hydrocarbon receptor (AhR), recombinant murine hepatoma cell line H1G1.1c3 was exposed to 10-point serial dilution curves of each extract and fluorescence readings were taken at 24, 48, and 72 hours. Preliminary results demonstrate that environmental samples induced fluorescence signals significantly above what was seen in response to a non-deployed, clean PE at all time points. Results from chemical and biological analysis at each site will be compared to determine whether specific site types exhibited distinct potencies, and whether concentrations of specific compounds or compound groups correlated with potency.

This study offers proof-of-concept for the use of PEs coupled with in vitro bioassays as a promising tool for measuring integrated effects of environmentally relevant mixtures.

MP068 Assessment of storage conditions for wastewater influent and effluent intended for in vitro bioassay analysis

S. Beitel, Univ of Saskatchewan – Toxicology Centre / Dept of Chemical and Environmental Engineering; C. Hoppe-Jones, L. Flahr, Univ of Arizona / Dept of Chemical and Environmental Engineering; S. Wu, Univ of Arizona; K. Daniels, Univ of Arizona / Chemical and Environmental Engineering; I. Lopez, J. Habit, N. Villagomez-Marquez, Univ of Arizona / Dept of Chemical and Environmental Engineering; S.A. Snyder, Univ of Arizona / Chemical and Environmental Engineering

Receptor mediated cellular bioassays are becoming increasingly popular to screen surface waters for chemicals of emerging concern (CECs), including pharmaceuticals, personal care products, steroid hormones, and endocrine disrupting chemicals. Since water samples cannot always be processed and tested immediately after sampling, it is important to identify what storage and preservation techniques will ensure the integrity of samples for bioassay testing. The aim of this study was to investigate how different storage conditions, mainly bottle type, temperature, time, presence of a preservative, and presence of an oxidant quenching agent impacted the response of a CEC mixture using a suite of in vitro bioassays. Briefly, 250 mL of influent or 500 mL of effluent was placed in either amber glass or HDPE bottles. Sodium azide (NaAz) or sodium omadine (NaOm) were added to the bottles at a concentration of 1.0 g/L or 64 mg/L, respectively, along with a no preservative control. Sodium sulfite as an oxidant quenching agent was tested only with effluent samples. A mixture of 48 CECs was added to each bottle to a final concentration of 2 ppb for influent and 1 ppb for effluent. Samples were stored at 20, 4 or -18°C for 0 h, 24 h, 48 h, 72 h, 7 d, or 21 d, with all treatments and conditions tested in triplicate. At each time point, an aliquot from each bottle was taken for targeted chemical analysis, with the remaining sample being extracted by solid phase extraction with Oasis HLB cartridges. GR-UAS-blaHEK 293T and ER alpha-UAS-bla GripTite cell based assays (Invitrogen) were used to identify the glucocorticoid and estrogenic potential of the extracts. Preliminary bioassay results for effluent samples indicated that bottle type did not impact the response of the mixture in either assay, and the response was stable in samples stored at 20?C for up to 72 h, and for 3 weeks when stored at 4?C or -18?C without a preservative or with NaAz. The use of NaOm did impact the response of the glucocorticoid receptor assay, with the response being lesser in samples stored at 20?C for 72 h and at 4?C for 3 weeks. Analytical quantification of the water samples will be used to investigate the stability of each compound over time and as a confirmation of overall bioassay response tied to analytical values. Ongoing research involves testing the effluent sample extracts along with conducting additional bioassays to develop a standardized procedure to be used across laboratories.

MP069 Monitoring Ecological Impacts of Environmental Surface Waters using Cell-based Metabolomics

H. Nguyen, Environmental Protection Agency; H. Zhen, D. Ekman, USEPA / National Exposure Research Laboratory; D.L. Villeneuve, USEPA / National Health and Environmental Effects Research Laboratory; J.E. Cavallin, USEPA / USEPA Mid-Continent Ecology Division; G.T. Ankley, USEPA / National Health and Environmental Effects Research Laboratory; T. Collette, USEPA / National Exposure Research Laboratory; P. Bradley, USGS / SAWSC; Q. Teng, USEPA / EMMD / National Exposure Research Laboratory

Optimized cell-based metabolomics has been used to study the impacts of contaminants in surface waters on human and fish metabolomes. This method has proven to be resource- and time-effective, as well as sustainable for long term and large scale studies. In the current study, cell-based metabolomics is used to investigate the impacts of contaminants in surface waters on biological pathways in human and ecologically relevant cell lines. Water samples were collected from stream sites nationwide, where significant impacts have been primarily measured from the most potentially contaminated sources (i.e. waste water treatment plants, concentrated animal feeding operations, mining operations, and plant-based agricultural operations that use intensive chemical applications). Zebrafish liver cells (ZFL) were used to study exposure impacts on in vitro metabolomes. In addition, a small number of water samples were studied using two human cell lines (liver cells, HepG2 and brain cells, LN229). The cellular metabolites were profiled by nuclear magnetic resonance (NMR) spectroscopy and gas chromatography mass spectrometry (GC-MS). Detailed methods and results will be reported.

MP070 Cell-based metabolomics approach for assessing the impact of wastewater treatment plant effluent on downstream water quality

H. Zhen, H. Nguyen, D. Ekman, T. Collette, USEPA / National Exposure Research Laboratory; S.T. Glassmeyer, USEPA / Office of Research and Development; Q. Teng, USEPA / EMMD / National Exposure Research Laboratory

Wastewater treatment plants (WWTP) are a known source of various types of chemicals including pharmaceuticals and personal care products (PPCPs), naturally occurring hormones, and pesticides. There is great concern regarding their adverse effects on human and ecological health through low-level, chronic exposure. In some areas where water resources are limited, the WWTP may be located in the same watershed as drinking water treatment plants (DWTP) and thus have a potential negative effect on downstream water quality. In this study, we investigated the possible impacts of contaminants as they travel from WWTP into DWTP in a water usage cycle by using cell-based metabolomics. Zebrafish liver cells (ZFL) were exposed to water samples collected along a river, where a WWTP was located 9 miles upstream of a DWTP. The sampling sites include upstream of WWTP, WWTP effluent discharging point, downstream of WWTP, drinking water intake place and the treated drinking water. After 48 hrs, the intracellular metabolites of ZFL cells were extracted. The polar and non-polar fractions of metabolites were analyzed by ^{1}H NMR spectroscopy and GC-MS, respectively. Multivariate statistical analysis revealed distinct changes of polar and non-polar metabolite profiles in response to effluent exposure from WWTP. The impact of effluent on the polar fraction of ZFL metabolome gradually diminished downstream of the WWTP and become non-significant at the drinking water intake location. However, the impacts of effluent on non-polar metabolome were still substantial for cells exposed to downstream WWTP sample and drinking water intake sample. ZFL exposed to treated drinking water did not exhibit significant changes of polar and non-polar metabolome compared to upstream WWTP sample, implying that the contaminants from WWTP effluent were efficiently removed in drinking water treatment processes. This study demonstrated the utility of cell-based metabolomics in determining the impacts of WWTP effluent on downstream water quality.

MP071 Nanomaterial Toxicity through a High Throughput Screening Approach on Mytilus Edulis Hemocytes

A. Barrick, Université Catholique de lOuest; M. Bruneau, Université Catholique de lOuest / LUNAM Université Mer Molécules Santé MMS; C. Mouneyrac, Université Catholique de lOuest / UNAM Université Nantes Angers Le Mans Mer Molécules Santé MMS; A. Chatel, Université Catholique de lOuest / Sciences Environnement

Nano-scale products are being produced faster than current toxicity screening can keep up with, making it difficult to develop a universal regulatory policy. The use of in vitro assays and high throughput screening (HTS) addresses this growing demand for a rapid means of developing a comprehensive regulatory framework for engineered nanomaterials (ENMs). Under the project NanoReg II, funded by the European Union, the objective of our research is to provide a means in which nanomaterials can be incorporated into REACH guidelines. In this context, the aim of this study is to develop an HTS platform based on toxicity screening through a cell culture on marine mussel (Mytilus edulis) hemocyte cells exposed to different ENMs at different stages of their life-cycle produced by industrial partners. In addition to this, sublethal concentrations were selected in order to assess biomarker responses to the presence of ENMs and to develop a response profile. Future work will focus on characterizing the mechanistic pathways of toxicity for these ENMs and providing a comprehensive risk assessment and life-cycle analysis of products tested. This work is funded by the European project NanoregII (Development and implementation of Grouping and Safe-by-Design approaches within regulatory frameworks)

MP072 Estrogen-driven apical endpoints in Menidia beryllina

K.J. Kroll, Univ of Florida / Physiological Science; A.C. Mehinto, Southern California Coastal Water Research Project / Dept of Toxicology; O. Adeyemo, Univ of Ibadan; E. Li, East China Normal Univ; S.M. Bay, Southern California Coastal Water Research Project / Toxicology Dept; K.A. Maruya, SCCWRP; N.D. Denslow, Univ of Florida / Physiological Sciences

The inland silverside (Menidia beryllina) is an established fish model for estuarine toxicity and is useful to determine effects of estrogenic chemicals on apical endpoints. Focusing on estrogenic chemicals commonly found in wastewater effluents, we exposed Menidia to increasing concentrations of 17β-estradiol (E2), estrone (E1) and 4-nonylphenol (4-NP) to determine changes in gonadal differentiation and growth, two important apical endpoints used for risk assessment. In vivo endpoints included alterations in molecular gene expression of two genes controlled by estradiol, vitellogenin and choriogenin. Growth was measured after 14 days and gonadal differentiation and sex ratio were measured after 28-days of constant exposure to the chemicals and after two months of transfer to clean water. Critical for the success of the experiment was to start the exposures before tissue differentiation in females and nutrition based on dechorionated artemia. Concentrations required for sex ratio skewing towards females was 200 ng E2/L and 100 ng E1/L. NP did not cause sex ratio skewing. All three of the chemicals caused retardation of growth. Some of the apical effects were still present in fish after 2 months in clean water. Early exposures to endocrine disrupting chemicals may change the nature of the population of this estuarine species.

