Abstract. We report the nanofabrication and characterization of x-ray transmission gratings with a high aspect ratio and a feature size of down to 65 nm. Two nanofabrication methods, the combination of electron beam and optical lithography and the combination of electron beam, x-ray, and optical lithography, are presented in detail. In the former approach, the proximity effect of electron beam lithography based on a thin membrane of low-*z* material was investigated, and the x-ray transmission gratings with a line density of up to 6666 lines/mm were demonstrated. In the latter approach, which is suitable for low volume production, we investigated the x-ray mask pattern correction during the electron beam lithography process and the diffraction effect between the mask and wafer during the x-ray lithography process, and we demonstrated the precise control ability of line width and vertical side-wall profile. A large number of x-ray transmission gratings with a line density of 5000 lines/mm and Au absorber thickness of up to 580 nm were fabricated. The optical characterization results of the fabricated x-ray transmission gratings were given, suggesting that these two reliable approaches also promote the development of x-ray diffractive optical elements. © 2017 Society of Photo-Optical Instrumentation Engineers (SPIE) [DOI: [10.1117/1.JMM.16.3.034503](https://doi.org/10.1117/1.JMM.16.3.034503)]

Keywords: Au transmission gratings; electron beam lithography; x-ray lithography; x-ray spectroscopy.

1 Introduction

Au transmission gratings (TGs) are invaluable optical elements in numerous applications. More specifically, x-ray telescopes such as Chandra and the Solar and Heliospheric Observatory adopted a huge amount of x-ray TGs with a feature size of 100 and 200 nm.^{1–3} High-aspect-ratio Au TGs were used for hard x-ray differential phase-contrast imaging.^{4–7} In x-ray spectrometers, x-ray TGs with a high line density are key dispersing elements for both spectral and imaging goals.^{8–11} The heavy demands of x-ray TGs in scientific instruments with a compact size, light weight, and high degree of design flexibility have motivated considerable research on nanofabrication techniques. Various performance goals of x-ray TGs pose an extreme challenge to nanofabrication technologies.

Currently, the methods for manufacturing high-line-density gratings include interference lithography plus deep reactive ion etching,^{12,13} interference lithography followed by anisotropic Si wet etching,^{14,15} nanoimprint and multistep etching,¹⁶ ion beam lithography,^{17,18} etc. In addition, electron beam lithography (EBL) and its combination with other nanofabrication technologies are of great interest for fabricating x-ray diffractive optical elements including x-ray TGs.^{9–21} EBL tools have been developed with a fast 100-MHz line frequency and a beam diameter of several nanometers.²² A remarkable progress has also been made in which nanostructures with a high aspect ratio of up to 20 nm and patterns with 4.5-nm half-pitch have been

achieved by a single EBL step.^{23–25} For many specific applications, EBL continues its path to obtain features with smaller dimensions and higher aspect ratios and can be combined with other lithographic technologies to realize the desired elements.²⁶ However, every above-mentioned lithographic method has strengths and weaknesses and still suffers from many challenges such as sophisticated deep-reactive-ion etching process, mask fabrication, and low writing speed.^{12,16,19}

Here, we report on our recent progress on nanofabrication and characterization of high-line-density x-ray TGs. On one hand, to fabricate 6666 lines/mm x-ray TGs, EBL was used to directly write patterns on the membrane of low-*z* material and combined with ultraviolet lithography (UVL) to define supporting frames. To meet the heavy demands of x-ray TGs with 5000 lines/mm density, 100 nm bar width, and 580 nm height, EBL, x-ray lithography (XRL) and UVL were combined to fabricate TGs in low volume production. Two combined approaches are capable of directly patterning nanoscale resist structures with a vertical cross section, avoiding the sophisticated etching process. Both of them are robust fabrication procedures under tight process control with a large process latitude. The former is able to fabricate finer gratings, and the later has higher yields. For the individual combination, to precisely control the line/space ratio and achieve a vertical cross section, some improvements have to be made such as writing patterns on membrane substrates in EBL, pattern correction on the mask, and mask/wafer gap control in XRL. The subsequent characterization

*Address all correspondence to: Changqing Xie, E-mail: xiechangqing@ime.ac.cn

of fabricated x-ray TGs has shown their satisfying optical performances.

