Abstract. We present a comprehensive analysis of the applicability of the effective medium approximation to deeply subwavelength (period $\leq \lambda/50$) all-dielectric multilayer structures. We demonstrate that even though the dispersion relations for such multilayers differ from the effective medium prediction only slightly, there can be regimes when an actual multilayer stack exhibits significantly different properties compared to its homogenized model. In particular, reflection near the critical angle is shown to strongly depend on even very small period variations, as well as on the choice of the multilayer termination. We identify the geometries for which the influence of the subwavelength features is maximized and demonstrate that the difference between the reflectance from the actual multilayer and the effective medium prediction can be as great as 0.98. The results of this analysis can be useful for high-precision multilayers ellipsometry and in sensing applications.

Keywords: dielectric metamaterial, multilayer, effective medium, photonic crystal, nanostructured device.

1. Introduction

Multilayer optics – the study of light propagation in photonic multilayer structures – is the cornerstone subject within the broader field of electrodynamics of inhomogeneous media [1]. On the conceptual level, the multilayer geometry is the simplest possible case of inhomogeneous media: a multilayer structure, being fully homogeneous in two spatial directions and piecewise homogeneous in the third direction, is only one step apart from a truly continuous medium in terms of complexity. On the methodological level, photonic multilayers are subject to several simple and illustrative mathematical theories for their analysis (see, for example, [2] and historical overview in [3]). This concerns both spatially infinite periodic multilayers, which exemplify a very simple variety of one-dimensional photonic crystals [4], and multilayers with a finite number of layers, for which very efficient semi-analytical approaches were developed, based on the transfer matrix [1,2,5] and Airy-type recurrent relations [6,7] formalism. Finally, on the practical level, multilayers easily lend themselves to various planar deposition methods and can, therefore, be fabricated in a reliable and cost-effective manner. For all these reasons, photonic multilayers are one of the most extensively studied optical systems to date, with profound theoretical knowledge and many established applications [8]. As a few characteristic examples, one may mention antireflection coatings, all-dielectric Bragg mirrors and omnidirectional reflectors [9,10], band-pass and multiband-pass filters [2,11,12], devices with tailored

frequency and group velocity dispersion [13,14], and devices with enhanced nonlinear optical effects [15,16]. Moreover, the optical multilayer model can be transferred to other physical systems governed by similar equations, such as acoustic multilayers [1,17] and multiple-quantum-well heterostructures [18].

As was shown in these extensive studies, most interesting properties of photonic multilayers originate from optical interference effects similar to those that underlie the physics of photonic crystals [4]. Therefore, research has traditionally focused on structures with characteristic layer thicknesses d comparable to the wavelength of light λ . As a notable example, the Bragg mirror, which is none other than a stack of alternating low-and high-index dielectric layers, features maximum reflectance if the optical thickness of each layer is close to one quarter of the wavelength [19]. Structures with much larger layer thicknesses qualify as macroscopic optical systems (also well-studied but with somewhat different methodology). On the other hand, structures with much smaller layer thicknesses ($d \ll \lambda$) have long been thought of as not very interesting from the photonic band gap structures point of view. Indeed, if the layers are much thinner than the wavelength of light, then the field variations inside such layers should be very small, leading to negligibly weak interference effects. Therefore, it can be adopted that the light wave would not feel the individual layers in such a “deeply subwavelength” structure. Instead, light can be thought of as interacting with the entire composite material, which can be treated as effectively homogeneous and assigned some effective material parameters (see, e.g., [20] and references therein) in much the same way as the ordinary materials are treated as homogeneous media despite having atomic, molecular, or any other intrinsic structure.

This concept of *homogenization*, which can be traced back to the earliest days of electromagnetic theory in presence of media, becomes really central in *metamaterials* [21], defined as artificial composite materials where the elements (“meta-atoms”) are much smaller than the wavelength. Since the geometry and composition of the meta-atoms can theoretically be arbitrary, the effective medium parameters of metamaterials such as negative refractive index [21–23] or near-zero dielectric permittivity [24] can be very different from those of the naturally occurring materials.

