Abstract — This paper describes modeling, fabrication and high power optical characterization of thin gold films embedded in silicon dioxide. The propagation vector of surface plasmon polaritons has been calculated within the effective index method for the wavelength range of 750-1700 nm and for the waveguide thicknesses of 15, 30 and 45 nm. Fabrication process of such plasmonic waveguides with widths in the range of 1-100 μm and their quality inspection are described. Results of optical characterization of plasmonic waveguides using a high power laser with the peak power wavelength 1064 nm show significant deviation from the linear propagation regime of surface plasmon polaritons at the average input power of 100 mW and above. Possible reasons for this deviation are heating of the waveguides and subsequent changes in the coupling and propagation losses.

Keywords—nanophotonics; optical waveguides; plasmons

I. INTRODUCTION

The first experimental observation of surface plasmons in thin gold films embedded in silicon dioxide was published in 2000 [1]. A comprehensive study of long-range surface plasmon polaritons in thin gold films was performed by P. Berini and co-workers and described in [2]. Optical characterization at the wavelength of 1550 nm showed good agreement between theoretical and experimental data. Effects of surface electromagnetic waves propagation in thin metal films can be used for development of integrated optics elements [3,4,5]. In some case, polymer benzocyclobutene is also used as a cladding of plasmonic waveguides instead of silicon dioxide. A review about surface plasmon polaritons is presented in [6].

In the present work, we describe modeling, fabrication and high power optical characterization of thin gold films embedded in silicon dioxide. The effective index method [7] was used for modeling plasmonic waveguides, and relevant calculations were performed using MATLAB. The modeling is described in section II. The fabrication of samples was performed in the university cleanroom and discussed in section III. The optical characterization of plasmonic waveguides was done using a high power laser with the peak power wavelength 1064 nm. The experiment and obtained results are described in section IV.

II. MODELING OF PLASMONIC WAVEGUIDES

Modeling of thin gold films starts from the Maxwell equations, boundary conditions and calculation of dielectric permittivity of gold and silicon dioxide for the wavelength of interest [7,8].

The dielectric permittivity of silicon dioxide can be assumed constant for simplicity and equal to the following value at the wavelength 1064 nm:

$$\varepsilon_{2} = 2.12.$$  (1)

The dielectric permittivity of gold is calculated using the Drude model [7,8] and parameters from [7]:

$$\varepsilon_{2} = Re[\varepsilon_{2}] + i \cdot Im[\varepsilon_{2}],$$  (2)

$$Re[\varepsilon_{2}] = 1 - \frac{\lambda^{2} \cdot \omega_{p}^{2} \tau^{2}}{\lambda^{2} + \tau^{2} - 4 \pi^{2} \varepsilon_{2}^{2}},$$  (3)

$$Im[\varepsilon_{2}] = \frac{\omega_{p}^{2} \tau \cdot \lambda^{3}}{2 \pi \cdot \lambda^{2} + 8 \pi^{2} \varepsilon_{2}^{3} \tau^{2}}.$$  (4)

Here, $\omega_{p} = 1.37 \cdot 10^{16}$ rad/s is the plasma frequency of gold, and $\tau = 2.9 \cdot 10^{-14}$ s is the relaxation time of gold, $c$ is the speed of light in vacuum, and $\lambda$ is the wavelength of interest.

A thin gold film can be modeled as an infinitely wide slab with thickness $t$ and dielectric permittivity $\varepsilon_{2}$, embedded in medium with dielectric permittivity $\varepsilon_{1}$ (Fig. 1). Surface electromagnetic waves can propagate along the top and bottom boundaries of the slab and form coupled electromagnetic oscillations, one of which is called a long-range surface plasmon polariton. The propagation vector $\beta$ for the long-range mode of surface plasmon polaritons in this configuration can be found from the dispersion equation [8,9]:

$$\operatorname{tanh}\left(\frac{t}{2} \sqrt{\beta^{2} - \varepsilon_{2}^{2} \frac{4 \pi^{2}}{\lambda^{2}}} + \frac{\varepsilon_{2}}{\varepsilon_{1}} \sqrt{\beta^{2} - \varepsilon_{1}^{2} \frac{4 \pi^{2}}{\lambda^{2}}} \right) = 0$$  (5)

