Abstract

The growth dynamics of layered carbon is studied by means of *in situ* transmission electron microscopy in order to obtain a deeper insight into the growth by chemical vapor deposition, which at present is the technique of choice for growing layered carbon. *In situ* growth of layered carbon structures on nickel using acetylene as carbon precursor gas is studied in the electron microscope at various gas pressures. By following the growth of individual graphene layers on the Ni surface, local growth rates are determined as a function of precursor pressure. Two growth regimes are identified, an initial rapid growth, which does not show a strong dependence on pressure, followed by a slower growth with a strong pressure dependence.

1. Introduction

Carbon based materials like carbon nanotubes (CNTs) and graphene attract a lot of interest due to their mechanical and electronic properties and their low mass [1]. The most efficient and preferred synthesis method is chemical vapor deposition (CVD) on metallic catalysts in the form of nanoparticles for CNTs [2] and polycrystalline wafers or foils for graphene. Copper (Cu) is mainly used for growing single layer graphene, as it shows a self-limiting growth [3–5]. One drawback of Cu as catalyst is the high process temperature of about 1000 °C leading to technological challenges for oven material and high process energy costs. Nickel (Ni), as an alternative, turns out to be a good catalyst for low-temperature graphene growth at about 450–650 °C [6,7] and can grow multilayer graphene, which can be of use for certain electronic applications [8] or as diffusion barrier [9] and corrosion protection [10]. However, the growth process is more difficult to control especially for single or few layer graphene. The main reason for the difference in controllability is assumed to be connected to the solubility of carbon in the two metals, which is higher in Ni than in Cu [11]. The solidification of carbon from gaseous carbon containing precursors to (multi-layer) graphene has been suggested to involve dissolved carbon, which after super-saturation of the nickel leads to precipitation. The appearance of carbon species at the surface and in the subsurface during growth was confirmed by X-ray photoelectron spectroscopy (XPS) studies [7,12]. To control the growth of single layer graphene on the catalyst, a fundamental understanding of the growth of layered carbon itself is needed. Direct observation of the layer growth will unquestionably contribute to this. *In situ* transmission electron microscopy (TEM) experiments were conducted on the growth of carbon fibers on Ni nanoparticles. From these experiments, growth rates of these fibers were obtained and a growth mechanism proposed which involve the diffusion of carbon through the particle [13], whereas a growth mechanism mainly involving carbon diffusion on the Ni surface was proposed elsewhere [14]. However, the dynamics of the individual layer growth was not

investigated. As the situation for an extended flat surface might be completely different due to the lower surface curvature and the volume of the catalyst, we perform *in situ* TEM on more extended surfaces to get a deeper insight in the growth of individual layers and address the question of growth dynamics.

2. Experimental

In order to mimic the flat surface of Ni foils or wafers used in large-scale *ex situ* CVD growth of layered carbon, but are unsuited for TEM investigations, nickel oxide (NiO) powder with a particle size up to a few hundred nanometers was used as a precursor for the catalyst in the present study. Furthermore, the geometry of the NiO particles provides extended Ni surfaces with small curvature after reduction, allowing for direct observation of the (multi-layered) graphene in the environmental transmission electron microscope (ETEM). The small curvature is clearly different to the large curvature of nanometer sized Ni particles which result in carbon nanotube growth [14]. NiO resembles the native oxidized surface of Ni, which is always present when stored under ambient conditions requiring a reduction procedure before CVD growth.

In situ electron microscopy growth of layered carbon structures and corresponding analysis using an ETEM is performed by exposing Ni to a precursor gas atmosphere of acetylene (C_2H_2). The ETEM is operated at 300 kV in order to optimize the microscope performance in terms of resolution and signal-to-noise ratio while operating in a gaseous atmosphere [15], even though this is above the threshold for knock-on damage of carbon atoms within a graphene sheet [16]. Great care was taken to minimize electron beam damage of the grown carbon structures. Under the chosen conditions, with the dose rate at a maximum of about $2 \times 10^6 \text{ e}^-/(\text{nm}^2\text{s})$, no obvious degradation of the grown graphene layers was observed. The electron microscope itself is

cleaned by bake-out of the gas feed lines and internal plasma cleaning between experiments in order to minimize cross contamination between individual experiments.