Therefore the applicability of the homogenization concept to particular metamaterials has been a topical and ongoing discussion since the conception of the field [20,25]. While it was found that there are intricate meta-atom geometries that do not readily lend themselves to homogenization [25], the applicability of the effective medium theory to the geometries as simple as a multilayer stack have hardly ever been questioned. Even though subwavelength metal-dielectric stacks with effectively indefinite dielectric permittivity tensor (planar hyperbolic metamaterials [26,27]) were found to be subject to a much tighter subwavelength condition than simply $d \ll \lambda$ [28], the origin of this tighter restriction on d results from the existence of plasmonic propagating waves with wave vector k significantly larger than the one inferred from the vacuum wavelength ($k_0 = c/\omega$), and consequently, with actual wavelength λ much smaller than $\lambda_0 = 2\pi c/k_0$ [29–32]. The principal condition of homogenization applicability, namely that the layer thicknesses must be small compared with the wavelength of light *that interacts with them*, remains unchanged. Hence, all-dielectric subwavelength multilayers, in which no plasmonic waves with extremely large wave vectors are supported, have been expected to obey the effective medium approximation (EMA) very well [33,34].

Nevertheless, a recent theoretical paper by H.H. Sheinfux et al. [35] demonstrates that this commonly believed assumption may fail in certain regimes. Namely, when the angle of incidence is close to the critical angle of the total internal reflection, the actual multilayer and its effective-medium counterpart can have significantly different transmission spectra despite the deeply subwavelength layer thicknesses (smaller than $1/50$ of the wavelength). Moreover, it was shown that the spectra become sensitive to variations of the layer

thicknesses (the structure period variation) on the scale of one nanometer, i.e. 500 times smaller than the wavelength. Additionally, if the refractive indices of the medium behind the multilayer is carefully chosen, the transmission spectra become dependent on the choice of the outermost (“opening”) layer (i.e., ABAB...AB vs. BABA...BA), totally contrary to the effective medium theory results. This “anomalous” EMA breakdown reportedly happens because for a wave incident at a near-critical angle, the optical properties of the multilayer arise from the interference effects between phases of Fresnel reflection and transmission coefficients in the frustrated total internal reflection regime rather than between phases accumulated during wave propagation in subwavelength layers [35].

Such EMA breakdown is both enlightening and practically promising, e.g. for sensing and switching applications. However, the breakdown of the EMA reported in [35] only becomes noticeable when the multilayer contains a large number of layers (on the order of several hundreds), which should have equal thickness, as even a very minor thickness randomness would smear the effect due to its extreme sensitivity to the layer thicknesses. Such a structure, having at least 150-200 layers with 10 nm thickness and <1 nm tolerance, would be impractical for any experimental realization. To facilitate the experimental verification and practical applications of this newly observed EMA breakdown, it is necessary to reproduce this effect in practically realizable structures.

In this paper we present a systematic analysis of the anomalous EMA breakdown in deeply subwavelength all-dielectric multilayers. We start from the dispersion relation discrepancies in infinite and semi-infinite multilayers and move on to the description of the effect in finite-thickness multilayer slabs. We then suggest a resonator-enabled geometry, where the EMA breakdown is further enhanced. We identify the parameter range, where the EMA breakdown is the strongest and can be observed in structures feasible for fabrication using state-of-the-art techniques such as atomic layer deposition (ALD). Specifically, we demonstrate that the difference between the reflectance of actual multilayer and the EMA prediction can be as large as 0.98, and the difference between reflectance for different opening layers (ABAB...AB vs. BABA...BA) can reach 0.99. These results can be employed to improve the accuracy and reliability of ellipsometric measurements, to devise new high-precision ellipsometry techniques, and to design new types of ultracompact all-dielectric refractive index sensors with much lower losses compared to plasmonics-based ones.

The remainder of the paper is organized as follows. We describe the methodology of our study in the Section 2. Section 3 follows with the results, with subsections covering different geometries: infinite, semi-infinite, finite multilayer slab, and finite slab with added resonator layer. Finally, in Section 4 we discuss the results and conclude.

2. Methods

We consider the multilayer structure shown in Figure 1(a), consisting of two lossless dielectrics with refractive indices n_A and n_B and thicknesses d_A and d_B , respectively. The total period is $d = d_A + d_B$, and we define the filling fraction of material A as $f = d_A/(d_A + d_B)$. Since the theoretical study presented here neglects material dispersion for the sake of simplicity, it is convenient to normalize all geometrical sizes to the free-space wavelength of incident light λ , which is what we do throughout the paper.

