18   **ABSTRACT**

19   Mouldy building materials, such as chip wood and gypsum, should be a good source for fungal strains with

20   high production of lignocellulolytic enzymes. Screening of 21 common indoor fungal strains showed,

21   contrary to the expected, that the *Chaetomium* and *Stachybotrys* strains had little or no cellulolytic and

22   xylanolytic activities using AZCL-assays. On the other hand, both *Cladosporium sphaerospermum* and

23   *Penicillium chrysogenum* showed the highest cellulase, β-glucosidase, mannase, β-galactanase and

24   arabinanase activities and would be good candidates for over-producers of enzymes needed to supplement

25   or boost the bioconversion of lignocellulose-rich biomass.

1. Introduction

Filamentous fungi are among the most efficient degraders of plant biomass, whether it is undesired, as in the deterioration of Army Cotton Canvas, or by design, as in the bioconversion of organic waste material. They are, therefore, the main source of commercial lignocellulase production (Glass et al., 2013) and high yielding fungal strains are always in demand in the biotech industry (Pedersen et al., 2009; Hansen et al., 2015). The most commonly used organism for commercial enzyme production is *Trichoderma reesei* (Glass et al., 2013), but it has its limitations. *Trichoderma reesei* produces a high amount of exo-cellulases, but is a poorer producer of e.g. β-glucosidase (Okeke, 2014).

Research and screening of filamentous fungi for new high-yielding strains have shown that the original habitat of a strain is important in order to get as specific an enzyme profile as possible. Most of the commercial enzyme producers originate from habitats and substrates rich in lignocellulose, such as compost or agricultural soil (Hansen et al., 2015). Pedersen et al. (2008) showed that *Ulocladium* strains originating from cereal grain (starch) had the highest production of amylase compared to strains from the indoor environment (lignocellulose), which in return had the highest production of arabinanase.

Incidences of fungal deterioration of indoor environments are increasing and can now be seen in most of the western world (WHO, 2010). It is most obvious on lignocellulose rich materials, such as chip wood or plywood, where the fungal growth can be substantial. It has been shown that there are particular fungal associations between 1) *Cladosporium sphaerospermum* and plywood 2) *Stachybotrys chartarum* and gypsum board and 3) *Ulocladium alternariae* and wallpaper (Andersen et al., 2011). Mouldy building materials should therefore be a good source for discovery of fungal strains that either produce novel enzyme profiles or over-produce known desirable enzymes.

50   The purpose with this study was to screen and compare the ten most common fungal species from water-

51   damaged buildings for their production of lignocellulases using *T. reesei* RUT C30 as a reference strain.

52

53   **2. Materials and Methods**

54   2.1. Fungal strains, media, growth conditions and enzyme extraction

55   Twenty-one common indoor strains and one reference strain were used in the study. The identity, source

56   and geographic origin of all fungi are listed in Table 1. All fungal strains are held at the IBT culture collection

57   at Department for Systems Biology, DTU, Denmark. To generate inoculum and check the identity, each

58   strain was inoculated on Campbell's V8 juice agar (V8, Samson et al., 2010) and incubated for 7 days at 25

59   °C. For enzyme production a semi-solid wheat bran/sphagnum peat (WB/SP) medium was made containing

60   (per kg): 256.25 g wheat bran (Finax, Denmark), 153.75 g sphagnum peat (Mosebrug, Denmark) and 590 g

61   water. 40.0 g of WB/SP medium was placed in each 250 ml shake flask and autoclaved. Each fungal strain

62   was inoculated by cutting 3 agar plugs (10 mm in diameter) with spores and mycelium from the V8 plate

63   and transferring these to the shake flask with the WB/SP medium. The shake flasks were incubated at 25 °C

64   and shaken twice a day manually for one week. The experiment was performed in triplicates (66 shake

65   flasks in total).

66

67   Each shake flask was added 50 ml double distilled autoclaved water and shaken at 175 rpm overnight at 4

68   °C. Each extract was filtered through Miracloth into a 50 ml falcon tube and centrifuged at 10,000 g at 5 °C

69   for 15 min. The supernatant (enzyme extract) was transferred to a clean 50 ml falcon tube and stored at

70   4°C prior to screening.