Soil Contaminants: Fate, Bioavailability, Environmental Toxicology and Risk Assessment

MP073 Use of an in vivo rat model to evaluate relationships between bioaccessibility and bioavailability of nickel in ultramafic soils

J. Sowa, Univ of Guelph-SES / School of Environmental Sciences; L. Vasiluk, Univ of Guelph / School of Environmental Sciences; M.D. Dutton, Vale Canada Limited; P. Sanborn, Univ of northern British Columbia / Ecosystem Science and Management Program; B.A. Hale, Univ of Guelph / School of Environmental Sciences

Nickel (Ni) is one of the leading soil contaminants found at former mining and smelting sites across Canada. Unfortunately, current deterministic generic soil quality guidelines often overestimate actual risk of toxicity via contaminated soil ingestion. Agencies are now turning toward probabilistic risk assessments by analyzing two key factors of soil Ni toxicity: the bioaccessibility and bioavailability. This study tested three hypotheses to relate findings of Ni bioaccessibility using the Solubility/Bioavailability Research Consortium (SBRC) method and Ni bioavailability using an in vivo rat model in a grouping of different naturally Ni elevated soils ("Ultramafic Soils"). Findings of this study indicated that with increasing Ni-compound solubility, there was increased absorbance in the small intestine of animals and thus an increase in the bioavailability of the Ni from soil. Second, Ni bioavailability was able to be adequately determined from urine content; however bioavailability was not able to be linearly correlated with bioaccessibility measurements. Lastly, while bioaccessibility was found to generally overestimate bioavailability, this relationship was not found to be consistent amongst the soils tested. Overall, findings demonstrate that the relationship of bioaccessibility and bioavailability of Ni in these soils are not straightforward. It is concluded that there are additional factors that may convolute this relationship, including speciation and mineralogy of the soil. However, research into bioaccessibility and bioavailability relationships continue to move toward probabilistic risk assessment.

MP074 Bioaccessible Nickel in Various Particle Sizes of House Dust from Communities Close to Nickel Mining and Smelting

N. Dai, Univ of Guelph-SES / School of Environmental Sciences; L. Vasiluk, Univ of Guelph / School of Environmental Sciences; M.D. Dutton, Vale Limited Canada; B.A. Hale, Univ of Guelph / School of Environmental Sciences

Indoor dust particles that settle on surfaces adhere upon contact to the hands and are ingested through hand-to-mouth behaviours. Ingestion of elevated levels of nickel from dust may be a significant source of exposure. Nickel accumulation in mammalian organs can lead to chronic inflammation, increasing the risk for cancer, especially from soluble nickel compounds. Bioaccessible nickel, the amount of nickel that becomes available for intestinal absorption as a result of digestion in the stomach, is likely a more accurate exposure measure than total nickel concentration present in house dust. For bioaccessible nickel, the role of particle size depends on the site of origin and the distribution of organic and inorganic nickel phases with their varying rates of dissolution and adsorption to dust. We are examining the relationship between particle size and nickel bioaccessibility in Sudbury house dusts. Samples were separated using plastic sieves into ranges of < 10 µm, 10-41 µm, 41-70 µm, 70-105 µm, 105-250 µm particle size fractions. Bioaccessibility was determined using SBRC glycine digestion, which simulates stomach pH and churning via shaking the dust with extraction fluid in a water bath at body temperature. Nickel concentration was determined using GFAAS, and multiple linear regression was used to analyze the data. Dust particle size and total nickel concentration together explain 88% of the variance in bioaccessible nickel concentration (adjusted $R^2 = 0.88$, $p < .001$). Dust particle size was strongly and inversely correlated with bioaccessible nickel concentration ($r = -0.66$), and moderately correlated with total nickel concentration ($r = -0.43$). Bioaccessibility enables adjustment of exposure estimates for risk assessment. Thus, the results of this study will help inform risk assessors on the contribution of indoor dust to total nickel exposure through ingestion, for populations close to nickel mining and smelting activities.

MP075 Using XANES to identify the effect of ageing, speciation and mineral association of nickel on its bioaccessibility in soil

R.J. Thorn, The Univ of Guelph / school of environmental science; B.A. Hale, Univ of Guelph / School of Environmental Sciences; M.D. Dutton, Vale Limited Canada

Changes in the speciation and bioaccessibility of Ni in soil columns spiked with nickel-sulphate-hexahydrate were measured over a 168 day period as a function of soil organic content and synthetic precipitation (leach) rate. X-ray Absorption Near Edge Structure (XANES) spectroscopy identified a rapid conversion of added $NiSO_4 \cdot 6H_2O$ to less labile phases post spiking because of surface sorption kinetics and precipitate formation. Soils with an average pH >7 contained 47-70% $Ni(OH)_2$/NiO within fourteen days, while only 37% of Ni was present as $Ni(OH)_2$/NiO at day 1 in soil with a pH < 7. Conversion to $Ni(OH)_2$/NiO slowed substantially after day 1 in all soils, due to slower ageing processes such as diffusion, incorporation into crystal lattices, and Ostwald ripening of precipitates. Bioaccessibility was significantly increased with the presence of increased SOM due to the higher proportion of exchangeable complexes with carbonate and organics. Bioaccessibility decreased at nearly identical rates (0.11-0.13% day^{-1}) in all columns. Leach rate did not significantly influence speciation, but Ni bioaccessibility was increased in wetter soils. Increased stability of Ni complexations and the formation of Ni precipitates are assumed to account for much of the reduction of bioaccessible Ni through ageing related mechanisms.

MP076 Evaluating the ability of Alyssum murale to extract aged nickel from nickel-enriched organic soils

K. Zupfer, Univ of Guelph / School of Environmental Sciences; M.D. Dutton, Vale Canada Limited; B.A. Hale, Univ of Guelph / School of Environmental Sciences

Port Colborne, Ontario, has an area of nearly 30km^2 that has been contaminated by emissions from a nickel (Ni) refinery that was in operation between 1918 and 1984. Elevated Ni concentrations in the surrounding soil are causing phytotoxicity and are suspected of reducing crop yield in some agronomic species. Common remediation techniques (such as 'dig and dump') are not feasible or economically efficient because of the large area that has been contaminated. Phytoremediation would be a sustainable alternative if its efficacy could be demonstrated on spatial and temporal scales. Nickel hyperaccumulating species are able to accumulate at least 1000 mg kg^{-1} of Ni in their dry biomass without succumbing to toxicity. Alyssum murale, a hyperaccumulator of Ni that is native to Ni-rich serpentine soils from Mediterranean Europe, is a species of interest for phytoremediation techniques. Tissue concentrations of Ni in shoots of A. murale have been determined using field contaminated soils in pot and field studies; however the spatial and temporal capacity of this species as a perennial crop to measurably reduce the concentration of Ni in soils has not been demonstrated. The uptake of aged Ni by wild-type A. murale from Ni-contaminated organic soils will be compared to extractable soil Ni as it is influenced by varying chemical and physical properties of soil, and sequential cropping. From this study, we will establish a hypothetical timeline for reduction in soil Ni concentration, for consideration in a site remediation plan.

MP077 Metal Mixtures in Soil: Testing the Concentration Addition Approach as a Risk Assessment Tool

P. Arora, Univ of Guelph / School of Environmental Sciences; S. Siciliano, Univ of Saskatchewan / Toxicology Group and Dept of Soil Science; B.A. Hale, Univ of Guelph / School of Environmental Sciences

The risk assessment of metal mixtures in soils is critical to Canada's mining industry and regulatory system. The assessment of mixtures relative to impacts of mining and associated activities is of high priority for Environment Canada and Canadian base metal mining sites. There is limited data available on the toxicity of mixtures to soil organisms, particularly in field application. The proposed research will evaluate the validity of the concentration addition (CA) model in predicting the toxicity of a ternary metal mixture (As, Co, Zn). Toxic units (TUs) are widely used in the comparison of single compounds when assessing mixture toxicity. This study will use current regulatory TUs to predict toxicity of metal mixtures to test the CA model. Metal mixture impacts on higher plant species, barley (Hordeum vulgare) and tomato (Lycopersicon escultenum), will be assessed for growth parameters (root and shoot length; root and shoot dry weight) and metal uptake using field contaminated, reference, and artificial soils. Soils from Deloro, ON, contaminated with anthropogenic sources of metals, will be collected and used in the toxicity testing. The outcomes of this research will serve as a predictive risk assessment tool for mixtures and their interaction in soils at base metal mining sites in Canada, as well other similar contaminated sites around the world.

MP078 Risk assessment of heavy metal-contaminated sediment based on heavy metal speciation and extractability

K. Kim, M. Kim, Seoul National Univ; S. Im, Hyundai Engineering & Construction Co., Ltd / Research Development Division; G. Yu, S. Kang, Seoul National Univ; K. Nam, Seoul National Univ / Dept of Civil and Environmental Engineering; Y. Choi, Seoul National Univ / Dept of Civil and Environmental Engineering

Sediments in navigational routes and estuarine channels are often found to contain significant level of heavy metals. For the beneficial reuse of dredged sediments in terrestrial environment, ecological risk by the exposure of heavy metals to terrestrial receptors should be assessed. However, the commonly applied approach of ecological risk assessment based on total metal content in sediment analyzed by exhaustive extraction may overestimate the risk, leading to excessive and costly treatment of the dredged sediment prior to reuse. Therefore, development of an ecological risk assessment method considering heavy metal bioavailability is needed for cost-effective and reasonable management of dredged sediment. Because of the uncertainties and intensive labor requirements involved in biological tests, chemical extraction methods are often applied to predict the potentially bioavailable fraction of heavy metals in sediments from heavy metal speciation and extractability. In this study, different chemical extraction methods including sequential extraction (SE), toxicity characteristic leaching procedure (TCLP) and a single extaction test (H_2SO_4 1.5 M, and HCl 0.5 M) were applied to a heavy metal-contaminated sediment sample dredged from one of the major ports in Korea. Ecological risk and contamination level of the sediment sample was charcterized from the heavy metal speciation using risk assessment code (RAC) and individual contamination factor (ICF) suggested in the literature. The amount of heavy metals extracted by TCLP and single extraction was greater than the sum of weakly bonded metal forms (exchangeable and carbonate bound fractions) from SE. RAC indicated high risk for Zn and Cd and low to moderate risk for Ni, Cu and Pb. ICF indicated that Zn and Cu posed a serious contamination while Cd posed a moderate contamination. Because different results and conclusions can be obtained from the various extraction and assessment methods, these methods should be more comprehensively reviewed in comparison with biological tests for the incorporation of heavy metal bioavailability to ecological risk assessement. Acknowledgement: This study recReived substantial support from the Geo-Advanced Innovative Action (GAIA) Project of the Korea Environmental Industry & Technology Institute (KEITI).

MP079 Overcoming Challenges in Assessing Risks to Wildlife at a Former Lead/Zinc Mine in the Yukon Territory

C.E. Mackintosh, E. Franz, R. Hill, N. Healey, E.A. Power, R.F. Baker, P.J. Allard, M. Gebauer, Azimuth Consulting Group

Ecological Risk Assessment (ERA) studies were conducted at a former lead-zinc mine located in the Yukon Territory of Northern Canada. These studies were conducted concurrently with site characterization and other investigations to support permanent closure of the mine. While the mine only operated for 16 months in the early 1990s, metal concentrations in soils in areas of environmental concern (AEC) were well above applicable standards. Metal concentrations in terrestrial plants, invertebrates and small mammals were also elevated in contaminated mine site areas, relative to reference locations. Wildlife were evaluated in the ERA using scenarios and phased analyses to overcome several challenges: (1) ERA delivery alongside site characterization and closure planning, (2) spatially disconnected AECs and contributions from natural mineralization (3) supporting further understanding of the potential consequences to wildlife species of elevated metals concentrations. Phases of the wildlife ERA included: Phase 1: Modeling hazard quotients for 17 bird and 16 mammal species for multiple scenarios including: Current, predicted post-closure and alternative management actions, Mine site or smaller spatial scales, depending on receptor home range. Phase 2: Effects characterization (i.e., potential types and sizes of effects) using model-estimated doses compared to multi-study literature-derived dose-response datasets. Phase 3: Wildlife analysis assessing species presence and densities in various areas of the mine. Receptor and contaminant combinations showing potential risks were carried forward into subsequent phases of the ERA for further refinement of risk estimates. The scenario testing provided area-specific conclusions for directed management actions. Phases 2 and 3 characterized potential consequences including types and magnitude of effects, and number of individual organisms (for listed species) or proportion of mine site population (for common species) potentially affected. This phased and scenario-based approach to ERA provided managers, regulators and First Nations with supplementary information to support site closure decision-making.