Conventional Maxwell-Garnett homogenization applied to the multilayer geometry does not introduce any approximations other than the assumption that the layer thicknesses are much smaller than the wavelength. It gives the effective permittivity tensor [5] $\hat{\epsilon} = \text{diag}(\epsilon_t, \epsilon_t, \epsilon_z)$, where

$$\begin{aligned}\epsilon_t &= f\epsilon_A + (1-f)\epsilon_B, \\ \epsilon_z &= \left(\frac{f}{\epsilon_A} + \frac{1-f}{\epsilon_B} \right)^{-1},\end{aligned}\quad (1)$$

and the coordinate system used is given in Figure 1(a). The dispersion equation for the waves in such an ideal homogenous uniaxial medium yields circular isofrequency contours for one polarization (TE or transverse electric with $E_z = 0$) and elliptical isofrequency contours for the other polarization (TM or transverse magnetic with $H_z = 0$):

$$\begin{aligned}q^2 + \kappa^2 &= \epsilon_t \text{ (TE)}, \\ \frac{q^2}{\epsilon_z} + \frac{\kappa^2}{\epsilon_t} &= 1 \text{ (TM)},\end{aligned}\quad (2)$$

where $q = k_z/k_0$ and $\kappa = k_t/k_0$ are normalised wavevector components and $k_0 = \frac{\omega}{c} = \frac{2\pi}{\lambda}$ is the wavevector in vacuum.

Figure 1. (a) Schematics of the multilayer dielectric structure considered. (b) Example of the isofrequency contours for the homogenized uniaxial medium ($n_A = 1, n_B = 4, f = 0.5, d/\lambda = 0.1$) according to Eqs. (1)-(2) (TM – dashed black, TE – dashed red) and solutions of dispersion equation (3) (TM-solid green, TE – solid cyan). (c) Discrepancy between the periodic material and homogenised medium increases with period d ($n_A = 1, n_B = 4, f = 0.5$). (d-f) Illustration of the transfer matrix method: (d) an interface between two dielectrics, (e) propagation in a homogenous layer, (f) illustration of the main idea behind the analytic expression (7) for Fresnel reflection from a semi-infinite structure.

The dispersion relation for the actual multilayer structure can also be determined analytically. It is known from Bloch's theorem that the existence condition for propagating waves in a one-dimensional periodic medium is directly related to the properties of one period of the structure and the dispersion equation is [28]

$$\cos(q k_0 d) = \cos q_A k_0 d_A \cos q_B k_0 d_B - \frac{1}{2} \left(K + \frac{1}{K} \right) \sin q_A k_0 d_A \sin q_B k_0 d_B, \quad (3)$$

where $q_{A,B} = \sqrt{n_{A,B}^2 - \kappa^2}$ and $K = q_2/q_1$ (TE) or $K = (\varepsilon_1/\varepsilon_2)(q_2/q_1)$ (TM).

Typically, the isofrequency contour from Eq. (3) for the TE polarization results in an ellipse of a larger size than homogenization predicts [Figure 1(b)], while the contour for the TM polarization is of a more complex shape than elliptical. For a certain value of tangential component κ equations (2) and (3) give the same q for the TM polarization.

To characterize the discrepancy between the Bloch and homogenized solutions, we introduce the quantities [see Figure 1(b)]

$$\delta_z = (q_{\text{Bloch}} - q_{\text{homogenized}})|_{\kappa=0}, \quad \delta_t = (\kappa_{\text{Bloch}} - \kappa_{\text{homogenized}})|_{q=0}, \quad (4)$$

These quantities are chosen because the discrepancy between the homogenized and the Bloch dispersion relations are maximum for $\kappa = 0$ and $q = 0$, as seen in Figure 1(b). Both these quantities increase with the structure period, as shown in Figure 1(c). The dependency is very close to quadratic, and for smaller period values $d/\lambda < 0.05$ it was confirmed that $\delta_{z,t} \sim (d/\lambda)^2$.

For calculations of the reflectance from finite-sized multilayer structures we used the transfer matrix method similar to [2], which we briefly outline here for the sake of completeness. For an interface between two materials [see Figure 1(d)] with refractive indices n_i and n_{i+1} the relations between electric field amplitudes a and b corresponding to the waves propagating in the two directions are

$$\begin{pmatrix} a_i \\ b_i \end{pmatrix} = M_{i,i+1} \begin{pmatrix} a_{i+1} \\ b_{i+1} \end{pmatrix} = \frac{1}{s_{21}} \begin{pmatrix} 1 & s_{11} \\ s_{21} & 1 \end{pmatrix} \begin{pmatrix} a_{i+1} \\ b_{i+1} \end{pmatrix}, \quad (5)$$

where $s_{11} = \frac{1-\gamma}{1+\gamma}$, $s_{21} = \frac{2\gamma}{1+\gamma}$ and $\gamma = \frac{q_{i+1}}{q_i}$ (TE) or $\gamma = \frac{q_{i+1}}{q_i} \frac{\varepsilon_i}{\varepsilon_{i+1}} = \frac{q_{i+1}}{q_i} \frac{n_i^2}{n_{i+1}^2}$ (TM).

