ABSTRACT

Aim

Body size is a master trait with significant ecological importance. Seasonal changes in body size within diverse ectothermic species can result from different environmental conditions experienced during ontogeny in subsequent generations. Whilst intra-specific changes in adult size have been well studied under controlled experimental conditions and across geographic ranges, comprehensive analyses of temporal changes are lacking, and there remains considerable unexplained variation in body size responses within aquatic taxa. Using planktonic copepods as an exemplar taxon, we quantify variation in adult body mass within seasonally varying marine and freshwater environments. We describe how size variation relates to temperature, food concentration (chlorophyll-*a*) and life history characteristics, including feeding strategy.

Location

Global.

Methods

Using a meta-analytic approach, we extract quantitative data from published literature on seasonal size responses of copepods. We analyse competing models to determine the best predictors of these responses, and compare the relative importance of temperature and chlorophyll-*a* concentration in explaining body size variation.

Results

We quantify 140 seasonal size responses from 33 different global locations, representing 48 planktonic copepod species from 4 taxonomic orders. We find that temperature ($r^2=0.50$), rather than food ($r^2=0.22$), is the dominant explanatory variable of adult body size variation across seasons. A striking outcome is that current-feeding calanoids exhibit a 4-fold greater reduction in adult body mass per °C (-3.66%) compared to ambush feeding cyclopoids (-

0.91%). By contrast, species body size or reproductive strategy did not explain variation in the seasonal temperature-size response.

Main Conclusions

Our findings lead us to suggest that feeding strategies may play a significant role in dictating the magnitude of seasonal temperature-size responses in copepods, with potential implications for other ectotherms with diverse feeding methods. Seasonal temperature-size responses were typically much more variable than responses in laboratory studies providing excess food, suggesting that field conditions modify the temperature-size response.

INTRODUCTION

Biologists have long been fascinated by body size variation (Bergmann, 1847; Schmidt-Nielsen, 1984), in part because this ‘master trait’ affects all vital rates, including feeding (Burns, 1968; Kiørboe, 2011), growth (Poston, 1990; Kiørboe & Hirst, 2014), metabolism (Peters, 1983; Glazier, 2005; Hirst *et al.*, 2014) and reproduction (Honěk, 1993; Arendt, 2011), as well as many other aspects of the biology of an organism (Andersen *et al.*, 2016). Consequently, identifying and understanding what drives variation in body size is of fundamental biological importance. Body size is sensitive to environmental conditions, due to the temperature dependence of physiological processes, as well as other effects such as changes in food availability. Ectothermic species that have short life-cycles and inhabit seasonal environments are typically subjected to varying environmental conditions across subsequent generations within a year. This is commonly linked to marked temporal shifts in adult body size over an annual cycle, as sequentially recruited adults are affected by different abiotic and biotic conditions over their ontogeny. Intra-specific variation in size related to seasonal variation in temperature has been found across a wide range of uni- and multicellular organisms, including bacteria (Chrzanowski *et al.*, 1988), rotifers (Diéguez *et al.*, 1998), copepods (Liang & Uye, 1997; Hirst *et al.*, 1999; Riccardi & Mariotto, 2000; Dutz *et*

al., 2012), cladocerans (Miyashita *et al.*, 2011) and insects (Kari & Huey, 2000), yet broad-scale analyses of temporal changes in adult body size are lacking.

By contrast, intra-specific variation in size at stage has been well described in the laboratory under different conditions (Atkinson, 1994; Forster *et al.*, 2012), and also spatially over latitude or across regions (Horne *et al.*, 2015). The most frequently observed intra-specific response to warmer temperatures in ectotherms is a reduction in size-at-stage; this has been formalised as the Temperature-size Rule (TSR) (Atkinson, 1994). This phenotypically plastic response can be achieved within a single generation (Forster & Hirst, 2012; Forster *et al.*, 2013), and in many metazoans the proximate cause is attributed to differences in the temperature dependence of growth and development during ontogeny (van der Have & de Jong, 1996; Forster *et al.*, 2011a; Forster *et al.*, 2011b; Zuo *et al.*, 2012). The ultimate cause of this outcome however may be a complex of several factors (e.g. see Forster *et al.* 2012; Horne *et al.* 2015). Uncertainty still remains in the degree to which these responses are found in natural field conditions, where multiple variables can act simultaneously to influence body size. For instance, the relative contribution of food and temperature in determining seasonal shifts in adult size still needs to be resolved. Food availability impacts size at maturity, but while slower growth at lower temperature is frequently coupled with an increase in adult size, slower growth with reduced food availability is typically associated with smaller size at maturity (Berrigan & Charnov, 1994). Further, food quality can dramatically alter the T-S response, even to the extent that the sign of the T-S response can be reversed under poor food quality (Diamond & Kingsolver 2010). Identifying and understanding seasonal variation in body size will not only help to determine the ultimate causes of such variation, but will also aid in predicting future shifts associated with changes in climate (IPCC, 2014) and phenology (Visser & Both, 2005). Our study aims to synthesise and quantify seasonal patterns in adult size of multivoltine species, going beyond previous species- and location-specific studies, so that we might provide a broader understanding of such patterns.