2 Design of Self-Supporting X-Ray TGs

Figure 1 shows the schematic geometry of x-ray TGs, consisting of free-standing gold grating bars with a width of down to several tens of nanometers supported by coarse mesh or polyimide membranes. The diagram does not show proper proportions. The diameter of the supporting silicon frame is 20 mm, and the grating area is from several to a few tens of square millimeters, which can be patterned by direct-writing electron beam lithographic tools. In the soft x-ray region from 0.1 to 2 keV, x-ray is intensively absorbed in any known material.^{27,28} Therefore, x-ray must freely pass through gaps between gratings bars without any absorption. In other applications where photon energy is above 2 keV, grating bars can be fabricated on x-ray transparent membranes of low- z materials.²⁹ The refraction index of x-ray in any material can be written as $n = 1 - \gamma - i\beta$, where γ and β are very small for all materials, resulting in much difficulty in deflecting x-rays and designing x-ray diffractive optical elements.³⁰ When x-rays pass through fine structures of high- z materials, both the intensity and phase are modulated simultaneously,^{31,32} offering a multifunctional and flexible way to diffract or focus x-rays.

Spectral performance of gratings is mainly determined by two factors: the period and the absorber thickness.³⁷ At normal incidence, the first-order diffraction angle of the grating can be expressed as

$$\theta = \sin^{-1}(\lambda/p), \quad (1)$$

where θ is the diffraction angle, λ is the wavelength of incident light, and p denotes the grating period.³³ To obtain a large diffraction angle (i.e., high spectral resolution), one needs to decrease the period of TGs to 150 nm for their applications in high spectral-resolution spectrometers.

Another crucial parameter of x-ray TGs is the efficiency, especially for their applications in x-ray spectrometers. The diffraction efficiency of wire gratings with a rectangular cross section can be calculated as^{34,35}

Fig. 1 Schematic geometry of x-ray TGs with free-standing Au grating bars supported by coarse gold frames.

$$\eta_m(\lambda) = \left[\frac{\sin\left(\frac{m\pi a}{p}\right)}{m\pi} \right]^2 \left[1 + e^{-\frac{4\pi\beta}{\lambda}z} - 2e^{-\frac{2\pi\beta}{\lambda}z} \cos\left(\frac{2\pi}{\lambda}\delta z\right) \right], \quad (2)$$

where $m \neq 0$, a is the gap between grating bars, z is the absorber thickness, λ is the wavelength of incident x-ray light, β is the imaginary part of the refractive index, and δ is the real part of the refractive index. On one hand, it can be deduced that when the ratio of gap to period (i.e., duty cycle) is 0.5, the first-order efficiency reaches a maximum, and all even orders disappear. If the duty cycle is up to 0.75 or down to 0.25, the efficiency decreases to 50% of the maximum. On the other hand, the efficiency of x-ray TGs is also determined by the thickness of gratings. According to Eq. (2), the efficiency approaches its maximum when z is $\lambda/(2\delta)$ and the phase shift is correspondingly π . To achieve enough diffraction efficiency, 300 to 600 nm of bar height is required in the x-ray region. In addition, the diffraction efficiency decreases when the cross section deviates from the rectangle.³⁶

To achieve high spectral resolution, enough efficiency, and desired phase shift, nanoscale grating bars with nanoscale width, desired height of absorber, and precisely controlled line/space ratio must be constructed to be free-standing or on membranes of low- z materials.

3 High-Line-Density X-Ray Transmission Gratings Fabricated by Electron Beam Direct Writing

3.1 State-of-Art of X-Ray TGs Fabrication

Until now, a variety of lithographic techniques have been developed to realize design targets of x-ray TGs. Both advantages and tradeoffs exist for each lithographic technique. Researchers at Massachusetts Institute of Technology and Max-Planck-Institut für Physik und Astrophysik (Germany) have accomplished the pioneering work and developed a huge amount of x-ray TGs with bar widths of 100 and 200 nm using interference lithography.^{37–40} This process can also be followed by wet anisotropic etching to achieve x-ray critical point TGs with extremely high aspect ratios.^{41,42} Extreme ultraviolet (EUV) interference lithography and its variants can scale the EUV gratings pitch down to 50 nm and fabricate periodic structures smaller than 10 nm, but they suffer from the limitation of periodic patterns and uniformity in large areas.^{43–47} Nanoimprint provides a low-cost approach to fabricating gratings with high spatial resolution. However, for many applications, there are still many challenges such as defects and template patterning.^{48,49} In recent years, anisotropic Si wet etching in hydrofluoric acid and hydrogen peroxide solutions enables to achieve silicon nanostructures with an extremely high aspect ratio of up to 120, but how to transfer patterns from silicon to metal is challenging.⁵⁰