For propagation inside layer i [see Figure 1(e)]

$$\begin{pmatrix} a_{i,\text{left}} \\ b_{i,\text{left}} \end{pmatrix} = P_i \begin{pmatrix} a_{i,\text{right}} \\ b_{i,\text{right}} \end{pmatrix} = \begin{pmatrix} \exp(-i q_i k_0 d_i) & 0 \\ 0 & \exp(i q_i k_0 d_i) \end{pmatrix} \begin{pmatrix} a_{i,\text{right}} \\ b_{i,\text{right}} \end{pmatrix}. \quad (6)$$

The transfer matrix M for an arbitrary number of layers $2N$ is obtained through subsequent multiplication of matrices $M = \begin{pmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{pmatrix} = M_{\text{in},1} P_1 M_{1,2} \dots M_{2N-1,2N} P_{2N} M_{2N,\text{out}}$, where the subscripts “in” and “out” denote the ambient media to the both sides of the stack. The reflectance from the structure is then $R = |r|^2 = \left| \frac{m_{21}}{m_{11}} \right|^2$. For example, the transfer matrix M_P for one period of the considered structure (dielectric layers A and B are surrounded with material n_{in} from both sides) is $M_P = \begin{pmatrix} m_{P11} & m_{P12} \\ m_{P21} & m_{P22} \end{pmatrix} = M_{\text{in},A} P_A M_{A,B} P_B M_{B,\text{in}}$. The transfer matrix for N periods of such a structure can then be written as $(M_P)^N$, using the identity $M_{B,\text{in}} M_{\text{in},A} = M_{B,A}$.

Finally, to calculate the reflectance from a semi-infinite stack we use the fact that adding one period to a semi-infinite structure does not change the overall reflectance, as illustrated in Figure 1(f). Thus

$$\begin{pmatrix} 1 \\ r_\infty \end{pmatrix} = M_P \begin{pmatrix} 1 \\ r_\infty \end{pmatrix} F = \begin{pmatrix} m_{P11} & m_{P12} \\ m_{P21} & m_{P22} \end{pmatrix} \begin{pmatrix} 1 \\ r_\infty \end{pmatrix} F, \quad (7)$$

where the factor F stands for the reduction of the wave amplitude after propagation through one period. Equation (7) gives a quadratic equation for determination of r_∞ with two roots. One of the roots, for which the reflectance is larger than 1, is discarded as non-physical.

3. Results

3.1. Infinite multilayer structure: dispersion equation

We start our investigation from the infinite periodic multilayer structure [Figure 1(a)]. In such a system, there are four independent parameters to vary: refractive indices n_A , n_B and layer thicknesses d_A , d_B expressed as the lattice period $d = d_A + d_B$ and the filling fraction $f = d_A/d$. Most of the low-loss dielectrics in the optical and near infrared region have refractive indices in the range $1 - 4$, therefore we stay within this limit.

Figures 2 and 3 show the characteristic dependencies of the discrepancies $\delta_{t,TM}$, $\delta_{t,TE}$ and δ_z , as defined in Equation (4), on refractive indices. We can see that the discrepancies increase with the difference of refractive indices $|n_A - n_B|$ nearly monotonically (see Figure 2). This gradual decrease of the accuracy of EMA is the expected result since the optical thickness of a layer increases with its index of refraction, so even for a physically subwavelength layer (e.g., $d_B/\lambda = 0.05$), one can have $n_B d_B/\lambda = 0.2$ for $n_B = 4$, which is already approaching the quarter-wave layer optical thickness of 0.25. We note that the dependence of $\delta_{t,TM}$ on n_A and n_B is slightly more complicated than for $\delta_{t,TE}$ and δ_z , namely, the isolines $\delta_{t,TM}(n_A, n_B) = \text{const}$ are slightly curved rather than straight [cf. Figure 2(a) and (b-c)]. This means that, e.g., the dependence $\delta_{t,TM}(n_A = \text{const}, n_B)$ has a maximum for $1 < n_B < 4$, whereas the corresponding functions $\delta_{t,TE}(n_A = \text{const}, n_B)$ and $\delta_z(n_A = \text{const}, n_B)$ are monotonic in that range.