A recent meta-analysis of terrestrial and aquatic arthropods identified an impressive match between T-S responses measured under controlled laboratory conditions and intra-specific body size clines observed in the field across latitudes (Horne *et al.*, 2015). The magnitude and direction of these responses revealed consistent differences in the strength and sign of the response between aquatic and terrestrial species. These results suggest that laboratory T-S responses and latitudinal body size clines may be driven by similar selective pressures within arthropods, specifically, by voltinism and season length trade-offs in terrestrial species (Kozłowski *et al.*, 2004; Walters & Hassall, 2006), and the need to balance oxygen demand and supply in larger aquatic species (Woods, 1999; Atkinson *et al.*, 2006; Forster *et al.*, 2012). However, in many small organisms, in which oxygen diffusion under normoxic conditions is likely to adequately meet metabolic demand, size reductions with warming are still very common; they are for example observed in bacteria, protists and small metazoans, such as copepods (Atkinson *et al.*, 2003; Forster *et al.*, 2012). Copepods are possibly the most numerous metazoan on the planet, are ecologically important, and play a pivotal role in marine and freshwater biogeochemistry and trophodynamics (Banse, 1995). Reduction in size with increasing temperature, consistent with the T-S rule (Atkinson, 1994), has been shown in many copepod species, both in controlled laboratory experiments (Horne *et al.*, 2015), and across seasons in the field (Seasonal T-S responses) (Uye *et al.*, 1983; Riccardi & Mariotto, 2000; Hirst *et al.*, 1999; Drif *et al.*, 2010). Furthermore, the strength of the laboratory temperature-size response varies widely between species, to the extent that Horne *et al.* (2015) observed an approximate 30-fold difference between the strongest and weakest copepod T-S responses in their dataset on arthropods. It would appear, therefore, that another factor (or other factors) may be responsible for size reductions with warming observed in these smaller taxa, and identifying the likely causes is an important next step. Planktonic copepods are excellent model organisms in which to investigate seasonal size responses. Temporal changes in adult body size have commonly been examined in this

taxon (Figure 1), especially in mid-latitude environments which demonstrate strong shifts in temperature and food, while most species have multiple generations within a year and short generation times of >10 to <100 days (Hirst & Kiørboe, 2002). Thus, here we present and test a number of alternative hypotheses that may help to explain the considerable variation observed in body size sensitivity to warming in planktonic copepods.

Mature adult size is dependent in part upon obtaining sufficient food to meet maintenance and growth requirements, and size at maturity is controlled by different body size scaling of catabolism and anabolism (von Bertalanffy, 1957; Perrin, 1995):

$$\frac{dM}{dt} = c_s \cdot M^s - c_l \cdot M^l$$

where $s > 0$ and $l > 0$ are exponents for energy supply and loss respectively, and $c_s > 0$ and $c_l > 0$ represent the temperature dependence of the intercept terms in log-log scale. The point at which metabolic supply and demand intersect defines an organism's asymptotic mass ($\left. \frac{dM}{dt} \right|_{M_A} = 0$). In mathematical terms, the asymptotic mass, M_A , is given by

$$c_s \cdot (M_A)^s = c_l \cdot (M_A)^l \Rightarrow \log(M_A) = \frac{\log(c_s/c_l)}{l-s}$$

Temperature changes will affect both energy supply and expenditure, forcing the organism into a new asymptotic mass. Hence, we can predict the induced relative change in asymptotic mass per degree Celsius, noting that $f'(x) / f(x) = f'[\log(x)]$:

$$\frac{1}{M_A} \frac{dM_A}{dT} = \frac{d}{dT} [\log(M_A)] = \frac{1}{l-s} \cdot \frac{d}{dT} \left[\log \left(\frac{c_s}{c_l} \right) \right]$$

Thus, the temperature dependence scales inversely with the difference in the mass scaling of supply and demand ($l-s$), and is also influenced by the temperature dependence of the

intercepts. Moreover, within this framework, the strength of the T-S cline should be independent of body mass.

