8 **Abstract**

9 Platinum-based oxidation catalysts applied for diesel exhaust aftertreatment constitute a significant part of
10 system costs. Effective utilization of platinum is therefore relevant to reduce costs while retaining
11 performance. To this end, the influence of Pt particle size on catalytic activity for CO, hydrocarbon, and NO
12 oxidation was studied. 1 wt.% Pt/Al₂O₃ catalysts were prepared by wet impregnation, drying, and different
13 calcination and thermal treatments, yielding Pt particles with diameters between 1.3 and 18.7 nm, as
14 determined by CO pulse titration and transmission electron microscopy. Activity measurements for CO, C₃H₆,
15 and NO oxidation showed an optimal Pt particle size with respect to the mass based activity between 2-4 nm
16 for all three reactions. From measured turnover frequencies and site statistics of Pt particles, the reactions
17 appear to be mainly catalyzed by terrace atoms, which are most abundant between 2-4 nm. The decrease in
18 catalytic activity for large Pt particles is therefore due to the diminishing Pt surface area, while the decrease in
19 activity for small particles is due to the lack of terrace atoms required for CO, HC, and NO oxidation.

20

21 **1. Introduction**

22 In order to comply with strict emission control regulations [1, 2], modern diesel-driven vehicles are equipped
23 with a catalytic exhaust aftertreatment system to reduce the emission of harmful compounds [3]. The main
24 harmful compounds in a diesel exhaust gas are particulate matter (soot particles), NO_x , CO, and unburnt
25 hydrocarbons (HC), which are converted to CO_2 , H_2O , and N_2 in the aftertreatment system [3]. To achieve this,
26 a modern aftertreatment system typically consists of a diesel oxidation catalyst (DOC), a diesel particulate filter
27 (DPF) and a catalytic NO_x abatement unit further downstream, which consists of a catalyst for the selective
28 catalytic reduction with NH_3 (NH_3 -SCR) combined with an ammonia slip catalyst (ASC) for oxidation of residual
29 NH_3 (see Figure 1).

30

31 **Figure 1.**

32

33 The temperature in the exhaust gas varies, depending on the driving load, but generally lies in the range 200-
34 500°C [3-5]. The combination of a high exhaust gas flow (500-1500 m^3/h) [4] and a limited space for catalysts
35 requires a good catalyst performance at high space velocities while maintaining a low pressure drop at any
36 operating temperature. This is achieved by using catalysts coated on monolith substrates [6]. Furthermore,
37 diesel fuel contains sulfur compounds that when combusted lead to SO_x in the exhaust gas, which can poison
38 and deactivate catalysts during operation [5, 7].

39 The main purpose of the DPF is to capture the soot particles produced in the engine. A common type of filter is
40 the wall-flow filter, in which the exhaust gas is forced through the walls of a monolith, whereby the soot
41 particles are retained [3, 5]. The amount of soot accumulated in the filter increases with time, which results in

42 an undesired pressure drop. Therefore, some regeneration of the filter is required. One method to do this is
43 active regeneration, which entails periodically raising the temperature to above 600°C by injection of post
44 engine fuel, which causes the soot to burn in the oxygen of the exhaust gas [3, 5]. An alternative method is
45 passive regeneration, in which the temperature for soot oxidation is lowered to the normal operating
46 temperature range (350-500°C), which makes a continuous soot oxidation under normal operation possible. To
47 this end, a catalyst for soot oxidation can be applied to the DPF, or NO₂ generated in the DOC can be used for
48 the removal of soot [3, 5].

49 The NO_x abatement system consists of a catalyst for the selective catalytic reduction with NH₃ (NH₃-SCR)
50 combined with an ammonia slip catalyst (ASC) [3]. In the SCR reactions, NO_x is converted by ammonia and
51 oxygen to N₂ and H₂O, with high selectivity [3, 5, 8]. The ammonia is usually provided by injection of urea at the
52 inlet to the SCR unit. In practice, a 5-10% excess of ammonia is used in the NH₃-SCR to improve the
53 performance [8], and the ASC removes the excess ammonia by selective oxidation of ammonia with oxygen to
54 N₂ and water [9]. The presence of NO₂, up to a NO₂/NO_x ratio of 0.5, can also improve the SCR performance, as
55 it allows for the fast-SCR reaction to occur [5, 8].

56 The DOC removes CO and unburnt hydrocarbons in the exhaust gas by oxidation to CO₂ and H₂O. Additionally,
57 the DOC is used to oxidize NO to NO₂, which, as mentioned above, may improve SCR performance and enhance
58 the regeneration of the DPF in systems using passive regeneration [3, 5, 7]. DOC formulations are usually based
59 on Pt supported on metal oxides [5, 7]. Pt is also less sensitive to sulfur, compared to other noble metals and
60 metal oxides [5, 7], making the catalysts robust in environments with small amounts of SO₂ and SO₃. To
61 improve the thermal stability of the DOC and reduce cost, some of the Pt can be replaced by Pd, although Pd is
62 significantly less tolerant to sulfur [5, 7].

63 The support materials used in a DOC are common metal oxides, such as Al₂O₃, SiO₂, CeO₂, TiO₂, ZrO₂, zeolites,
64 or a combination of these [5]. A common support material is γ-Al₂O₃, due to its high surface area (100-200
65 m²/g) and good thermal stability [5]. Therefore, Pt/Al₂O₃ is a good model catalyst for a DOC, and has been used
66 in many studies on Pt catalysts [5, 10-45].

67 A focus area for DOC development is the improvement of low temperature catalytic activity [5, 10, 46]. This is
68 relevant due to the development of more fuel-efficient engines, which result in lower exhaust gas
69 temperatures. In addition, a good low temperature activity also helps reduce the emissions during cold start of
70 the engine, which account for a significant part of the total emissions [3, 4].

71 Another development of the DOC is aimed at cost reduction, either by replacement of the noble metal with
72 cheaper materials or by a more effective use of the noble metals, allowing for a significant reduction of the
73 noble metal content [5, 11, 46]. High catalytic activity and cost-effective utilization of metals is generally
74 associated with small particles (high dispersion) of the active phase [5, 12, 13]. However, small Pt particles
75 show a low turnover frequency (TOF) for CO oxidation [12, 47, 48], HC oxidation [13-18], and NO oxidation [12,
76 19, 20] in studies with a large excess of oxygen relative to reactants, similar to conditions in diesel exhaust
77 aftertreatment, e.g. 10 vol.% O₂, 5 vol.% H₂O, 1000 ppm NO_x, 300 ppm HC, 1000 ppm CO [49]. As a result, an
78 optimum in Pt particle size exists, with a corresponding maximum in catalytic activity.