In addition, EBL has shown its potential in fabricating of high-line-density x-ray TGs due to its high resolution and large penetration depth in the resist. An 100-keV electron beam writer can directly pattern gold gratings with 1 μ m height and 45 nm width.²⁰ 50-nm-wide and 300-nm-thick platinum grating structures were fabricated from a trilayer resist exposed by EBL and followed by reactive ion etching plus electroplating.²¹ The beam size can be focused within

several nanometers to fabricate EUV TGs with a lines density of 10,000 lines/mm and an absorber height of 80 nm.²⁷ Although EBL is capable of patterning gratings with line density of up to 10,000 lines/mm in the EUV region, the thickness of the absorber is several tens of nanometers. Moreover, how to combine EBL with other lithographic techniques to manufacture x-ray TGs in high throughput has been challenging for several decades.³⁸ Furthermore, EBL can generate arbitrary patterns for more flexible designs including variable gratings and binary optical elements.⁵¹ To date, the nanofabrication of high-line-density x-ray TGs operating in the x-ray region is still technically challenging.

3.2 Combination of EBL and Optical Lithography

The desired 6666 l/mm x-ray TGs consist of grating bars with a 75 nm half-pitch and a 350 nm thickness on a 2.0- μm -thick polyimide membrane that is x-ray transparent in a 2.0- to 4.0-keV region. In the fabrication process, the combination of EBL and UVL was adopted to pattern the grating structures. EBL can be performed to directly pattern grating structures, taking advantages of extremely high resolution, acceptable writing speed, and large penetration depth of electrons. To our knowledge, few works have been able to realize x-ray TGs with line density of up to 6666 lines/mm that can operate at a photon energy of up to 4 keV.

The process of the combination of EBL and UVL, which is shown in Fig. 2, consists of two main steps in which EBL was used to pattern nanoscale gratings and UVL was performed to generate coarse supporting frames. First, the process started by depositing of 15-nm CrAu on a polyimide membrane using electron evaporation; second, an extremely fine electron beam with a 100 kV accelerating voltage and a 200 pA current (JBX6300FS, JEOL) was used to directly write patterns in polymethylmethacrylate (PMMA, 5% 2200k in anisole, resist 1 in Fig. 2) resist, followed by gold electroplating in the gaps of the resist structures. Third, to define supporting frames on the grating structures, a PMMA-based resist of SX AR-N 4800/16 (resist 2 in Fig. 2) was exposed by an aligner, developed in the mixture of methyl-isobutylketone (MIBK) and isopropyl alcohol (IPA), and rinsed in IPA. Fourth, electroplating was performed to form coarse supporting gold frames. Finally, x-ray TGs were

finished after removing the CrAu seed layer by argon plasma etching.

In the above processes, PMMA coated on the polyimide membrane was exposed by an electron beam writer with 100 kV accelerating voltage to decrease the proximity effect due to two factors. One is that the membrane substrate can effectively decrease the extrados caused by backscattered electrons. Another is that the accelerating voltage of 100 kV makes it possible to prevent the obvious beam size broadening due to little forward scattering.⁵² To demonstrate the proximity effect in PMMA resist and the membrane, the distribution of absorbed energy in 400-nm PMMA on a polyimide membrane coated with 5-nm Cr and 10-nm Au was calculated by the Monte Carlo simulation method (Tracer, GenIsys). In the simulation, electron beam energy of 100 keV and the electron number of 10^6 were used. Figure 3 shows the radial distribution of energy density absorbed in 400-nm PMMA, 15-nm CrAu seed layer, and 2- μm polyimide membrane. The embedded zoom-in image in the bottom-left shows the energy distribution near the incident point. In the radial direction, when the energy density decreases by two orders, the widths of energy distribution from the zero point on the top and bottom of the resist are 2.37 and 2.48 nm, respectively. The simulation result demonstrates the ability to pattern high-line-density gratings with a vertical cross section and high aspect ratio, both of which are crucial in the nanofabrication of x-ray TGs.