Despite overwhelming evidence in favour of the TSR in a diverse range of ectotherms, there remains considerable unexplained variation in the strength of the response between species and taxonomic groups, which are most likely attributed to key differences in life history traits and their associated metabolic constraints. In copepods and many other small zooplankton, food acquisition is governed by prey availability and uptake. Species within the order Calanoida largely utilise feeding currents to entrain and capture prey (Kiørboe, 2011), with a few exceptions; by contrast, species within the non-Calanoida orders, i.e., the Harpacticoida, Cyclopoida and Poecilostomatoida, lack an ability to produce a feeding current and are either ambush feeders (Cyclopoida; Paffenhöfer 1993), or they feed on surfaces, which in the planktonic environment is provided by marine snow aggregates (Harpacticoida; Koski *et al.* 2005), or they are parasitic (e.g. many Poecilostomatoida; Huys & Boxshall 1991). There is evidence that feeding mode is an important correlate of metabolic rates (respiration), clearance, growth and ingestion rates (Kiørboe & Hirst, 2014). Ignoring parasitic copepods, the body mass dependence of clearance rate differs between feeding current feeders and more passive ambush and surface feeders (Kiørboe, 2011), suggesting a possible difference in the temperature-body size sensitivity between different feeding behaviours. We cannot yet predict the magnitude and direction of the T-S response since we do not know how metabolic rates change with mass during ontogeny, and we also do not know how the intercept terms vary with temperature. However, these considerations lead us to suggest that some of the variability in T-S responses may be due to differences in feeding behaviour.

Another potential influence on the T-S response is reproductive strategy. In copepods, reproductive strategy can be divided into broadcast spawning and sac spawning. Sac

spawners carry eggs in external sacs, and have much lower fecundity rates than broadcast spawners (Hirst & Kiørboe, 2002). Sac spawners commonly do not lay the next batch of eggs until the previous batch has hatched from the attached sac(s) (Ward & Hirst, 2007), hence egg production is limited by the egg hatch time (Hirst & Bunker, 2003). By contrast, broadcasters have much higher fecundity rates, and are less likely to be limited by clutch size or egg hatch rates in the same way. The potentially different thermal sensitivities of egg development versus egg production rates may produce different solutions for size at maturity (and in turn its temperature dependence) between these two reproductive strategies. However, even in the absence of clear evidence of such a difference in thermal sensitivity of egg production and hatching, optimum size may change to different degrees if the cost of carrying *versus* not carrying egg sacs is temperature dependent. For example, feeding rates of ectotherms, including predators such as fish, typically increase with warming (Barneche *et al.*, 2008), and such increased risk of mortality to prey organisms may amplify any small differences in size- and fecundity- related trade-offs observed between broadcast and sac spawners at cooler temperatures. In principle, therefore, differences in the optimum body size response to temperature between the two spawning strategies can be hypothesized.

Our study therefore aims to: 1. Quantify and synthesise for the first time the seasonal temperature-size responses of a wide range of planktonic copepod species, and to compare these with responses under controlled laboratory conditions. 2. Examine the temperature dependence of size at maturity in copepods, based around major differences between taxonomic orders, species body sizes, modes of feeding (feeding current vs. active ambush feeding), and reproductive strategy. 3. Assess the relative importance of food concentration and temperature in driving seasonal size change.

METHODS

We searched the literature for studies in which the adult body size of planktonic copepods was assessed on multiple occasions during an annual cycle. In addition to temperature we also recorded the concentration of phytoplankton pigment chlorophyll-*a* (Chl-*a*) when this was reported. Chl-*a* concentration is commonly used as a proxy for phytoplankton biomass and food availability; indeed, adult fecundity and juvenile growth in many copepods correlates to this term (Hirst & Bunker, 2003; Bunker & Hirst, 2004). To reduce potential sampling bias in the sizes of animals collected, only those studies in which the adults were sampled across the entire depth of the water column, or across most of the depth range of the species, were included. Adult size data were collected as either lengths or dry, wet, or carbon mass. These measurements were subsequently converted to dry mass (mg) using published intra-specific regressions. If these were not available, regressions for closely related species, or more general inter-specific regressions, were used. A list of the data sources is found in Appendix 1. All raw data and conversions are detailed in Data S1 in Supporting Information. Taxonomic order and family were confirmed for each species using the World Registry of Marine Species (WoRMS Editorial Board, 2015).

In order to test which equation form best describes the relationship between mass and temperature within a species, we used AIC (Akaike Information Criterion) to compare linear, quadratic, exponential and allometric fits to the data. We found that the exponential equation form was overwhelmingly favoured for modelling seasonal T-S responses, as judged by Akaike weights (see Table S1 in Supporting Information for full details). We therefore used an exponential equation form to model the seasonal temperature-size response for each species from each study in our dataset, separating responses by sex. Species-specific slopes of the natural log (ln) of dry mass vs. temperature were determined for all individuals and transformed into percentage change in dry mass per degree Celsius, using the formula $(\exp^{(\text{slope})} - 1) * 100 = \% \text{ change in mass per } ^\circ\text{C}$ (Forster *et al.*, 2012). This value represents the seasonal temperature-size response, with a negative value showing a reduction in body

mass with increasing temperature, and hence following the same trend as the Temperature-Size Rule. Size responses from multiple studies of the same species were then combined into a simple mean to generate a single species-specific seasonal T-S value, separated by sex.