79 To our knowledge, no studies investigate the influence of Pt particle size on the oxidation of CO, HC, and NO,
80 relevant for the diesel oxidation catalyst, over the same catalysts. Furthermore, few studies include H₂O in the
81 feed gas, which is present in diesel exhaust gas (2-12 vol.% H₂O) and promotes CO oxidation while inhibiting
82 both HC and NO oxidation [7, 21-23]. It was therefore the purpose of this work to investigate the effect of Pt
83 particle size for all three oxidation reactions relevant for the DOC (CO, HC, and NO) under diesel exhaust gas
84 conditions, and identify the respective optimal Pt particle sizes over a broad range of average Pt particle

85 diameters (between 1.3-18.7 nm). The feed gas for activity measurements contained either 2.8 or 7.8 vol.%
86 water vapor and about 10 vol.% O₂ in order to better emulate the catalytic activity under diesel exhaust gas
87 conditions. We show that the oxidation of CO, C₃H₆, and NO all exhibit the same optimum Pt particle size range
88 and that the high mass based catalytic activity does not necessarily coincide with the maximum TOF. We relate
89 these observations to the change in abundance of corner, edge, and terrace atoms.

90 **2. Experimental**

91 **2.1 Catalyst Preparation**

92 To prepare Pt/Al₂O₃ catalysts with different Pt particle sizes, two batches of alumina were impregnated with 1
93 wt.% Pt and dried. The batches were then split into smaller portions before being calcined and thermally
94 treated with different temperatures, gas atmospheres, and durations (see Table 1) in order to obtain a series of
95 nine catalysts with different Pt particle sizes in the range 1.3 to 18.7 nm.

96 For the impregnations, 3 g or 10 g of γ -Al₂O₃ support material (Puralox NWA-155; Sasol; surface area 153.7
97 m²/g) was suspended in an aqueous solution (20 mL solution/g γ -Al₂O₃) of 2.59 mM H₂PtCl₆·6H₂O (ACS reagent;
98 Sigma-Aldrich) under stirring at 50°C in an open beaker [48]. The water evaporated overnight and a dry solid
99 sample remained. The samples were dried further in a horizontal tube furnace (ETF 30-50/15-S; Entech) in 3 NL
100 N₂/min at 80°C for 4 hrs. Subsequent calcination and thermal treatments were done in the same horizontal
101 tube furnace. From the first batch of 3 g, two portions of 1 g each were given the oxidative calcination
102 treatments (O₂/N₂ or H₂O/O₂/N₂) presented in Table 1, yielding samples A and B. The entire second batch of 10
103 g was calcined in a 3 NL/min flow of N₂ at 550°C for 8 hrs and a 1 g portion was taken as sample C. Six 1 g
104 portions of the remaining batch were then exposed to the different thermal treatments presented in Table 1,
105 yielding samples D to I. The use of a chlorine Pt precursor can lead to residual chlorine after calcination that
106 can inhibit catalytic activity [50, 51], but the calcination and thermal treatments applied in this study, together

107 with the presence of H₂O in the reactor feed (Section 2.2.2), will effectively remove chlorine [50, 51].
108 Additionally, a commercial 1 wt.% Pt/Al₂O₃ powder catalyst (205966; Sigma-Aldrich) was used as a benchmark
109 in both fresh, SA1, and thermally treated states, SA2. The properties and thermal treatment of the benchmark
110 catalysts are also presented in Table 1. Table 1 presents an overview of the eleven catalysts studied, indicating
111 their calcination and thermal treatments, as well as the resulting Pt dispersion and average Pt particle diameter
112 calculated from the CO adsorption capacity and verified by TEM (Section 2.2.1).

113

114 **Table 1.**

115

116 The Pt contents of samples A, D, and SA1 were determined by inductively coupled plasma optical emission
117 spectrometry (ICP-OES), and were assumed to be representative of each respective batch. The Pt contents of
118 the three batches were very similar with 0.94 wt.% Pt for the first batch (samples A and B), 0.98 wt.% Pt for the
119 second batch (samples C to I), and 0.92 wt.% Pt for the commercial catalyst (samples SA1 and SA2). These Pt
120 contents were used for subsequent calculations. The eleven catalyst samples were tableted, crushed, and
121 sieved to a fraction of 150-300 μm before further characterization and testing.

122 **2.2 Catalyst Characterization**

123 **2.2.1 Pt Particle Size**

124 The catalysts were analyzed by CO pulse titration (Autosorb-iQ₂; Quantachrome Instruments) to measure CO
125 adsorption capacity, which was used to calculate the Pt dispersion and average Pt particle diameter. The
126 procedure for pretreatment and CO pulse titration was as follows: First, a 0.5 g sample was heated to 100°C
127 (10°C/min) and dried in a 30 Nml/min flow of air for 30 minutes. To remove impurities, the sample was then
128 heated to 350°C (10°C/min) and oxidized in a 30 Nml/min flow of air for 30 minutes. Next, the system was

129 evacuated and the sample cooled to 100°C under vacuum. A 30 NmL/min flow of pure H₂ was then introduced
 130 and the sample was heated to 350°C (10°C/min) and reduced for 120 minutes. The system was then
 131 evacuated and the sample was heated to 550°C (10°C/min) under vacuum and held at 550°C for 120 minutes
 132 to remove any adsorbed water formed from the oxidative and reductive treatments. After cooling to 35°C
 133 under vacuum, CO pulse titration was performed at 35°C using a 279 µL injection loop filled with pure CO and a
 134 30 NmL/min flow of He carrier gas. A thermal conductivity detector (TCD) at the sample cell outlet measured
 135 the CO in the effluent gas and was used to determine the CO adsorption capacity ($N_{CO\ ads}$; mmol CO_{ads}/g_{Pt}). After
 136 CO pulse titration, the sample was heated to 550°C (20°C/min) in a 30 NmL/min flow of He to desorb CO from
 137 the catalyst surface and then cooled to room temperature. For most samples, the characterization was
 138 repeated for a second portion of the catalyst sample and the average of the two measurements was used.
 139 Analyzed samples were subsequently stored at room temperature in ambient air.

140 Assuming that CO adsorbs as a monolayer on the Pt surface atoms, the CO adsorption capacity is directly
 141 proportional to the number of surface Pt atoms ($N_{Pt,S}$; Pt_s atom/g_{Pt}). Using a stoichiometric factor of unity for
 142 the adsorption of CO on Pt [42, 52, 53], the Pt dispersion (D_{Pt} ; %) is calculated as the ratio of surface Pt atoms
 143 to the total number of Pt atoms (N_{Pt} ; Pt atom/g_{Pt}):

$$D_{Pt} = \frac{N_{Pt,S}}{N_{Pt}} \cdot 100\% = \frac{N_{CO\ ads}}{N_{Pt}} \cdot 100\% \quad (1)$$

144 Note that for equation (1), the units of $N_{CO\ ads}$ are simply number of CO molecules/g_{Pt}. The surface-averaged Pt
 145 particle diameter (d_{Pt} ; nm) is calculated from the ratio of Pt volume (V_{Pt} ; Å³ Pt/g_{Pt}) to Pt surface area ($A_{Pt,S}$; Å²
 146 Pt/g_{Pt}), assuming hemispherical Pt particles [52]. The Pt volume is calculated from the Pt density (ρ_{Pt} ; 2.145·10³
 147 g_{Pt}/Å³ Pt [53]), while the Pt surface area is calculated from $N_{Pt,S}$ and the cross-sectional area of one Pt atom
 148 ($A_{Pt,X}$; 8.0 Å² Pt/Pt atom [53]). The equation for the average Pt particle diameter is therefore:

$$d_{Pt} = 6 \cdot \frac{V_{Pt}}{A_{Pt,S}} = \frac{6}{\rho_{Pt} \cdot N_{Pt,S} \cdot A_{Pt,X}} \quad (2)$$

149 Catalyst samples C, D, and I were analyzed using Transmission Electron Microscopy (TEM) to verify the average
150 Pt particle diameters determined from CO pulse titration. A FEI Titan ETEM, running at a 300 kV acceleration
151 voltage with spherical aberration corrector was used to characterize the samples in vacuum at room
152 temperature. The Pt particles observed had a close to circular shape and the Pt particle diameters were
153 therefore measured for a circle that tightly outlined each particle.