MP080 Arsenic uptake by beets (Beta vulgaris) cultivated in a roxarsone-contaminated medium

J. Houser, H. Craddock, Univ of Tennessee at Chattanooga / Biological Geological and Environmental Sciences; S.M. Richards, Univ of Tennessee-Chattanooga / Biological Geological and Environmental Sciences

Arsenic (As) is a global toxicant that negatively impacts human health. Roxarsone (ROX) is an organoarsenical administered to poultry to control internal parasites. ROX is excreted from poultry unchanged and the waste may be used for vegetable fertilizer. This experiment was conducted with beets (Beta vulgaris) by adding 0, 1, 10, and 100 mg/kg As (T_1, T_2, T_3, and T_4 respectively, with ROX, presented as As concentrations) to a growing medium prepared with topsoil in a greenhouse. The study aimed to determine effects of As-contaminated soils on biomass production, uptake of As by beets, and allocation of As to tissues. Results showed that biomass production of beets was negatively correlated with As concentrations in the growing medium ($r = -0.3286$, $p < 0.0001$). As uptake by beets was positively correlated with As concentrations in the growing medium (roots, $r_s = 0.7577$, $p < 0.0001$; shoots, $r_s = 0.8406$, $p < 0.0001$). As uptake by beets was observed with median values in the roots of 0.267 ± 0.004 mg/kg, 0.271 ± 0.001 mg/kg, 0.271 ± 0.289 mg/kg, and 3.76 ± 1.92 mg/kg for T_1, T_2, T_3, and T_4 respectively; the shoots took up 0.259 ± 0.006 mg/kg, 0.263 ± 0.313 mg/kg, 0.271 ± 0.373 mg/kg, and 3.94 ± 0.72 mg/kg for the respective treatments. Beets took up 4.3 ± 2.3% of available As and distributed it equally into tissues. The results suggest that As could be transferred to humans through the food chain via beet consumption.

MP081 Tools for Development of Site-specific Clean-up Values Protective of Soil Ecological Receptors at Metal and Metalloid-contaminated Soils

R.G. Kuperman, Edgewood Chemical Biological Center / Operational Toxicology Branch; R. Checkai, US Army Edgewood Chemical Biological Ctr / Molecular Toxicology Environmental; K. Oorts, ARCHE

Until recently, there was no uniform guidance for developing site-specific Soil Clean-up Values (SCVs) for metals and metalloids in contaminated soils. Ecological soil screening levels (Eco-SSLs), although appropriate for screening, have been misapplied for soil remediation at contaminated sites. Using soil invertebrate, plant, and microbial toxicity data, available in the European REACH (Registration, Evaluation, Authorisation and Restriction of Chemicals) datasets, we present the tools that can be utilized for developing an SCV, using metalloid Mo as an example. These tools include accounting for the chemical bioavailability as a function of specific soil parameters of the contaminated site, correcting for differences in bioavailability between laboratory and field conditions, the development of Species Sensitivity Distribution (SSD) for ecologically relevant soil biota and critical soil processes, and review of the options for the selection of site-specific risk ranges for SCVs. A transparent generic approach is presented for the application of these tools and selection of appropriate effect thresholds (ECx) and hazardous concentration (HC) values (e.g., HC5 or HC50 protection level) to help site managers and regulators to derive an SCV resulting in an adequate protection of plants, soil invertebrates, and critical soil processes in a specific site.

MP082 Development and standardization of an ecotoxicological test method for the environmental risk assessment of genetically modified plants

S. Jaensch, J.E. Bauer, D. Leube, J. Roembke, ECT Oekotoxikologie GmbH; H. Teichmann, M. Otto, Federal Agency for Nature Conservation

Before a genetically modified plant (GMP) may be released into the environment and placed on the market in the European Union (EU), an environmental risk assessment (ERA) according to EU directive 2001/18/EC must be performed. Currently, testing of the effects of GMPs on non-target organisms is mainly based on ecotoxicological test methods developed for the assessment of chemicals. This does not fully comply with directive 2001/18/EC, which demands a case-specific ERA. According to Annex II of the directive a 'case' is defined as a combination of the parent organism, its genetic modification and the possible receiving environment related to the intended release and use of the GMP. As the standard test organisms used for the assessment of chemicals do usually not occur in the receiving environment of GMP, they cannot be considered adequate. According to an ecology-based selection approach test species should be selected from organism groups relevant to the receiving environment and to the various exposure pathways. In addition, different taxonomical and physiological groups should be covered. Nevertheless, testing of any species in the laboratory also needs to be practical for a standardized application. Hence, the aim of a German R&D project (2012-2016) was the development and standardization of a laboratory ecotoxicological test especially for the ERA of GMP. This aim was reached in three steps. First, the black fungus gnat Bradysia impatiens Johannsen (Sciaridae: Diptera) was identified as a suitable test species and its mass rearing in the laboratory was established. The second work step comprised the actual development and trial of the test method that meets the above mentioned characteristics of the assessment of GMP. In the third and final work step the method was described in a draft guideline according to the specifications of the OECD. In this contribution said draft guideline and key results obtained during the method development will be presented.

MP083 Morphological, biochemical and yield response of Capsicum annum grown at different SLASH (sewage sludge and fly ash mixture) amendment rates

B. Sharma, Inst of Environment and Sustainable Development, Banaras Hindu Univ, Varanasi; R.P. Singh, Banaras Hindu Univ / Environment and Sustainable Development

Unplanned and improper disposal of solid wastes in most of the developing countries results in hazardous effects on environment. Agricultural utilization of sewage and fly ash mixture (SLASH) can be explored as one of a sustainable approach to manage these wastes. Land application of Slash can improve the physicochemical properties of soils and may help in promoting plant growth due to presence of beneficial plant nutrients. Slash mixture has more balanced properties, in which fly ash can serve as a potential stabilizing agent for sewage sludge by neutralizing it, killing pathogens, reducing toxic heavy metals availability and consequent damage to plants. The present study was conducted to assess the feasibility of agricultural utilization of SLASH mixture in terms of morphological, biochemical and yield response of Capsicum annum (Chili), a commonly grown household vegetable. Four amendment ratios of sewage sludge (SS): fly ash-(FA) (viz. 4 (SS):1 (FA), 4:2, 4:3, and 4:4 denoted as A, B, C and D, respectively) were mixed with the soil at two different rates of 20% and 40%. Significant increase in foliar protein content was reported in different Slash amendment rates with maximum increase in D40%. Peroxidase activity increased significantly in all the SS-FA amendments as compared to control plants except for C40% and D40%. Proline content was also found to increase insignificantly in most of the SS-FA amendments in Chili plants with highest significant increase at B40%. Morphological parameters and total plant biomass also increased significantly due to SS-FA amendments as compared to unamended soil. Maximum increment in shoot length, leaf area and total biomass was observed in amendment D20% and in root length and number of leaves in A20%. Yield also increased significantly across all the amendments with maximum increase of 94.6% at D20% followed by D40% (91.5%) and A20% (88.6%). Owing to positive morphological, biochemical and yield response amendments A and D can be recommended for Chili (Capsicum annum) plants

MP084 Advances in the Development of Procedures to Establish the Toxicity of Non-Extractable Residues (NER)

G. Sanders, Givaudan International SA / Regulatory Affairs and Product Safety; J. Harmsen, Alterra, Wageningen-UR / CALM; D. Hennecke, Fraunhofer IME – Inst for Molecular Biology and Applied Ecology / Ecological chemistry; K. Hund-Rinke, Fraunhofer IME; J. Lahr, Alterra – Wageningen; J.W. Deneer, Alterra Wageningen UR / ERA team; M. Galay-Burgos, ECETOC; B. Hubesch, European Chemical Industry Council – CEFIC; C.V. Eadsforth, Shell International / Shell Health; C. Finnegan, Unilever / SEAC Environmental Protection; G. Roberts, GR Consulting

The bioavailability and ecotoxicological relevance of Non Extractable Residues (NER) has been a major subject of debate for at least the past four decades. The debate focuses on the question, are NER an efficient detoxification process or are they an "environmental time-bomb" ? The ECO25 project sponsored under the CEFIC (European Chemical Industry Council) Long-Range Research Initiative research programme aims to shed some light on this subject. The principal deliverable from this research is to develop a scientific tool which is capable of responding to the demands of regulatory risk assessment needs to define the impact of NER. Because NER are not measurable in real life, the project has focused on the measurable fractions of the chemical in the soil compartment. New, but standardised extraction procedures are used to permit the evaluation of the ecotoxicity of fractions representing different degrees of bioavailability of test chemicals. It will also provide a clear, mechanistically driven, definition of NER and methodology to confirm the potential ecotoxic effects of NER. A series of ecotoxicity assays to determine the potential adverse effects of NER have been used including an Earthworm avoidance test, adaptation of the soil microflora toxicity test, Microtox^{Ò} screen and an acute Daphnia toxicity test. Three ^{14}C-radiolabelled molecules of distinctly differing chemistry and physicochemical properties have been investigated in three well characterised soils of varying composition. The intrinsic ecotoxicity of the chemicals in soils has been studied using the battery of assays by considering the effects immediately after application and then, after 6 months incubation (aging of the soil residue). The effect of formation of NER on the soil ecotoxicity of each test substance will be presented, discussed and interpreted in relation to current regulatory risk assessment of NER.

