11 Abstract

12 The new paradigm for used water treatment suggests the use of short solid retention times (SRT) to minimize organic substrate mineralization and to maximize resource 13 14 recovery. However, little is known about the microbes and the underlying biogeochemi-15 cal mechanisms driving these short-SRT systems. In this paper, we report the start-up and operation of a short-SRT enhanced biological phosphorus removal (EBPR) system 16 17 operated as a sequencing batch reactor (SBR) fed with preclarified municipal 18 wastewater, which is supplemented with propionate. The microbial community was ana-19 lysed via 16S rRNA amplicon sequencing. During start-up (SRT=8 d), the EBPR was

20 removing up to 99% of the influent phosphate and completely oxidized the incoming 21 ammonia. Furthermore, the sludge showed excellent settling properties. However, once 22 the SRT was shifted to 3.5 days nitrification was inhibited and bacteria of the *Thiothrix* taxon proliferated in the reactor, thereby leading to filamentous bulking (sludge volume 23 24 index up to SVI=1100 mL/g). Phosphorus removal deteriorated during this period, likely due to the out-competition of polyphosphate accumulating organisms (PAO) by sul-25 phate reducing bacteria (SRB). Subsequently, SRB activity was suppressed by reducing 26 the anaerobic SRT from 1.2 day to 0.68 day, with a consequent rapid SVI decrease to 27 28 ~200ml/g. The short-SRT EBPR effectively removed phosphate and nitrification was 29 mitigated at SRT=3 days and oxygen levels ranging from 2 to 3 mg/L.

31 Keywords

Enhanced biological phosphorus removal; microbial diversity; resource recovery; short
solid retention time activated sludge systems; sulphate reducers.

34 1 Introduction

The conventional activated sludge (CAS) process has been used for more than 100 years for wastewater treatment (Schneider 2014). The process relies on a microbial community formed mainly by bacteria able to remove organic carbon, nitrogen and phosphorus from sewage. Current research, however, proposes a new approach whereby wastewater components are recovered rather than destroyed (Verstraete et al., 2009). This new par-

adigm suggests considering the wastewater treatment plant (WWTP) as a biorefinery,
whereby nutrients, energy, water, minerals or biopolymers can be separated and recovered (Sheik et al., 2014).

43 Anaerobic digestion plays an important role in energy recovery from wastewater. One 44 option is to directly digest wastewaters with high organic carbon content (Shoener et 45 al., 2014). However, this alternative suffers from the loss of dissolved methane in the 46 effluent, which can be stripped to the atmosphere, thus contributing to climate change 47 (Verstraete et al., 2009). As an alternative, CAS can be combined with anaerobic diges-48 tion, whereby the excess biomass wasted via solid retention time (SRT) control is an-49 aerobically digested for biogas production. Operating CAS at long SRTs would lead to 50 the emission of large amounts of carbon dioxide in the aeration basins, thereby decreas-51 ing the amount of organic carbon conveyed to the digester (Batstone et al., 2015). Short 52 SRT systems (i.e. SRT < 4 days) have been proposed as a means to promote carbon as-53 similation (i.e. microbial growth) and accumulation as stored polymers rather than oxi-54 dation (Jimenez et al., 2015). The effluent of these systems are rich in nitrogen and 55 phosphorus, which can be recovered through physicochemical processes (e.g. ammonia 56 stripping or struvite precipitation, Verstraete et al., 2009) or via biological assimilation (e.g. green microalgae cultivation, Shilton et al., 2012). 57

Enhanced biological phosphorus removal (EBPR) systems operated at short SRT can
integrate phosphorus upconcentration with energy recovery (Ge et al., 2013 and 2015).
Growth of polyphosphate accumulating organisms (PAO) in EBPR systems is promoted
by circulating the mixed liquor through a sequence of anaerobic and aerobic environ-

62 ments (Mino et al., 1998). PAO release stored polyphosphate under anaerobic environments in the presence of bioavailable organic carbon, preferably volatile fatty acids 63 (VFA), which PAO take up and store as polyhydroxyalkanoates (PHA). PAO then use 64 the stored PHA under aerobic conditions as a carbon source for growth while accumu-65 lating bioavailable phosphate in excess of their metabolic needs. Importantly, EBPR 66 systems can be used to create phosphorus rich effluent streams, optimal for P-recovery, 67 68 following two different strategies: either directly by partial diversion of the effluent from the anaerobic reactor after phosphorus release (e.g. Barat and van Loosdrecht, 69 70 2006) or indirectly as a result of phosphorus release induced by anaerobic digestion of 71 EBPR sludge (Yuan et al., 2012).

72 EBPR systems are a mature technology widely studied both in laboratory- and full-scale systems (Oehmen et al., 2007). The microbial communities in EBPR systems are also 73 74 very well-known as most of the full scale plants have a similar microbial diversity with only the abundance of bacterial groups appearing to be plant specific (e.g. Nielsen et 75 76 al., 2010; Albertsen et al., 2012; Mielczarek et al., 2013). However, most of these studies are based on long SRT system observations, where nitrification also occurs. Only a 77 few studies have focused on short-SRT EBPR systems (Mamais and Jenkis, 1992; 78 79 Brdjanovic et al., 1998; Ge et al., 2015; Valverde-Pérez et al., 2015 and 2016). Short-SRT activated sludge systems, i.e. A-stage systems, have different communities than 80 81 those reported for CAS (González-Martínez et al., 2016; Meerburg et al., 2016). Whilst the main microbial groups and factors that affect their abundance in A-stage systems 82 83 have been widely reported, we lack the same information for short-SRT EBPR systems.

84 Only Ge et al. (2015) identified a novel PAO organism, belonging to the Comamonadaceae family, which became dominant and drove P-removal in a short-SRT EBPR 85 treating abattoir wastewater. As a consequence, the available models, both ecological 86 and mathematical, may lack relevant bacterial groups to properly describe short-SRT 87 88 EBPR systems. Therefore, the main objectives of the present study are i) to describe the 89 start-up and operation of a short-SRT EBPR system ; ii) to assess the microbial com-90 munity dynamics and identify operation strategies promoting effective process perfor-91 mance; iii) to identify the limitations of available biochemical process models and pro-92 pose potential extensions to model the short-SRT EBPR process.