The NiO powder is dispersed on a micro electro-mechanical systems (MEMS)-based heating chip with a holey Si₃N₄ membrane on top (DENSsolutions). The samples are plasma cleaned (Ar/O₂ gas) prior to insertion in the ETEM in order to reduce surface contamination. Moisture within the porous structure of the NiO agglomerates is minimized by heating the sample to 350 °C for about 30 min in the microscope. The NiO sample is then reduced *in situ* in the ETEM at 500 °C in flowing hydrogen (H₂) building up to a pressure of 1.2 mbar for 1h. The temperature is increased to the growth temperature of 650 °C and C₂H₂ gas is added to the H₂ gas flow. This procedure ensures that the catalyst is maintained in a consistent and reproducible state of metallic Ni and prevents high-temperature reoxidation due to residual oxidizing agents in the ETEM. With the proposed procedure a clean system is ensured, leading to a reproducible and successful route to graphene growth.

3. Results

To confirm that NiO is reduced to catalytic active metallic Ni in the electron microscope, spectroscopic information by means of electron energy-loss spectroscopy (EELS) are acquired during reduction in H₂. The spectra acquired from extended surface areas of individual catalyst particles (up to at least 20 nm from the particle surface) clearly show the reduction from NiO to metallic Ni (Fig. 1). The fine-structure of the Ni L_{2/3}-edge observed at an energy-loss

Figure 1: Electron Energy-Loss Spectra of the catalyst in vacuum (black) and under H₂-atmosphere after reduction (red) in the electron microscope. The change in the fine structure of the Ni L_{2/3}-edge (a) combined with the absence of the oxygen K-edge after reduction (b) indicates the success of reducing the catalyst from NiO to Ni.

1 between approx. 855 eV and 880 eV in the black and red spectra in Fig. 1a is characteristic of
2 oxidized and metallic nickel, respectively [17]. Additionally, the O K-edge at about 532 eV
3 (Fig. 1b) is absent in the reduced state. **Therefore, a full reduction of the surface area of at least**
4 **20 nm thickness is confirmed. Possible unreduced NiO fractions within the Ni particles or**
5 **agglomerates, as reported previously [18], are neglected and no influence of reduction products**
6 **on the environment is assumed.** In order to check for carbon contaminants on the catalyst before
7 initiating the growth, the EELS signal around 284 eV is also acquired (carbon K-edge). No
8 sign of carbon was observed, **which means that if carbon is present, it is below the detection**
9 **limit.**

10 To investigate the pressure dependence of the growth of carbon layers, two different partial
11 pressures of C₂H₂ of approximately 1×10^{-4} and 3×10^{-4} mbar were used. Figure 2 shows the
12 development from single/few layer graphene to a relatively thick graphitic structure illustrated
13 by stills from acquired movies of the dynamic process. The *in situ* growth results in well-
14 aligned carbon layers with an inter-layer distance of about 0.34 nm corresponding to the
15 interlayer distance in graphite. Furthermore, EELS of the grown layered material shows a
16 strong carbon signal (Fig. 2d) characteristic of layered graphitic carbon.

1 Quantitative data from the *in situ* growth is extracted by plotting the number of carbon layers
2 formed as function of time. Only fully-formed carbon layers (within the field of view) are
3 considered in the growth analysis. Figure 3 shows the layer growth rate extracted from
4 observation of growth at a C_2H_2 pressure of approx. 3×10^{-4} mbar. The data is extracted from
5 three distinct areas and shows the same trend. The data from area 1 and 2 are aligned in time

Figure 2: Images from the experiments at growth (650°C , $P(C_2H_2) = 3 \times 10^{-4}$ mbar). The layered structure on the Ni surface is clearly visible. EELS data from the layered structure clearly shows the carbon K-edge with the characteristic π^* and σ^* bands.

at the observation of 4 formed layers, the data of area 3 is aligned to 2 for 42 formed layers. Missing data in the growth curves are either due to frames, which could not be analyzed as the image was out of focus, severe drift or not acquired due to limited data file buffer size.

The measured data are fitted linearly in six time regimes (a-f), which give the layer growth rate as a function of time / carbon structure thickness. Figure 3 shows at least two different growth regimes. After an initial high layer growth rate (a and b), the growth slows down in the range of 10 to 15 carbon layers (c and d), and slows down further after 30-40 layers are formed (e and f). The initial growth is relatively fast with a rate of 0.6-0.8 layer/s. As the number of layers increase the observed growth rate decreases to 0.19 layer/s in the timeframe of the experiment.

The pressure dependence of the growth in general and the growth rate in particular is studied by repeating the experiment with a C_2H_2 pressure of 1×10^{-4} mbar. The decreased precursor pressure still result in aligned carbon layers on top of the Ni catalyst. Again, two regimes are found in the layer growth rate as shown in Fig. 4. The first 30 layers grow rapidly, with a growth rate of about 0.4 layer/s. As in the ‘high-pressure’ case, for higher number of layers

Figure 3: Number of carbon layers per time extracted from in situ TEM movies of the growth at three distinct areas. a-f give the distinct linear fits. $T = 650^\circ\text{C}$, $P(C_2H_2) = 3 \times 10^{-4}$ mbar.