154 2.2.2 Activity Measurements

155 The catalysts were tested for the oxidation of CO, HC, and NO. All samples used in the activity measurements
156 were taken from the portion previously used in the CO pulse titration, and which had subsequently been stored
157 at room temperature in ambient air (Section 2.2.1).

158 The CO oxidation activity was measured using a quartz U-tube reactor ($D_i = 3$ mm). The reactor was loaded with
159 a mixture of 10 mg catalyst (150-300 μm) and 50 mg glass beads (212-300 μm), fixed between two plugs of
160 quartz wool. The flow was directed upwards through the catalyst bed, and the temperature was measured with
161 a thermocouple placed inside the reactor at the catalyst bed outlet.

162 To measure the CO oxidation activity, a flow of a 310 NmL/min was used with a feed gas consisting of 240 ppm
163 CO, 2.8 vol. % H_2O , 9.7 vol. % O_2 , and balance N_2 , resulting in a space velocity of 0.021 mol/(g_{cat}·s). Water vapor
164 was added to the gas mixture by bubbling it through a heated water flask at 30°C. The activity measurements
165 were done by heating the catalyst from 40°C to 550°C at a rate of 5°C/min, holding at 550°C for 1 hour,
166 followed by cooling to about 40°C. The cooling rate was set to 5°C/min, which could be followed until about
167 425°C where the cooling rate became limited to the natural cooling of the system. The concentrations of CO
168 and CO_2 in the gas were measured using a continuous gas analyzer (Uras-26; ABB) and the concentration of
169 water was determined using a humidity probe (HC2-IC102; Rotronic), which were both placed after the reactor.

170 The heating and cooling procedures were repeated on the same reactor loading in most cases, to check
171 repeatability of the results.

172 The catalysts were tested for hydrocarbon oxidation in the same manner as described above for CO oxidation,
173 by replacing CO with 145 ppm of propene. Even though a typical diesel exhaust contains a variety of
174 hydrocarbon components, propene (C_3H_6) was used as a model compound for hydrocarbon oxidation,
175 following common practice [5, 10, 11, 23, 24, 46]. The propene conversion was determined based on the CO_2
176 concentrations measured in the product gas, using the same analyzer as for CO oxidation, and the
177 stoichiometry of the reaction equation, forming three CO_2 molecules per C_3H_6 molecule. The CO_2
178 concentrations measured at $550^\circ C$ corresponded to full conversion and these were used to determine the feed
179 concentration of propene, which agreed well with that expected from the set gas flows.

180 For NO oxidation, a different flow reactor setup equipped with a NO_x analyzer was used. A quartz U-tube
181 reactor ($D_i = 6$ mm) was loaded with a mixture of 20 mg catalyst sample (150-300 μm) and 100 mg glass beads
182 (212-300 μm), fixed between two plugs of quartz wool. The gas flowed upwards through the catalyst bed and
183 the temperature was measured with a thermocouple placed inside the reactor at the catalyst bed outlet. The
184 feed gas was 485 ppm NO, 7.8 vol. % H_2O , 9.7 vol. % O_2 , and balance N_2 , with a total flow of 1030 NmL/min,
185 resulting in a space velocity of $SV = 0.035$ mol/($g_{cat} \cdot s$). Water was added to the gas mixture by bubbling a
186 separate flow of N_2 through water at $80^\circ C$. The concentrations of NO and NO_2 were measured using a
187 continuous gas analyzer (Limas11-HW; ABB) and the concentration of water was determined using a humidity
188 probe (HC2-IC102; Rotronic). The procedure for the activity measurements were similar to those used in CO
189 and C_3H_6 oxidation, with heating from $100^\circ C$ to $550^\circ C$ at a rate of $5^\circ C/min$, holding at $550^\circ C$ for 1 hour, and
190 cooling to $100^\circ C$. The cooling was done at an initial rate of $5^\circ C/min$ until the heat loss became controlling at
191 $450^\circ C$ and the cooling rate became lower. For NO oxidation, heating and cooling procedures were repeated a

192 second and third time for two different catalysts, and these showed no significant difference (see Figure S4 in
193 Supplementary Data). Therefore, the repeated cycles were omitted for all other samples in the measurement
194 for NO oxidation.

195 **3. Results**

196 **3.1 Determination of Pt Particle Size**

197 Table 1 presents the CO adsorption capacity measured by CO pulse titration for the different catalysts, as well
198 as the calculated Pt dispersions and average Pt particle diameters. Since Pt dispersion and Pt particle diameter
199 are inversely proportional, we choose to use the Pt particle diameter to describe the dispersion and to obtain a
200 direct reference to the Pt particle size. The data in Table 1 shows that the calcination atmosphere and
201 subsequent thermal treatments with various temperatures, gas atmospheres, and durations can be used to
202 vary the average Pt particle diameter of the catalyst.

203 The smallest Pt particles were obtained for samples A, B, and C that were only calcined at 550°C for 8 hrs, with
204 different gas atmospheres during calcination having a limited effect. Calcination in a wet oxidative atmosphere
205 produced the smallest Pt particles of 1.3 nm (sample A) and the dry oxidative atmosphere yielded slightly
206 larger Pt particles of 1.6 nm (sample B), while calcination in a dry inert atmosphere of N₂ resulted in a small
207 additional increase to 2.1 nm (sample C). These results indicate that Pt particles of 1-2 nm are obtained from
208 the initial calcination of [PtCl₆]²⁻ adsorbed on the surface of γ-Al₂O₃ and can be controlled to some extent by
209 varying the calcination atmosphere between pure N₂ and wet or dry oxidative atmospheres.

210 Pt particles larger than 2 nm were formed by thermally treating catalyst samples that had been prepared by
211 calcination in a dry N₂ atmosphere at 550°C for 8 hrs, corresponding to sample C. The increase in Pt particle
212 diameter was controlled by varying the temperatures, durations, and atmospheres of the thermal treatments.