By exposing 400-nm PMMA resist on a 2- μm polyimide membrane, extremely high contrast of resist can be achieved in exposure. During the electron beam exposure, the calibration of electron beam was automatically carried out every 5 min to avoid the writing field distortion caused by the surface height fluctuation. After development and electroplating, the fabricated grating structures are shown in Fig. 4(a). In addition, the polyimide membrane was used to support grating structures due to its robustness and excellent radiation resistance. However, during UVL, the polyimide membrane becomes wrinkled, and patterns on the membranes get distorted when polyimide membrane is immersed into alkaline-based developer. Thus, SX AR-N 4800/16 negative resist was used to define coarse supporting frames since it can be dissolved in an organic developer mixed by MIBK and IPA, which do not lead to wrinkled polyimide

Fig. 2 The combined process of EBL and UVL for fabricating x-ray TGs.

Fig. 3 Simulated radial energy density absorbed in the stack of 400-nm PMMA/10-nm Au/5-nm Cr/2- μm polyimide, the energy of incident electrons is 100 keV.

Fig. 4 Achieved high-line-density x-ray TGs consisting of (a) grating bars fabricated by EBL and electroplating and (b) coarse frame defined by UVL with SX AR-N 4800/16 negative resist.

membrane. The UVL was performed to pattern the coarse meshes on the grating bars, and the overlay accuracy of EBL and UVL was kept within $2\ \mu\text{m}$. After exposure, the resist structures were transferred to the Au layer by electroplating. Finally, the achieved device is shown in Fig. 4(b). Grating bars are perpendicular to the supporting bars. Every opening area of grating is $150\ \mu\text{m} \times 92\ \mu\text{m}$ and supported by $21\text{-}\mu\text{m}$ wide bars. The grating area patterned by EBL is $450\ \mu\text{m} \times 92\ \mu\text{m}$, and the writing time was 15 min. The area could be several times larger if the trade-off between electron current and beam diameter has been made to optimize the lateral resolution and the writing speed. In addition, in the final step, the CrAu seed layer was removed by a maskless process of induced plasma coupling etching. Using a high platen power, the 15-nm-thick CrAu seed layer was etched and the width of the gold bars was hardly changed.

3.3 Characterization of 6666 Lines/mm X-Ray TGs

The diffraction pattern of fabricated 6666 lines/mm x-ray TGs was obtained at a 4B7A beamline on a Beijing synchrotron radiation facility, which covers the photon energy range from 2 to 6 keV. The incident x-rays passed through the shutter and the x-ray TGs and reached the detector. Behind the sample, an x-ray charge-coupled device with 2048×2048 pixels and $13.5\ \mu\text{m}$ pixel size was used to

receive the diffraction pattern. Figure 5(a) shows the diffraction pattern that is symmetrically distributed on both sides of the zeroth-order when the photon energy of incident x-ray was 2.9 keV. The second-order cannot be neglected, while any third-order is not visible. This is due to the deviation of the grating bar width from the original design. The measured grating bar width is 65 nm rather than the desired 75 nm in Fig. 4(a). Figure 5(b) shows the measured ratio of first-order to zeroth (i.e., relative diffraction efficiency) at an energy range of 2.1 to 4.0 keV. The relative first-order efficiency is from 8.89% to 9.41%, which is acceptable for 150-nm period x-ray TGs operating at 4.0 keV. Because of the 350 nm thickness of the absorber, the efficiency gradually decreases at photon energy above 3.5 keV.