71

72   2.2. AZCL assay preparation and screening

73

74 Six different Azurine cross-linked (AZCL) substrates were used for screening: arabinan, arabinoxylan (wheat

75 and birchwood), HE-cellulose, galactan and β-galactomannan (Megazyme, Bray, Ireland). For each AZCL

76 assay plates were made containing (per 500 ml): 144 ml stock solution, 356 ml double distilled water, 7.5 g

77 agarose (Litex, HSB 200 Protein grade) and 0.5 g AZCL substrate. The stock solution consisted of phosphoric

78 acid (0.08 M) (Merck, Ortho-Phosphorsaure, 85 %), glacial acetic acid (0.08 M) (Merck, 100 %) and boric

79 acid (0.08 M) (Merck) in double distilled water. To prepare the different AZCL assay plates, 200 ml double

80 distilled water was added to the 144 ml stock solution. The pH was adjusted to 6 and double distilled water

81 was added again to give a total volume of 500 ml. Agarose was added and the solution was autoclaved at

82 120 °C. The AZCL substrate was pre-soaked in 96 % ethanol for 10 min before use. When the agarose

83 solution had cooled to approximately 65 °C, the AZCL substrate suspension was added while stirring. The

84 agarose solution was poured into Petri dishes (90 mm in diam.) and when solidified, 8 wells (5 mm in diam.)

85 were cut in the plates and stored at 4 °C.

86

87 For screening 35 µl of enzyme extract was added to each well of the six different AZCL assay plates. The

88 plates were incubated for 24 h at 30 °C. The activity of each enzyme was measured as the radius of the

89 zone of released azurine dye (the blue halo) around each application well. The radius was recorded and

90 converted to area (mm^2).

91

92 2.3. β-glucosidase assay and screening

93 Screening for β-glucosidase activity was done using para-nitrophenyl-β-D-glucopyranoside (pNPG) 5 mM

94 (Sigma Aldrich) as substrate in 50 mM sodium citrate (pH 4.8). The screening was carried out in a

95 microtiter-plate format according to (Sørensen et al., 2011). A 10 µl volume of enzyme extract was added

96 to 100 µl substrate in 1.5 ml Eppendorf tubes and incubated in a Thermomixer® comfort (Eppendorf) at 50

97 °C for 15 min. At the end of the reaction 60 µl of the reaction volume was transferred to a microtiter plate

98 already containing 100 µl 1 M Na_2CO_3 for termination of the reaction. Absorbance at 400 nm was measured

99 in a plate reader (BioTek, EL800). Para-nitrophenol was used for preparation of a standard curve. One unit

100 (U) of enzyme activity was defined as the volume of enzyme needed to hydrolyze 1 µmol of pNPG in 1 min.

101 Background subtraction was prepared for each sample with 100 µl substrate at reaction temperature.

102 Hereafter, 100 µl stop reagent was added to the Eppendorf tube then 10 µl enzyme for reaction time 15

103 min. 160 µl of the reaction mixture was then transferred to the microtiter plate and the absorbance was

104 measured at 400 nm.

105

106 **3. Results**

107 The AZCL enzyme screenings of the 21 indoor strains were made from crude enzyme extracts from 7 day-

108 old wheat bran/sphagnum peat (WB/SP) medium in solid state fermentations. The analyses showed that

109 both *Chaetomium elatum* and *C. globosum* had low or no cellulase, mannase or galactanase activities (Fig.

110 1) with the exception of *C. globosum* (IBT 7029) that had an average mannase activity, compared to the

111 highest activities (Fig. 1b). None of the strains of *Stachybotrys chartarum* or *S. chlorohalonata* showed any

112 cellulase, mannase or β-galactanase activity (Fig. 1). *Penicillium chrysogenum* showed the highest cellulase

113 and mannase activities (Fig. 1a and b), while *Cladosporium sphaerospermum* showed the highest

114 galactanase activity (Fig. 1c). *Trichoderma*, including the reference strain (*T. reesei* RUT C30), had in general

115 good cellulase and mannase activities, but very low galactanase activity (Fig. 1).

116

117 The β-glucosidase screening again showed that all the *Chaetomium* and *Stachybotrys* strains had a very low

118 activity (0.008 - 0.154 U/ml) compared to the reference strain (*T. reesei* RUT C30) that had an activity of

119 0.513 U/ml (Fig. 2a). Compared to the high activities (7.823 - 7.653 U/ml) shown by *P. chrysogenum* and *C.*

120 *sphaerospermum*, both *T. harzianum* and *T. reesei* (RUT C30) showed low activities (Fig. 2b).

121

122 The screening for xylanase production was done on xylan from both wheat and birch and gave similar

123 results (Fig 3a and b). It showed all ten *Chaetomium* and *Stachybotrys* strains as the low producers, while

124 *Aspergillus versicolor* and *T. harzianum* were the high producer for both types of xylanases (Fig. 3a and b).

125

126 The arabinanase screening, however, showed that neither *T. harzianum* nor *A. versicolor* had any activity,

127 while *P. chrysogenum* had the highest (Fig. 3c). Some of the *Chaetomium* and *Stachybotrys* strains had

128 average activities (e.g. *C. globosum* (IBT 7029) and *S. chlorohalonata* (IBT 40285)), while others showed no

129 arabinanase activity after growth on the WB/SP medium.