213 Thermally treating the catalysts in a flow of N₂ at 600°C, 650°C, or 750°C for 12 hrs gave limited increases in Pt
214 particle diameter for samples D (2.7 nm), E (3.0 nm), and F (3.2 nm) in Table 1. Furthermore, increasing the
215 duration of the thermal treatment in a flow of N₂ at 750°C from 12 hrs (sample F) to 48 hrs (sample G) led to a
216 slight increase in Pt particle diameter from 3.0 nm to 4.3 nm. To form the large Pt particles of samples H (7.7
217 nm) and I (18.7 nm), the thermal treatments of catalysts were done in a flow of N₂, O₂, and water vapor at
218 650°C or 750°C for 8 hrs. Similarly, the fresh Sigma-Aldrich catalyst with 2.1 nm Pt particles (sample SA1) was
219 thermally treated in a flow of N₂, O₂, and water vapor at 550°C for 8 hrs, yielding sample SA2 with relatively
220 larger Pt particles of 4.5 nm. Overall, these results indicate that the combination of oxygen, water vapor, and
221 high temperature drives the sintering of Pt particles.

222 Figure 2 shows TEM images for catalyst samples C, D, and I, alongside the number based particle size
223 distributions and the corresponding log-normal distributions. The Pt particles of sample C are mostly between
224 1-4 nm, with an average Pt particle diameter of 2.5 ± 1 nm, while most particles of sample D are between 1-4.5
225 nm with an average Pt particle diameter of 2.8 ± 1 nm. These Pt particle sizes match well with 2.1 and 2.7 nm
226 found from CO pulse titration. For sample I, which has much larger particles, only 19 particles were identified
227 by TEM. The sizes vary from 11-63 nm, but the majority of the particles are between 11 and 22 nm. This is also
228 in good agreement with the results from CO pulse titration, with an estimated average particle size of 18.7 nm.
229 These results indicate that the average Pt particle diameters obtained by CO pulse titration are a good estimate
230 of the Pt particle size.

231

232 **Figure 2.**

233

3.2 Effect of Pt Particle Size on Activity

During the 1st heating cycle to 550°C, changes in the prepared catalysts occur leading to higher activity, while the data for the 1st cooling and 2nd heating/cooling cycles are comparable, indicating that the catalysts have reached a stable state after the initial heating to 550°C (see Figures S1, S2, S3, and S4 of the Supplementary Data). Sintering may occur during the 1st heating and cooling cycle, but the overlaying activity measurements of SA1 (2.1 nm) and SA2 (4.5 nm) for C₃H₆ oxidation (see Figure S2a and S2b), which unlike CO and NO oxidation does not exhibit hysteresis behavior [54], indicate that sintering is negligible for samples with Pt particles of 2.1 nm or larger. The samples with Pt particles smaller than 2.1 nm, such as A (1.3 nm) and B (1.6 nm), will still have the smallest Pt particles after the 1st heating and cooling cycle, and sintering will at most shift the particle sizes partly towards 2.1 nm. This gives a small margin of uncertainty in the exact Pt particle size of A and B used in the following presentation of results.

The activity measurements from the 1st cooling cycles for CO oxidation, C₃H₆ oxidation, and NO oxidation, are shown in Figure 3. All catalysts are active for each of the three oxidation reactions, but clear differences in the temperatures at which the rate of each reaction becomes appreciable are observed. For the most active catalysts, this occurs in the range of 45-65°C for CO oxidation, 100-130°C for C₃H₆ oxidation, and 150-250°C for NO oxidation.

Figure 3.

Figure 3a shows the CO conversion during the 1st cooling cycle. Above 120°C, the catalysts all maintain complete oxidation of CO to CO₂. For the catalysts with average particle diameters of 1.6 (B), 2.1 (C), 2.1 (SA1),

255 2.7 (D), and 3.2 nm (F), the CO oxidation starts at the lowest temperature and these are therefore the most
256 active. The catalysts with smaller and larger particles all require a higher temperature for CO oxidation and are
257 therefore less active, pointing to an optimal Pt particle size for CO oxidation. The oscillatory behavior seen for
258 sample C (2.1 nm) in Figure 3a and for sample F (3.0 nm) in Figure S1c of the Supplementary Data, is known for
259 CO oxidation over Pt and the phenomena associated with this have been thoroughly discussed elsewhere [25,
260 26, 55], and is beyond the scope of this article.

261 A similar trend is observed for C₃H₆ oxidation. In Figure 3b, the C₃H₆ conversion during the 1st cooling cycle
262 shows that the onset temperature of the reaction is higher than for CO oxidation. Below 100°C, no significant
263 C₃H₆ conversion is obtained for any catalyst and above 180°C full conversion of C₃H₆ is reached. The catalysts
264 with Pt particles diameters of 2.1 (SA1), 2.7 (D), and 3.2 nm (F) were the most active, while smaller and larger
265 Pt particles resulted in a lower catalytic activity, indicating an optimum in Pt particle size for C₃H₆ oxidation as
266 well.

267 For NO oxidation, the data looks quite different compared to CO and C₃H₆ oxidation. Figure 3c shows the NO
268 conversion during the 1st cooling cycle with a maximum in conversion between 325-450°C. This maximum is
269 due to the NO₂ decomposition imposed by the thermodynamic equilibrium of the reaction $\text{NO} + \frac{1}{2} \text{O}_2 \leftrightarrow \text{NO}_2$,
270 which shifts toward $\text{NO} + \text{O}_2$ with increasing temperature, resulting in a lower NO conversion at higher
271 temperatures. The equilibrium NO conversion is indicated by the dashed black line in Figure 3c. Below 300°C,
272 where the contribution of the reverse reaction is limited, there are significant differences in catalytic activity
273 observed. The most active catalysts have an average Pt particle diameter of 2.1 (SA1), 2.7 (D), 3.0 (E), and 4.3
274 nm (G). This indicates that there is an optimal particle size for NO oxidation, like for CO and C₃H₆ oxidation.

275 In order to better visualize the observed trends of activity with the Pt particle diameter, we used the
276 temperature at which 50% conversion was measured (T_{50}) for CO oxidation and C₃H₆ oxidation. For NO

277 oxidation, not all catalyst samples reached 50% conversion and therefore, the temperature for 20% conversion
278 (T_{20}) was used instead. A lower T_{50} or T_{20} corresponds to a higher activity; the choice of conversion level is
279 arbitrary and different choices did not lead to significantly different trends. Figure 4 shows the observed trends
280 for the T_{50} and T_{20} with the Pt particle size, derived from 1st cooling and 2nd heating/cooling cycles for CO, C₃H₆,
281 and NO oxidation. In Figure 4, for catalysts with repeated CO pulse titration measurements, the end points of
282 the error bars indicate the individual Pt particle sizes calculated from the repetitions.

