Abstract: We demonstrate the emission of highly indistinguishable photons from a quasi-resonantly pumped coupled quantum dot–microcavity system operating in the weak coupling regime. Furthermore we model the degree of indistinguishability with our novel microscopic theory.

1. Introduction

Single indistinguishable photons are key to applications in the field of quantum communication [1], quantum networks [2], linear optical quantum computing [3] and quantum teleportation [4]. One of the most promising platforms for single photon sources are solid-state quantum dots (QDs) [5]. When embedded in a bulk semiconductor, however, QDs suffer from poor photon extraction efficiencies since only a minor fraction of the photons can leave the high refractive index material. This problem can be mitigated by integrating QDs into optical microcavities [8], which can enhance extraction efficiencies to values beyond 50%.

2. Experiment

In this work, we exploit a microcavity with a high Purcell factor and weak non-resonant contributions of spectator QDs to probe the interference properties of photons emitted from a single QD as a function of the QD-cavity detuning. The QD is placed in an adiabatic micropillar [9] with a diameter of $d = 1050$ nm and a quality factor of $Q = 3200$. Via temperature tuning, we can sweep the QD-emission through the fundamental optical mode of the pillar. For spectral resonance between QD and cavity, we observe a pronounced enhancement of the emission. Via time-resolved measurements, we are able to measure the lifetime of the QD-excitation for different detunings which yields a Purcell enhancement of $F_P = (7.8 \pm 2.3)$.

The QD was excited quasi-resonantly with a pulsed Ti:Sapphire Laser (repetition rate 82 MHz) assisted by a longitudinal optical phonon transition. Due to this excitation scheme, we were able to measure pure single photon emission with $g^{(2)}(0)$ -values as low as $g^{(2)}(0) = (0.036 \pm 0.005)$.

Via a fiber-coupled unbalanced Mach-Zehnder-interferometer (MZI) we carried out two-photon-interference (TPI) measurements. Fig 1(a) shows the measured two-photon probability versus the time delay between both arms of the MZI resulting in the Hong-Ou-Mandel-dip with a maximal TPI-visibility of $v = (83 \pm 5)\%$.

Furthermore we studied the influence of the QD-cavity detuning on the degree of indistinguishability of the emitted photons (see Fig 1 (b)). In contrast to previous studies, where non-resonant coupling to spectator QDs [10] or strong temperature induced dephasing [11] dominated the experiments, we observe a strong improvement of the TPI-visibility on resonance, which exceeds a factor of 3 compared to the off-resonant case. We extend the theoretical model of Ref. [12] to derive an expression for the Hong–Ou–Mandel dip including the effects of both time-jitter and pure-dephasing on- and off-resonance. This allows us to reject timing-jitter, and attribute sources of pure-dephasing as the dominant factor limiting the indistinguishability of our photons. Furthermore, we show that the degree of symmetry

we observe for positive and negative detuning suggests pure-dephasing caused by both phonon coupling and spectral diffusion.