93 2 Materials and Methods

94 2.1 Reactor description

95 The EBPR system was a sequenced batch reactor (SBR) with 8 L volume, operated at 96 hydraulic retention time (HRT) of 18 h and SRTs of 8, 3.5 and 3 days (operational con-97 ditions are summarized in Table 1). The initial operation sequence was 2 hours of an-98 aerobic phase, 3 hours of aerobic phase and 1 hour of settling and idle phase. The reac-99 tor was fed during the first 2 minutes of the anaerobic phase. The SBR was fed with 100 pre-clarified wastewater from Lundtofte WWTP (Kgs. Lyngby, DK) and spiked with 101 synthetic wastewater supplemented with propionate and ortho-phosphate. 200 mg-102 COD/ml of propionate were dosed to avoid organic carbon limitation, simulating propi-103 onate dosing strategies based on primary sludge fermentation (Chanona et al., 2006). It 104 should be noted that Lundtofte WWTP relies on chemical precipitation for phosphorus

removal due to the low influent content on organic carbon. Phosphate was dosed to ensure that incoming phosphorus levels ranged between 6-10 mg-P/L. Oxygen was supplied from a pressurized air-line and was manually controlled via needle valve manipulation. The system was inoculated with biomass from a full-scale wastewater treatment
plant (Lynetten WWTP, Copenhagen, DK). The SBR operation was controlled using
LabView VI (National Instruments, Austin, USA).

111

<Table 1>

112 2.2 Analytical methods

113 Process performance was assessed by monitoring bulk liquid concentrations of ammo-114 nia, nitrite, nitrate, phosphate and sulphate using test kits supplied by Merck[©] (USA) 115 after filtration through 0.2 µm filter. Soluble and total COD were measured with Hach-116 Lange[©] test kits (USA). Dissolved oxygen (DO) and pH were monitored using FDO 925 and SenTix 980 probes, respectively (WTW, Germany). Sludge volume index (SVI, 117 118 Ekama et al., 1997) was monitored on a daily basis. Total suspended solids (TSS) were 119 measured using glass fibre filter (Advantec[©], USA) with a pore size of 0.6 µm (APHA, 120 1995).

121 **2.3 Microbial analysis**

Quantitative polymerase chain reaction (qPCR) was carried out on all the extracted DNA samples to determine the abundance of ammonia oxidizing bacteria (AOB) and nitrite oxidizing bacteria (NOB, both *Nitrobacter* and *Nitrospira*), *Thiothrix, Microthrix parvicella* and sulphate reducing bacteria (SRB). DNA was extracted according to Te-

rada et al. (2010). Detailed protocols on DNA extraction and qPCR are included in the
supplementary information (SI-1).Quantitative fluorescence *in situ* hybridization
(qFISH) was performed as specified in Nielsen et al. (2009). Details of the qFISH protocol are shown in SI-2.

130 Community 16S rRNA genes were subject to partial PCR amplification as suggested by 131 Gülay et al. (2016) and amplicons were sequenced using the Illumina MiSeq platform at 132 the DTU Multi Assay Core Center (Copenhagen, DK). Bioinformatic approaches from 133 Gülay et al. (2016) were applieded in this study. Canonical correspondence analysis 134 (CCA) was used to examine the relationships between microbial community composi-135 tion and system performance. Diversity of SRB was assessed via phylogenetic analysis 136 of clone libraries of genes involved in dissimilatory sulphite reductase: dsrA (Ben-Dov 137 et al., 2007) and dsrB (Geets et al., 2006). Further details can be found in SI-3.

138 3 Results and discussion

139 3.1 Reactor performance

The SBR system performance during the 190 days of operation is shown in Fig.1. During the operation at SRT 8 days (first 50 days), temperature varied between 16 and 19 °C, DO in the aerobic phase was always above 2 mg/L and pH ranged between 7.5 and 8. Under these conditions ammonia was fully oxidized. All non-discharged nitrate was fully denitrified in the consecutive cycle (i.e. initial nitrate concentration up to 10 mg-N/L; Fig. 1A). Nitrogen removal varied between 75 % and 91%. Phosphorus was effec-

146 tively removed and effluent concentrations were always below 1 mg-P/L (Fig. 1B). The phosphorus removal varied between 80 and 98% (Fig. 1D). Phosphate concentration at 147 148 the end of the anaerobic phase dropped from 28 mg-P/L the first day down to 24 mg-149 P/L after day 10, ranging from that day between 20 and 25 mg-P/L (Fig. 1B). Striking-150 ly, phosphorus removal was poor (about 70% of phosphate removal) only during the 151 first week, when phosphate at the end of the anaerobic phase was highest. During that 152 period, most of the influent COD was removed in the anaerobic phase, whilst only 1 to 153 10 mg-COD/L were further removed along the aerobic phase (Fig. 1C). Likely, the ex-154 tent of the anaerobic phase led initially to residual phosphorus release, due to PAO hy-155 drolysing stored polyphosphate for maintenance under anaerobic conditions in absence 156 of available COD (Maurer and Gujer, 1995). Under aerobic conditions PAO could not 157 take up the released phosphorus, as they were limited by stored PHA. After an adapta-158 tion period of 1 week, the internal PHA and polyphosphate storage were balanced and 159 all anaerobically released phosphorus was taken up in the subsequent aerobic phase. 160 TSS in the reactor decreased from 5 g/L to 1.8 g/L after 10 days, and then, depending 161 on the influent COD, varied between 1.5 and 2 g/L (Fig. 1F). The SVI was consistently 162 below 90 mL/g (Fig. 1E), indicating good sludge settling behaviour. Despite the fact 163 that nitrate was present at the beginning of the anaerobic phase, the SRT was high 164 enough to avoid PAO out-competition.

165 On day 50, the system SRT was reduced to 3.5 days. DO, temperature and pH remained 166 in the same ranges as in the previous period. Over a period of 28 days, nitrate in the ef-167 fluent decreased, while nitrite accumulated as high as 4 mg-N/L (end of phase A, Fig.