283

284 **Figure 4.**

285

286 For CO oxidation, in Figure 4a, the catalysts with an average Pt particle diameter of 1.6 (B), 2.1 (C), 2.1 (SA1),
287 2.7 (D), and 3.2 nm (F) show the lowest T_{50} at around 60 °C, and therefore are the most active catalysts for CO
288 oxidation. The T_{50} for smaller particles is about 75°C for 1.3 nm (A) and about 110 °C for very large particles of
289 18.7 nm (I), indicating a significantly lower activity for these catalysts. A similar trend is observed for C₃H₆
290 oxidation in Figure 4b; catalysts with an average Pt particle diameter of 2.1 (SA1), 2.7 (D), and 3.2 nm (F)
291 achieve the lowest T_{50} of about 135°C. The T_{50} for both the smallest particles of 1.3 nm (A) and largest of 18.7
292 nm (I) are about 148°C. For NO oxidation, in Figure 4c, the T_{20} is lowest for samples with Pt particle diameters
293 of 2.1 (SA1), 2.7 (D), 3.0 (E), and 4.3 nm (G) at about 220°C. The largest Pt particles of 18.7 nm (I) show an
294 increase in T_{20} to 275°C, related to a decrease in activity. In contrast, decreasing the Pt particle diameter to 1.3
295 nm (A) results in a very significant increase of T_{20} to 380°C and therefore a significant decrease in the catalytic
296 activity. These data show that the highest activity for all three reactions relevant for application of Pt as diesel
297 oxidation catalyst is obtained for catalysts with an average Pt particle diameter in the range of 2-4 nm.

298 To check whether the loss of activity for larger particles is due to the loss of Pt surface area, the turnover
299 frequency (TOF = mol/(s·mmol Pt_s)) was determined for the CO, C₃H₆, and NO oxidation reactions. If the loss of
300 surface area solely causes the loss of activity for larger Pt particles, then the TOF should remain constant. The
301 TOF was calculated from the mass based rate of reaction ($r' = \text{mol}/(\text{s} \cdot \text{g}_{\text{Pt}})$) and the number of surface Pt atoms,
302 $N_{\text{Pt},S}$ per gram platinum, as derived from the CO adsorption capacity, $N_{\text{CO ads}}$. The rate of reaction rate, r' , was
303 evaluated for each reaction at the temperature at which 10% conversion was reached for the most active
304 catalyst, to ensure differential conditions. The TOF was therefore evaluated at 50°C for CO oxidation (10% CO
305 conversion for sample D (2.7 nm)), at 105°C for C₃H₆ oxidation (10% conversion for sample F (3.2 nm)), and
306 190°C for NO oxidation (10% conversion for sample SA1 (2.1 nm)).

307 The TOFs for CO, C₃H₆, and NO as function of average Pt particle diameter are presented in Figure 5 along with
308 the rates of reaction and CO adsorption capacities. From Figure 5a, the TOF for CO oxidation increases from 1.3
309 (A) to 2.7 nm (D), achieving the maximum TOF value for 2.7 nm (D). An increase in the Pt particle diameter to
310 4.5 (SA2) and 18.7 nm (I) causes a steep decrease in the TOF for CO oxidation. Furthermore, the maximum in
311 rate of reaction for CO oxidation coincides with the maximum TOF at a Pt particle size of 2.7 nm (D). For the
312 C₃H₆ oxidation TOF in Figure 5b, the TOF increases with the Pt particle diameter from 1.3 (A) to 3.2 nm (F). For
313 larger Pt particles, the TOF continues to increase slightly, unlike the TOF for CO oxidation. Although the highest
314 C₃H₆ TOF value is observed for 18.7 nm (I) Pt particles, the maximum mass based rate of reaction is measured
315 for the samples with a Pt particle size between 2-4 nm. Similarly, the TOF for NO oxidation in Figure 5c
316 increases with a change in the Pt particle diameter from 1.3 (A) to 2.1 (SA1) - 2.7 nm (D), and has significantly
317 higher values for 7.7 nm (H) and 18.7 nm (I). For C₃H₆ and NO oxidation, the maximum TOF does therefore not
318 correspond to the maximum in the mass based rate of reaction for 2-4 nm Pt particles. The fact that the TOF
319 for C₃H₆ and NO oxidation does not decrease significantly for large particles is consistent with a loss of activity
320 due to a decrease of Pt surface.

321 4. Discussion

322 An optimum in the rate of reaction for the oxidation of CO, C₃H₆, and NO was observed for Pt particle
323 diameters of 2-4 nm for all three reactions. For application as a DOC, this means that tuning the Pt particle size
324 to this range enhances the CO, HC (C₃H₆), and NO oxidation reactions. However, the TOF does not follow this
325 trend. For CO oxidation, the maximum in TOF occurs for 2-3 nm Pt particles [12], while the TOF increases with
326 Pt particle size for both HC oxidation [13-18] and NO oxidation [12, 19, 20]. The observation that the optimum
327 particle diameter coincides with a maximum in TOF for CO oxidation but not for HC and NO oxidation indicates
328 that the reasons for the maxima in rates of reaction are different.

329 A phenomenon occasionally used to explain particle size effects is the transition from a metallic to a non-
330 metallic behavior that occurs when Pt particles become sufficiently small, since the band structure responsible
331 for the metallic character of Pt cannot fully develop for very small particles [30, 31, 56, 57]. In general, this
332 effect is most significant for clusters and particles below 1 nm in size for Pt/γ-Al₂O₃ [30, 57]. The smallest
333 average Pt particle diameter considered in this work is 1.3 nm, and therefore we expect this effect to have a
334 minor contribution to the lower TOF for the small Pt particles in this study. Instead we focus on the changes in
335 the distribution of types of surface Pt atoms with variation in Pt particle sizes, and the resulting influence on
336 catalyst behavior.

337 A change in Pt particle size affects the relative number of corner, edge, and terrace atoms, and since the
338 contribution of these surface Pt atoms to the catalytic activity can be different, the catalytic activity becomes
339 dependent on the Pt particle size. Figure 6 shows the calculated total and relative abundance of corner, edge,
340 and terrace Pt atoms as a function of the Pt particle diameter for a 1 wt.% Pt loading, with the assumption that
341 the Pt particles have a truncated octahedral shape and are supported on a (111)-plane. The calculations are
342 done as outlined in the supplementary material of reference [58]. Figure 6a shows that Pt particles smaller

343 than 4 nm have an appreciable number of edge and corner atoms, and that the number of terrace atoms starts
344 to decrease, while the large Pt particles are dominated by terrace atoms. A comparison of Figure 6a with
345 Figures 5b and 5c indicate that the TOFs for C₃H₆ and NO oxidation follow the relative amount of Pt terrace
346 atoms, and the highest C₃H₆ and NO TOFs are obtained for large Pt particles, as previously reported [5, 12-20].
347 As a consequence, the maximum rates for HC and NO oxidation coincide with the maximum total number of
348 terrace atoms, which occurs in the range of 2-4 nm. The decrease in reaction rate for large particles is then due
349 to a lower number of Pt atoms in terraces.

350

351 **Figure 6.**

352

353 In contrast to HC and NO oxidation, the oxidation of CO exhibits a maximum in TOF at 2.7 nm and very low TOF
354 for large Pt particles. Particles of 2.7 nm in diameter have a high amount of edge atoms, but the maximum
355 amount of edge atoms is found at about 1.5 nm. If CO oxidation were governed by edge sites alone, then we
356 should have found the highest CO oxidation activity for catalyst B, with a particle size of 1.6 nm. This indicates
357 that edges are not the only source of catalytic activity for CO oxidation, and the maximum in TOF occurring
358 close to the maximum in terrace atoms points to a contribution of the terrace atoms as well. The reason for the
359 lower CO-oxidation activity of large Pt atoms is then the lack of edge sites, rather than the loss of terrace sites
360 as was the case for HC and NO oxidation.