Figure 2. Discrepancies $\delta_{t,TM}$ (a), $\delta_{t,TE}$ (b) and δ_z (c) between Bloch and EMA dispersion equation increase with the difference of refractive indices $|n_A - n_B|$. Other parameters are $d/\lambda = 0.1$ and $f = 0.5$.

The same gradual frustration of EMA can be observed in the monotonically increasing dependencies of $\delta_{t,TM}$, $\delta_{t,TE}$ and δ_z on the lattice period d , as shown in Figure 3. To be able to consider the refractive indices of surrounding materials below and above n_A and n_B while staying within the range $1 - 4$ for all materials, we fix $n_A = 2$ and $n_B = 3$ and use them throughout the rest of the paper. The dependencies of $\delta_{t,TM}$, $\delta_{t,TE}$ and δ_z on filling fraction f feature a maximum at values between 0.3 and 0.6 depending on polarization. This is also reasonable, since for the limiting cases $f = 0$ and $f = 1$ the multilayer stack becomes a homogenous material for which the EMA is automatically valid; on the other hand, at the intermediate values of f the effects brought about by the non-homogeneity of the structure are expected to be stronger.

Since the dependencies in Figures 2 and 3 are featureless and only predict the gradual frustration of the EMA as the layers become optically thicker, we can pick any values of multilayer parameters for further investigation in other geometries. For the rest of the paper we use the period size $d/\lambda = 0.02$. For this period the maximum of $\delta_{t,TM}$ occurs for $f = 0.35$, maximal $\delta_{t,TE}$ and δ_z are reached for $f = 0.52$, and for

the filling fraction $f = 0.47$ all δ are equal [Figure 3(d)]. To facilitate direct comparison between the two polarizations, we stick to this filling fraction $f = 0.47$ throughout the rest of the paper, yielding the permittivity tensor components $\varepsilon_t = 2.579^2$ and $\varepsilon_z = 2.381^2$ according to Equations (1).

Figure 3. (a-c) Discrepancies $\delta_{t, TM}$ (a), $\delta_{t, TE}$ (b) and δ_z (c) between Bloch and EMA dispersion equation increase with the period d/λ and experience maximum at a certain filling fraction f for a fixed d/λ . Refractive indices are $n_A = 2$, $n_B = 3$. (d) Discrepancies for $d/\lambda = 0.02$ experience maximum at the filling fraction $f = 0.35$ ($\delta_{t, TM}$) and $f = 0.52$ ($\delta_{t, TE}$ and δ_z); they are equal for the crossing point at $f = 0.47$.

3.2. Semi-infinite multilayer structure

Our next goal is to consider a structure that would be minimally more complex than an infinite periodic multilayer, i.e., a semi-infinite periodic multilayer bordering some ambient homogeneous material with refractive index n_{in} . Since the translation invariance is broken by that interface, the Bloch theorem is no longer rigorously applicable, so in order to characterize the EMA applicability, we analyze discrepancies in the Fresnel reflection coefficient for a wave incident from the ambient medium onto the multilayer structure. Such scenario is also much more relevant than the dispersion relation from the experimental point of view because the reflectance is directly measurable.

Specifically, and following two main results in [35], we will introduce two quantities:

$$\begin{aligned} \Delta R_d &= R_{d/\lambda=0.02} - R_{d/\lambda=0.001}, \\ \Delta R_o &= (R_{ABAB\dots} - R_{BABA\dots})|_{d/\lambda=0.02}. \end{aligned} \quad (8)$$

The first one, ΔR_d , is essentially the difference between the reflectance of the actual multilayer and its homogenized counterpart, since the structure with $d/\lambda = 0.001$ can be regarded as “quasi-homogenous”; we recall that all discrepancies δ , as defined in Equation (4), scale quadratically with the period of the structure [cf. Figure 1(c)], so $d/\lambda = 0.001$ is “400 times more homogenous” than $d/\lambda = 0.02$. This quantity will be non-zero if finite thickness of layers, even as small as $\lambda/50$, has an influence on the reflectance of the entire multilayer, indicating the breakdown of the EMA. The second quantity in Equation (8), namely ΔR_o , is the difference between reflectance for the same structure (with $d/\lambda = 0.02$) starting with the either layer A or layer B. This quantity signifies the influence of the layers ordering (hence the subscript “o”), again indicating the breakdown of homogenization because, obviously, two otherwise identical multilayers that only differ by layer ordering are homogenized to the same material.