(here about 30) the growth rate decreases significantly to 0.02 layer/s. Apparently, the initial growth rate is only slightly lower for the low pressure (1×10^{-4} mbar) study compared to the high pressure (3×10^{-4} mbar) indicating that the underlying mechanism at this stage is less pressure-dependent. However, the growth rate after approx. 30 layers is an order of magnitude lower for the low pressure study than for the high pressure study. The *in situ* measured growth rates are summarized in Tables 1 and 2.

Table 1: Layer by layer growth rates extracted from linear fits of in situ observed layer growth (Fig. 3). $T = 650$ °C, $P(\text{C}_2\text{H}_2) = 3 \times 10^{-4}$ mbar.

1 In order to study the growth in greater detail, the *in-plane* layer growth rate, the growth rate of
 2 projected individual graphene layers is extracted from the acquired movies. The frames are
 3 spatially aligned using the plugin StackReg in ImageJ [19]. After the first graphene layer
 4 formed at the Ni surface, additional carbon layers are formed at the nickel/carbon interface by
 5 a ledge growth mechanism as illustrated in Fig. 5. The relative position of the growth front
 6 (illustrated by arrows) is extracted from individual frames and converted to a growth rate. In
 7 some cases two layers are observed to grow simultaneously within the same limited field of
 8 view. The projected rate of the *in-plane* layer growth is plotted for several layers in Fig. 6 and
 9 7 (the color coding is identical to Fig. 3 and 4). In both experiments the growth rate appears
 10 very scattered, but is clearly slower in the lower pressure range, which matches the decreased
 11 layer growth rate. However, in the higher pressure range there seems to be a trend of the in-
 12 plane growth rate slowing down with time. This becomes apparent when comparing the data
 13 points of growth regimes d and f. These data come from the same area at different growth
 14 times. Correlating the layer growth rate with the *in-plane* growth rate, both seem to be

Figure 4: Number of carbon layers per time extracted from *in situ* TEM movies of the growth at two distinct areas. *a* and *b* give the distinct linear fits. $T = 650\text{ }^{\circ}\text{C}$, $P(\text{C}_2\text{H}_2) = 1 \times 10^{-4}\text{ mbar}$.

1 connected, as for the higher layer growth rate (d compared to f in Fig. 3) the *in-plane* growth
 2 rate also seem to have a tendency of being higher (red and pink data points of area 2 in Fig. 6).

3

Figure 5: Image series with 0.61 s between the images. Following the arrow, one can follow the *in-plane* growth of the carbon layers. (d) dashed arrow ($v_{in-plane}$) indicates the *in-plane* growth, dotted arrow (v_{layer}) indicates the layer growth. $T = 650\text{ }^{\circ}\text{C}$, $P(\text{C}_2\text{H}_2) = 3 \times 10^{-4}\text{ mbar}$.

Figure 6: Growth rate in-plane; growth rate for growth regime d, e and f (Fig. 3). $T = 650\text{ }^{\circ}\text{C}$, $P(\text{C}_2\text{H}_2) = 3 \times 10^{-4}\text{ mbar}$. Colors correspond to colors in Figure 3.

Figure 7: Growth rate in-plane; growth rate for growth regime b (Fig. 4). $T = 650\text{ }^{\circ}\text{C}$, $P(\text{C}_2\text{H}_2) = 1 \times 10^{-4}\text{ mbar}$. Colors correspond to colors in Figure 4.

4. Discussion

The fast initial growth might be connected to the solubility of carbon in Ni, as found in XPS studies [7,12,20]. After carbon (super)saturation of the first few atomic Ni layers, a graphene seed nucleates and carbon diffuse to the surface and nucleate at the seed resulting in the formation of the first graphene layer. This is in agreement with the model suggested by Patera *et al.* [20]. If carbon for the initial growth is coming from the Ni bulk, the growth rate could be assumed to be less precursor pressure dependent as it is limited by the diffusion kinetics in

solid nickel. However, the absolute time for saturation is dependent on the gas pressure, which influence the incubation time. Furthermore, the carbon depth profile is influenced by kinetics and might show pressure dependence. With higher pressure more carbon can diffuse into Ni at once. But as carbon has a very limited solubility in Ni, the first Ni sublayers are saturated faster meaning the thickness of saturated Ni sublattice is thin, the depth profile is shallow. At lower pressure less carbon diffuse into Ni at once and it takes longer to saturate the first Ni sublayers. This means carbon can diffuse deeper into the Ni sublattice until saturation of the first layers is reached, the depth profile should reach deeper. So the thickness of Ni sublattice with dissolved carbon is thicker for lower pressures (more carbon dissolved), which leads to more layer growth in the first growth regime. This matches the observation of up to about 30 layers in the faster growth regime for the lower pressure and about 15 for the higher pressure.