361 From the discussion above, it follows that the role of the terrace sites in HC and NO oxidation is different
362 compared to CO oxidation. The higher activity of the terraces for the oxidation of NO has been ascribed to a
363 reaction of O₂ with vacancies on terraces nearly saturated with O* adatoms [19]. As terraces bind the oxygen

364 atoms weaker, the vacancies are easier to create on terraces, thus favoring the NO oxidation. For hydrocarbon
365 oxidation, the weakly bound O* species on terrace atoms are needed for the removal of H atoms in
366 hydrocarbon oxidation [18]. For CO oxidation, the presence of edge sites is important, and the CO oxidation
367 occurs preferentially between oxygen chemisorbed to step sites and CO adsorbed to terrace atoms [59-62].
368 The CO oxidation reaction then becomes dependent on the presence of both terrace and edge sites.

369 An alternative explanation for the importance of edge sites in CO oxidation is the effect of water on the CO
370 oxidation reaction. By using isotopically labeled oxygen, it was shown that water is actually the main source of
371 the oxygen in CO₂ in the low temperature CO oxidation over Pd/Al₂O₃ in a wet feed gas [63]. This suggests that
372 CO₂ is in fact formed from CO and water in a water gas shift reaction, rather than by an oxidation of CO with
373 oxygen. Pt is also an efficient catalyst for water gas shift [64], and therefore the water gas shift reaction can
374 also occur in CO oxidation under the wet conditions in a diesel exhaust gas. The water gas shift reaction
375 requires dissociation of the water molecule to form adsorbed OH fragments, which then react with CO to form
376 CO₂. DFT calculations indicate that this step is difficult on a Pt(111) surface and large particles, but becomes
377 easier with decreasing Pt particle size due to an increase in edge and corner atoms [65, 66]. Furthermore, the
378 enhanced O₂ dissociation on the edge sites may actually be beneficial for the dissociation of H₂O, since H₂O can
379 readily react with O* in the presence of an extra H₂O to facilitate the formation of OH* ($\text{H}_2\text{O}^* + \text{O}^* + \text{H}_2\text{O}^* \rightarrow 2$
380 $\text{OH}^* + \text{H}_2\text{O}^*$) [67-69]. The subsequent formation of COOH* from CO* and OH* occurs more easily on terrace
381 atoms (0.56 eV activation energy on Pt(111)) compared to step atoms (1.4 eV activation energy on Pt(211))
382 [70], and the final step, in which CO₂ is formed, occurs readily through the transfer of H from COOH* to a
383 neighboring OH*, forming H₂O [69]. This means that the reaction pathway depends on both the edge atoms -
384 for the dissociation of O₂ and H₂O - and on the terrace atoms for formation of COOH* [67, 68], in agreement
385 with our observation that the maximum rate of CO oxidation is observed for a particle size that lies between
386 the sizes corresponding to the maximum amount of edge and terrace atoms. In HC and NO oxidation, a similar

387 reaction path with water does not exist, and consequently, water has an inhibitive effect on HC and NO
388 oxidation [7, 21-23].

389 The lower activity for small Pt particles below 2 nm can also be understood from the site distribution shown in
390 Figure 6. Small particles contain mostly edge and corner atoms, and the lack of terrace atoms, which are
391 required for the CO, HC, and NO oxidation reactions, then results in the low activities. Figure 6 shows that
392 particles smaller than 2 nm contain less terrace atoms, which is in good agreement with our observation that
393 both the activity and TOF are lower for catalysts with Pt particle size below 2 nm. Furthermore, small Pt
394 particles are also more easily oxidized than large particles [40, 41, 68, 71] and, consequently, the reduction of
395 small Pt particles becomes harder. This is indicated by the 100-150 °C higher reduction temperature of oxidized
396 Pt particles of 1.5 nm in size compared to for Pt particles of 4 nm [40, 71]. However, as oxygen always is
397 present under the typical conditions in a DOC, it is difficult to distinguish whether the lower activity is the result
398 from a change in chemistry due to oxide formation, or due to the loss of active sites, as both effects always will
399 occur simultaneously.

400 According to the discussion above, the optimal Pt particle size of 2-4 nm for the oxidation of CO, C₃H₆, and NO
401 over Pt/Al₂O₃ catalysts in the presence of water is mainly determined by the number of terrace sites. For the
402 oxidation of C₃H₆ and NO, Pt particles larger than approximately 4 nm are less active due to the loss in surface
403 area, but the TOF remains more or less constant. For CO oxidation, edge sites also play a role, and therefore
404 the larger particles are less active due to the loss of edge sites, resulting in a lower TOF for large particles. The
405 lower activity and TOF for the oxidation CO, C₃H₆ and NO for particles smaller than 2 nm can be understood by
406 the lower amount of terrace sites in such particles, although the effects of a higher stability of Pt oxide in small
407 particles are possible and indistinguishable.

408 **5. Conclusion**

409 The optimum Pt particle size for the oxidation of CO, C₃H₆, and NO was investigated through preparation,
410 characterization, and activity measurements of a range of 1 wt.% Pt/Al₂O₃ catalysts. The catalysts were
411 prepared by wet impregnation and different calcination and thermal treatments, in order to obtain a range of
412 samples with Pt particles diameters of 1.3-18.7 nm, as determined from CO pulse titration and verified by TEM.
413 Comparison of catalytic activity as a function of temperature and Pt particle diameter showed that the greatest
414 catalytic activities were achieved for Pt particle diameters between 2-4 nm for all three reactions. The results
415 indicate that for C₃H₆ and NO oxidation, terrace surface atoms achieved the highest TOF values and were
416 identified as the most active type of surface atoms, with the greatest abundance of terrace atoms
417 corresponding to the optimum Pt particle diameter between 2-4 nm. With increasing Pt particle size, the rate
418 of reaction decreases due to the significant decrease in Pt surface area relative to the slight increase in TOF.
419 For CO oxidation, the particle size dependency is more complex and a maximum in TOF was observed for 2.7
420 nm, suggesting that CO oxidation under diesel exhaust conditions is dependent on both terrace and edge
421 atoms. The dependence of CO oxidation on both terrace and edge atoms results in an optimum TOF between
422 2-4 nm, since the absence of terraces in small particles or edges in large particles effectively decreases the
423 reaction rate of the individual reactions.
424 Based on the results in this study, a diesel oxidation catalyst based on Pt/Al₂O₃ with Pt particles between 2 and
425 4 nm in diameter is optimal for CO, hydrocarbon, and NO oxidation in the presence of water.