To quantify relationships between body mass and Chl-a, the species-specific slopes of the natural log (ln) of dry mass vs. Chl-a concentration (μg per litre) were determined for all individuals and transformed into percentage change in dry mass per $\mu\text{g.L}^{-1}$, again using the formula $(\exp^{(\text{slope})} - 1) * 100 = \% \text{ change in mass per } \mu\text{g.L}^{-1}$, to generate a chlorophyll-size (C-S) response. The mean 95% confidence intervals of T-S and C-S responses, calculated from the 95% confidence intervals of the individual estimated slopes, are presented for each order in Table S2 of our Supporting Information. For all datasets in which we had both a measure of temperature and Chl-a concentration ($n=80$), we compared the coefficient of determination (R^2) of both parameters (i.e. by comparing the R^2 of each seasonal T-S response with its corresponding C-S response), to determine whether one consistently explained significantly more of the variation in seasonal body size clines than the other. Given that temperature is a mechanistic driver of variation in primary productivity, we also utilised an alternate approach to examine these relationships; first we regressed body mass against temperature and then subsequently regressed the residuals from this on Chl-a concentration, to determine how much of the seasonal variation in body size could be attributed to Chl-a after accounting for temperature.

All statistical analyses were conducted using the free statistical software package R (R Core Team, 2014). We derived several candidate models to determine the best predictors of seasonal T-S responses based on the Akaike's information criterion (AIC). In order to determine whether species body size impacts the T-S response, we included $\log_{10}$ species

mass at a reference temperature (15°C) as a predictor, as such an allometric relationship has previously been shown to be significant (Forster *et al.*, 2012; Horne *et al.*, 2015). Taxonomic order, $\log_{10}$ body mass (at 15°C calculated using species and sex-specific slopes) and sex were incorporated as fixed variables in a global linear mixed effects model (using package lme4), with species nested within family, and latitude included as random effects on the intercept. When selecting our random effects, we considered the estimates of variance explained by each of our proposed random variables (environment type (marine vs. freshwater), latitude, and species nested within family) and used stepwise elimination of non-significant terms to determine which parameters to include in the final model. All possible combinations of the global model terms were compared using the dredge function in the MuMIn package in *R*. The best model was identified as that with lowest small-samples corrected AIC (AICc), and Akaike weights (w_i) were used to determine the probability (0-1) of each candidate model being the best fit model (i.e. if $w_i=0.9$, there is a 90% probability that a given model is the best fit model among those considered and given the data available). Where the difference between a model's AICc and the lowest AICc (i.e. $\Delta AICc$) is <2 , a set of best fit models, rather than a single best model, can be assumed, and model averaging may be used to identify the best predictor variables across the top candidate models and determine their relative importance (computed for each variable as the sum of the Akaike weights from all models in which they appear). In addition to AIC, a series of *F* tests (using the 'anova' function in *R*) were used to verify the significance ($p<0.05$) of each parameter's effect on the strength of the seasonal T-S response. *Post hoc* comparisons were made using a Tukey HSD test.

To compare seasonal T-S responses with laboratory T-S responses, we used the extensive T-S response dataset of Horne *et al.* (2015), supplementing this where possible with newly identified data following identical methods for acquiring data.

RESULTS

We derived a total of 140 seasonal T-S responses from 33 different global locations (Fig. 1), within the latitudinal range of 25° to 61°, hence largely falling around mid-latitudes (with a dominance of northern hemisphere locations). This in part reflects well-studied temperate environments with strong seasonality, while also being inhabited by copepod species with multiple generations in a year. The data set included 48 planktonic copepod species from 4 taxonomic orders (Calanoida, Cyclopoida, Harpacticoida, Poecilostomatoida). These species-specific seasonal T-S responses had negative slopes in 87% of cases, with a mean reduction in size of $-2.87 \pm 0.65\%$ (95%CI) body mass per °C (Fig. 2), reinforcing the generality of the negative T-S response in copepods. The overall strength or direction of the seasonal T-S response did not vary significantly across latitudes ($F_{1,138}=1.20$, $p=0.27$). Of the 80 seasonal body size clines for which we had a measure of Chl-*a* concentration (corresponding to 33 species), across all orders we observe a mean body mass response of $0.98 \pm 2.01\%$ (95%CI) per $\mu\text{g L}^{-1}$, which does not differ significantly from zero ($t_{79}=0.97$, $p=0.34$) (Fig. 2). On average, across all taxonomic orders temperature explained more of the variation in seasonal body mass than Chl-*a* concentration: this is inferred from the mean R^2 values of each parameter when both were modelled separately (0.44 ± 0.07 vs. 0.22 ± 0.05 respectively (95%CI)), and also when comparing body mass-temperature regressions with regressions of the resulting residuals against Chl-*a* concentration (0.44 ± 0.07 vs. 0.07 ± 0.03 respectively (95%CI)) (see Fig. S1 in Supporting Information). Considering each of the four orders separately, temperature always explained more of the variation in adult body mass than did Chl-*a* concentration.