Nevertheless, from the Ni-C phase diagram [21] a maximum solubility of carbon under equilibrium conditions of about 2.7 at% is reported, which can be extended up to about 7.4 at% at 1314 °C in a metastable phase. By calculating the volume and surface of a Ni sphere 100 nm in diameter and the number of carbon atoms in a single graphene layer covering this surface, the carbon concentration needed is about 2.4 at% close to the saturation concentration, assuming a homogeneous distribution of carbon in the Ni sphere. For 10 layers a concentration of about 20 at% is needed. This rough estimate already shows that the carbon for the numerous graphene layers cannot solely come from the dissolved carbon in the Ni.

The slower and apparently more pressure-dependent growth regime fits a diffusion driven mechanism, namely the carbon atoms to the active Ni surface at the Ni-graphene interface from the gas phase itself. The energy barrier for diffusion of carbon atoms at the Ni-graphene interface is low (about 0.5eV) and additional carbon atoms tend to nucleate at the existing graphene edge [14,22]. Step edges which should facilitate the growth of graphene cannot be observed clearly, which might be due to the projected image of the rather large particle.

1 The growth of numerous graphene layers in the experiments has two prerequisites: access of
2 the gaseous specie to the Ni surface to decompose into carbon atoms, and diffusion of the
3 carbon atoms to the growth front. Diffusion through the defect free graphene layers is unlikely
4 [23,24], but as we are dealing with grown graphene layers on rather large particles and particle
5 agglomerates, the presence of defects in the graphene layers, can allow gas to diffuse to the C-
6 Ni interface, or areas with little or no graphene layers, can act as gateways for carbon precursor
7 to the catalytic surface. It has been reported that carbon can easily diffuse at the Ni-graphene
8 interface and the Ni subsurface [14,22], but the diffusion length in our experiment still remains
9 long. From the growth movies of the present experiments the carbon diffusion at the Ni
10 (sub)surface has to be at least several tens of nanometers from source to growth front as no
11 defects in the layered carbon was observed in the field of view. This rather long diffusion length
12 and the small curvature geometry of the catalyst particles shows the clear difference to carbon
13 nanotube growth and the underlying mechanisms, as the particles size for nanotube growth
14 ranges below 10 nm. The results obtained here should be much closer to the flat wafer or foil
15 geometry of a large scale CVD process.

16 The scatter of the *in-plane* growth rate found in both, the ‘high pressure’ experiment and the
17 ‘low pressure’ experiment indicates that the formation of carbon layers might be difficult to
18 control. Especially the scattering within the growth of one layer in the lower pressure
19 experiments suggests a strong dependency of the substrate structure, like orientation and
20 defects [25–27], which is subject to future *in situ* studies. **However, in the present work we**
21 **were not able to uniquely determine the surface termination of the Ni during growth.**
22 Furthermore, several layers of carbon are formed very quickly on the nickel surface in the
23 initial stage. This process seems to be less pressure dependent than the latter growth process,
24 making it very hard to limit the growth to single or double layer graphene under the present
25 growth conditions.

As the growth rate is extracted from a projection, and influenced by the actual number of carbon atoms joining the carbon layers per time depending on the thickness of the sample perpendicular to the electron beam needs to be taken into account. For the same particle, this effect should be negligible as the grain thickness should not change within the recorded movie.

5. Conclusion

Successful *in situ* graphene growth on Ni at 650 °C in the ETEM was performed. From movies recorded during growth, layer growth rates and *in-plane* growth rates were extracted. At least two growth regimes were observed: an initial fast regime for the first few layers followed by a slower regime for higher layer numbers. The *in-plane* growth rate appears to correlate to the layer growth rate. Furthermore, the slower growth regime shows pressure dependence, whereas the faster growth regime seems to be significantly less pressure dependent. A resulting thickness of the perfectly aligned carbon structures of tens of nanometers indicate a continuous supply of carbon to the growth front from the gas phase.

Supplementary

Three growth movies are included as supporting information. Movie1.avi showing the initial growth at higher pressure, Movie2.avi showing the slower growth after few layers growth at higher pressures, Movie3.avi showing the slower growth after few layers growth at lower pressures. This material is available online.