168 1A). Nitrite accumulation suggests that nitrite oxidizing bacteria (NOB) were phased 169 out of the system, while ammonia oxidizing bacteria (AOB) were still active. Nitrite 170 was fully denitrified, thereby leading to a nitrogen removal higher than 80%. At tem-171 peratures ranging between 16 and 19 degrees, AOB apparently grew faster than NOB, 172 and the 3.5 days SRT was insufficient to keep NOB in the reactor (Hellinga et al., 173 1998). Phosphate removal was comparable to the previous period, ranging between 83 174 and 99 % (Fig. 1D). Phosphate in the effluent was kept below 1 mg-P/L (Fig. 1B), except for 2 days when the influent phosphate concentration was comparably higher (ap-175 176 prox. 15 mg-P/L). Phosphate concentration at the end of the anaerobic phase (Fig. 1B) 177 decreased to 18 mg-P/L towards the end of this period. COD was also removed mainly 178 in the anaerobic phase. However, increasing amounts of COD were bleeding through to 179 the aerobic phase, thereby supporting aerobic heterotrophic growth (up to 97 mg-180 COD/L when the influent TCOD was 620 mg-COD/L, Fig. 1C). TSS concentration 181 range decreased to 1-1.5 g/L. During this period, the SVI increased and ranged between 182 98 and 130 mL/g (Fig. 1E), indicating relatively good sludge settling properties.

The aerobic phase length was reduced from 3 to 2.5 hours for 5 days (phase B), thus reducing the aerobic SRT from 1.75 to 1.45 days, to effectively wash-out AOB. Nitrite concentrations immediately decreased and effluent ammonia concentration started to increase. As a result of the shorter aerobic phase phosphorus removal also deteriorated decreasing to a minimum value of 36% (Fig. 1D). Furthermore, the SVI increased up to 157 ml/g by the end of this period (Fig. 1E).

Although the reduced aerobic phase led to ammonia accumulation in the SBR, phospho-189 190 rus removal was comparably low, likely due to a too short aerobic SRT for PAO 191 growth, and the 3 hours aerobic phase was restored and kept for another 26 days (phase 192 C). During the first week of this period, air supply failure led to oxygen concentrations 193 during the aerobic phase ranging from 0.5 to 2 mg/L. Ammonia was kept within the 194 same range as in the previous 5 days, whilst phosphate removal was restored to a range 195 of 55-80%. However, SVI increased up to a maximum of 343 ml/g, representative of 196 filamentous bulking, as consequence of comparably low oxygen levels in the aerobic 197 phase (Martins et al., 2003). Once the oxygen level was restored above 2 mg/L we ex-198 pected that phosphate removal and SVI were restored. However, SVI further increased 199 to a maximum of 1100 mL/g, showing high variability along consecutive days (e.g. var-200 iations of about 250 mL/g per day). Parallel, phosphorus removal decreased down to a 201 minimum of 23%, coincident with the maximum SVI. The decrease in PAO activity was 202 also reflected by much lower phosphate concentrations at the end of the anaerobic 203 phase, ranging from 7.4 to 13 mg-P/L (Fig. 1B). Since high oxygen levels are reported 204 to hinder filamentous bulking (Martins et al., 2003), oxygen was subsequently main-205 tained higher than 4.5 mg/L (from day 102 to 109), without any positive impact on the 206 system performance.

Sulphate reduction during the anaerobic phase was 30% at the end of period C (Fig.
S16), suggesting that SRB were active in the EBPR. Previous studies have demonstrated the coexistence of sulphate reducing bacteria (SRB), *Thiothrix*, PAO and ordinary
heterotrophs in EBPR systems (Yamamoto-Ikemoto et al., 1996). *Thiothrix*, a filamen-

211 tous bacterium that contributes to filamentous bulking (Tandoi et al., 2006), can effec-212 tively grow on the reduced sulphur compounds produced by the SRB under aerobic 213 conditions. To mitigate the growth of SRB, the anaerobic SRT was decreased from 1.2 214 days to 0.88 days for 23 days (phase D). SVI decreased to 363 ml/g within two weeks. Phosphate removal was partially restored, ranging from 55 to 77%. During the aerobic 215 216 phase, to prevent the growth of other filamentous bacteria, DO was kept higher than 4.5 217 mg/L. Ammonia was the main nitrogen form in the effluent, although nitrite ranged be-218 tween 0.1 and 3.2 mg-N/L.

219

<Figure 1>

220 Given the positive system response to the reduction of anaerobic SRT, we further re-221 duced it to 0.68 days for the next 24 days (phase E). Within this period, after one week 222 of stable and high SVI (413-568 mL/g) and moderate phosphorus removal (58-70%), 223 the SVI progressively decreased to a minimum of 123 ml/g. Phase E was characterized 224 by limited filamentous bulking, with a SVI ranging between 123 and 213 ml/g, and a 225 sharp increase in phosphorus removal, restored to 85-99%. Indeed, after the first week, 226 the phosphate level in the effluent was below 0.8 mg-P/L. Sulphate reduction correlated 227 relatively well ($R^2=0.65$, Fig. S16) with phosphate removal, suggesting that as a conse-228 quence of the sulphate reduction the PAO may have been outcompeted by SRB.

229

The phosphate concentration at the end of the anaerobic phase was as high as 18-24 mgP/L. Sulphate reduction was not observed from day 120 onward. DO was kept higher

than 4.5 mg/L to prevent bulking due to other filaments. However, AOB activity returned, and nitrite was detected during the aerobic phase, reaching a maximum of 10.3 mg-N/L, which could potentially lead to phosphorus uptake inhibition. TSS varied between 0.5 and 1.2 g/L in this period. Towards the end of this period, the temperature range slightly increased to 17-21 $^{\circ}$ C.