In explaining variation in the strength of the seasonal T-S response among planktonic copepods, the model with the lowest AICc includes only taxonomic order as a fixed variable,

whilst all other candidate models have a $\Delta AICc > 2$ (Table 1). Thus, given the data available, we may reject the other candidate models in favour of a single best fit model in which taxonomic order has a significant independent effect on the strength of the seasonal T-S response ($F_{3,82}=9.43$, $p<0.001$). *Post hoc* comparisons (Tukey HSD) show that Calanoida ($n=66$, mean= $-3.66 \pm 0.70\%$ body mass $^{\circ}\text{C}^{-1}$; 95%CI) have a significantly stronger negative seasonal T-S response than both Cyclopoida ($n=12$, mean= $-0.91 \pm 0.59\%$ body mass $^{\circ}\text{C}^{-1}$; 95%CI) and Poecilostomatoida ($n=6$, mean= $1.36 \pm 3.06\%$ body mass $^{\circ}\text{C}^{-1}$; 95%CI), but not Harpacticoida ($n=2$, mean= $-1.19 \pm 3.60\%$ body mass $^{\circ}\text{C}^{-1}$; 95%CI), though our seasonal data for this order are sparse, including only male and female *Euterpina acutifrons*. We note specifically the different temperature response between the calanoids, which use feeding-currents, and ambush feeding cyclopoid copepods, with a 4-fold difference in the strength of the seasonal T-S response observed between these two groups (Fig. 3). We find no significant change in the strength of the response with mean species body mass in either the Calanoida ($F_{1,101}=0.11$, $p=0.75$) or non-Calanoida orders ($F_{1,35}=2.75$, $p=0.11$), supporting our prediction that any change in mature body size is independent of mean species body mass in these smaller taxa (Fig. 4).

Reproductive strategy also varies within and between orders; calanoid species can be either broadcast or sac spawners, but are more commonly the former ($n=44$ vs. $n=22$ for broadcast and sac spawners respectively in our dataset), whilst all species in the three remaining orders considered here are sac spawners. Given that taxonomic order and reproductive strategy correlate exactly in 3 of the 4 orders in our dataset, while in calanoids both reproductive strategies occur, we tested for differences in the seasonal T-S response between broadcasters and sac spawners exclusively in calanoids, finding no significant effect ($F_{1,64}=0.71$, $p=0.40$). Equally, we tested for order-level differences in the seasonal T-S response exclusively in sac spawners (i.e. by excluding any broadcast spawning calanoid species), and find significant differences in the strength of the seasonal T-S response

between taxonomic orders, still observing a 4-fold significant difference between calanoids and cyclopoids (t -test; $t=-4.51$, $df=31$, $p<0.0001$). This leads us to suggest that reproductive strategy is not responsible for driving the observed differences in seasonal T-S responses between taxonomic orders and, hence, explains why we chose to exclude the latter from our global linear mixed effects model.

Despite the numerous other variables that may act to obscure the correlation between body mass and seasonal temperature, we find a strong match between the mean Calanoida seasonal T-S response ($-3.66\pm0.70\%$) and mean T-S response ($-3.20\pm0.49\%$) measured in the laboratory under conditions of excess food (t -test; $t=-1.09$, $df=79$, $p=0.28$). However, we note that the two datasets comprise different species. Indeed, when we regress species-specific seasonal T-S responses against laboratory T-S responses for the small number of species for which we have both sets of data ($n=12$), separating responses by sex, we observe much greater variation in seasonal T-S responses than those measured under controlled laboratory conditions (Fig. 5). This suggests that food quantity/quality, and potentially other environmental variables, are impacting the T-S response in the field. There appears to be no systematic difference in the strength of laboratory and seasonal T-S responses between the sexes, such that sex has no significant effect on the strength of the seasonal T-S response, either across species ($F_{1,84}=0.03$, $p=0.86$) or intra-specifically (paired t -test; $t=1.35$, $df=37$, $p=0.19$). Unfortunately we are unable to make further meaningful comparisons between field and laboratory responses. For example, we could not compare the broad differences between taxonomic orders we observe in the seasonal T-S data with laboratory data, as very few laboratory studies on species other than calanoids have been conducted; our dataset contains male and female laboratory T-S responses for just 2 planktonic cyclopoid species and a single harpacticoid species.