In addition to the parameters of the multilayer stack analysed in the previous section, there are two additional parameters, namely the above-mentioned refractive index of the ambient material n_{in} and angle of incidence α for the impinging wave. It was found that layer ordering difference ΔR_o is negligible (on the level of the numerical noise), while layer thickness difference ΔR_d is shown in Figure 4. It can be seen in Figure 4 (a) and (b), where the logarithmic scale is used for clarity, that ΔR_d is small (around 10^{-3}) for most n_{in} and α below the critical angle. Interestingly there are distinct lines of local minima [two crossing lines for TM in Figure 4(a) and one line for TE in Figure 4(b)], corresponding to crossings between the homogenized and actual multilayer dispersion relations, as seen in Figure 1(b). In contrast, for α above the critical angle (where total internal reflection occurs) the reflectance difference is exactly zero [black areas in Figure 4 (a) and (b)], making the transition to the total internal reflection regime clearly marked.

The most significant feature of the dependence $\Delta R_d(n_{in}, \alpha)$ is seen to occur immediately before the critical angle. As seen in Figure 4(c) and (d), where the region in the vicinity of the critical angle is magnified, and as confirmed by plotting the explicit reflectances in Figure 4(e)-(f), the reflectance difference can be as large as 0.1. This occurs for the combination of parameters when the homogenized multilayer is in the total internal reflection regime, so that $R_{d/\lambda=0.001} = 1$, but the field in multilayer with finite layer thicknesses, weakly evanescent in lower-index (A) layers and propagating in higher-index (B) layers, forms a quasi-propagating Bloch wave (giving $R_{d/\lambda=0.02} < 1$). This regime corresponds to the case described in [35], and therefore Figure 4 confirms that the anomalous EMA breakdown actually occurs at near-critical incident angles and can be present already in semi-infinite multilayers.

In what follows, we will focus on the detailed investigation of this anomalous breakdown in a variety of geometries, and will therefore use the input refractive index $n_{in} = 3$ for the rest of the paper. This value corresponds to the critical angle 52.5 degrees (TM) and 59.3 degrees (TE) for the quasi-homogenous structure. Figure 4 (e) and (f) shows the reflectance from the actual and quasi-homogenous structures for this value. It is seen that the difference ΔR_d is maximal at the incidence angle exactly equal to the critical angle. Therefore we will use $\alpha = 52.5^\circ$ (TM) and $\alpha = 59.3^\circ$ (TE) for the rest of the paper.

Figure 4. (a-b) Difference of reflectance $|R_d| = |R_{d/\lambda=0.02} - R_{d/\lambda=0.001}|$ for the actual periodic structure and quasi-homogenous structure. Reflectance difference in a broad range of input refractive indices n_{in} and incidence angles α for TM (a) and TE (b) polarizations. Black area corresponds to the total internal reflection. (c-d) Region of n_{in} and α close to the critical (total internal reflection) angle for TM (c) and TE (d). (e-f) Reflectances for the periodic ($d/\lambda = 0.02$) and quasi-homogenous ($d/\lambda = 0.001$) structures are significantly different only in the vicinity of the critical angle ($n_{in} = 3$) both for TM (e) and TE (f) polarizations.

3.3. Finite multilayer stack

Now we consider the case of a finite multilayer stack, which is the simplest practically relevant geometry because such a stack can be not only characterized in reflectance measurements (as the semi-infinite stack in principle can), but also fabricated. Having already fixed the parameters of the multilayer structure, the ambient material and incidence angle, we vary the parameters specific to this new geometry, namely the

thickness of the multilayer D and refractive index of the output material n_{out} (see inset in Figure 5). For the sake of simplicity, we use D as a continuously varying parameter, keeping in mind that all real calculations are made with an integer number of periods.

Figure 5. (a-b) Reflectance difference between the actual periodic and quasi-homogenous structures ΔR_d for TM (a) and TE (b) polarizations for the finite stack. (c-d) Reflectance difference ΔR_o for the periodic structure with opening layer A and B for TM (c) and TE (d) polarizations. Insets show the magnified region around maximum reflectance difference. (e-f) Reflectances for A and B opening layer, for periodic and quasi-homogenous structures depending on the angle in the vicinity of the critical angle for TM (e) and TE (f) polarizations.