237 Finally, at day 150 the SRT was lowered to 3 days to repress AOB activity. Oxygen 238 level was kept between 2 and 3 mg/L, sufficiently high to support P uptake by PAO, as 239 suggested by previous model-based studies (Valverde-Pérez et al., 2015). As shown in 240 Fig. 1A, nitrite at the end of the anaerobic phase was reduced, whilst ammonia in-241 creased again. Any nitrogen removal, about 40 % of the influent ammonia, observed at 242 this stage was likely due to assimilation, as neither nitrite nor nitrate were observed in the effluent. Both, phosphorus removal kept high (85-99%) and SVI ranged between 90 243 244 and 290 ml/g. The SBR was kept stable at SRT=3 days, DO 2-3 mg/L and anaerobic 245 and aerobic phase lengths of 70 minutes (i.e. anaerobic SRT of 0.58 days) and 3 hours 246 (i.e. 1.5 day of aerobic SRT, above the minimum aerobic SRT reported by Brdjanovic et 247 al., 1998), respectively, for 35 days (> 3 SRTs).

3.2 Variation in microbial community composition and diversity

Illumina MiSeq sequencing generated 1,745,605 raw assembled reads from 21 samples
with an average length of 420 bp. A total of 1,098,943 (63%) sequences passed quality
checks, and clustered across 167,622 OTUs, defined at 97% sequence similarity (Fig.

III - 12

S1). The sample taken at day 30 was excluded from further analysis due to the low number of sequences available in the sample library. High-quality sequences were normalized by rarefying to 11,940 sequences per sample for further diversity and taxonomic comparisons.

257 In Fig. 2, the distribution of the most abundant taxa is shown at the order level. It is 258 clear that from day 50, when the system SRT was reduced, the *Thiothrichales* order in-259 creased in abundance, mostly comprising *Thiothrix spp*. This increase continued during 260 the bulking event. From a relative abundance of 50% onward (based on sequencing analysis), the relative *Thiothrix* abundance strongly correlated with the extent of fila-261 mentous bulking (characterised using SVI as surrogate – $R^2=0.92$; Fig. S17). From day 262 263 101 to 109 the anaerobic SRT was reduced to 0.88 day. These conditions resulted in a reduction of *Thiothrix* abundance. However, no obvious patterns in known SRB taxa 264 (Fig. S11) – presumed to be responsible for *Thiothrix* growth by reducing sulphate to 265 sulphide – were found. After SVI correction and phosphorus removal restoration, the 266 267 microbial diversity became similar to the one by the end of the SRT=8-day phase based on the H index (Fig. 3 and Fig. S2). Similar trends were confirmed via qPCR quantifica-268 tion (Fig. S10). 269

270

<Figure 2>

Rhodocyclales were relatively abundant during good phosphorus removal and were only
displaced during filamentous bulking. *Rhodocyclales* include *Accumulibacter phospha- tis*, which is believed to be the main driver of phosphorus removal in EBPR systems
(Oehmen et al., 2007). However, *Accumilibacter* abundance was very low (<1%) com-

III - 13

275 pared to previous studies (Fig. S4, Nielsen et al., 2010). Nevertheless, Rhodocyclales 276 positively correlated with phosphate removal suggesting that members other than Ac-277 cumulibacter could have been involved in phosphorus removal (Fig. 6), e.g., 278 Dechloromonas related PAO (Lv et al., 2015). However, qFISH analysis revealed high-279 er abundance of Accumulibacter than that indicated by the sequencing data, especially 280 towards the end of the operational period (up to 18% of total bacteria, Fig. S13). This is 281 a major difference compared to the study by Ge et al. (2015), who did not find Accumu*libacter* in the short-SRT EBPR. Similar to the A-stage systems, it may be the case that 282 283 microbial communities are case specific, contrary to CAS, which contains a core com-284 munity of abundant microorganisms (González-Martínez et al., 2016). Tetrasphaera 285 remained low during the operational period (Fig. S4 and S13).

286 Saprospriales, Flavobacteriales and Burkholderiales are heterotrophic microorganisms 287 that appeared at relatively high abundance along the operation of the reactor. In the case 288 of Burkholderiales the considerable abundance could be a consequence of their extreme 289 nutritional versatility and adaptability to different environmental conditions. Burkholderiales are often found in EBPR systems (Sadaie et al., 2007), and include Comamona-290 291 daceae, which have been reported as putative PAO (Ge et al., 2015). However, abun-292 dance of Comamonadaceae did not follow the trends on phosphorus removal (Fig. S5). Saprospriales are specialized in the hydrolysis of proteins and are abundant in conven-293 294 tional EBPR systems (Nielsen et al., 2012), but also in short-SRT EBPR systems (Ge et 295 al., 2015). Finally, *Flavobacteriales* are rather nutritionally restricted, with the ability to 296 consume glucose and very few other carbon compounds. Nevertheless, they can hydro-

297 lyze several biopolymers and particulate products from bacterial decay (Kircham 2012). They have also been found in Danish EBPR systems (Albertsen et al., 2012): they might 298 299 grow little in the actual treatment plant but are present due to their high abundance in 300 the influent sewage (Saunders et al., 2016). The higher abundance of *Flavobacteriales* 301 in the short-EBPR system compared to full scale EBPR (7% vs ~1% reported by Saun-302 ders et al., 2016) suggests that microbial composition of short-SRT EBPR communities 303 is more closely related to the influent microbial communities, as suggested for the A-304 stage systems (González-Martínez et al., 2016).

Following the trends in performance, NOB were washed out from the system from the onset of SRT reduction (Fig. S8). AOB followed a similar trend, but their abundance in the amplicon libraries was one order of magnitude lower. Targeted qPCR analysis was conducted to quantify *Nitrosomonas, Nitrobacter and Nitrospira*. AOB guild ranged between 3.6-13.6 % while *Nitrospira* ranged from 1 to 4.3% (Fig. S9, Table S12).

310 Despite their low abundance (Fig. S7 and S11), the role of SRB is also worth mention-311 ing. Our results suggest that SRB can reduce sulphate at very low abundance (<0.15%), 312 as was the case for data presented by Pester et al. (2010). According to Fig. 3, the genus 313 Desulfarculus is strongly and negatively correlated with phosphorus removal. This is in 314 agreement with the process performance of the SBR, which showed very poor phospho-315 rus removal when sulphate reduction was relatively high (Fig. SI-16). Desulfarculus is a 316 completely carbon oxidizing SRB, which is able to consume a wide range of organic 317 substrates. Furthermore, it is oxygen tolerant so it can survive during the aerobic phase 318 (Sun et al., 2010). *Desulfuromonas* also correlated negatively with phosphorus removal

319 (Fig. 3). Similarly to *Desulfarculus*, these bacteria can also oxidize propionate and ace320 tate to carbon dioxide. However, *Desulfuromonas* is only able to reduce sulphur and not
321 sulphate (Pfennig and Biebl, 1976).