DISCUSSION

Our work combines field data from numerous studies worldwide (Fig. 1), going beyond controlled laboratory-based T-S studies to demonstrate broad patterns in the thermal size responses of marine and freshwater planktonic copepods. Despite numerous other variables that may act to complicate the T-S signal in the field, we show that almost 90% of copepod species in our dataset follow the Temperature-Size Rule (TSR) in seasonal environments, maturing at a smaller adult body mass in warmer conditions. Yet, as we may expect, seasonal T-S responses appear much more variable compared to those measured under controlled conditions in the laboratory (Fig. 5), suggesting that other environmental factors, in addition to temperature, may play a role in driving seasonal body size variation in the field. We should also consider that the temperature at which adults are collected is unlikely to correspond exactly to temperatures experienced during ontogeny, and this may be further complicated by the existence of a winter diapause, during which many copepods will cease recruitment over late winter to early spring. Throughout this period their prosome length will change little, and yet temperatures may vary considerably.

Food availability has also been shown to have a direct influence on body size (Berrigan & Charnov, 1994; Diamond & Kingsolver, 2010), though we find that Chl-a concentration explains very little of the seasonal variation in body mass, when both modelled independently and after accounting for the effects of temperature. This suggests that temperature is much more significant in driving body size responses in these natural populations. Higher food quantity typically leads to larger size at maturity in ectotherms, and we observe a positive but non-significant percentage change in adult body mass with increasing Chl-a concentration on average (Fig. 2). Chl-a concentration commonly correlates significantly with juvenile growth and adult fecundity rates in many natural populations of planktonic copepods (Hirst & Bunker, 2003; Bunker & Hirst, 2004), and hence is generally

considered a reasonable proxy of food availability. However, many copepods have an omnivorous diet that does not exclusively include prey containing this pigment (e.g. including heterotrophic ciliates and flagellates (Calbet & Saiz, 2005)), and the proxy also fails to account for variation in prey quality (Pond *et al.*, 1996), which has been shown to alter the temperature-size response, even reversing its sign at times (Diamond & Kingsolver, 2010). Here we find little evidence for sign reversal when comparing laboratory and field animals. Time lags might also obscure the correlation between Chl-a concentration and body size. As food availability commonly varies over a much shorter timescale than generation time, whilst temperature varies over a relatively longer timescale, correlations with the latter are likely to be much more reliable. Although greater chlorophyll concentration is often associated with increased growth (Hirst & Bunker, 2003; Bunker & Hirst, 2004), consumer abundance is also predicted to increase with primary productivity (O'Connor *et al.*, 2009). Our analysis does not account for the abundance of the copepods, and hence we are unable to assess the role of food availability on a *per capita* basis. Assuming metabolic rate has a Q_{10} of 2.5 and scales with body mass^{0.75} (Zuo *et al.*, 2012), a simple calculation suggests that an organism would have to decrease its body mass by approximately 11.5% per °C of warming to offset the increase in metabolic rate associated with this temperature increase. Given that calanoid copepods on average reduce their body mass by only 3.66% °C⁻¹, this compensates for approximately a third of the increase in metabolic rate per °C of warming. If resources were limiting and kept constant then population abundance would have to fall substantially with warming to accommodate the extra metabolic demand, even with reduced body size of individuals.

Beyond variation in temperature and food availability, we might expect predation by ectotherms to increase with warming in the field (Kordas *et al.*, 2011). This in turn may lead to increased copepod mortality, selecting for earlier maturation and resulting in a reduced adult body size. Copepods can also detect and perceive chemical signals released by

predators, such as fish kairomones, the presence of which has been shown to trigger faster development and earlier maturation at a smaller body size in calanoids (Gutiérrez *et al.*, 2010). Thus, increased predation risk in the warm and associated increases in mortality and the presence of chemical cues may amplify the temperature-size response in the field.

The relative strength of the seasonal T-S response does not vary significantly between the sexes in this study, evidence of which can also be observed in Figure 5. These findings agree with the broader analysis across Arthropoda, for which T-S responses were found to not significantly differ between the sexes (Hirst *et al.*, 2015). Rensch's rule suggests that male body size varies more than female body size, irrespective of which is the larger sex (Rensch, 1960). Applied within species, the rule would predict an increase in sexual size dimorphism (SSD) with increasing body size in species where males are the larger sex, and a decrease in SSD with body size in species where females are larger. Thus males should consistently have the greater size variation, yet we find no evidence to support this pattern at the intra-specific level. Our finding at the intra-specific level here concurs with there being isometry between male and female size seen across copepod species (Hirst & Kiørboe 2014), and suggests that the selection pressures on the seasonal T-S response have been equally as strong for both males and females.

