Considerable research is being undertaken in the quest to reach consensus on the mechanism of high-temperature superconductivity [1] and the associated pseudogap phase [2] in copper-oxide materials (cuprates). The energy scales governing the physical properties of these layered materials therefore remain of great interest. It is known that these materials are characterized by a strong superexchange interaction \( J_1 = 4t^2/U \) where \( t \) is the nearest-neighbor hopping integral and \( U \) is the Coulomb interaction. To first order, this energy scale sets the bandwidth of the spin-excitation spectrum. Resonant inelastic x-ray scattering (RIXS) experiments [3] have demonstrated that this bandwidth stays roughly unchanged across the entire phase diagram [4,5] of hole doped cuprates. It has also been demonstrated that the cuprates belong to a regime (of \( t \) and \( U \)) where the second-order exchange interaction \( J_2 = 4t^3/U^2 \) contributes to a spin-excitation dispersion along the antiferromagnetic zone boundary (AFZB) [6–9]. Moreover, it is known from band-structure calculations and experiments that the next-nearest-neighbor (diagonal) hopping integral \( t' \) constitutes a non-negligible fraction of \( t \) [10]. Empirically [11], the superconducting transition scales with the ratio \( t'/t \) whereas Hubbard-type models predict the opposite trend [12,13]. As a resolution, a two-orbital model—in which hybridization of \( d_{x^2-y^2} \) and \( d_{x^2-y^2} \) states suppresses \( T_c \) and enhances \( t' \)—has been put forward [14].

Here, we address the question as to how \( t' \) influences the spin-excitation spectrum at, and in the vicinity of, the antiferromagnetic zone boundary. We have therefore studied—using the RIXS technique—slightly underdoped compounds of \( \text{La}_{2-x}\text{Sr}_x\text{CuO}_4 \) (LSCO) with \( x = 0.12 \) and 0.145. Even though the system is not antiferromagnetically ordered at these dopings, we quantify the zone-boundary dispersion \( \omega(\vec{q}) \) by \( E_{ZB} = \omega(\vec{q}) - \omega(\vec{q})_{\parallel} \). In doped LSCO a strongly enhanced zone-boundary dispersion is observed. As will also be shown, within the \( t - t' - t'' - U \) Hubbard model, one generally expects that the zone-boundary dispersion scales with \( t'/t \) with a prefactor that depends on \( U/t \). The Fermi-surface topology of LSCO, obtained from photoemission spectroscopy and analyzed with a single-band tight-binding model, suggests that \( t' \) decreases with increasing doping [10,15]. The Hubbard model is thus within a single-band picture not consistent with the experiment. However, using a two-orbital model, hybridization between \( d_{x^2-y^2} \) and \( d_{x^2-y^2} \) states enhances \( t' \) [14]. This provides a satisfactory description of the zone-boundary dispersion. We thus conclude that the two-orbital model [14] is necessary to understand the spin-excitation spectrum of doped LSCO.

II. METHOD

The RIXS experiment was carried out at the Advanced Resonant Spectroscopies (ADDRESS) beamline [16,17] at the Swiss Light Source (SLS) with the geometry shown in Fig. 1(h). The newly installed CARVING RIXS manipulator allowed us to probe the full kinematically accessible reciprocal space \( \vec{q} = (h,k) \) with a scattering angle of 130°. Incident photons with an energy of 933 eV (at the Cu L_{3-edge}
resonance) gave an instrumental energy and momentum resolution of 132 meV and 0.01 Å\(^{-1}\) respectively. Both the linear horizontal (LH) and linear vertical (LV) light polarizations were applied to probe high-quality single crystals of La\(_{2-x}\)Sr\(_x\)CuO\(_4\) with \(x = 0.12\) and 0.145 \((T_c = 27\) and 35 K respectively). These crystals were grown by the traveling floating zone method \[18\] and previously characterized in neutron [19–21] and muon spin-resonance (\(\mu\)SR) [22] experiments. Ex situ prealignment of the samples was carried out using a Laue diffractometer. The samples were cleaved in situ using a standard top-post technique and all data were recorded at \(T = 20\) K. Although being in the low-temperature orthorhombic (LTO) crystal structure, tetragonal notation \(a = b \approx 3.78\) Å \((c \approx 13.2\) Å) is adopted to describe the in-plane momentum \((h,k)\) in reciprocal-lattice units \(2\pi/a\).