322

<Figure 3>

Finally, GAO were barely detected in the libraries, indicating low abundance (<0.1%) 323 324 for both Competibacter- and Defluviicoccus- related GAO (Fig. S6). Despite the importance of these organisms in EBPR systems, they may have been effectively outcom-325 peted from the SBR due to the dosing strategy (propionate cannot be consumed by 326 327 *Competibacter*) and the relatively low temperatures and high pH, which give competi-328 tive advantages to PAO over GAO (López-Vázquez et al., 2009). qFISH revealed higher 329 abundance of both Competibacter and Defluviicoccus, but always below 3.8% and 1%, 330 respectively (Fig. S12, Table S12). Other putative GAO, such as *Micropruina* (Kong et 331 al., 2001), were also present at low abundance (<0.1%, Fig. S6).

332 3.3 Discrepancies between quantification methods

There is a discrepancy between the results from the amplicon sequencing and data estimated via qPCR or qFISH (Tables S11 and S12). For example, the abundance of *Nitrosomonas* or *Nitrospira* determined via sequencing is comparably lower than the qPCR estimate, as was observed by Pellicer-Nácher et al. (2014). A plausible explanation is related to the understimation of low abundant bacteria by the amplicon sequencing method. González et al. (2012) demonstrated that the amplification via PCR of low abundant bacteria DNA is considerably less efficient than the amplification of highly

340 abundant bacteria DNA, thus leading to the overestimation of highly abundant microbial groups. This is clearly the case for Thiothrix population, which has been underesti-341 342 mated via sequencing at abundances below 5% and overestimated in other cases (Table 343 S11 and S12). When comparing sequencing and qFISH results other factors should be 344 taken into account, such as DNA extraction efficiency, which may introduce significant 345 bias into PCR-based estimates (Kim et al., 2013). As an example, Albertsen et al. 346 (2012) reports high discrepancy between qFISH based and sequencing based results for 347 Gram positive bacteria (e.g. *Tetrasphaera* or *Microthrix parvicella*) presumably, due to 348 innefficient DNA extraction. However, they found a good agreement between both data 349 sets for *Competibacter* or *Accumulibacter* bacteria, which suggests that discrepancies in 350 our study may have a different origin. Analyzing the correspondence between qFISH 351 probes targeting Accumulibacter, it can be seen that they detect low abundance within 352 the sequences amplified by the PCR. Therefore, the sequencing results may be biased 353 by the universal primer selection (Hong et al., 2009). To get a better overview of the 354 microbial diversity it is recommended to combine different techniques, preferably com-355 bining methods that rely on DNA extraction (e.g. PCR based methods) with tools that 356 do not require this step (e.g. qFISH).

357

358

3.4 Synergies and competitions between bacteria in short SRT EBPR systems

At SRT=3.5 days, NOB were effectively washed out from the system, thus leading to nitrite accumulation (e.g. from day 50 to day 55). Likely, the operation of the EBPR

361 system at an aerobic SRT=1.75 days, combined with relatively high oxygen levels, had 362 a detrimental effect over Nitrospira sp. and not Nitrosomonas, thus leading to nitrite 363 rather than nitrate accumulation (Regmi et al., 2014). Additionally, high ammonia lev-364 els at pH close to 8, e.g. phase E (Fig. 1A), may have inhibited NOB activity (Chandran and Smets, 2000). Nitrite accumulation in this period could potentially lead to the inhi-365 366 bition of PAO activity. Nitrite has been reported as a potent inhibitor for P-uptake under both anoxic and aerobic conditions (e.g. 0.5·10⁻³ mg-N-HNO₂/L lead to 50% anabolic 367 368 activity inhibition; Meinhold et al., 1999; Pijuan et al., 2010). Indeed, previous experi-369 mental runs at SRT=4-5 d lead to the wash out of PAO likely due to nitrite accumula-370 tion in the aerobic phase. Therefore, these operational conditions were not tested in this 371 study (Valverde-Pérez et al., 2015b). Surprisingly, nitrite presence did not negatively 372 affect PAO performance. On the one hand, at the observed pH levels (ranging between 373 7.5 and 8), the concentration of free nitrous acid (FNA), which is the true inhibitor of 374 PAO activity, was varying between $0.8 \cdot 10^{-3}$ and $0.2 \cdot 10^{-3}$ mg-N /L, i.e., below the inhibi-375 tion levels reported by Pijuan et al. (2010). On the other hand, PAO could have adapted 376 to the presence of nitrite (Wang et al., 2014). Additionally, if AOB or NOB are not ef-377 fectively phased out at SRTs ranging from 4 to 6 days, PAO may be outcompeted by 378 denitrifying heterotrophs due to substrate competition during the anaerobic phase 379 (Guerrero et al., 2011). This has been demonstrated through dedicated simulation stud-380 ies (Valverde-Pérez et al., 2015). Based on the stoichiometry reported on the activated 381 sludge model 2d (ASM2d, Henze et al., 1999), about 30% of the influent COD was con-

382 sumed by denitrifying bacteria, leaving enough COD (about 30mg-COD L-1 per cycle)
383 available to replenish the PHA storage from PAO.