426 **6. Acknowledgements**

427 The authors would like to thank Ian Joseph Allen (Technical University of Denmark) for catalyst characterization
428 with TEM and Henrik Teglberg (Technical University of Denmark) for assistance in catalyst preparation. The
429 financial support from Innovation Fund Denmark under grant number 103-2012-3 is gratefully acknowledged.

432 **Figure 1:** Diagram of a typical diesel exhaust aftertreatment system consisting of a diesel oxidation catalyst
433 (DOC), a diesel particulate filter (DPF), the injection of urea or NH_3 , a catalyst for the selective catalytic
434 reduction of NO_x with NH_3 (NH_3 -SCR), and an ammonia slip catalyst (ASC).

435

436 **Table 1:** Overview of catalysts prepared. Catalysts from the first batch (A-B) were given oxidative calcinations at
437 550°C for 8 hours, and no further thermal treatment. Catalysts from the second batch (C-I) were all initially
438 calcined in a flow of N_2 at 550°C for 8 hours, and most samples (D-I) were subsequently given thermal
439 treatments with different temperatures, atmospheres, and durations. 1 wt.% $\text{Pt}/\text{Al}_2\text{O}_3$ catalysts from Sigma-
440 Aldrich, fresh (SA1) or thermally treated (SA2), were also considered. The atmospheres for calcination and
441 thermal treatments were pure N_2 , 10 vol.% O_2 in N_2 , or 3 vol.% H_2O and 10 vol.% O_2 in N_2 . The CO adsorption
442 capacity, Pt dispersion, and average Pt particle size were determined by CO pulse titration. Average Pt particle
443 diameters determined with TEM for samples C, D, and I are given in parentheses.

444

445 **Figure 2:** Left column: TEM images for samples C, D, and I. Right column: Number based Pt particle size
446 distributions based on TEM images and corresponding log-normal distributions for samples C, D and I. μ is the
447 number average Pt particle diameter with a standard deviation of σ .

448

449 **Figure 3:** Conversion curves for 1st cooling cycles. a) CO oxidation: 10 mg catalyst, 310 NmL/min gas flow, $\text{SV} =$
450 $0.021 \text{ mol}/(\text{g}_{\text{cat}}\cdot\text{s})$, 240 ppm CO, 2.8 vol.% H_2O , 9.7 vol.% O_2 , and balance N_2 . b) C_3H_6 oxidation: 10 mg catalyst,
451 310 NmL/min gas flow, $\text{SV} = 0.021 \text{ mol}/(\text{g}_{\text{cat}}\cdot\text{s})$, 145 ppm C_3H_6 , 2.8 vol.% H_2O , 9.7 vol.% O_2 , and balance N_2 . c) NO
452 oxidation: 20 mg catalyst, 1030 NmL/min gas flow, $\text{SV} = 0.035 \text{ mol}/(\text{g}_{\text{cat}}\cdot\text{s})$, 485 ppm NO, 7.8 vol.% H_2O , 9.7
453 vol.% O_2 , and balance N_2 . The dashed black line is the thermodynamic equilibrium for NO and NO_2 .

454 **Figure 4:** Temperatures for 50% conversion (T_{50}) for 1 wt.% Pt/Al₂O₃ with varying Pt particle diameters during a)
455 CO oxidation: 10 mg catalyst, 310 NmL/min gas flow, SV = 0.021 mol/(g_{cat}·s), 240 ppm CO, 2.8 vol.% H₂O, 9.7
456 vol.% O₂, and balance N₂, and b) C₃H₆ oxidation: 10 mg catalyst, 310 NmL/min gas flow, SV = 0.021 mol/(g_{cat}·s),
457 145 ppm C₃H₆, 2.8 vol.% H₂O, 9.7 vol.% O₂, and balance N₂. c) Temperatures for 20% conversion (T_{20}) for NO
458 oxidation: 20 mg catalyst, 1030 NmL/min gas flow, SV = 0.035 mol/(g_{cat}·s), 485 ppm NO, 7.8 vol.% H₂O, 9.7
459 vol.% O₂, and balance N₂. The end points of the error bars indicate the individual Pt particle sizes for catalysts
460 with repeated CO pulse titration measurements. For all three graphs, the black lines are to help guide the eye.

461

462 **Figure 5:** The turnover frequency (TOF, red) for varying Pt particle diameters calculated for a) CO oxidation at
463 50°C, b) C₃H₆ oxidation at 105°C, and c) NO oxidation at 190°C from the rate of reaction (r' , blue) and CO
464 adsorption capacity ($N_{CO\ ads}$, green), which is directly proportional to the number of available Pt atoms. The
465 measurements are for the 1st cooling cycle. Solid lines for rate of reaction (r' , blue) and turnover frequency
466 (TOF, red) are to help guide the eye.

467

468 **Figure 6:** Calculated total and relative number of corner, edge and terrace atoms for Pt particles of different
469 sizes, assuming a truncated octahedron geometry and perfectly uniform particle size distributions. Bottom
470 panel: The total number of different Pt atoms per gram Pt (mmol Pt atoms/g_{Pt}). Top panel: The relative number
471 of corner, edge, and terrace Pt atoms per specific Pt particle size, given as a percentage.

472 Figure 1.

486 The Effect of Pt Particle Size on the
487 Oxidation of CO, C₃H₆, and NO over Pt/Al₂O₃
488 for Diesel Exhaust Aftertreatment

493 **A.1 Supplementary Data**

494 Figures S1 and S2 show the activity measurements for CO and C₃H₆ oxidation over the 1 wt.% Pt/Al₂O₃ catalysts
495 with varying Pt particle size for the a) 1st heating cycle, b) 1st cooling cycle, c) 2nd heating cycle, and d) 2nd
496 cooling cycle. The activity measurements during the 1st heating cycle behave significantly different compared to
497 the subsequent cooling and heating phases. This suggests that the catalysts undergo a change during the
498 heating cycle shown in Figure S1a and Figure S2a, and that the catalysts reach a stable state after the initial
499 heating to 550°C, indicated by the subsequently similar CO conversion curves.

500

501 **Figure S1**

502

503 **Figure S2**

504 Figure S3 shows the NO oxidation activity measurements for the a) 1st heating cycle and the b) 1st cooling cycle.
505 Similarly to CO and C₃H₆ oxidation, the 1st heating curve for NO oxidation is significantly different than the
506 subsequent cooling curve, indicating again a change in the catalyst.

507

508 **Figure S3.**

509

510 For NO oxidation, we decided to exhibit two different catalyst samples to repeated heating and cooling cycles
511 in order to verify the stability of the catalysts tested. Figure S4 shows repeated heating and cooling cycles for 1
512 wt.% Pt/Al₂O₃ catalysts with an average Pt particle diameter of a) 1.3 nm (tested with four heating and cooling
513 cycles) and b) 2.7 nm (tested with three heating and cooling cycles). The catalysts were prepared using the
514 methods described in Section 2.1, with 1.3 nm Pt particles prepared using the same procedure as for sample A,
515 while the sample with 2.7 nm Pt particles used the same procedure as for sample C, but with a calcination
516 temperature of 750°C and a duration of 12 hours. Figure S4 shows again the significant change in catalytic
517 activity from the 1st heating cycle to the subsequent cooling and heating cycles, for both samples. The
518 subsequent cooling and heating cycles show a stable catalytic activity, with only limited changes occurring
519 between the cooling cycles. Based on this we chose to limit the NO oxidation activity measurements to one
520 heating and cooling cycle and used the activity measurement during the 1st cooling curve to compare catalytic
521 activity of samples.