III. RESULTS

Figures 1(a)–1(c) display grazing exit RIXS spectra of La\(_{1.98}\)Sr\(_{0.12}\)CuO\(_4\) recorded with incident LH light polarization along three trajectories as indicated in Fig. 1(g). Data along the same directions but measured with incident LV polarization are shown in Figs. 1(d)–1(f). Besides the strong elastic scattering found at the specular condition \((Q = (0,0))\), an elastic charge-density-wave (CDW) reflection is found—consistent with existing literature \[23,24\]—along the \((h,0)\) direction at \(Q_{\text{CDW}} = (\delta_1, \delta_2)\) with \(\delta_1 = 0.24(6)\) and \(\delta_2 \simeq 0.01\). The charge order reflection serves as a reference point, demonstrating precise alignment of the crystal. For grazing exit geometry, it has previously been demonstrated that spin excitations are enhanced in the LH channel \[4\].

In Figs. 2(a) and 2(b), selected raw RIXS spectra recorded with LH polarization are shown for momenta near the \((1,0)\) and \((1,1/2)\) points. The low-energy part of the spectrum consists of three components: a weak elastic contribution, a smoothly varying background, and a damped spin excitation. It is immediately clear that the excitations near \((1,1/2)\) are significantly softened compared to those observed around the \((1,0)\) point [see Figs. 2(a) and 2(b)].

For a more quantitative analysis of the magnon dispersion, we modeled the elastic line with a Gaussian for which the standard deviation \(\sigma = 56\) meV was set by the instrumental energy resolution. A second-order polynomial function is used to mimic the background. Finally, to analyze the spin excitations we adopted the response function of a damped harmonic oscillator \[4,26,27\]:

\[
\chi''(\omega) = \frac{\gamma}{(\omega^2 - \omega_0^2)^2 + \omega^2 \gamma^2}
\]

\[
= \frac{\chi_0''}{2\omega_1} \left[ \frac{\gamma/2}{(\omega - \omega_1)^2 + (\gamma/2)^2} - \frac{\gamma/2}{(\omega + \omega_1)^2 + (\gamma/2)^2} \right],
\]

where the damping coefficient \(\gamma = \sqrt{\omega_0^2 - \omega_i^2}\). The RIXS intensities are modeled by \(n_{\text{g}}(\omega) + 1)\chi''(\omega)\), where \(n_{\text{g}}(\omega) = [\exp(\hbar \nu / k_B T) - 1]^{-1}\) is the Bose factor. As shown in Figs. 2(a) and 2(b), fitting to this simple model provides a good description of the observed spectra. In this fashion, we extracted the spin-excitation pole dispersion \(\omega_1(\vec{Q})\) [Figs. 2(c)–2(e)] along the three trajectories shown in the inset. To avoid the influence of CDW ordering on the spin-excitation dispersion \[28\], we analyzed around the charge ordering...
The spin-excitation dispersion of doped LSCO is analyzed in principle be accessed by measuring the dd excitations. For LCO, interpretations of the dd excitations have consistently placed the d₂ level above (i.e., closer to the Fermi level) both the dxy and dx²-yy states. This is also consistent with density functional theory (DFT) and \textit{ab initio} calculations of the electronic band structure that find the d₂ band above the t2g states. In doped LSCO x = 0.12, the spectral weight of the dd excitations is redistributed and the “center of mass” is shifted to lower energies (see Fig. 3). The dxy states are expected to be the least sensitive to crystal-field changes. Therefore, it is conceivable that the dxy and d₂ states are shifting to lower energies. Again from DFT calculations (see Appendix C), we expect the d₂ states to appear above those of dxy. Our experimental results thus (Fig. 3) suggest that the crystal-field splitting E₂: in doped LSCO x = 0.12 is smaller compared to LCO. Yet, the zone-boundary dispersion is larger in LSCO x = 0.12 (Fig. 2). The present experiment is therefore not lending support for a correlation between the zone-boundary dispersion and the crystal-field splitting E₂.