Though recent studies have begun to identify broad trends in both the magnitude and direction of the T-S response, for example between terrestrial and aquatic species (Forster *et al.*, 2012; Horne *et al.*, 2015), there remains a large amount of variation in the strength of the response that is yet to be explained. This is especially true for planktonic species which are only a few millimetres in size or less, where oxygen availability in most conditions appears unlikely to be a driver. Indeed, our most compelling finding is the significant difference in the strength of seasonal T-S responses between species of calanoid and

cyclopoid (Fig. 3), both of which typically employ different feeding modes. We find that calanoids exhibit much greater size plasticity upon temperature changes than non-calanoids. This is consistent with the hypothesis that feeding mode may influence the T-S response, since all calanoids can produce a feeding current to harvest prey, while none of the other orders do so. The extent to which the T-S response differs between these two feeding modes depends on the differences in both size-scaling and thermal response of feeding in relation to metabolism. Thus, in order to thoroughly test this hypothesis, one would need estimates of within-species mass scaling and temperature dependence of feeding and metabolism. While some estimates of between-species body mass scaling of respiration and feeding of the two groups exist (e.g., Kiørboe & Hirst 2014), the body mass-dependent changes in vital rates during ontogeny are typically different (Hirst *et al.*, 2014; Glazier *et al.*, 2015), and thus needed for these groups. A further complication arises from the fact that feeding mode may change during ontogeny: while all cyclopoids are ambush feeders throughout their development, many calanoids are ambush feeders during the nauplii stage, and feeding current feeders during the copepodite stages; or they may switch between feeding modes in the copepodite stages (Kiørboe, 2011).

We note the association between taxonomic order and feeding mode in our dataset, and appreciate the potential difficulty in disentangling effects of feeding strategy from other order-specific differences in physiology and behaviour. For example, all cyclopoids in our dataset are sac spawners, whilst calanoid species can be either broadcast or sac spawners, but are more commonly the former. However, we find no substantial effect of reproductive strategy on the sensitivity of mature body mass to temperature. Whilst broadcast and sac spawning planktonic copepods have markedly different rates of adult fecundity (Bunker & Hirst, 2004), egg mass production rates (Hirst & Bunker, 2003) and egg mortality (Hirst & Kiørboe, 2002), they appear to have somewhat similar rates of juvenile growth, development and mortality (Hirst & Kiørboe, 2002; Hirst & Bunker, 2003). The T-S responses of species with

determinate growth are largely generated during the juvenile phase of ontogeny (Forster & Hirst, 2012). Similarity of important life history rates during the juvenile phase may therefore explain the lack of difference in the T-S responses within the calanoids based upon reproductive strategy. Expanding our analysis in future to consider ambush feeding calanoid copepods, such as in the genera *Tortanus* and *Pareuchaeta*, will help to more definitively separate effects of feeding strategy from order-level differences. Unfortunately at present, suitable data are not available on these taxa. We recommend that future experimental studies comparing species-specific size variation in response to temperature, both within and between taxonomic orders, should focus on those taxonomic groups that are currently data deficient.

Given that body size is an important predictor of fitness, and warming is a prominent feature of climate change, there is an urgent need to accurately predict changes in body size with temperature. This is particularly the case in zooplankton which globally represent a primary resource for invertebrates and vertebrates, including fish (Ware & Thomson, 2005). Changes in body size will not only affect individual and population fitness, but may impact feeding rates and alter food web connectivity given the size dependency of trophic processes (Hansen *et al.*, 1994; Rice *et al.*, 2015), as planktonic food webs are especially highly size-structured (Webb, 2012). Measuring and accounting for abundance in the field would also help to define the relationship between food availability *per capita* and adult body size under natural conditions. This may be particularly informative in light of the fact that the temperature-size response in the majority of ectotherms appears to compensate for only a small proportion of the predicted increase in metabolic rate with temperature, whilst metabolic rate in autotrophs (and thus primary productivity) increases substantially less with warming than metabolic rate in heterotrophs (Allen *et al.*, 2005).

ACKNOWLEDGEMENTS

We wish to thank the many authors who kindly donated their data or clarified aspects of their studies. CRH is supported by a Natural Environment Research Council Studentship NE/L501797/1. AGH was supported by the Natural Environment Research Council and Department for Environment, Food and Rural Affairs [grant number NE/L003279/1, Marine Ecosystems Research Programme]. The Centre for Ocean Life is a VKR Centre of Excellence supported by the Villum Foundation. We thank the reviewers, their comments helped to greatly improve the paper.