MP085 Measures of Chemical Availability for Enhancing Risk Assessments of PAHs in Soil

J.M. Conder, Geosyntec Consultants; K. Sorensen, US Navy, SPAWAR SSC / Environmental Sciences Branch; R. George, US Navy, SPAWAR SSC; M.M. Grover, Geosyntec Consultants

A major uncertainty of many site-specific human health and mammalian risk assessments is the digestive bioavailability of Polycyclic Aromatic Hydrocarbons (PAHs) consumed via the incidental ingestion of contaminated soils. Relative to the bioavailability of PAHs used in spiked foods used in laboratory toxicity tests, soil-associated PAHs at contaminated sites are generally much less available. For example, laboratory tests that have measured in vivo exposures have noted that PAHs in soil contaminated with solid materials (e.g., soot) or weathered petroleum are many times less bioavailable compared to PAHs that have been freshly spiked with solvent or unweathered petroleum. This reduced bioavailability can be quantitatively accounted for in risk assessments using a Relative Bioavailability (RBA) value. However, laboratory feeding trials with live animals are expensive ($50,000 to $100,000 range or more) and require many weeks of experimental work. Fortunately, less expensive and more rapid chemical availability measures can be used to provide RBA information. This presentation provides an evaluation of two such tools: 1) Physiologically Based Extraction Tests (PBET) that extract PAHs from soil using a simulated digestive matrix; and 2) determination of freely-dissolved PAHs in soil via a commercially-available polyethylene passive sampling device. PBET and passive sampling results were evaluated for soils contaminated with solids-associated PAHs and compared to dose and RBA estimates for benzo(a)pyrene values generated from a laboratory experiment with rodents fed small amounts of the soils. Freely-dissolved PAHs data from the passive sampling measurements indicated that PAHs were approximately 10 to 100 times less available than PAHs spiked with unweathered petroleum and solvent, respectively, confirming the low availability of the solids-associated PAHs in the soils tested. Both chemical measures were positively correlated with benzo(a)pyrene bioavailability measurements obtained from the rodent feeding trial, indicating that empirical models may be able to be developed to relate chemical PAH availability measures to RBA estimates such that PBET and passive sampling data may be used to predict RBA values for use in risk assessments. PBET and passive sampling chemical measurements appear to be cost- and time-effective tools for predicting mammalian digestive PAH availability and improving the accuracy of site-specific PAH risk assessments.

Bioavailability of Organic Chemicals for Retrospective Risk Assessment: Measurement, Applications and Communication

MP086 How to communicate bioavailability science in regulation of organic chemicals?

J. Ortega-Calvo, Instituto de Recursos Naturales y Agrobiologia / Agroquimica y Conservacion del Suelo; J. Harmsen, Alterra, Wageningen-UR / CALM; J. Parsons, Univ of Amsterdam / IBED; J. Roembke, ECT Oekotoxikologie GmbH; M. Aitken, Univ of North Carolina / Environmental Sciences and Engineering; K.T. Semple, Univ of Lancaster / Lancaster Environment Centre

The bioavailability of organic chemicals in soil and sediment is an important area of scientific research. However, this area remains only partially recognized by regulators and industries working in the environmental sector. Based on the positive experiences already made with metals, regulators have recently started to consider bioavailability within retrospective risk assessment (RA) frameworks (e.g. of contaminated sites). By doing so, realistic decision-making in terms of hazard definition and priority considerations finally resulting in optimised cost allocation can be achieved, rather than relying on the established approach of using total-extractable concentrations. However, implementation of bioavailability remains difficult because scientific developments on bioavailability are not always translated into ready-to-use approaches for regulators and, therefore, no integrated approach for implementation is available. For the same reason, bioavailability remains largely unexplored within prospective regulatory frameworks that address the approval and regulation of organic chemicals. To facilitate the inclusion of bioavailability within more realistic RA frameworks, agreement and common understanding between scientists and regulators is required. In this identified communication need, we should try to answer the following questions: 1) What general message should be communicated, and which specific topics or benefits from bioavailability science can attract the interest of the regulators? 2) What is the best approach to convey these messages to the regulatory community? And 3) How can we establish a dialogue to verify that the messages are being considered and can be adapted to the satisfaction of all stakeholders? This contribution has been prepared by the six proposing authors that represent a bigger group of authors from academia, industry and regulation, who started this process, discussed bioavailability concepts and methods, and arrived at an agreement. The developments achieved at the Special Science Symposium focused on bioavailability, held in 2014 by SETAC Europe (http://sesss10.setac.eu/), led to a featured paper (Environ. Sci. Technol. 49:10255-10264, 2015). We propose a simplified approach in which the assessments of soil/sediment and the target chemicals should be based on two measurable values: the total extractable concentration, and the bioavailable concentration as measured with robust and reproducible chemical or biological methods.

Assessing Risks of Pesticides to Federally Listed (Threatened and Endangered) Species at a National Level – Part 1

MP088 Estimating the magnitude of effect using predicted pesticide exposure concentrations and toxicity data for an endangered species: A case study

C.M. Rossmeisl, USEPA; K.V. Garber, USEPA / Office of Pesticide Programs Environmental Fate and Effects Division; C.A. Laetz, NOAA / Northwest Fisheries Science Center; M. McKernan, US Fish & Wildlife Service / Ecological Services

The U.S. Environmental Protection Agency (USEPA), the U.S. Fish and Wildlife Service (USFWS), and the National Marine Fisheries Service (NMFS), with assistance from the U.S. Department of Agriculture (USDA), are working together to develop an approach for evaluating risks of pesticides to species listed as threatened and endangered under the Endangered Species Act. Recently, a draft Biological Evaluation was completed for the organophosphate insecticide chlorpyrifos, which concluded that this chemical is likely to adversely affect individuals of the majority of listed species. Currently, the USEPA and Services are developing methods for assessing risks of chlorpyrifos to species at the population level. This population-level assessment will utilize exposure (i.e., modeled exposure concentrations) and effects (i.e., dose-response relationships) data to determine the magnitude of effect. Exposure concentrations are predicted on and near treated fields, including spray drift and runoff, for both terrestrial and aquatic habitats. Sublethal impacts to reproduction and behavior will be considered and are important for understanding population-level consequences of a pesticide exposure. A case example will be presented to show the predicted effects in both terrestrial and aquatic habitats for an amphibian species following labeled chlorpyrifos uses.

MP089 Approaches for Mapping the Habitat of Listed Species without Federally Declared Critical Habitat

J. Amos, Waterborne Environmental, Incorporated / Geospatial Data Technologies; M.L. Sebasky, Waterborne Environmental; B. Kearns, Waterborne Environmental, Inc. / Geospatial Data Technologies; S. Kay, Pyxis Regulatory Consulting, Inc. / Spatial Technologies Group

Spatially explicit sub-county habitat for federally listed species based on defensible scientific approaches allows for greater confidence and more realism in assessing the potential risk that pesticides have to listed species. Currently, refined spatial habitat information for a large number of listed species remains unresolved. Of the nearly 1,680 listed species in the US, approximately 788 have federally declared Critical Habitat suitable for use in national scale regulatory assessments. In the draft Biological Evaluations for three organophosphate compounds published in the spring of 2016, USEPA incorporated species range maps provided by The Services to make effects determinations for nearly all listed species; however, these range maps are not yet publicly available. This poster presents a study to explore approaches for efficiently generating spatial habitat using current data sources and techniques. While the habitat generated cannot represent "Critical Habitat", it should represent the physical and biological features occupied by the species. The goal is spatial data of appropriate accuracy and resolution for use with potential pesticide use sites in national-scale pesticide risk assessments. The science applied must be transparent and instill confidence in stakeholders that the data are representative and protective of the listed species. Federal Registry, USFWS reports, and NatureServe species profiles are highlighted as sources of textual habitat descriptions to inform both suitable habitat delineation and subsequent refinements to represent the often localized distributions of many endangered species. Tiered habitat maps are presented that show a tapering view from range to the biophysical parameters selected to represent suitable habitat. Several terrestrial, plant, and/or aquatic species across taxonomic groups are showcased.

MP090 Refined endangered species risk assessment for static aquatic habitats: Part 2 – Effects assessment and risk characterization

S. Teed, Intrinsik Environment Sciences Inc.; R.L. Breton, Intrinsik Environmental Sciences, Inc.; L. Padilla, Stone Environmental, Inc.; M.F. Winchell, Stone Environmental, Inc. / Environmental Systems Modeling; P. Whatling, FMC Corporation / Senior Manager of Regulatory Science

The current USEPA approach to static aquatic exposure modeling at Step 2 of their interim process for national endangered species assessments uses simplified assumptions about water body characteristics, the surrounding landscape, and agronomic practices. At best, this approach may be considered suitable for screening purposes. A refined approach is proposed (Padilla et al. 2016 – Part 1) where 1000 30-year Pesticide Root Zone Model (PRZM)/Variable Volume Water Model (VVWM) realizations are applied that account for application timing, weather, soil and slope conditions, and crop configurations around ponds using probability distributions, by listed species. These VVWM realizations are then integrated with refined effect metrics (e.g., dose-response curves from appropriate taxonomic surrogates; species-sensitivity distributions) to generate refined risk estimates that incorporate differences in sensitivity between individuals or species. The use of the modeling along with other lines of evidence (e.g., monitoring data, incident reports, in situ toxicity studies, biological surveys) provides risk managers with the information and context required to evaluate the potential for pesticide risk to individual listed aquatic species. To demonstrate an approach, a case study for several species of aquatic invertebrates was developed and will be presented.

MP091 Environmental risks of synthetic pyrethroids in seawater

F. Tucca, H. Moya, Facultad de Ciencias Ambientales/Centro EULA, Universidad de Concepción / Sistemas Acuáticos; E. Eljarrat, IDAEA-CSIC / Dept of Environmental Chemistry; C. Vargas, Facultad de Ciencias Ambientales/Centro EULA, Universidad de Concepción / Sistemas Acuáticos; R.O. Barra, Universidad de concepcion / Aquatic systems

Emissions of synthetic pyrethroids from salmon farms have been a concern. Pyrethroids are used as a chemotherapy alternative to control parasitic diseases in fish. However, environmental impacts of pyrethroids on marine organisms are still not well known under environmental conditions. Pyrethroids such as cypermethrin (CP) and deltamethrin (DE) used by salmon farms can be rapidly diluted in seawater after to be released, but its action mechanisms can be effective even with low concentrations on invertebrates, mainly on larvae stages. The objective of this work was design a method of risk assessment for several salmon farms treated with pyrethroids. Pyrethroid concentration measured in field and its effects on invertebrates of early life were compared using a probabilistic risk assessment method. Our study area was located in Chiloe Island (north Chilean Patagonia) where salmon farm activities are intensives. Passive water samplers were deployed around salmon cages during a treatment period with pyrethroid to determinate the measured environment concentration (MEC). For effect assessment, toxicity data collected from literature and bioassay in laboratory were included in the analysis. Physiological responses (clearance and ingestion rates) on Mytilus chilensis larvae were carried out in laboratory. Results showed that, passive samplers detected higher CP concentrations (MEC_{max}= 87 ng L^{-1}) than DE (MEC_{max}=3.2 ng L^{-1}) within a radius of 4 m around salmon cages for all salmon farms studied. In conclusion, probabilistic assessment suggests a higher risk of CP than DE exposed at invertebrate larvae in the marine environment. Acknowledgements: CRHIAM/Conicyt/Fondap N° 15130015; Fondecyt N° 1140466 project; Musels Millennium Nucleus (Ministry of Economy, Chile) NC 120086; (FIPA) Nº 2014-42 project.