The resulting dependencies $\Delta R_d(D, n_{\text{out}})$ and $\Delta R_o(D, n_{\text{out}})$ are shown in Figure 5. Several interesting features can be seen. First, for the semi-infinite stack ΔR_d can reach values on the order of 0.1 [Figure 4 (a)-(b)], while for a finite slab [Figure 5 (a) and (b)] ΔR_d yields the maximum values of 0.24 and 0.41 for TM and TE polarization, respectively. This means that the anomalous EMA breakdown near the critical angle identified in the semi-infinite case persists in the finite multilayer case too. Second, the area where ΔR_d is significantly non-zero is quite narrow along the horizontal axis n_{out} , so the EMA breakdown effect is quite

sensitive to output refractive index n_{out} . Specifically, the maximum discrepancy is observed for $n_{\text{out}} = 2.579$ (TE) and $n_{\text{out}} = 2.382$ (TM), which is very close to $\sqrt{\epsilon_t}$ and $\sqrt{\epsilon_z}$, respectively. This is in full accordance with the findings in [35], where this high sensitivity was attributed to the impedance matching conditions at the output interface of the multilayers. Third, it is seen that the dependence on D is non-monotonic as well, but is much weaker. There are rather broad maxima at $D/\lambda = 1.64$ (TE) and $D/\lambda = 1.12$ (TM), and it can be seen that the range of D/λ where ΔR_d stays above 0.04 spans from 0.1 to around 2.

In stark contrast to the semi-infinite multilayers, the ordering reflectance difference $\Delta R_o = R_A - R_B$ [Figure 5 (c) and (d) and insets therein] is significantly greater than zero. It shows the same dependence on n_{out} and D as ΔR_d reaching the maximal absolute values 0.46 (TE) and 0.32 (TM) at the same values of n_{out} and D/λ . Remarkably, the maxima of ΔR_d and ΔR_o are broad with respect to D/λ , so even though the maxima of the reflectance difference ΔR_d and ΔR_o occur at relatively large multilayer stack thickness $D/\lambda > 1$, the reflectance difference is measurable ($\Delta R_d = 0.04$ and $\Delta R_o = 0.07$ for both TE and TM polarizations) even at the stack thickness as small as $D/\lambda = 0.1$ (only five periods).

Figure 5 (e) and (f) show the explicit reflectance dependence on the incidence angle near the critical angle for the multilayered ($d/\lambda = 0.02$) and quasi-homogeneous ($d/\lambda = 0.001$) structures with A or B opening layers. The reflectances for the actual multilayer structure generally follow the quasi-homogenous trend, oscillating around it; oscillations for opening layers A and B are of the opposite signs with respect to the quasi-homogenous line, and all the curves coincide at certain angles. Interestingly, the critical angle shift [observed in Figure 4(e) and (f)] is not observed anymore in Figure 5 (e) and (f). It results from fact that the total internal reflection depends mainly on the substrate, which is identical for all cases.

3.4. Finite multilayer stack with resonator layer

The final geometry that we consider here includes an additional finite-thickness layer between the multilayer structure and the substrate (see inset in Figure 6). This intermediate layer acts as a photonic resonator with resonance conditions determined by its thickness L . Such a geometry is highly relevant because previous research has shown that a resonator (even a very primitive one such as a single layer of carefully chosen thickness) can considerably improve impedance matching in many photonic devices, leading to enhancement of various effects such as nanoantennas excitation [36] and metasurface polarization conversion [37]. It is expected that the already measurable discrepancies between the reflectance from the actual multilayer and its homogenized counterpart may be enhanced in the resonator set-up.

Following the same adopted methodology of gradually working from the simpler geometry to the more complicated, we fix the refractive index of the resonator layer to be the optimal n_{out} determined in the previous section, namely, $n_{\text{out}} = 2.382$ (TM) and $n_{\text{out}} = 2.579$ (TE), and use resonator thickness L and refractive index of the substrate beneath the resonator n_{sub} as new variable parameters. The total thickness of the multilayer stack is fixed at $D/\lambda = 1.64$ (TE) and $D/\lambda = 1.12$ (TM).

Figure 6. (a-b) Reflectance difference ΔR_d between the actual periodic and quasi-homogenous structures for TM (a) and TE (b) polarizations for the finite stack with an additional layer of refractive index n_{out} and thickness L . (c-d) Reflectance difference ΔR_o for the periodic structure with opening layer A and B for TM (c) and TE (d) polarizations.