BIOSKETCH

The work presented here results from an ongoing collaboration between researchers from Queen Mary University of London, the University of Liverpool and the Centre for Ocean Life, Technical University of Denmark. We use a range of approaches such as meta-analysis, experimentation, conceptualisation and modelling to establish and test governing rules of ecology and evolution. A major focus is the ecology, physiology and population processes of marine species, especially plankton, including the impact of a changing climate. Further information, including details of our latest research and publications, can be found at our research group website: www.aquatic-ecology.co.uk

Table 1. AIC output comparing the relative strength of candidate models in explaining variation in seasonal T-S responses. The best model, shown in bold, is identified as that with the lowest small-samples corrected AIC (AICc). Given that the difference between the lowest AICc and those of the alternative models (i.e. $\Delta AICc$) is >2 , we may favour a single best fit model in which taxonomic order has a significant independent effect on the strength of the seasonal T-S response. An 'intercept only' model, shown in italics, is included for comparison. Akaike weight (w_i) denotes the probability of a given model being the best fit model in the candidate set. The number of parameters (K) in each model is shown. Mass is the species adult body mass at 15°C.

Model	K	Log-likelihood	AICc	$\Delta AICc$	w_i
<i>Intercept</i>	5	-328.40	667.25	5.08	0.04
Order	8	-322.53	662.16	0.00	0.52
Order+Sex	9	-322.51	664.40	2.24	0.17
Log ₁₀ Mass+Order	9	-322.53	664.44	2.27	0.17
Log ₁₀ Mass+Order+Sex	10	-322.51	666.72	4.55	0.05
Log ₁₀ Mass	6	-327.89	668.41	6.25	0.02
Sex	6	-328.38	669.40	7.24	0.01
Log ₁₀ Mass+Sex	7	-327.77	670.38	8.22	0.01

FIGURE LEGENDS

Fig. 1. World map indicating the location of studies (n=33) from which copepod seasonal size responses were recorded. Studies from freshwater environments are indicated by the light grey circles whilst marine environments are indicated by the dark grey circles.

Fig. 2. Species-specific % change in body mass ($\pm 95\%$ CI) for seasonal T-S (per $^{\circ}\text{C}$) and C-S (per $\mu\text{g.L}^{-1}$) responses, averaged by order. Solid grey lines shows the mean seasonal T-S and C-S response across all orders with 95%CI indicated by the shaded area.

Fig. 3. (A) Seasonal temperature-size responses of adult copepods for individual species, including both males and females, categorized by order (Calanoida, Cyclopoida, Harpacticoida, Poecilostomatoida) and family (Acartidae (Ac), Calaniidae (Ca), Centropagidae (Ce), Clausocalanidae (Cl), Diaptomidae (Di), Paracalanidae (Pa), Pseudodiaptomidae (Ps), Temoridae (Te), Cyclopidae (Cy), Oithonidae (Oi), Euterpinidae (E), Corycaeidae (C), Oncaeidae (On)). Where more than one study has been undertaken on a species, the mean (and $\pm\text{SE}$) are plotted. Dashed horizontal lines indicate the mean seasonal T-S response for the Calanoida and Cyclopoida orders. Dashed vertical lines divide taxonomic families. Species names preceded by an asterisk are sac spawners, whilst all other species are broadcast spawners. (B) Species-specific seasonal T-S responses ($\pm 95\%$ CI), averaged by order. Different letters above data points indicate significant differences, whilst shared letters indicate no significant difference. Note the significant difference between feeding-current feeding Calanoida and ambush feeding Cyclopoida.

Fig. 4. Seasonal temperature-size responses (% change in body mass $^{\circ}\text{C}^{-1}$) versus species $\log_{10}$ adult dry mass (mg), categorized by taxonomic order. We find no significant

relationship between the strength of seasonal T-S responses and species body mass across either Calanoida ($F_{1,101}=0.11$, $p=0.75$; solid line) or non-Calanoida species ($F_{1,35}=2.75$, $p=0.11$; dashed line). Data for both females and males are included where possible. “NS”=not significant.

Fig. 5. Male (M) and female (F) species-specific laboratory temperature-size (T-S) responses versus seasonal T-S responses in planktonic copepods. Seasonal T-S responses are much more variable than laboratory T-S responses and there is a significant positive correlation (RMA regression; $R^2=0.25$) between the two. Dashed grey line indicates $y=x$ for comparison. There appears to be no significant difference in the strength of seasonal and laboratory T-S responses between the sexes.