This equation was solved numerically for $\beta$ in MATLAB for the thickness values of 15, 30 and 45 nm and for the wavelength range of 750-1700 nm. The real part of the propagation vector $Re[\beta]$ is shown in Fig. 2. The calculation step is 50 nm, and the obtained points are connected by straight lines. The real part of the propagation vector monotonically decays over the wavelength range and differs very little for selected values of the slab thickness. The obtained results show that the effective refractive index of plasmonic waveguides...
does not have significant dependence on the waveguide thickness for the wavelength range of interest.

Fig. 1. Thin gold film as a silicon dioxide embedded in the waveguide

The imaginary part of the propagation vector \( \text{Im}[\beta] \) is shown on Fig. 3. The calculation step is 50 nm, and the obtained points are connected by straight lines. The imaginary part of the propagation vector monotonically decays over the wavelength range, and differs significantly for selected values of the slab thickness. It is almost one order of magnitude smaller for the thickness of 15 nm than that for the thickness of 45 nm. The imaginary part of \( \beta \) is responsible for absorption and propagation losses in a plasmonic waveguide. Thinner plasmonic waveguides have less losses and, thus, longer propagation length of surface plasmon polaritons. The long range mode of surface plasmon polaritons can propagate over several millimeters and can be observed and studied experimentally for the selected thickness and wavelength range [7].

The obtained results and literature data [2, 7, 9] were used for the design and fabrication of plasmonic waveguide structures. The effective penetration depth for surface electromagnetic waves in gold is around 21-22 nm for the selected wavelength range and effective penetration depth in silicon dioxide is around the wavelength value. Thus, the gold film thickness should be around 50 nm or thinner and covered by several micrometers of dielectric from top and bottom side to observe the propagation of long-range surface plasmon polaritons.

III. FABRICATION

The prototype samples with plasmonic waveguides were fabricated in the university cleanroom. A photolithography mask was designed in CteWin layout editor and ordered from a commercial supplier. A silicon wafer with pre-made 6.5 \( \mu \)m of the silicon dioxide cladding was used as a substrate. Standard ultraviolet lithography process was applied, and gold films were deposited on top of silicon dioxide afterwards using a sputtering machine. A chemical solution Piranha was used to remove the photoresist layer. A top cladding of silicon dioxide was deposited using the plasma-enhanced chemical vapor deposition method. The quality of plasmonic waveguides was checked using a scanning electron microscope. Image with several waveguides of different width obtained by the microscope is shown in Fig. 4. The waveguides are bright lines with widths 1, 2, 3, 4, 5, 6, and 7 \( \mu \)m. One fabricated wafer contained two groups of waveguides: thin waveguides and wide waveguides. Thin waveguides had width in the range of 1-10 \( \mu \)m, with width step of 1 \( \mu \)m. Wide waveguides had width in the range of 10-100 \( \mu \)m, with width step of 10 \( \mu \)m. The distance between neighbor waveguides was 100 \( \mu \)m. This value is much bigger than typical penetration depth of surface electromagnetic waves in silicon dioxide, and each plasmonic waveguide could be investigated standalone, without influence on another neighbor waveguides. The difference between the nominal and fabricated widths of plasmonic waveguides was within the range of 1 \( \mu \)m. The thickness of waveguides was measured using a Dektak XT profilometer and was around 35 nm. The thickness and refractive index of silicon dioxide were measured using a Filmtek 4000. The total thickness of silicon dioxide layer was around 11.5 \( \mu \)m, thus the thickness of deposited top cladding was around 5 \( \mu \)m. The refractive index of silicon dioxide was around 1.456 at 1064 nm. The fabricated wafer was diced, and 15 rectangular slices with plasmonic waveguides of different width and length were collected in the chessboard (Fig. 5). The width of rectangular slices was 1.5 cm, and the length was 2, 3, 4, 5 and 6 mm. The top raw contains slices with 5 identical groups of wide plasmonic
waveguides, each group has waveguides with the width in the range of 10-100 μm and the groups are separated by the distance of 500 μm. The total number of waveguides in each slice is 5 × 10 = 50. The middle raw contains slices with 10 identical groups of thin waveguides, each group has waveguides with the widths of 1-10 μm and the groups are separated by the distance of 150 μm. The total number of waveguides in each slice was 10 × 10 = 100.