4 X-Ray TGs Nanofabrication in High Throughput

4.1 Combination of EBL, XRL, and UVL

Although EBL can generate patterns with extremely high spatial resolution and a high aspect ratio, it suffers from its serial writing strategy. The fabrication process of x-ray TGs is very time-consuming, and membrane-based x-ray TGs are definitely fragile in their characterization and use. To meet the heavy demands of x-ray TGs in their applications, the combination of EBL, XRL, and UVL was developed to manufacture nanostructures in high throughput.^{54–56} EBL has the ability to pattern structures with less than 5-nm

Fig. 5 Characterization results of 6666 lines/mm x-ray TGs, including (a) diffracted pattern at 2.9 keV and (b) the measured relative first-order efficiency in 2.1- to 4.0-keV energy range.

critical dimension and generate arbitrary complex patterns. XRL enables the efficient replication of nanostructures with a sub-20-nm spatial resolution or a high aspect ratio due to the short wavelength, large depth of focus, and low x-ray absorption in resist.⁵⁷ Although the fabrication of XRL mask by EBL is costly and time consuming, once one or two masks have been finished, a large number of specimens with a high aspect ratio in high fidelity can be promptly achieved without sophisticated induced coupling plasma etching.

To fabricate x-ray TGs in high throughput, the combination of EBL, XRL, and UVL was developed to fabricate 5000 lines/mm x-ray TGs, as shown in Fig. 6. First, in the EBL process, a scanning electron beam with a diameter of several nanometers was focused to pattern resist structures with low aspect ratios on silicon nitride or silicon carbide membranes covered by CrAu seed layers. After exposure, Au gratings were formed through spaces between resist structures. Second, with the mask fabricated in the EBL process, XRL and electroplating were formed to replicate nanostructures with high aspect ratios on resist/AuCr/polyimide/Si stacks. Third, in the UVL step, an aligner and Au electroplating were performed to pattern supporting frames. Finally, the backside silicon of substrate was removed by fluoric acid-based solution; the seed layer and polyimide were removed by argon and oxygen plasma, respectively.

4.2 Pattern Correction of Master Mask

Before the replication of x-ray TGs by XRL, the EBL step started by vapor-coating a 5-nm Cr layer and a 10-nm Au layer as a plating base on 2- μ m-thick Si₃N₄ membranes. The resist of 400-nm-thick PMMA (5% 2200k in anisole) was spin-coated and baked at 160°C for 30 min in an oven. Then, the resist was exposed using a 100-kV electron beam writer. The beam current was 0.2-nA, and the dose was 1800 μ C/cm² (JBX6300FS, JEOL). The length and width of grating area were 10 and 0.1 mm, respectively. Resist patterns with an aspect ratio of 4 were obtained after development in MIBK: IPA (1 : 3) for 40 s and rinsed in IPA for 30 s. The 350-nm-thick gold structures were formed by a pulse reverse electroplating process in a gold sulfite solution

(Elevate gold RTU 7790). After that, PMMA was removed in an acetone solution, and the seed layer was etched by argon plasma. To get a stable process in EBL, electrons were focused to expose the resist on the Si₃N₄ membrane, which can eliminate the backscattering effect similar to that on polyimide membrane demonstrated in Sec. 3.2. Compared with backscattered electrons on bulk silicon substrates, more electrons pass through the membrane substrate and less are scattered by the atoms in the substrate.

To achieve nanoscale Au grating bars with equal widths and gaps using XRL, pattern correction must be considered when starting the fabrication of x-ray mask the EBL step. Based on previous empirical experience and theoretical analysis (presented in Sec. 4.3), to pattern grating bars with a width of 75 to 100 nm, 5 to 10 nm bias of the grating bar on the mask for XRL is needed. While for 150- to 250-nm wide grating bars, 25 nm bias of bar width on the mask for XRL is suitable. For example, grating structures of 110-nm wide lines and 90-nm wide spaces on the mask are required for replicating 100-nm wide line/space gratings by XRL. The difference of bias for bars with different widths is mainly determined by the diffraction effect when x-rays pass through the mask/wafer. In EBL, to achieve an optimal line/space ratio, the resist was exposed with different line-space-ratio patterns on the layouts at different doses. By exposing layout patterns with 90-nm line and 110-nm spacing at 1800 μ C/cm² dose, the desired grating patterns were achieved, as shown in Fig. 7, with the line width of 110 nm on the mask. The bias of grating bars was precisely kept as 10 nm. Generally, the error of bar width must be within ± 5 nm, which will benefit the replication of gratings with equal widths of bars and gaps in the following XRL step.