MP092 What to do when predictions of risk models are at odds with real world observations: The Kirtland's warbler example for chlorpyrifos and malathion

D. Moore, S. Teed, Intrinsik Environmental Sciences Inc.; C. Greer, Intrinsik Environmental Sciences (US), Inc. / Biology; A. Olson, Intrinsik Environmental Sciences; P. Havens, Dow AgroSciences LLC; P. Whatling, FMC Corporation; N. Poletika, Risk Analysis Solutions, LLC

The United States Environmental Protection Agency (EPA) recently released draft endangered species Biological Evaluations (BEs) for chlorpyrifos, diazinon and malathion. As part of the draft BEs, EPA conducted refined risk assessments for selected listed bird species including the Kirtland's warbler (Setophaga kirtlandii). The Kirtland's warbler is an endangered migratory species that nests exclusively in young jack pine stands in Michigan and Wisconsin, and winters in the Bahamas. EPA's refined risk assessment for the Kirtland's warbler relied on the probabilistic Terrestrial Investigation Model (TIM) and Markov Chain nest productivity model (MCnest). Despite being probabilistic models, the models are hyperconservative in many aspects. For example, TIM assumes that Kirtland's warblers spend a significant portion of their foraging effort in and immediately adjacent to treated pastures during the breeding season. Decades of intense observation, however, indicate that Kirkland's warblers only forage in young jack pine forests during the breeding season and in similar habitats during migration. Because of their hyperconservative assumptions, TIM and MCnest predicted catastrophic mortality and near total reproductive failure for chlorpyrifos and significant adverse effects for malathion. No bird species, listed or otherwise, could withstand such effects without going extinct. The Kirtland's warbler, however, has dramatically increased in abundance in recent decades despite widespread usage of chlorpyrifos and malathion. This contradiction indicates that a more scientifically defensible modeling effort is required. We developed probabilistic, species-specific exposure and risk models to assess risks of chlorpyrifos and malathion to Kirtland's warblers during the breeding season and during spring and fall migrations. The breeding area model included several key information sources that EPA ignored in its draft BEs, e.g., species-specific foraging behavior, proximity of breeding territories to treated areas, and pesticide-specific data on prey concentrations. Similarly, the migration model took advantage of over a century of observations of when, where, and for how long Kirtland's warblers forage in different habitats during the course of their migration. The models found that chlorpyrifos and malathion pose negligible risk to Kirtland's warblers. These predictions are in line with the real world observations of the recovering Kirtland's warbler.

MP093 Developing population models for pesticide risk assessments: a systematic approach (for herbaceous plants)

A. Schmolke, Waterborne Environmental, Inc. / College of Biological Sciences; P. Rueda-Cediel, Univ of Minnesota / Dept of Ecology Evolution Behavior; K.E. Kapo, Waterborne Environmental, Inc.; R. Brain, Syngenta Crop Protection, Inc. / Dept of Environmental Risk Characterization; V. Forbes, Univ of Minnesota / Ecology Evolution Behavior

Population models have been recognized as important tools in pesticide risk assessments for species listed under the Endangered Species Act. However, not many population models for this specific purpose have been developed to date. A systematic, transparent approach to developing population models for pesticide risk assessment would ease the development of new models and the assessment and adaptation of existing models for this kind of risk assessment. We introduce a decision guide for the development of population models of herbaceous plants to be applied in pesticide risk assessment. The guidance walks the model developer through necessary steps that consider the specific questions to be addressed by the model, the life history of the species, and the data availability for species and habitat characteristics as well as pesticide exposure and effects. The guidance can either be applied to a single species or can be used to address a group of similar species. The resulting minimal conceptual model can serve as a blueprint for the implementation of a new model or to assess the applicability of an existing model for use in the context of pesticide risk assessment. Population- or species-level risk assessment is an extensive task given the number of species currently listed. Population models provide a tool to link population-level dynamics, species and habitat characteristics as well as exposure and effect information in a single approach. Developing such models in a systematic, transparent way will increase their applicability and credibility, reduce development efforts, and result in models that are readily available for use in risk assessments with varying compounds and exposures. We present the systematic approach for developing population models for herbaceous plant species and intend that the approach be adapted to provide model development guidance for other organism groups as well.

MP094 Endangered Species Risk Assessment Approaches for a Data-Rich Insecticide-Carbaryl

M.E. Kern, Waterborne Environmental, Inc. / Ecotoxicology Risk Assessment; K.S. Henry, NovaSource/Tessenderlo Kerley, Inc.; N. Snyder, Waterborne Environmental, Inc.; J. Amos, Waterborne Environmental, Incorporated / Geospatial Data Technologies; S. Kay, Pyxis Regulatory Consulting, Inc. / Spatial Technologies Group; J. Akins, NovaSource Tessenderlo Kerley Inc / Regulatory Affairs

National-scale endangered species risk assessments for crop protection products continue to be challenging due to the large amount of data and uncertainties involved in these analyses. The variety of use patterns, volume of environmental fate and ecological effects data, overall diversity and number of federally listed species, and other factors can substantially add to the complex nature of these assessments. At the same time, this volume of information greatly enhances the assessor's ability to increase the overall reliability and relevance of the risk assessment to listed species by allowing for more specific surrogacy assignments and exposure reflecting actual use patterns in potential proximity to species habitat areas. The insecticide carbaryl is an example of a well-studied crop protection product with decades of use experience and whose rich database allows for a pragmatic and detailed endangered species risk assessment. Like most products, biological sensitivity ranges are based on factors such as mode of action, receptor sites, metabolism etc. This information is crucial to understand differences in sensitivities between and within species taxa so that toxicity data can be better related to potential effects to specific listed species. Equally important is the thorough understanding of species habitats and locations so that exposure estimates can be accurately characterized. The full range of exposures and effects must then be uniquely related to use patterns, geographies and listed species for risk to be appropriately characterized to populations. In this paper, we will demonstrate examples of how this data can be collected, analyzed and applied to a national scale risk assessment for carbaryl. The pragmatic use of these best available data will allow for a more accurate and species focused risk estimate so that resources can appropriately be directed to stressors and listed species.

Environmental Risk Assessment of Metals in Tropical Regions: Challenges, Potential Solutions and Information Needs

MP095 Cu toxicity to cardinal tetras in Amazonian waters: blackwater, whitewater, particles, unusual DOMs, speciation, and modeling

C.M. Wood, A. Cremazy, Univ of British Columbia / Dept of Zoology; S.D. Smith, Wilfrid Laurier Univ / Dept of Chemistry; M. Ferreira, Instituto Nacional de Pesquisas da Amazonia INPA; O. Johannsson, M. Mussoi Giacomin, UBC; A. Val, Instituto Nacional de Pesquisas da Amazonia INPA

The toxicity of Cu to the tropical fish cardinal tetra (Paracheirodon axelrodi) was investigated in two major tributaries of the Amazon watershed: the Rio Negro (filtered < 0.45 µm, pH 5.6, DOC = 8.4 mg/L, Na = 33 µM, Ca = 8 μM) and the Rio Solimões (both filtered and unfiltered < 0.45 μm, pH 6.7, DOC = 2.8 mg?L^{-1}, Na = 185 μM, Ca = 340 μM), as well as in a natural "reference water" (groundwater) which was almost DOC-free (pH 6.0, DOC = 0.34 mg?L^{-1}, Na = 53 μM, Ca = 5 μM). Acute 96-h mortality, Cu bioaccumulation and net flux rates of Na, Cl^-, and total ammonia were determined in tetrasexposed in each water. Cu speciation in each water was determined via thermodynamic modeling and potentiometry (ion selective electrode, ISE), and Cu toxicity was predicted based on the Biotic Ligand Model (BLM) framework. Our results indicate that high Na loss is the main mode of toxic action of Cu in P. axelrodi, in accordance with general theory. Cardinal tetra showed a particularly high ability to tolerate Cu and to maintain Na balance (i.e. a low sensitivity), similar to the ability of this and other endemic Rio Negro species to tolerate low pH and ion-poor conditions. Both particles (high in unfiltered Rio Solimões water) and DOM (high in Rio Negro water) protected against acute toxicity and physiological disturbance. Overall Cu toxicity was lower in Rio Negro than in the other waters (at the same dissolved[Cu]). Indeed the free [Cu^{2+}] at the LC50, as determined by direct ISE measurement or speciation modeling, was approximately 10-fold higher. This variation could not be captured by a realistic set of BLM parameters. At least in part, this observation may due to gill physiological alterations induced by the unusual dissolved DOM of the Rio Negro (FAPEAM, CNPq, ADAPTA, Science without Borders, NSERC Discovery, ICA/SETAC Chris Lee Award, UBC).

MP096 Copper toxicity to Mekong and Lancang River organisms: development of a tropical Cu-BLM and application for setting Cu water quality guidelines

T. Hoang, Loyola Univ Chicago / Inst of Environment and Sustainability; T.L. Bui, Inst for Environment and Resources , Vietnam National Univ Ho Chi Minh City / Environmental Toxicology; D. Lan Chi, Inst for Environment and Resources, Vietnam National Univ Ho Chi Minh City / Ecotoxicology; T. Dao, Vietnam National Univ; C. Boonthai IWAI, Khon Kaen Univ; Y. Liu, Kunming Univ of Science and Technology; B. PAN, College of Environmental Science & Engineering / Kunming Univ of Science Technology; R.C. Santore, Windward Environmental, LLC

Mekong River is the longest river in Southeast Asia (4,909 km) and is important to 60 million people in the four Lower Mekong River Basin countries (Cambodia, Laos, Thailand, and Vietnam). The recent industrial development, such as hydropower plants, mining, and metal processing along the Mekong River including the Upper River Basin in China poses potential metal contamination to the aquatic ecosystem of the Mekong River. A collaborative project between Loyola University Chicago, three universities in Asia, and Windward Environmental LLC on copper (Cu) bioavailability and toxicity to Mekong River and Lancang River organisms were conducted using field-collected waters in the past four years. The goals were to understand the sensitivity of Mekong River and Lancang River organisms to Cu, the influence of water quality parameters of Mekong River water on Cu bioavailability and toxicity, and to calibrate the US Cu-BLM to tropical environments in support of development of Cu water quality guidelines for the local ecosystems. In general, Mekong River organisms are sensitive to Cu. Copper toxicity decreased when water quality parameters, such as hardness (15 – 122 mg/L as $CaCO_3$), pH (6.39 – 8.30), and dissolved organic carbon (0.5 – 21.3 mg/L) were increased. The median lethal effect concentration ranged from 2.8 μg/L Cu (Ceriodaphnia cornuta, Vietnam) to 2,365 μg/L Cu (Ctenopharyngodon idellus, China). Experiments were also conducted to determine median lethal accumulation and critical values for Cu and Mekong River organisms. The US-Cu BLM was applied to the data set that was generated from the present study. In general, the US-Cu BLM did not predict well the toxicity of Cu to Mekong River organisms. However, using critical values for Cu and Mekong River organisms, the BLM predicted toxicity was strongly correlated with the measured toxicity. A species sensitivity distribution was also developed and will be used for setting Cu water quality guidelines for the Mekong River ecosystem.