The bottom raw contains slices with a thin gold film covering the whole surface of slices. The rectangular samples from the top raw containing wide waveguides were selected for optical characterization.

The experimental setup to characterize the samples is shown on Fig. 6. The laser source is picosecond SuperK EXTREME (NKT Photonics) with the maximum average power 15 W, repetition rate 78 MHz and peak power wavelength 1064 nm. A laser beam propagated in the step-index optical fiber to the fiber port, passed polarizers and coupled again to the polarization maintaining fiber. Two linear polarizers are used to tune the beam power without changing the laser operational current, and to keep the fixed linear polarization of output light. The first polarizer rotated to tune its polarization direction with respect to the second polarizer direction, and, thus, the beam power was tuned from 0 W to a half of the maximum value. The output beam polarization is maintained to match the transverse magnetic mode of surface plasmon polaritons in waveguides. The samples were placed by one on the moving platform and two positioners were used to implement the end-fire light coupling to plasmonic waveguides. A single mode fiber is used to collect and deliver the transmitted flux to the optical spectrum analyzer AQ6315E (Yokogawa). The samples motion and fibers alignment are controlled by the optical microscope Axiotech vario (Carl Zeiss). The polarization maintaining fiber is a photonic crystal fiber with the core diameter 10 μm. The single mode fiber is a photonic crystal fiber with the core diameter 10 μm. Plasmonic waveguides with the width of 10 μm were selected for investigation to have the most coupling efficiency. Results of transmission measurement for plasmonic waveguides of different lengths and at the average power in the range below 1 mW were reported in [10]. The new results of high power optical characterization are shown on Fig. 7.

The horizontal axis corresponds to the laser reference power measured without sample by the fiber to fiber direct coupling method. The polarization maintaining fiber was placed in front of the single mode fiber, and transmitted power was measured by the optical spectrum analyzer. Thus, the first polarizer was calibrated according to its polarization direction and values of transmitted power. The maximum possible power used in the experiment was limited by damage threshold of the first polarizer and also by coupling efficiency of the
We have described modeling, fabrication and high power optical characterization of plasmonic waveguides based on thin gold films embedded in silicon dioxide. The effective index method was applied to calculate the propagation vector of long-range surface plasmon polaritons. The real and imaginary parts of the calculated propagation vector monotonically decreases as the light wavelength increases. The real part of the propagation vector $Re[\beta]$ does not change significantly as the thickness of plasmonic waveguides changes from 15 nm to 45 nm, and the imaginary part of the propagation vector $Im[\beta]$ increases almost by one order of magnitude as the thickness of plasmonic waveguides changes from 15 nm to 45 nm.

Fabrication process of the samples with plasmonic waveguides was described in detail and the quality inspection of waveguides by the scanning electron microscope was discussed. The fabrication error for the width of plasmonic waveguides was within the range of 1 μm.

High power optical characterization of plasmonic waveguides with the width 10 μm, length 3 mm, and thickness 35 nm was performed. The obtained power trends for five waveguides of the same nominal geometry showed a deviation from the linear propagation regime for values of the reference power in the range of 100 mW and above. The differences in coupling loss and heating of waveguides by a high power laser beam could be possible reasons of the power deviation. The quantitative analysis of this phenomenon will be the subject of the further research in this direction.