The spin-excitation dispersion of doped LSCO is analyzed using an effective Heisenberg Hamiltonian derived from a...
The simplest version of the Hubbard model contains only three parameters: the Coulomb interaction $U$, the bandwidth ($4t$), and a renormalization factor $Z$—known to have little momentum dependence. To lowest order in $J_1 = 4t^2/U$, no magnon dispersion is expected along the zone boundary. Therefore, to explain the zone-boundary dispersion—first observed on La$_2$CuO$_4$—higher-order terms $J_2 = 4t^4/U^3$ were included [6,7] in the model. Later, it has been pointed out that higher-order hopping terms $t'$ and $t''$ can also contribute significantly [8,9]. Generally, the effective Heisenberg model yields a dispersion [8,9] $\omega(q) = Z\sqrt{A(q)^2 - B(q)^2}$ where $A(q)$ and $B(q)$—given in Appendix A—depend on $U$, $t$, $t'$, and $t''$. The zone-boundary dispersion can be quantified by $E_{ZB} = \omega(q)/t - 1/4 - \omega(q)/2t$. Using the single-band Hubbard model with realistic parameters [8,10,11] $(U/t \approx 8, |t'| \leq 2$ and $t'' = -t'/2)$ for hole doped cuprates, we find (see Appendix A)

$$
\frac{E_{ZB}}{12ZZJ_2} \approx 1 + \frac{1}{12}\left[112 - \left(\frac{U}{t}\right)^2\right]\left(\frac{t'}{t}\right)^2.
$$

A key prediction is thus that $E_{ZB}$ scales as $(t'/t)^2$ with a prefactor that depends on $(U/t)^2$.

This effective Heisenberg model is in principle not applicable to doped and hence antiferromagnetically disordered cuprates. For an exact description of the data, more sophisticated numerical methods have been developed [35]. However, in the absence of analytical models, the Heisenberg model serves as a useful effective parametrization tool to describe the damped spin excitations. Within a single-band tight-binding model, angle-resolved photoemission spectroscopy (ARPES) experiments have found that $t'$ decreases slightly with increasing doping [10,15]. The stronger zone-boundary dispersion can thus not be attributed to an increase of $t'$. Parametrizing the doping dependent zone-boundary dispersion would thus imply a strong renormalization of $U$ with increasing doping. For example, if we set $4t = 1720$ meV [obtained from local-density approximation (LDA) and ARPES [11,36,37]] and $t'/t = -0.16$ and $t'' = -t'/2$, a fit yields $U/t \sim 5$ and $Z \sim 0.7$. Although these parameters provide a satisfactory description of the dispersion, the values of $U$ and $Z$ are not physically meaningful. This failure combined with the observation of a reduced level splitting between the $d_1$ and $d_{2-3\gamma}$ states (Fig. 3) motivates a two-band model. It has been demonstrated that $d_{2-3\gamma}$ states contribute to effectively increase the $t'$ hopping parameter [14]. Keeping $Z \approx 1.219$ as in La$_2$CuO$_4$ [8] and $t'' = -t'/2$, a satisfactory description (solid line in Fig. 2) of the spin-excitation dispersion is obtained for $t'/t = -0.405$ and $U/t = 6.8$. Notice that a similar ratio of $t'/t$ has previously been inferred from the rounded Fermi-surface topology of Tl$_2$Ba$_2$CuO$_6$ [38–40] a material for which the $d_{2-3\gamma}$ states are expected to be much less important [41]. It could thus suggest that $t'/t \approx -0.4$ is common to single layer cuprates but masked in LSCO due to the repulsion between the $d_{2-3\gamma}$ and $d_{2}$ bands that pushes the Van Hove singularity close to the Fermi level and effectively reshapes the Fermi-surface topology [14]. The more realistic values of $U$ and $Z$ suggest that—for LSCO—the two-orbital character of this system is an important ingredient to accurately describe the spin-excitation spectrum.

Once having extracted $U/t$ and $t'/t$ by fitting the experimental spin-excitation spectrum, we plot—in Fig. 4—the normalized zone-boundary dispersion $E_{ZB}/(12ZZJ_2)$ versus $(t'/t)^2[112 - (U/t)^2]$. The same parameters were extracted (see Table I in the Appendix) from published RIXS data on La$_2$CuO$_4$ and Bi$_2$Sr$_2$La$_1$CuO$_{6+x}$ [32] and plotted in Fig. 4. All three compounds follow approximately the predicted correlation between $E_{ZB}/(12ZZJ_2)$ and $(t'/t)^2[112 - (U/t)^2]$. This suggests that the zone-boundary dispersion is controlled by the parameters $t'/t$ and $U/t$. It would be interesting to extend this parametrization to include higher doping concentrations of LSCO. However, from existing RIXS data on overdoped single crystals of LSCO it is not possible to perform the analysis presented here [26,42]. For LSCO $x = 0.23$, for example, the zone-boundary dispersion has not been measured [26].