MP097 Copper toxicity to tropical organisms: Are guideline approaches from temperate climates consistent with and protective for tropical species?

R.C. Santore, K.E. Croteau, A.C. Ryan, Windward Environmental LLC; T. Hoang, Loyola Univ Chicago / Inst of Environment and Sustainability

The process of developing guidelines for the protection of aquatic life is dependent on an understanding of the sensitivity of organisms to a given toxicant, as well as an understanding of the primary factors that affect toxicity. In North America and Europe a considerable amount of research has been directed towards understanding factors that affect the bioavailability and toxicity of metals, with the recognition that water quality characteristics such as pH, hardness, and the presence of natural organic matter (NOM) can modify metal toxicity and therefore should be considered in the development of regulatory guidelines for metals. These toxicity modifying factors have been formally considering using a computation approach called the Biotic Ligand Model (BLM). The BLM is currently used in the United States (U.S.) and the European Union (E.U.) as a method for considering water quality in the latest regulatory standards for copper in freshwater. A marine BLM for copper is in review in the U.S. for setting standards in marine and estuarine waters. While the BLM has been developed to be a general approach that can be used in any region, there are important questions that need to be addressed to consider whether it is applicable in tropical regions. For example, if NOM is an important toxicity modifying factor, are there differences in the nature of NOM from tropical regions that require a revised modeling approach? Are aquatic species in tropical regions similarly sensitive to metals compared with organisms in temperate regions? Can species sensitivity distributions that have been compiled to support the development of guidelines in temperate climates be used to inform risk assessment and regulatory approaches in tropical regions, or are new distributions based on local species required? In this presentation, we will begin to address these questions by compiling information on copper toxicity to freshwater and marine organisms for tropical waters. These toxicity data will be compared with species sensitivity distributions used in the U.S. and E.U. We will discuss whether water quality guideline approaches that have been used in temperate countries would be adequately protective for sensitive species in tropical regions.

MP098 Tropical environmental risk assessment research program for nickel: Data gathering in Southeast Asia and Melanesia

C.E. Schlekat, NiPERA; E.R. Garman, NiPERA / Ecotoxicologist; G. Merrington, wca; R. Smith, Hydrobiology Pty Ltd; J. Stauber, CSIRO / CSIRO Land and Water; F. Gissi, CSIRO Oceans and Atmosphere / CSIRO Oceans and Atmosphere; K.M. Leung, The Univ of Hong Kong

Global nickel production occurs around the world, and is increasingly dependent on lateritic deposits that occur in tropical regions such as Indonesia, New Caledonia, the Philippines, and Papua New Guinea. Refined environmental risk assessment approaches for nickel have been developed for temperate regions like Europe, where a bioavailability-based Environmental Quality Standard has been adopted under the European Union's Water Framework Directive. Applying the underlying ecotoxicity data and bioavailability models to tropical ecosystems is uncertain because of important differences in geochemistry, key taxonomic groups, and organism physiology between temperate and tropical systems. A broad research initiative was launched to address data gaps within the components of environmental risk assessment, including problem formulation, exposure and effects assessment, and risk characterization. Southeast Asia and Melanesia (SEAM) were chosen as the focus of this project because they represent the region of greatest tropical nickel production. The outcome of this research program will deliver the tools necessary for the nickel industry and regional regulatory authorities to perform advanced, refined environmental risk assessments of nickel in the SEAM region. A conceptual model was developed that identified key habitats of concern that included biologically structured ecosystems such as coral reefs, mangroves, and seagrass beds. Questionnaires were sent to regional stakeholders, and after QA/QC analysis, these resulted in a representative dataset covering the region. In terms of effects assessment, the existing literature was queried; high quality marine chronic ecotoxicity data were limited to three species of microalgae, one species each for echinoderms and anemone. In response to the paucity of existing high quality chronic ecotoxicity data, testing has been performed on corals, gastropods, crustacea, and fish. The next steps in the assessment process will be to validate effects thresholds based on laboratory results with higher ecological tier information, and to initiate a tiered risk characterization process based on well-characterized exposure scenarios.

MP099 Metal Fate and Transport in a Tropical River during Wet (Monsoon) Period: A Tale of Ligands domination

A. Gogoi, TEZPUR Univ / Environmental Science; Y. Li, Univ of NebraskaLincoln / Civil Engineering; P.J. Shea, Univ. Nebraska-Lincoln and Univ. Nebraska Medical; D.D. Snow, Univ of Nebraska / School of Natural Resources; M. Kumar, TEZPUR Univ / Environmental Science

Persistent and non-biodegradable metal contamination critically impacts riverine systems and dependent ecosystems through bioaccumulation and potential toxicity. In the river systems of developing countries in particular, metal contamination is a major water quality issue aggravated by rapid urbanization with its consequent copious runoff.We report aspects of metal fate and transport, seldom assessed in densely populated Brahmaputra River system in Assam, India with concomitant leaching escalating groundwater system vulnerability. The distribution of copper (Cu), lead (Pb) and zinc (Zn) between the dissolved and particulate phases of the Brahmaputra River, as well as chemical speciation and covariance with water quality parameters, was determined during wet (monsoon) periods in July 2014. Physicochemical properties of the water were characterized for geochemical speciation modeling using MINTEQA2. Free anions, cations and carbonates were dominant in the inorganic fractions and Cu, Pb and Zn concentrations were negligible in the anionic inorganic fractions. Metals were substantially higher in the particulate fractions than in the dissolved phase, attributable in part to high sediment loading during periods of high rainfall. Partition coefficients show high adsorption of Cu (3.1~6.1), Pb (3.4~6.5) and Zn (3.5~6.9) on suspended matter. Q-mode hierarchical cluster analysis (matrix of distances) of sampling locations illustrated associations governed by water quality parameters rather than the river course. R-mode (similarity) analysis implies affinity of the metals for ligands present in the water and suspended matter. Health risk index values were less than 1 for dissolved Cu, Pb and Zn but greater than 1 for total Pb and Cu, indicating potential human health risk. The binding of metals to naturally occurring dissolved organic matter or suspended particulates likely affects their bioavailability in the river during wet periods when sediment load is high. The combined empirical, computational and statistical analyses increase the understanding of the occurrence and speciation of metals and their interactions within a river system. Overall, metal fate and transport seems to be a tale of ligand domination and thus should be regulated through the proper discharge control of ligands.

MP100 Risk assessment for human health of fish consumption in two estuaries of Brazil

G. Santos, L.D. Piancini, Federal Univ of Paraná / Dept of Genetics; F.Y. Yamamoto, Federal Univ of Paraná / Dept of Cell Biology; C.d. Oliveira Ribeiro, Federal Univ of Paraná / Dept of Cellular Biology; M. Cestari, Federal Univ of Paraná / Dept of Genetics

Fishing is an important source of income for the population from estuaries of southern Brazil and has experienced difficulties arising from the contamination of the region mainly related to human activities. The yellow catfish (Cathorops spixii) is an abundant and economically important fish resource consumed by local population. The current study aimed to estimate the potential risk of metals (Pb, Sn and Hg) and arsenic (As) for human health through the ingestion of fish sampled in two important estuaries from southern Brazil. Fish were sampled in two sites of two estuaries from southern Brazil, Paranaguá and Guaratuba, during the summer/2013. Metals and As accumulation in muscle tissue were quantified and compared against national and international action levels regarding human consumption. In addition, the target hazard quotient (THQ) for metals and As, the cancer risk (CRisk) for As, and the number of safe meals per month were estimated. Among elements evaluated, As was accumulated at concentrations above action levels for human consumption in fish from all sampling sites (ranging 1.55 to 8.54 mg/kg). Hg was also detected in fish muscle. Highest THQs were estimated for fish collected in Paranaguá. In addition, CRisk above 10E-5 were estimated in all sampling sites. In a daily consumption scenario (356 days per year), it was possible to note risk to human health and CRisk in all sampling sites from both estuaries. In a weekly consumption scenario (56 days per year), the health risk was observed at one site of Paranaguá, however CRisk were high at both sites of Paranaguá and at one site of Guaratuba. Regarding the number of safe meals for adults, values lower than 16 meals per month were observed for one site of Guaratuba and one of Paranaguá. However, for children, lower rates of safe meals were observed for one site of Guaratuba and both sites of Paranaguá. In this study, it was possible to observe the accumulation of metals and As in fish muscle and possible consequences of this exposure to population from Paranaguá and Guaratuba. This exposure mainly to arsenic is primordial information to be included in the management of estuarine areas from southern Brazil. As observed, a daily consumption (even weekly for Paranaguá) of fish sampled in both estuaries sets up a risk for human health.

MP101 Preliminary investigation into the risk of environmental lead on the I.Q of pre-school children in Isiagu, Ebonyi State, Nigeria

I.N. Onwurah, Univ of Nigeria / Biochemistry; C. Onwurah, Univ of Nigeria / Educational Foundation; J. Ibaim, Univ OF NIGERIA NSUKKA NIGERIA / Depto of Educational Foundation

Isiagu town of Ebonyi State Nigeria is known for lead (Pb) mining and Pb is one of the oldest and most studied toxicants known. Its neurotoxicity is the most serious and has deleterious effect in children. Research on the relationship between the presence of low levels of blood lead in children, as a result of that found in the immediate environment, and a decrease in their cognitive-behavioral function, has been a source of controversy within the research literature; some researchers have argued that even very low levels of lead can have severe consequences on children's intellectual and academic functioning. In this preliminary human health risk assessment study, we carried out a proactive assessment of this issue by adapting the principle of bioaccumulation factor, to evaluate the consequences of environmental lead (Pb^+) in pre-school children in Isiagu town of Ebonyi State, Nigeria. This is a step in environmental and human health case study (project) being planned for the State. The sturdy examined the levels of Pb^+ in Isiagu ambient (air) environment at different intervals of the year, including that in the vegetables and crops mostly consumed by the community. Pre-school children numbering120, born within this community, aged 3-5 years, from three different pre-primary schools, also within this community constituted the sample for the cognitive function tests using Raven's Standard Progressive Matrices (SPM) while the control were children from two neighbouring communities, where no mining activity of any type had occurred. The data generated were analysed using (SPSS) version 21.0 and results expressed as mean ± standard deviation. The results were converted to intelligent quotient (IQ) using psychometrics. Students' t-tests for independent samples for the lead mining area and non mining area were used to compare the means. Pearson Correlation test was used to assess association between lead concentrations in the environment, in food crops and IQ of the children. P-value ? 0.05 was considered as significant (two-tailed analysis). The result of this investigation showed that environmental lead in Ishiagu was significantly high, as well as in the crops sampled, and the average IQ of pre-school children in this community was significantly lower than that in the control. This suggests that environmental lead could affect cognitive function in children and calls for an in-depth study involving blood sampling and other parameters.