384 If nitrifiers are effectively washed out of the reactor, at the beginning of the anaerobic 385 phase there is no nitrate nor nitrite. The fully anaerobic phase could then promote sul-386 phate reduction by SRB if sufficient sulphate is available. SRB were present in low 387 abundance along the study (Fig. S7 and S11) but sulphate reduction was not observed 388 when nitrate was recycled to the beginning of the anaerobic phase. SRB have been de-389 scribed as tolerant bacteria, which can grow even in the absence of sulphate, showing 390 high metabolic flexibility (Plugge et al., 2011). Furthermore, SRB have a wide variety 391 of protection strategies that let them survive in adverse environments, such as those 392 characterized by aerobic or high salinity conditions (Zhou et al., 2011). Hence, SRB 393 could use their capabilities to survive in the reactor under unfavourable conditions and 394 only actively reduced sulphate once NO_x were not present at the beginning of the anaer-395 obic phase of the SBR (i.e. when most of the propionate is available for their growth). 396 Alternatively, SRB could actively reduce sulphate in the presence of nitrate. However, 397 due to the prevalence of nitrate, reduced sulphur coumpounds could be oxidized back 398 via denitrification (Jensen et al., 2009). SRB may support the growth of *Thiothrix* by 399 producing sulphur reduced compounds available for their growth under aerobic condi-400 tions. Thiothrix is an obligate aerobic mixotroph, which frequently appears in EBPR 401 reactors treating industrial wastewaters (Nielsen et al., 2010). However, the high abun-402 dance found in this study has been only previously found in systems where SRB pro-403 vided them with enough sulphur reduced chemicals (Yamamoto-Ikemoto et al., 1991,

404 1994, 1996). *Thiothrix* can significantly deteriorate settling properties of activated
405 sludge at relatively high relative abundance (Fig. S17), but do not seem to be related to
406 poor phosphorus removal (Fig. 3).

407 SRB can interact with PAO in different ways. SRB produce sulphide, which can inhibit 408 phosphorus release, thereby reducing it to 50% at concentrations of 60 mg-H₂S/L (Saa 409 et al., 2013). Since phosphorus release is hindered under anaerobic conditions, PAO 410 cannot grow under aerobic conditions, thus leading to their wash out from the system. 411 Additionally, SRB take up organic carbon under anaerobic conditions. The most com-412 mon SRB in wastewater treatment systems are incomplete carbon oxidizers, such as 413 Desulfobulbos or Desulfovivbrio (Hao et al., 2014), both found via phylogenetic analy-414 sis (Fig. S14 and S15). The end product of incomplete oxidation process is acetate, 415 which is finally available for other bacteria, such as PAO (Yamamoto-Ikemoto et al., 416 1996). Therefore, there is limited competition for carbon between incomplete oxidizing 417 SRB and PAO. Other SRB, like Desulfarculus in this study, are able to completely oxi-418 dize organic carbon to carbon dioxide (Hao et al., 2014). Therefore, this second type of 419 SRB may compete with PAO for organic carbon in the anaerobic phase, thus leading to 420 incomplete phosphorus removal, as suggested by Fig. 3. To further support this hypoth-421 esis, the COD consumption was estimated, based on stoichiometric coefficients from 422 literature (Yamamoto-Ikemoto et al., 1996), for the day with maximum reported SVI 423 (SVI=1100 ml/g; sulphate reduction of 30%). About 35% of the influent COD was con-424 sumed for sulphate reduction. Surprisingly, sulphate reduction stopped before all COD 425 was consumed, as comparably high COD levels and sulphate were detected at the end of

426 the anaerobic phase along the bulking event (Fig. 1C). Presumably, VFA, propionate in this case, were taken up first by SRB or PAO, while the rest of the available COD needs 427 428 to be hydrolysed or fermented before it can be consumed by PAO and SRB. Since the 429 specific uptake rate of propionate by SRB is about 3 times higher than for PAO (calcu-430 lations based on Henze et al., 1999 and Cassidy et al., 2015 are reported in SI-7), SRB 431 could outcompete PAO for VFA uptake at the beginning of the anaerobic phase. Sulphate reduction may stop due to self-inhibition of SRB with the produced sulphide 432 (Reis et al., 1992). Additionally, sulphide may also inhibit fermentative microorgan-433 434 isms, thereby limiting the production of more easily biodegradable substrate available 435 for oxidation by SRB (McCartney and Oleszkiewicz, 1991). Several studies suggest that 436 sulphide is a strong inhibitor of microbial growth at relatively low pH levels, but others 437 observed that pH effect on inhibition was negligible (Chen et al., 2014). The COD 438 bleeding through from the anaerobic phase could enhance the growth of *Thiothrix* along 439 the aerobic phase (Vaiopoulou et al., 2007). Therefore, the most plausible explanation 440 for the inactivation of PAO is a combination of substrate competition at the beginning 441 of the cycle and inhibition due to sulphide. This could be the cause of poor phosphorus 442 removal of other systems where SRB coexisted with PAO (Yamamoto-Ikemoto et al., 443 1991; Vaiopoulou et al., 2007). In this study, SRB activity was controlled by manipulat-444 ing anaerobic SRT. When the anaerobic phase length was 2 hours, corresponding to 1.2 445 days - calculation without accounting for the 1 hour non aerated settling phase - those SRB with a growth rate higher than 1 day⁻¹ could grow in the reactor (Cassidy et al., 446 447 2015). Once sulphate reduction was avoided during the anaerobic phase, phosphorus

448 removal was restored, further supporting this hypothesis. These findings are relevant to 449 those WWTPs located close to the coastline, where the sulphate content in wastewater 450 is expected to be high (van den Brand et al., 2015). This is the case for Lundtofte 451 WWTP, which is barely 5 km from the sea. A two-month sampling campaign was per-452 formed to further verify this. Influent sulphate concentrations measured in the influent 453 to Lundtofte ranged from 35 to 162 mg-SO4⁻/L. It should be noted that there are also cases where the phosphorus and the sulphur cycle have been successfully combined. 454 such as the SANI process (Wu et al., 2014). Nevertheless, phosphorus removal in this 455 456 process is driven by microbes capable to oxidize sulphide rather than Accumulibacter 457 (Guo et al., 2016), which makes it non comparable to our study.

458 Interestingly, neither Competibacter nor Defluviicoccus seemed to affect phosphorus 459 removal during the operation. As stated before, the carbon source, propionate, dosed to 460 the system together with the relatively high pH and moderate temperature may have 461 outcompeted the GAO from the reactor (López-Vázquez et al., 2009). The low SRT 462 could also have contributed to the wash-out GAO. EBPR systems operated at SRT=3 days did not register instabilities due to the competition between GAO and PAO even at 463 30°C (Whang and Park, 2006). Nevertheless, should *Competibacter* grow at low SRTs, 464 465 attention should be paid to the incomplete oxidizing SRB. Since they can produce ace-466 tate as a final product, this may become available for *Competibater*, thereby making the dosing strategies proposed in the literature unsuccessful (López-Vázquez et al., 2009). 467 468 Additionally, inhibition by sulphide may be another selective factor between PAO and 469 GAO, which should be subject of future study.