130

131 A Principal Component Analysis in Figure 4 of all the enzyme screenings shows that *Chaetomium* and

132 *Stachybotrys* (to the left) had similar enzyme profiles, with a general low activity of all tested enzymes.

133 *Aspergillus* and *Trichoderma* (at the bottom) also had similar profiles, both showing high xylanase activities,

134 average cellulase, β-glucosidase and mannase activities and low or no β-galactanase and arabinanase

135 activities. *Penicillium*, *Cladosporium* and to some extent *Ulocladium* (at the top) were similar in having

136 average to high activities of all enzymes tested.

137

138 Three strains, *C. globosum* (IBT 7029), *U. alternariae* (IBT 9058) and *T. harzianum* (41332) fell outside their

139 respective groups. *Chaetomium globosum* (IBT 7029) had, overall, a higher activity than the other

140 *Chaetomium* strains, while *U. alternariae* (IBT 9058) and *T. harzianum* (41332) had a lower activity

141 compared to their sibling strains.

142

143 **4. Discussion**

144 Wheat bran/sphagnum peat (WB/SP) medium was used since it has been shown to be superior in inducing

145 a broad variety of enzymes (Kolasa M. et al., 2014; Meijer M. et al., 2011). WB was also the medium of

146 choice in the study of Pedersen et al., (2009), where 50 *Ulocladium* strains were screened for enzyme

147 activity using the AZCL substrates. An attempt to grow the indoor fungi on a similarly composed medium

148 with crushed chipboard/wallpaper instead of wheat bran/sphagnum peat resulted in no growth, probably

149 because the fungi needed a higher water activity to grow on this medium than WB/SP.

150

151 The study of Pedersen et al. (2009) also showed that there was variation between strains of the same

152 species. This was also seen in this study, for example, with the three *Penicillium chrysogenum* strains that

153 showed similar enzyme profiles in most assays, except for mannose, where *P. chrysogenum* (IBT 30128) had

154 no activity, while the other two strains had the highest activity.

155

156 The cellulolytic and xylanolytic activities of *Chaetomium* and *Stachybotrys* have been reported since the

157 1920s, where the fungi destroyed military equipment and other outdoor cotton fabrics (Greathouse and

158 Ames, 1945; Domsch et al., 2007). The results in this study show, contrary to the expected, that the

159 *Chaetomium* and *Stachybotrys* strains originating from water-damaged building materials showed little or

160 no cellulolytic and xylanolytic activities using AZCL-assays. Even *C. globosum* (IBT 7029 = CBS 148.51 = USDA

161 1042.4), which has been used for material testing (Reese et al., 1950), showed only average activities in the

162 AZCL assays. The fact that these fungi still are able to grow and destroy cellulose-rich building materials,

163 suggests that they have only exo-enzymes and/or membrane bound endo-enzymes, since the AZCL assays

164 screen for extracellular endo-enzymes (Vidal-Melgosa et al., 2015). Also the low β-glucosidase activity

165 suggests that these enzymes are membrane bound or intracellular. Another reason could be that

166 *Chaetomium* and *Stachybotrys* can utilize other carbon sources than cellulose in the building materials.

167 Similar results were seen for *Trichoderma*. The low β-glucosidase activity for *T. reesei* in this study is in

168 accordance with other studies (Okeke, 2014) and it has been suggested that this enzyme is membrane

169 bound or intracellular (Kubicek et al., 2009).

170

171   The other indoor fungi have larger varieties and higher activities of endo-enzymes compared to

172   *Chaetomium* and *Stachybotrys*, which might explain their higher frequency on and lesser specificity for

173   water-damaged building materials (Andersen et al., 2011). *P. chrysogenum* showed the highest activities for

174   most of the screened enzymes, which might explain its occurrence on most damp indoor surfaces. *C.*

175   *sphaerospermum* showed a similar result to that of *P. chrysogenum*, however, this fungus is more

176   specialized and also associated with plaster and grouts in bathrooms, due to its ability also to tolerate high

177   fluctuations in humidity (McGinnis, 2007).

178   The hypothesis of this study, that mouldy buildings constitute a good source for high cellulase and xylanase

179   producers, was partly proven, but not with the fungal species expected. However, both *C. sphaerospermum*

180   and *P. chrysogenum* would be good candidates for over-producers of enzymes needed to supplement or

181   boost e.g. *T. reesei* in bioconversion of e.g. garden/park waste or other lignocellulosic biomass into bio-fuel.