MP102 Assessment of heavy metals in tropical soils of Mayabeque and Havana provinces, Cuba. Challenges and information needs

D.S. Pacheco, CENSA; I. Hilber, Agroscope ART; A. Escobar Medina, CENSA; D. Bürge, Agroscope ISS; R. Faure Garcia, O. Fonseca, CENSA; T. Bucheli, Agroscope ART / Environmental Analytics Natural Resources and Agriculture

Cuba is mainly an agricultural country and food production and quality depends on the health of the soils. Although authors of several studies proposed quality reference values of heavy metals (HM) in different soils that face little human activity, HM are not yet regulated in Cuba. In a joint research project, funded by the Swiss National Science Foundation, between the animal and plant health institute CENSA from Cuba and Agroscope ISS from Switzerland agricultural soils were monitored to assess HM concentrations. The study was performed in the Mayabeque province, Cuba where the soils mostly belong to agriculture and the Havana province that represent urban soils. Mean HM values (mg Kg-1dry weight (dw)) of 39 sites in Mayabeque were: Cd (2.6), Cr (63), Cu (64), Ni (48), Pb (16), Zn (55) and Hg (0.09). A principal component analysis suggested that the concentrations of Cd, Cu, Zn, Pb and Hg originated from anthropogenic activities, Ni was mainly from lithogenic sources, and Cr derived from both, anthropogenic and lithogenic sources. Mean HM concentrations (mg Kg-1dw) of the 22 sites in Havana province were: Cd (0.8), Cr (71), Cu (134), Ni (107), Pb (138), Zn (170) and Hg (0.04). The concentrations were, for most HM, higher than the ones of Mayabeque province. The soils around the port of the capital that reflects highest industrial activities including traffic had the highest HM concentrations. Also, in agricultural soils of Havana province the concentrations of Cu (195), Pb (197), and Zn (118) were higher than those found in agricultural soils of Mayabeque: Cu (54), Pb (19) and Zn (59). According to Dutch regulations, the concentrations of Cu, Pb and some of Zn in agricultural soils in Havana province clearly exceeded the target values (in mg Kg-1dw Cu 36, Zn 140, Pb 85) that indicate potential risks to ecosystems. This study serves as a basis for the Cuban government to establish recommendation values and to develop HM regulation in the Mayabeque province. The study results were communicated to decisions makers and stakeholders. Furthermore, a soil monitoring in other provinces is planned to create a soil monitoring network. It will provide important information for a better understanding of the fate, behavior and risk of HM in Cuban soils.

Wildlife Ecotoxicology: From Food Chain Exposure to Population Effects

MP103 Fox Too Are Not Spatially Relevant at Contaminated Sites

L.V. Tannenbaum, US Army Inst of Public Health / Army Public Health Center Provisional

Ecological risk assessments (ERAs) should only evaluate those species that are spatially relevant to their contaminated environs. To that end, ERA practitioners should seek out opportunities to establish that species they may believe to be of interest, actually satisfy a key, but often overlooked receptor-of-concern selection criterion, namely a demonstrated high site affinity. The use of newly available, state-of-the-art GPS tracking equipment to investigate the worthiness of the inclusion of gray fox (Urocyon cinereoargenteus) in terrestrial assessments, brings forward exposure information of great value. As with the outcome of a similar spatial movements tracking effort for White-tailed deer (presented at a SETAC N.A. meeting a few years ago), gray fox will probably never be appropriate for consideration within an ERA setting. The acquired high-quality actual (as opposed to modeled) exposure data of this study contributes to a growing and persuasive thinking on the role of (i.e., need for) mammal inclusion in ERAs.

MP104 HexSim Networks: Spatial IBMs are no longer just for the birds

A. Brookes, USEPA; N. Schumaker, USEPA / ORDNHEERLWED; C. Jordan, NOAA National Marine Fisheries Service; M. Armour, South Fork Research

Legally protected animal populations are exposed to pesticides, the type and concentration of which vary extensively across space and time. Individuals from these populations are also simultaneously subjected to multiple other human-caused disturbance regimes such as landscape change, impacts from invasive species, and climate change. Our research community has relied heavily on models to quantify the impacts that pesticides have on wildlife, but to-date such models have dramatically simplified spatial structure and temporal dynamics, have had an organismal (not population) focus, and have ignored stressor interactions. While such simplifications have historically been born out of necessity, recent developments in simulation modeling are relaxing these constraints and changing what constitutes the "best available science". HexSim (www.hexsim.net) was developed specifically to quantify the impacts of multiple interacting disturbance regimes on wildlife and plant populations and this model can incorporate as much or as little detail about the study system as desired, including species life-history information, the distribution of dynamic interacting stressors, and effects due to other species. HexSim has recently been extended to include a complete suite of tools for simulating populations in river networks, making it a suitable platform for evaluating the impacts of pesticides and other anthropogenic disturbances on aquatic populations. This presentation will provide an overview of HexSim, targeting a SETAC audience, and then introduce our new HexSim networks toolkit.

MP105 Derivation of an Aquatic-Dependent Avian Tissue Residue Value (TRV) for Mercury Based on Current Toxicity Literature

A. Jarvis, M. Elias, USEPA / Office of Water; C. Bergeron, USEPA / Office of Water; K. Gallagher, USEPA / Office of Water

Mercury contamination of aquatic ecosystems is widespread and bioaccumulation of methylmercury through the aquatic food web potentially places predatory organisms at risk. Aquatic-dependent avian species appear to be particularly sensitive to mercury exposure, experiencing population level effects such as reproductive impairments at environmentally relevant concentrations (Burgess and Meyer 2008; Brasso and Cristol 2008). For most evaluations the results of several mallard studies (Heinz 1974, 1976a, 1976b, and 1979) were determined to be the most appropriate toxicity endpoints for the derivation of an avian Tissue Residue Value (TRV). These mallard studies demonstrated that exposure to dietary methylmercury reduced reproductive success at 0.5 ppm methylmercury (Heinz 1979). Recent studies suggest that mallards are less sensitive to mercury exposure than previously thought and may not be the most appropriate surrogate for some aquatic-dependent avian species. Additionally, current toxicity literature present lower toxicity endpoints (i.e., reproductive impairments at concentrations below 0.5 ppm) for sensitive aquatic-dependent avian species. This presentation discusses the derivation of a new draft TRV for aquatic-dependent avian species using the latest scientific literature focused on the effects of mercury.

MP106 Hepatotoxic Biomarkers in Crocodylus moreletii Adults from an Urbanized Lagoon in Tabasco, Mexico

S. Trujillo-Vazquez, J. Gomez-Olivares, Universidad Autonoma Metropolitana Iztapalapa / CIENCIAS DE LA SALUD; P. Ramirez Romero, U.A.M. Iztapalapa / Hidrobiologia; M. Lopez-Luna, Universidad Juarez Autonoma de Tabasco / Ciencias Biologicas

Crocodiles living in urbanized environments are exposed to a number of toxic compounds, which can produce harmful effects. Cholinesterases (ChEs) as acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE) are used as effective biomarkers of contamination. Transaminases as GOT (AST), GPT (ALT), GGT and ALP are of great importance to reinforce the diagnosis of tissue damage. Studies about enzimatic biomarkers in C. moreletii are scarce, which is why the aim of this study was to evaluate the exposure to hepatotoxic contaminants through differences in biochemical parameters of tissue damage and health status between a wild population living in an urbanized lagoon and another kept in captivity. We captured reproductive females and males of C. moreletii (22) from both populations: wild (Laguna) and captive (CICEA). Blood samples were obtained by puncturing the occipital sinus with syringes previously washed with EDTA-K_2, samples were maintained in heparinized Vacutainers at 4 °C. Transaminase activity was estimated by Reflotron analysis, cholinesterase activity was measured by Ellman's method (1961), measurement of albumin was made using green bromocresol and total protein was estimated by Biuret's method. Albumin levels of Laguna's crocodiles were always lower than those from CICEA, this has been related to poor nutritional status or hepatitis in other organisms. Females from Laguna presented the lowest protein count, which has been related to immune deficiencies and liver disease in humans, indicating that females of Laguna could potentially be suffering of these conditions. The average AChE and BuChE activity was higher in Laguna than in CICEA. In wild organisms, GOT and GPT activity are much higher than in organisms from CICEA, AP activity was higher in Laguna than in CICEA and GGT levels are similar in males and females from both, wild and captive, groups. GOT and GPT are highly linked to liver damage, and GOT is strongly related to necrotic liver damage, indicating increased tissue damage. ANOVA analysis showed that AChE, BuChE, GPT and GOT levels are significantly different between CICEA and Laguna, while GGT and FA are not, moreover, these differences were not related to the sex of the organisms, and therefore, Laguna organisms may be exposed to contaminants that could be causing chronic damage in breeding crocodiles.

MP107 Acetaminophen toxicity in reptilians; underlying biochemical pathways for use of controlling invasive species

P. van den Hurk, Clemson Univ / Biological Sciences; H. Kerkkamp, Leiden Univ / Inst of Biology Leiden

It has been known for a while that some snake species are very sensitive to acetaminophen, the active compound in Tylenol® and other commonly used pain treatment medications. On the island of Guam, this knowledge is used to control the population of an invasive snake species: the brown tree snake (Boiga irregularis). It has also been proposed to also use acetaminophen to control the invasive Burmese python (Python bivittatus) in South Florida, but concerns about toxicity to other indigenous snakes and other reptilians has prevented any field applications so far. Little is known about the underlying mechanisms of why snakes are so sensitive to acetaminophen. We set out to investigate this, by measuring the expression and activity of enzymes that are involved in the biotransformation of acetaminophen in a variety of snake species, and some other reptilians, in comparison to several mammalian species. Reptilian liver samples were obtained from other researchers investigating these species, and were tested for enzymatic activity of sulfotransferase (SULT), UDP-glucuronosyltransferase (UGT), glutathione S-transferase (GST) and N-acetyltransferase (NAT), using acetaminophen-related compounds as substrates. The results showed that snakes had virtually no UGT activity, and very little NAT activity. This combination will lead to accumulation of aminophenol, a toxic metabolite of acetaminophen, which is known to cause methemoglobinemia in cats, and has also been observed in experiments with the brown tree snake. Enzyme expressions were consistent among the snake species tested. Screening of published snake genomes also suggested that these species do not have a functional gene for the UGT isoform that is responsible for acetaminophen biotransformation in other vertebrate species. Interestingly, American alligator (Alligator mississippiensis) and snapping turtle (Chelydra serpentine) did have UGT activity, although much lower than mammalian species like rat and cow. In conclusion, differential expression of Phase 2 biotransformation enzymes in reptilian species does explain their sensitivity to acetaminophen, and can be used to design management strategies for invasive species.