The results are shown in Figure 6. As expected from the previous theoretical considerations [37], discrepancies ΔR_d and ΔR_o are greatly enhanced compared to the case when the resonator is absent. The primary factor affecting the enhancement is resonator thickness L , with both ΔR_d and ΔR_o periodically exhibiting maxima and minima with changing L/λ . The dependence on substrate refractive index n_{sub} is much weaker and essentially consists in the requirement $n_{\text{sub}} > n_{\text{out}}$: it can be seen in Figure 6 that the EMA breakdown vanishes otherwise. The dependenced $\Delta R_{d,o}(n_{\text{sub}})$ achieves saturation once n_{sub} exceeds n_{out} substantially, and there is a transition region for $n_{\text{sub}} \gtrsim n_{\text{out}}$ where the resonator has little effect so that the structure beneath the multilayer can be thought of as effectively bulk.

Specifically, finite-thickness difference ΔR_d reaches maximal absolute values 0.90 for $L/\lambda = 5.05$, $n_{\text{sub}} = 2.655$ (TM) and 0.98 for $L/\lambda = 8.50$, $n_{\text{sub}} = 2.587$ (TE) [see Figure 6 (a) and (b)]. Ordering reflectance difference ΔR_o [Figure 6 (c) and (d)] shows qualitatively similar behaviour, reaching maximal absolute values 0.97 for $L/\lambda = 5.05$, $n_{\text{sub}} = 2.635$ (TM) and 0.99 for $L/\lambda = 8.50$, $n_{\text{sub}} = 2.587$ (TE). For a thinner multilayer stack with $D/\lambda = 0.2$ (10 periods), it was shown that the resonator configuration also yields significant maximal reflectance differences, reaching $\Delta R_d = 0.10$ and $\Delta R_o = 0.20$ for both TE and TM polarization.

4. Discussion and conclusions

Our results show that all-dielectric subwavelength multilayer stacks exhibit surprisingly interesting properties. Even though their isofrequency contours do not differ much from the effective medium predictions (Figures 2 and 3), it turns out that under certain circumstances (surrounding materials refractive indices, angle of incidence, thickness of the stack) this can be enough to cause significant differences in reflection between the actual structure and EMA prediction (Figures 4-6). These differences clearly manifest as the anomalous breakdown of the EMA applicability. In other words, it is possible that an incident wave can excite guided modes in a multilayer stack, leading to less-than-unity reflectance, but would undergo total internal reflection from a slab of homogeneous material representing the stack under the EMA. Using a finite-size stack (Figure 5) and placing a resonator layer behind the multilayer (Figure 6), it is possible to further enhance the reflectance difference. The reflectance depends not only on the period, but also on the opening layer (A or B) in the stack. In the resonator geometry it is even possible to maximize the reflectance difference (Figure 6) up to 0.99. Our results corroborate the findings of H. Sheinfux et al [35], placing them in context of a systematic and comprehensive investigation and identifying the parameters where these findings could be experimentally verified using existing fabrication and measurement techniques.

The results are even more surprising taking into account that the structure consists of lossless dispersionless dielectrics (contrary to metal-based metamaterials) and no material resonances (contrary to resonant metamaterials) are involved. The analysis presented in this paper is general and wavelength-independent (all the sizes are normalized to the wavelength) so they are applicable for a broad range of frequencies from radio waves to light waves.

Two important practical conclusions can be drawn. First of all, one should be extremely careful doing ellipsometry of multilayer structures, since the applicability of the EMA, usually taken for granted, can be grossly invalid under certain circumstances. Existing ellipsometry models involving multilayer structures may be in need for correction due to this possibility.

Second, we notice that the observed effect generally happens in a narrow parameter window (surrounding materials refractive index, angle of incidence, stack thickness). Hence the investigated anomalous EMA breakdown can be used for sensing applications, where minute variation in the refractive index (primarily that of the medium immediately behind the multilayer structure) can be detected in reflectance measurements. The resonator geometry considered in Section 3.4 is particularly promising because of high performance and because it can be realized with a relatively small number of layers (for example, 10 periods). The multilayer structure can be placed on top of a microfluidic channel for lab-on-a-chip applications. In addition, high sensitivity to the total thickness of the stack, individual layer thickness, and multilayer termination (whether the opening layer is A or B) can be used as a new optical method of *in situ* monitoring of subwavelength multilayer deposition such as ALD. Finally, high sensitivity to the incidence angle can be used in precise angle measurements and control.

In summary, we have performed a general systematic analysis of deeply subwavelength dielectric multilayers and the anomalous EMA breakdown in such structures. We have determined the conditions for maximal reflectance difference between the actual periodic multilayer and its homogenized counterpart, as well as the maximal sensitivity to the choice of the opening layer in the stack. The presented results will be useful for ellipsometric characterization of multilayer stacks as well as for a variety of sensing applications.