III - 22

470 The proposed ecological model, based on the interactions between microbiological471 guildts found in this study, is shown in Fig.4.

<Figure 4>

472

3.5 Sludge settling properties

474 Poor settling may compromise effluent quality by increasing the TSS in the effluent of 475 the plant, thereby compromising pathogen removal (Schuler and Jang, 2007). According 476 to Fig. 3, *Thiothrix* was the main taxon affecting the settling properties. This is in 477 agreement with previous studies where extreme filamentous bulking was provoked by 478 Thiothrix (SVI>600 mg/L, Yamamoto-Ikemoto et al., 1991; Miyazato et al., 2006). As 479 suggested by Fig. S17, there is linear correlation between *Thiothrix* abundance and SVI 480 only beyond 50% relative abundance. The poor fitting at lower abundances can be a 481 consequence of the synergic effect of a decrease in biomass density due to the coinci-482 dent wash out of PAO, with filamentous bulking (Schuler and Jang, 2007). Since phos-483 phorus uptake by PAO was hindered by SRB, the polyphosphate content in sludge was 484 expected to be lower, thereby producing low density sludge. Low density sludge is more sensitive to filamentous bulking (Jassby et al., 2014), which could explain the highly 485 486 dynamic SVI found between days 80 and 150. On the other hand, previous studies have 487 shown poor correlation between filamentous bacteria abundance and SVI, suggesting as 488 an alternative to look for correlations with the hindered settling model parameters 489 (Wágner et al., 2015). Furthermore, Wágner et al. (2015) demonstrated that a specific filamentous bacteria (*M. parvicella*), can drive bulking regardless of other filamentous 490

491 bacteria (e.g., Chloroflexi), prevailing at significantly higher abundance level. Therefore, SVI dynamics found at relatively low abundance of *Thiothrix* could be driven by 492 493 other filaments which were much less abundant. As an example, filaments belonging to 494 the phylum *Firminicutes*, common filaments in EBPR systems (Mielczarek et al., 2012), 495 found at low abundance along the operation of the reactor, such as *Thrichococcus* (~1% 496 Fig. S3, Nielsen et al., 2009b), could affect the settling properties while *Thiothrix* were 497 not abundant. Strikingly, M. parvicella were found in low abundances (<1% at SRT<4 498 days). One plausible explanation is that these filaments are supressed at SRTs lower 499 than 5.7 days (Noutsopoulos et al., 2006).

500 Low SRT activated sludge systems are characterized by relatively unstable microbial 501 communities, which facilitate filamentous bacteria proliferation (Liao et al., 2006). Pre-502 vious work has demonstrated that SBRs are more robust than continuous flow systems 503 operated under the same conditions (Liao et al., 2006; Valverde-Pérez, 2015). This 504 work shows how, through careful control of the oxygen level and anaerobic SRT, fila-505 mentous bulking can be controlled. Since the SBR operation leads to substrate gradi-506 ents, flock forming bacteria are promoted over filamentous bacteria, thereby reducing the risk of filamentous bulking event (Tandoi et al., 2006). 507

3.6 Relevance to available models

509 The findings of this study point out several limitations of available models to describe 510 phosphorus removal in EBPR systems, both activated sludge models (ASM-2d, Henze 511 et al., 1999) and metabolic models (Oehmen et al., 2010). Indeed, the latter has focused

512 on describing the competition between GAO and PAO for different substrates and under different operational conditions (e.g. Carvalheira et al., 2014). Whilst this effort is very 513 514 valuable to model conventional EBPR systems, it seems incomplete when modelling 515 short SRT systems. The importance of the SRB in modelling anaerobic digestion pro-516 cesses has already been acknowledged (Jeppsson et al., 2013), but, according to Fig. 4, 517 they should also be included in other process units across the WWTP. Otherwise, mod-518 el-based optimization of EBPR systems may lead to model falsification (Sin et al., 519 2006).

520 Even though the reactor operation became stable after regulating the anaerobic SRT, the 521 SBR still run under moderate bulking conditions (i.e. SVI>200 ml/g). Low SRT systems 522 suffer from poor settling due to poor sludge flocculation (Meerburg et al., 2015). There-523 fore, settling models should be improved by including time dependent parameters able 524 to capture the sludge properties dynamics (Jeppsson et al., 2013). Some efforts have 525 already been presented in the literature to reduce the uncertainty of settling parameters 526 due to filamentous bulking (Wágner et al., 2015), which up until now has been consid-527 ered as a non-reducible uncertainty source (Belia et al., 2009).

528 4 Conclusions

This study describes the dynamics and successful start-up of a short-SRT EBPR system,
which is suitable for resource recovery, especially carbon and phosphorus. Our results
suggest that:

EBPR process can be run at a system SRT of 3 days, effectively removing phosphorus and organic carbon. SVI was relatively high (SVI~200ml/g), but stable.

NOB were effectively removed from the reactor at SRT below 3.5 days (corresponding to 1.75 days aerobic SRT). AOB were phased out from the SBR by lowering the SRT down to 3 days (i.e. 1.5 days of aerobic SRT) and controlling the oxygen level lower than 3 mg/L.

Sulphate reduction was observed at SRT 3.5 days, producing sulphur reduced chemi cals, which served as substrate for *Thiothrix*, thereby provoking filamentous bulking.
 SRB were shown to have a negative impact on phosphorus removal, although the in hibition mechanism could not be identified. SRB activity was suppressed by reducing
 the anaerobic SRT to 0.58 days and process performance was restored.

543 Models should include SRB related processes to properly address the competition be-544 tween them and PAO. Furthermore, since bulking cannot be completely avoided, future 545 research should address the inclusion of time varying parameters for settling models to 546 properly track changes of or in sludge properties.