Finally, we notice that recent RIXS experiments on LSCO thin films using SrLaAlO$_4$ (SLAO) substrates found a much less pronounced softening of the spin-excitation dispersion around the $(\frac{1}{4}, \frac{1}{4})$ point [43]. A possible explanation is that LSCO films on SLAO have a larger c-axis lattice parameter and hence also a larger copper to apical-oxygen distance than what is found in bulk crystals [44,45]. As a consequence, the $d_{2}$ states are less relevant and hence lead to a less pronounced zone-boundary dispersion.
V. CONCLUSIONS

In summary, a comprehensive RIXS study of underdoped LSCO \( x = 0.12 \) and 0.145 were presented. The spin-excitation dispersion was studied along three high-symmetry directions and a strong zone-boundary dispersion is reported. The spin-excitation dispersion was parametrized and discussed using the Heisenberg Hamiltonian derived from a Hubbard model including higher-order hopping integrals. Within this model, the zone-boundary dispersion scales with next-nearest-neighbor hopping integral \( t'' \). We argue that hybridization between \( d_{x^2-y^2} \) and \( d_{z^2} \), which is especially strong in LSCO, leads to an enhanced \( t'' \). This effect—consistent with the observations—leads to a stronger zone-boundary dispersion within the \( t - t' - t'' - U \) Hubbard model.

APPENDIX A

Here we describe the spin-excitation dispersion of the Heisenberg Hamiltonian derived from the \( t - t' - t'' - U \) Hubbard model in two steps. We first consider the simplest model where \( t' = t'' = 0 \) before including higher-order hopping terms.

Generally the dispersion takes the form

\[
\omega(q) = Z\sqrt{A(q)^2 - B(q)^2},
\]

where \( Z \) is a renormalization factor and \( \vec{q} = (h,k) \). When the Hubbard model contains only the nearest-neighbor hopping integral \( t \), we expand \( A(q) \) and \( B(q) \) to second order in \( t \):

\[
A(q) = A_0 + A_1 + \cdots \quad \text{and} \quad B(q) = B_0 + B_1 + \cdots.
\]

To express \( A_1 \) and \( B_1 \), we define \( J_1 = \frac{4 \epsilon^2}{U} \) and \( J_2 = \frac{4 \epsilon^4}{U^2} \). Moreover we set

\[
P_j(h,k) = \cos jha + \cos jka, \quad X_j(h,k) = \cos jha \cos jka, \quad X_{3j}(h,k) = \cos 3ha \cos ka + \cos ha \cos 3ka,
\]

where \( j = 1, 2, 3, \) or 4. With this notation we have

\[
A_0 = 2 J_1 \quad \text{and} \quad B_0 = -J_1 P_1
\]

and

\[
A_1 = J_2(-26 - 8X_1 + P_2) \quad \text{and} \quad B_1 = 16 J_2 P_1.
\]

When the zone-boundary dispersion is defined by \( E_{ZB} = \omega(q_0^1 - 0) - \omega(q_1^1 - 1) \), one finds \( E_{ZB} = 12 J Z_2 J_2 \). Therefore, a zone-boundary dispersion is only found when second-order terms \( J_2 \) are included. Notice also that since \( P_1(1^1, 1^1) = P_1(1^1, 1^1) = 0 \), the \( B \) terms are not contributing to the zone-boundary dispersion.

Now let us include second-nearest \( t' \) and third-nearest-neighbor \( t'' \) hopping integrals. This involves several additional contributions to \( A(q) \) and \( B(q) \):

\[
A(q) = A_0 + A_1 + A_0' + A_1' + A_1'' + A_1'''\quad \text{and} \quad B(q) = B_0 + B_1 + B_1' .
\]

To express these new terms, we introduce the following notation \( J_1' = \frac{4 \epsilon^2}{U} \), \( J_2' = \frac{4 \epsilon^4}{U^2} \), \( J_3' = \frac{4 \epsilon^6}{U^3} \), and \( J_3'' = \frac{4 \epsilon^8}{U^4} \). Geometrically the following contributions correspond to different hopping path combinations including the cyclic ones,

\[
A_0' = 2 J_1'(X_1 - 1) \quad \text{and} \quad A_0'' = J_1''(P_2 - 2),
\]

\[
A_1' = -\frac{8 J_1}{U^2}(-t''^2 + 4t' t'' - 2 t''^2)(P_2 - 2),
\]

\[
A_1'' = -\frac{8 J_1}{U^2}(-t''^2 + 4t' t'' - 2 t''^2)(P_2 - 2).
\]
solutions of the Hubbard model for values several of $U/t$. This approximation is valid as long as $t'/t \ll 1$ (as indicated) and $t'' = -t'/2$. The solid line is the approximated analytical solution for $U/t = 8$.