4.3 Simulation of Pattern Formation in XRL

Compared with other lithographic techniques, XRL has advantages of high resolution, large depth of focus, insensitivity to different substrates, etc. However, in printing 100-nm-wide gratings, the variation of patterns on the mask and the substrate cannot be ignored since the diffraction effect between the mask and wafer becomes more evident with smaller critical dimensions or larger mask/wafer gaps.^{58,59} Hence, pattern correction of the x-ray mask must be considered.⁵³ To predict the pattern variation at different mask/wafer gaps, the propagation of x-ray between mask and wafer was simulated by a one-dimensional beam-propagating-method program with fast Fourier transformation (1-D BPM-FFT). The simulation consists of x-ray propagation, x-ray Fresnel diffraction, and resist blur. In the simulation, width and period of bars on the mask are 110 and 200 nm, respectively. The blur of resist is 10 nm, and the working wavelength is 1 nm. Aerial image profiles with different gaps on the resist surface are shown in Fig. 8. The full width at full maximum (FWHM) of lateral intensity distributions with mask/wafer gaps from 1 to 5 μ m are 95, 85, 79, and 55 nm, respectively. The FWHM is changed from 95 nm at 1 μ m gap to 79 nm at 3 μ m gap, demonstrating that XRL has the potential to pattern high aspect ratio structures with 100 nm feature size and 2 μ m height. In the exposure, due to the transportation of secondary electrons and photoelectrons, the width of exposed bars will be broadened by 10 to 20 nm, which can partially compensate for the pattern shrinkage caused by the diffraction of x-rays between

Fig. 6 Process flow to fabricate x-ray TGs by the combined process of EBL, XRL, and UVL. The first part contains e-beam evaporation seed layer on Si₃N₄ membrane, electron beam exposure, electroplating, and removal of the resist and seed layer. The second part includes XRL, electroplating, resist removal, and backside silicon wet etching. The third part consists of UVL, electroplating, and etching of silicon, seed layer, and polyimide.

Fig. 7 Patterns with 10 nm bias on the master mask taken from (a) top view and (b) cross section tilted at 30 deg.

the mask and wafer. The above analysis indicates that, to replicate grating bars with 100-nm line/space, 110 nm width of bars on the mask is required and the gap of mask/wafer must be less than $3\ \mu\text{m}$. In the experimental setup, a magnetic force was applied on the mask/wafer holder to achieve a gap of less than $3\ \mu\text{m}$, which can be detected by counting Moire rings on the backside Si_3N_4 membranes.

4.4 Replication of Gratings with High Aspect Ratio

The replication processes are very similar to those for fabricating x-ray masks in the EBL step, as shown in Fig. 6. A 600-nm-thick PMMA resist coated on 2- μm -thick polyimide film with plating base was exposed at a dose range of 6 to 8 J/cm^2 , developed in MIBK: IPA (1:3) for 40 s and rinsed in IPA for 40 s; resist patterns were transferred to a

Fig. 8 Simulated aerial image profiles with different mask/wafer gaps of (a) 1, (b) 2, (c) 3, and (d) $5\ \mu\text{m}$, respectively.

Fig. 9 Replicated grating patterns including (a) resist patterns with rectangular cross section and (b) smooth gold gratings with equal widths of bar and gap.

gold layer using electroplating. After that, UVL was carried out to define coarse supporting frames on the grating structures with the overlay accuracy of $2\ \mu\text{m}$ and was followed by Au electroplating. Finally, bulk silicon on the backside was etched by the solution of hydrofluoric, nitric, and acetic acids. The replicated gratings with equal bar and gap widths, smooth edges, and rectangular cross section are shown in Fig. 9. The gold thickness in Fig. 9(b) is 580 nm.

To form x-ray grating bar gold structures, electroplating rather than the lift-off process is more frequently used because electroplating is able to transfer the resist pattern to thicker metal layer than lift-off. In the above process, no adhesion layer was used to stabilize the lithographic process, since an adhesion layer can frequently lead to failure in the following process. In this combined process, the pattern generation process is straightforward and robust. The

Fig. 10 Measured angular distribution of spectra at different wavelengths of (a) 5, (b) 6, (c) 7, and (d) 8 nm, respectively.

combined process is able to produce a large number of x-ray TGs within a limited period for heavy demands. Moreover, due to extremely large penetration depth of x-rays in exposure, it can generate nanopatterns with a high aspect ratio and rectangular cross section, which are desired in various x-ray diffractive optical elements.