522

523

524

525 **Figure S1:** CO oxidation conversion curves for the a) 1st heating cycle, b) 1st cooling cycle, c) 2nd heating cycle,
526 and d) 2nd cooling cycle. Operating conditions: 10 mg catalyst (150-300 μm), 50 mg inert glass beads (212-300
527 μm), 310 NmL/min gas flow, $\text{SV} = 0.021 \text{ mol}/(\text{g}_{\text{cat}}\cdot\text{s})$, 240 ppm CO, 2.8 vol.% H₂O, 9.7 vol.% O₂, and balance N₂.

528

529 **Figure S2:** C₃H₆ oxidation conversion curves for the a) 1st heating cycle, b) 1st cooling cycle, c) 2nd heating cycle,
530 and d) 2nd cooling cycle. Operating conditions: 10 mg catalyst (150-300 μm), 50 mg inert glass beads (212-300
531 μm), 310 NmL/min gas flow, $\text{SV} = 0.021 \text{ mol}/(\text{g}_{\text{cat}}\cdot\text{s})$, 145 ppm C₃H₆, 2.8 vol.% H₂O, 9.7 vol.% O₂, and balance N₂.

532

533 **Figure S3:** NO oxidation conversion over 1 wt.% Pt/Al₂O₃ with for a) 1st heating cycle and b) 1st cooling cycle.
534 Operating conditions: 20 mg catalyst (150-300 μm), 100 mg inert glass beads (212-300 μm), 1030 NmL/min gas
535 flow, $\text{SV} = 0.035 \text{ mol}/(\text{g}_{\text{cat}}\cdot\text{s})$, 485 ppm NO, 7.8 vol.% H₂O, 9.7 vol.% O₂, and balance N₂.

536

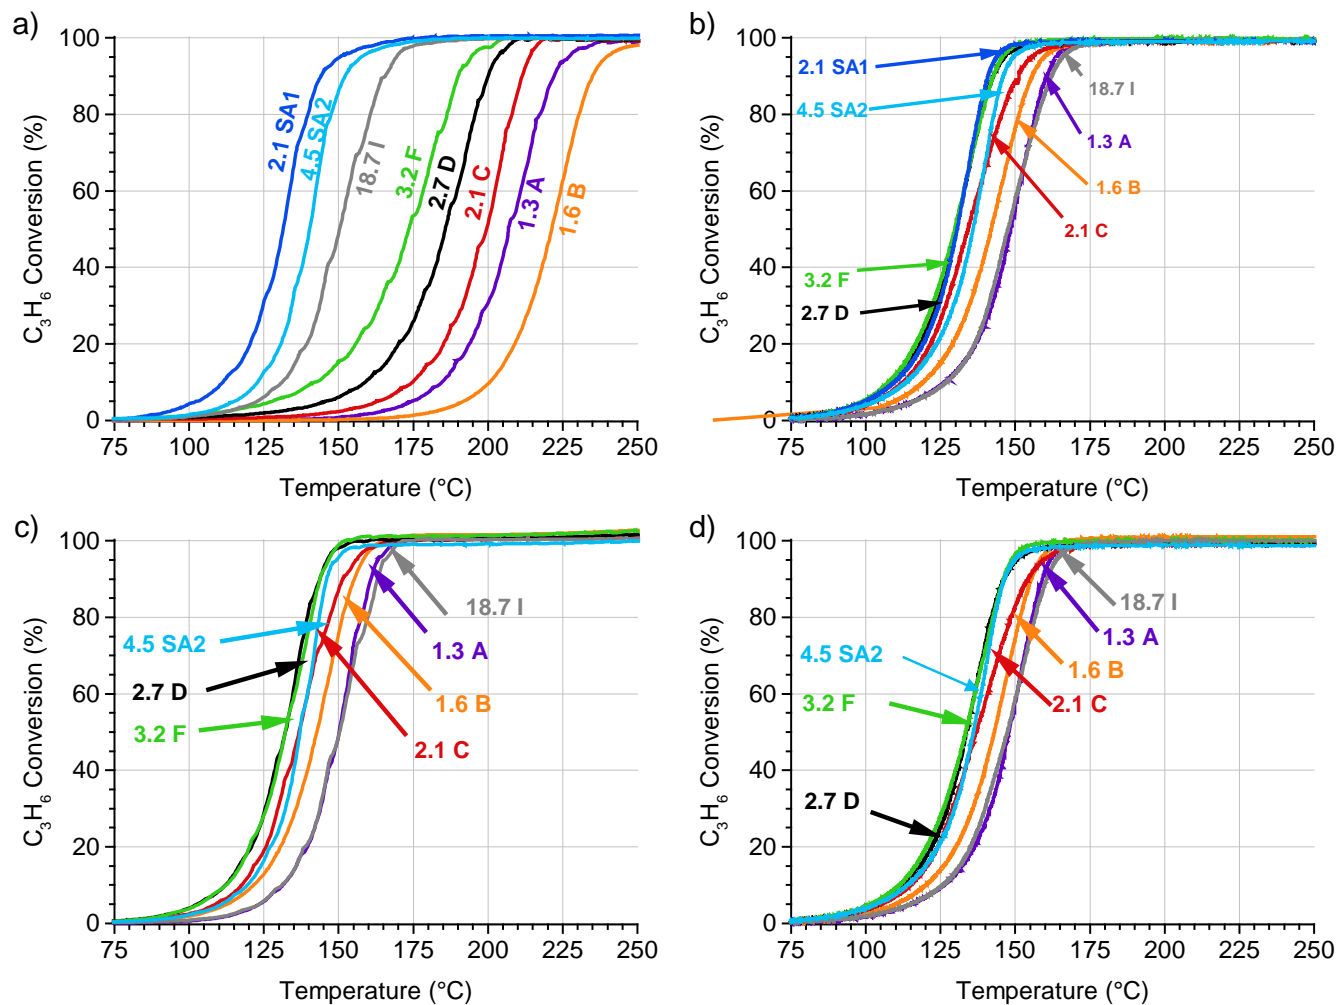

537 **Figure S4:** NO oxidation conversions over 1 wt.% Pt/Al₂O₃ for several heating and cooling cycles with average Pt
538 particle diameters of a) 1.3 nm and b) 2.7 nm. Operating conditions: 20 mg catalyst (150-300 μm), 100 mg inert
539 glass beads (212-300 μm), 1030 NmL/min gas flow, $\text{SV} = 0.035 \text{ mol}/(\text{g}_{\text{cat}}\cdot\text{s})$, 485 ppm NO, 7.8 vol.% H₂O, 9.7
540 vol.% O₂, and balance N₂.