$$B'_c = -\frac{4J_1}{U^2}[(6t'^2 - 4t''t')/(X_1 - 1) + 3t''^2(P_2 - 2)]P_1,$$

(A11)

$$A'_i = 2J'_2(X_2 + 4X_1 - 2P_2 - 1),$$

(A12)

$$A''_i = \frac{2J'_1J''_1}{U}(-3X_2 + 2X_1 + 5P_2 - X_3 - 7),$$

(A13)

$$A''_o = J''_2(P_4 - 8X_2 + 4P_2 - 2).$$

(A14)

As $B'_c$ scales with $P_1$, it is again found that $B(q)$ does not contribute to the zone-boundary dispersion. In Fig. 5, we show the numerical evaluation of $E_{ZB}$ for realistic values of $U/t$, $t'/t$, and with $t'' = -t'/2$. When neglecting terms scaling with $J'_2$, $J''_2$, and $J'_1J''_1$, only Eqs. (A9) and (A10) contribute. Using $P_2(\frac{1}{2},0) = 2$, $P_2(\frac{1}{2},\frac{1}{2}) = -2$, $X_1(\frac{1}{2},0) = -1$, and $X_1(\frac{1}{2},\frac{1}{2}) = 0$, we find

$$\frac{E_{ZB}}{12J_2} \approx 1 + \frac{1}{12} \left(112 - \frac{J_1}{J_2}\right)\left(\frac{t'}{t}\right)^2.$$  

(A15)

This approximation is valid as long as

$$\frac{U}{t} \geq \sqrt{\frac{28 + 112(\frac{t'}{t})^2}{2 + 3(\frac{t'}{t})^2}}, \quad \text{and} \quad \left|\frac{t'}{t}\right| \approx 0.686.$$  

(A16)

As shown in Fig. 5, this analytical expression is a good approximation to the full numerical calculation. Thus it is justified to neglect terms scaling with $J'_2$, $J''_2$, and $J'_1J''_1$ for a realistic cuprate values of $U/t$ and $t'/t$.

### APPENDIX B

Now, having derived the spin-excitation dispersion within the $t - t' - t'' - U$ Hubbard model, it is possible to fit the experimentally observed dispersion. A final comment goes to the prefactor $Z$. It is found that, including higher-order hopping integrals $t'$ and $t''$, $Z$ has a slowly varying momentum dependence. To simplify our analysis we used the mean value obtained [8] in the first Brillouin zone for the half filled compound La$_2$CuO$_4$. We thus have $Z = 1.219$ constant. From ARPES [36,37] experiments and LDA calculations [11] we have that $t = 0.43$ eV and $t'' = -t'/2$. Our fitting parameters are thus $U$ and $t'$. In this fashion we obtain a good description of the spin-excitation dispersion of LCO and LSCO $x = 0.12$ (see Fig. 2 in the main text). The obtained values are given in Table I. In Fig. 6 and Table I, we display in addition our fit and associated fit parameters from the spin-excitation spectrum measured on Bi2201 (Ref. [32]). With these values of $U$ and $t'$, the relation—shown in Fig. 4—between $E_{ZB}$ and $t'$ is established.

### APPENDIX C

To guide our intuition of how the $d_{z^2}$ states evolve as a function of doping, we have carried out DTF calculations.
The electronic structure has been shifted such that the overall 3$d$-shell filling reflects the doping $x$. The electronic structure has been approximated by a rigid band shift of all Cu $d$ orbitals. For every calculated doping value, the orbital resolved DOS (DOS) of LSCO in the tetragonal crystal structure. As shown in Fig. 7(a), the $d_{z^2}$ derived band disperses in a binding energy range of $E - E_F = -1.3 \text{ eV}$ close to $\Gamma$ and $E - E_F = -0.3 \text{ eV}$ at $M$. The orbital resolved DOS of the $d_{z^2}$ band has a peak at $E - E_F = -0.5 \text{ eV}$, while closer to $E_F$ the $d_{z^2}$ DOS rapidly decays. This peak originates from the flat shape of the $d_{z^2}$ band close to $M$. Therefore to track the doping dependence of the $d_{z^2}$ energy level, the position of the band at the $M$ point is plotted as a function of doping $x$ in Fig. 7(c). With increasing doping $x$ the $d_{z^2}$ energy level approaches the Fermi energy. Note that our DFT calculation agrees with recently published results obtained by ab initio calculations [14].