MP109 Re-evaluation of Osprey (Pandion haliaetus) Productivity and Contaminant Exposure in the Delaware Bay and River: Comparison between 2002 and 2015

B.A. Rattner, USGS-Patuxent Wildlife Research Ctr / Beltsville Lab; R. Lazarus, USEPA / Office of Pesticide Programs; T. Bean, Univ of Maryland, College Park / Environmental Science and Technology; T. McGowan, Fera Science Ltd; D.D. Day, USGS-Patuxent Wildlife Research Ctr; R.W. Scarborough, DE Dept Nat Res Environ Control / DE Coastal Programs; K.M. Fleming, DE Dept Nat Res Environ Control / DE Div Fish Wildlife

The last large-scale ecotoxicological study of ospreys nesting in Delaware Bay and River was conducted in 2002. Eggs collected in the northern region (C&D canal to north Philadelphia) had greater concentrations of organochlorine pesticides, PCBs, perfluorinated compounds, and PBDEs compared to the central Bay and southern Inland Bays. While reproductive success did not differ among regions, the probability of egg loss from nests was related to levels of halogenated pollutants, suggesting contaminants were a stressor. In 2015, ospreys nesting in the same regions were monitored to examine in productivity and pollutant exposure. A total of 27 nests were visited at 7-10 day intervals. A sample egg was collected from each nest for Persistent, Bioaccumulative and Toxic (PBT) contaminant analysis. A blood sample was also collected from a 40-45 day old nestling to assess exposure to pharmaceuticals and measure oxidative DNA damage as a general biomarker of toxicity. As in 2002, the percentage of eggs lost, eggs hatched and young fledged did not differ among regions. Productivity was within the range to maintain a stable population (0.8-1.15 fledglings/active nest). Nevertheless, ospreys appeared to have slightly lower productivity in the central Bay (1.11 fledglings/active nest in 2015 vs. 1.42 in 2002) and in the coastal Inland Bays (1.00 fledglings/active nest vs. 1.17 in 2002), while productivity appeared to increase slightly in the northern region (1.22 fledglings/active nest in 2015 vs. 1.00 in 2002). While the northern region exhibited 10.1% eggshell thinning in 2002, there were no differences across sites in 2015 ($p=0.39$; mean 0.50 ± 0.04 mm), with values approaching pre-DDT era thickness (0.505 mm). Two of 22 pharmaceuticals were detected in plasma. The analgesic, acetaminophen was present in 21 of 27 samples, with levels greater ($p=0.03$) in the urbanized northern region compared to the central region. The NSAID diclofenac was detected in 2 nestlings in the Inland Bays (< MDL-3.73 ng/mL). There was no evidence of genetic damage in blood among study regions ($p=0.61$). Our 2015 assessments of productivity, eggshell thickness, genetic damage and pharmaceuticals do not indicate substantial ecotoxicological risk for ospreys at the individual or population level. However, the status of fish-eating birds, and additional information on the overall environmental condition of Delaware Bay and River, will become clearer with results from the PBT contaminant analysis.

MP110 Increased rodenticide exposure rate and risk of toxicosis in barn owls from SW Canada – linkage with demographic not genetic factors

A. Huang, Environment and Climate Change Canada; J.E. Elliott, Environment and Climate Change Canada / Science Technology Branch; S. Hindmarch; F. Maisonneuve, Environment and Climate Change Canada; K. Cheng, Univ of British Columbia; V. Bowes, Britsh Columbia Ministry of Agriculture; S. Lee, K. Martin, Environment and Climate Change Canada

Among many anthropogenic drivers of population decline, continual rapid urbanization and industrialization pose major challenges for the survival of wildlife species. Barn owls (Tyto alba) in southwestern British Columbia (BC) face a multitude of threats ranging from habitat fragmentation to vehicle strikes. They are also at risk from secondary poisoning of second-generation anticoagulant rodenticides (SGARs), a suite of toxic compounds which at high doses results in a depletion of blood clotting factors leading to internal bleeding and death. Here, using long-term data (N=119) for the hepatic residue levels of SGAR, we assessed the risk of toxicosis from SGAR for the BC barn owl population over the past two decades. We also investigated whether sensitivity to SGAR is associated with genetic factors, namely Single Nucleotide Polymorphisms (SNPs) found in the CYP2C45 gene of barn owls. We found that residue concentration for total SGAR was significantly higher in 2006-2013 (141ng/g) relative to 1992-2003 (57ng/g). The proportion of owls exposed to multiple SGAR types was also significantly higher in 2006-2013. Those measures accordingly translate directly into an increase in toxicosis risk level. We also detected demographic differences, where adult females showed on average lower concentration of total SGAR (64ng/g) when compared to adult males (106ng/g). Juveniles were overall more likely to show signs of toxicosis than adults (33.3% and 6.9%, respectively), and those symptoms were positively predicted by SGAR concentrations. We found no evidence that SNPs in the CYP2C45 gene of barn owls were associated with intraspecific variation in SGAR sensitivity. We recommend several preventative measures be taken to minimize wildlife exposure to SGAR.

MP111 Anticoagulant rodenticide residues in badger and fisher from southern British Columbia

<u>J.E. Elliott</u>, Environment and Climate Change Canada / Science Technology Branch; R. Weir, British Columbia Ministry of Environment; S. Lee, F. Maisonneuve, Environment and Climate Change Canada

A number of studies from Europe and North America have reported relatively high incidence of liver residues of commonly used second generation anticoagulant rodenticide (SGAR) compounds, in mammalian predators. Some animals, primarily from California, also came from locations relatively remote from intensive urban or agricultural development. A proportion of animals tested have exhibited symptoms of anti-coagulant poisoning. For the present study we tested 40 samples of two species of mammal, the American badger Taxidea taxus, an endangered species in British Columbia, and a furbearer, the fisher Martes pennant, collected over the period 2004 to 2013 from locations in southern British Columbia, Canada. Of 30 badgers analyzed, 43% (13) contained residues of one of more AR. First generation, or FGARs, were the most commonly detected, wth warfarin and chlorphacinone predominant, but many animals had residues of both forms of AR. A total of 27% contained SGAR residues, most of which were > 0.1 µg/g with several > 0.5 µg/g. Bromadiolone was the most commonly detected SGAR but brodifacoum and difethialone were also regularly detected. Of 10 fisher tested, 60% (6) contained AR residues, five of which had SGARs, two in the range 0.4 to 0.6 µg/g. Spatial details will be presented along with an assessment of toxicological and conservation implications.

MP112 Investigating potential growth, behavioural, and reproductive effects of nestling exposure to methylmercury in Zebra Finches (Taeniopygia guttata)

<u>S. Morran</u>, Simon Fraser Univ / Dept of Biological Sciences; M.L. Eng, Univ of Saskatchewan / Toxicology; J. Young, Simon Fraser Univ; T. Williams, Simon Fraser Univ / Dept of Biological Sciences; J.E. Elliott, Environment and Climate Change Canada / Science Technology Branch; N. Basu, McGill Univ / Dept of Environmental Health Sciences; M. Perkins, McGill Univ / Natural Resource Sciences

Methylmercury is a widespread contaminant that has been shown in multiple studies to cause behavioural and reproductive effects on piscivorous birds. It has been previously thought that birds that do not feed on fish (such as passerines) are not at risk for methylmercury toxicity. However, in recent years high blood mercury levels have been found in free living passerines. This has opened up a new area of study for methylmercury toxicity in avian species. Of the few previous studies on passerine species, most of them are lifetime exposure studies. Our lab's goal is to do shorter term exposures at different life stages using Zebra Finches (Taeniopygia guttata) as a model species to determine which stages are most sensitive. In the current study, the nestling stage was the target. Chicks hatched from clean (non-mercury exposed) parents were dosed with methylmercury (water only, 0.063 ug/ul, or 0.15 ug/ul per gram of body weight per day) from days 1 to 21 post hatch. This dosing period was used to simulate exposure from food provisioning by the parents. Growth of the chicks were measured until age 30, which is when they are considered independent. Despite a dose response relationship shown in our blood mercury analyses, no effects of dose were found for growth of the chicks. Once the chicks were over 90 days old (sexual maturity), mating trials with song recordings were conducted on the males while breeding experiments were conducted on the females. There were also no treatment effects found for male mating trials and song analyses or the female breeding trials. The lack of treatment effects in these experiments indicate that the nesting stage might be less sensitive in passerines, likely due the methylmercury burden being transferred to the growing feathers.

MP113 Pesticide transfer between fish and waterbirds of the West coast of Yucatan, Mexico

<u>E. Norena-Barroso</u>, Universidad Nacional Autonoma de Mexico / Unidad de Química Sisal; M. Canul-Parra, Universidad Nacional Autonoma de Mexico / Unidad de Química Sisal Facultad de Química; A. Arteaga-Segovia, C. Robles-Mendoza, Universidad Nacional Autonoma de Mexico / UMDI Sisal Facultad de Ciencias

Pesticide inputs in the Yucatan Peninsula have increased in the last years affecting coastal areas due to soil's karstic nature, which favors water to permeate through rock pores, cracks and solution conduits, causing the aquifer to be highly susceptible to the presence of pollutants. In this study, organochlorine (OCP) and organophosphate (OPP) pesticides were quantified in fish tissue (Gambusia yucatana and Poecilia velifera), as well as in alimentary bolus and plasma of three piscivorous waterbird species (snowy egret Egretta thula, great egret Ardea alba and roseate spoonbill Platalea ajaja) collected in Sisal and Celestun, located in the Western coastal area of Yucatan, Mexico. Pesticides were determined by ultrasonic assisted extraction, SPE (Florisil or C-18 6 mL/500 g cartridges), QuEChERS® clean-up and analytes were quantified by GC-MS. Total OCP concentrations in fish ranged from 131 to 948 ng/g dw and total OPP from 74 to 156 ng/g dw; no significant differences ($p< 0.05$) in pesticide levels were found between fish species and sampling sites. Samples of alimentary bolus were only obtained from A. alba (n=22) and E. thula (n=1) and pesticide content ranged from 48 to 708 ng/g dw for OCP and from 36 to 470 ng/g dw for OPP; statistically significant differences ($p< 0.05$) were found between sampling site. Minimum and maximum concentrations of OCP and OPP in plasma were 1 to 575 ng/mL and not detected to 127 ng/mL, respectively; significant differences in lindane, malathion and total OPP content in plasma were found and highest concentrations were detected in the roseate spoonbill (P. ajaja). Lindane, endosulfan, malathion, parathion and methyl parathion were detected in >85 % of the samples in fish tissue, bird alimentary bolus and bird plasma. Pesticides detected in fish and waterbirds suggest the transfer of these pollutans along food webs in the coast Yucatan; nevertheless, further studies are needed to evaluate if this transfer represents a risk for wild populations living in such ecosystems.

MP114 Experimental manipulation of dietary arsenic levels in great tit nestlings: effects on antioxidant molecules and lipid peroxidation

<u>P. Sánchez Virosta</u>, S. Espín, S.R. Ruiz, Univ of Turku / Biology; A.J. García-Fernández, Univ of Murcia / Sociosanitary Sciences; T. Eeva, Univ of Turku / Dept of Biology