4.5 Characterization of Replicated 5000 Lines/mm X-Ray TGs

The characterization of replicated x-ray TGs was performed at U26 beamline, Hefei Synchrotron Radiation Light Source. The geometric position of gratings was controlled by a sample holder with 0.005 deg accuracy between the Si photodiode detector and filter plus slit. X-rays from the storage ring were selected by the monochromator gratings (600 and 1800 lines/mm), and the contribution of higher diffraction orders was limited by setting different filters. The 100- μm slit was used to collimate the light on the x-ray TGs, and all measurements were performed with monochromatic radiation normal to the gratings.

The obtained spectra at different wavelengths are shown in Figs. 10(a)–10(d). The ratio of different order efficiencies can be formulated as $T_{m/n}$. The measured $T_{1/0}$, $T_{2/1}$, and $T_{3/1}$ are 51.3%, 6.3%, and 13.8%, respectively. $T_{2/1}$ is much smaller than $T_{3/1}$, demonstrating that the line/space ratio was precisely controlled as 1:1. From the spectra at different wavelengths, the value of a/d was developed as 0.44, which is definitely close to the ideal value of 0.5 compared with the measured data of x-ray TGs fabricated by interfering lithography.⁶⁰ With 580 nm height of grating bars, the first-order diffraction efficiency of TGs is 7% for 10 keV hard x-rays, which is sufficient for many applications. The testing results have highlighted the advantages of the combination of EBL, XRL, and UVL for fabricating x-ray diffractive optical elements with a high lines density and a high aspect ratio.

5 Conclusions

Two combined lithographic methods have been developed for fabricating high-line-density x-ray TGs with a vertical cross section. The former one, combined by EBL and optical lithography, is able to individually fabricate x-ray TGs with extremely high line density. The later one consisting of EBL, XRL, and UVL can manufacture x-ray TGs in high throughput. To realize x-ray TGs with a line density of up to 6666 lines/mm, EBL was performed to directly pattern grating structures on polyimide membrane, which can effectively suppress the proximity effect caused by the forward and backscattered electrons. Thus, the cross section can be defined to be vertical, and the feature size of grating bars was down to 65 nm. The relative diffraction efficiency in a photon energy range of 2.1 to 4.0 keV was achieved as 8.89% to 9.41%. Aiming at heavy demands of x-ray TGs, EBL, XRL, and UVL were combined to fabricate x-ray TGs with line density of up to 5000 lines/mm in high throughput and in high fidelity. X-ray diffraction effect between mask and wafer was simulated by a 1-D FFT-BPM method. It demonstrated that the gap of mask/wafer must be kept within 3 μm ; thus, one can obtain a high-aspect-ratio structures with feature size of down to 100 nm and height of up to 2 μm . Using the straightforward process, x-ray TGs with a line density of 5000 lines/mm were fabricated in volume

production. The characterization results have implied that the ratio of grating bar and space was controlled as 0.44, definitely close to the optimal value of 0.5. More importantly, both the former and the later combined methods are able to not only construct nanoscale and high-aspect ratio structures but also generate arbitrary patterns, providing more flexibility and design freedom for x-ray diffractive optical elements and promoting the development of x-ray scientific instruments.

Acknowledgments

We would like to extend our gratitude to Professor Gang Liu (USTC) and Futing Yi (IHEP, CAS) for their help on x-ray lithography, senior engineer Hongjun Zhou (USTC) and Professor Mingqi Cui (IHEP, CAS) for their help on testing, and Mr. Matteo Todeschini (Danchip, DTU) for his assistance in grammar. This work was supported by the National Key Research and Development Program of China (2017YFA0206002) and China Scholarship Council (201504910112).

Xiaoli Zhu is an associate professor in the Institute of Microelectronics of Chinese Academy of Sciences. He received his BS degree in applied physics from Lanzhou University in 1999, his MS degree in optics from Beijing University of Technology in 2005, and his PhD in microelectronics from the Institute of Microelectronics of Chinese Academy of Sciences in 2008. His current research interests include nanoscale lithography, micro- and nanofabrication, X-Ray and EUV diffractive optical elements, and their applications.