547 5 Acknowledgement

548 Borja Valverde-Pérez and Dorottya S. Wágner thank the Integrated Water Technology 549 (InWaTech) project (http://www.inwatech.org) for the financial support. We would like 550 to thank Ms. Lene Kirstejn Jensen and Dr. Marlene Mark Jensen for their assistance 551 conducting the qPCR measurements and Dr. A. Gizem Mutlu and Dr. Aranud Dechesne 552 for their guidance when conducting the qFISH analysis.

7 Quantitative polymerase chain reaction (qPCR)

Reactor biomass was collected as 2 mL samples, centrifuged at 13000xg, supernatants were removed and pellets were stored at -20 °C until further analysis. A 0.5 g subsample of reactor samples was subject to genomic DNA extraction using the MP FastDNA[™] SPIN Kit (MP Biomedicals LLC., Solon, USA) per manufacturer's instructions. The concentration and purity of extracted DNA were checked by spectrophotometry (NanoDrop Technologies, Wilmington, DE, USA). Extracted DNA was stored at -20 ⁰C in Tris-EDTA buffer until further processing. Quantitative PCR (qPCR) was carried out on all the extracted DNA samples to determine the abundance of ammonia oxidizing bacteria (AOB) and nitrite oxidizing bacteria (NOB, both Nitrobacter and Nitrospira) as suggested by Terada et al., (2010), Thiothrix (protocol adapted from Vervaeren et al., 2005), Microthrix parvicella (protocol adapted from Kaetzke et al., 2005; Kumari et al., 2009; and Vanysacker et al., 2014) and sulphate reducing bacteria (SRB, protocol adapted from Wagner et al, 1998; and Geets et al., 2006). Primers used in this work to target the 16S rRNA genes and the functional gene dsrB for SRB are included in Table S1, together with the PCR protocols. For quantification, 1 copy of 16S rRNA gene for AOB and NOB, 1.33 copies of 16S rRNA gene for Microthrix parvicella, and 4.1 copies of 16S rRNA gene for total bacteria (Stoddard et al., 2014), 2 copies of 16S rRNA gene for Thiothrix (Lapidus et al., 2011) and 1 copy of the functional gene dsrB for SRB (Karkhoff-Schweizer et al., 1995) were considered.

8 Quantitative fluorescence *in-situ* hybridization (qFISH) analysis:

The samples were pre-treated and fixed with 4% paraformaldehyde and stored at -20° C until qFISH analysis was done. $1-5\mu$ l of fixed sample were used for the analysis. The EUBmix probe, which comprises EUB338, EUB338-II and EUB338-III, was used to target total bacteria (Daims et al., 1999). *Accumulibacter* were targeted using PAOmix probes (PAO 651, 462 and 846, Crocetti et al., 2000) and *Tetrasphaera* were targeted with Actino-221a and Actino-658a, together with the competitors per Kong et al. (2005). *Competibacter* were targeted using the GB probe by Kong et al. (2002). *Defluviicoccus* cluser I was targeted using probes TFO_DF218 and TFO_DF618 (Wong et al., 2004) and cluster II was targeted using probes DF988 and DF1020 combined with the helper probes per Meyer et al. (2006). A Leica SP5 confocal laser scanning microscope with a 20x objective was used to image the samples. As suggested by Nielsen et al. (2009), 20 randomly chosen images were taken and analysed using daime (digital image analysis in microbial ecology) software (Daime et al., 2006).

Table S10: Probes for qFISH analysis

Organism	Probe	Dye	Sequence $(5' \rightarrow 3')$	Reference		
Most Eubacteria	EUB338		GCTGCCTCCCGTAGGAGT	Amann et al., 1990		
Planctomycetales	EUB338-II	Fluo (green)	GCAGCCACCCGTAGGTGT	Daims et al., 1999		
Verrumicrobiales	EUB338-III		GCTGCCACCCGTAGGTGT	Daims et al., 1999		
	PAO462		CCGTCATCTACWCAGGGTATTAAC			
Most Accumuli- bacter	PAO651	Cy3 (red)	CCCTCTGCCAAACTCCAG	Crocetti et al., 2000		
	PAO846		GTTAGCTACGGCACTAAAAGG			
	Actino-221a	Cy5 (blue)	CGCAGGTCCATCCCAGAC			
	c1Actino-221	-	CGCAGGTCCATCCCATAC			
Actinobacteria	c2Actino-221	-	CGCAGGTCCATCCCAGAG	V 1 2005		
(Tetrasphaera)	Actino-658a	Cy5 (blue)	TCCGGTCTCCCCTACCAT	Kong et al., 2005		
	c1Actino-658	-	TCCGGTCTCCCCTACCAC			
	c2Actino-658	-	ATTCCAGTCTCCCCTACCAT			
Competibacter	GB	Cy5 (blue)	CGATCCTCTAGCCCACT	Kong et al., 2002		
Defluviicoccus	TFO_DF218		GAAGCCTTTGCCCCTCAG			
(cluser I)	TFO_DF618	Cy3 (red)	GCCTCACTTGTCTAACCG	Wong et al., 2004		
Defluviicoccus	DF988	Cy3 (red)	GATACGACGCCCATGTCAAGGG Meyer et			

(cluser II)	H966	-	CTGGTAAGGTTCTGCGTTGC	
	DF1020	Cy3 (red)	CCGGCCGAACCGACTCCC	
	H1038	-	AGCAGCCATGCAGCACCTGTGTGGCGT	

9 PCR amplification, pyrosequencing and bioinformatics analysis

9.1 PCR amplification and pyrosequencing

10 ng of extracted DNA were PCR amplified using Phusion (Pfu) DNA polymerase (Finnzymes, Finland) and 16S rRNA gene targeted modified universal primers PRK341F (5'- CCTAYGGGRBGCASCAG-3') and PRK806R (5'-GGACTACNNGGGTATCTAAT-3') to amplify the V3-V4 hypervariable region (Yu et al., 2005). PCR was performed as follows: an initial denaturation at 98 °C for 30 s, 30 cycles of denaturation at 98 °C for 5 s, annealing at 56 °C for 20 s and elongation at 72 °C for 20 s, and a final elongation step at 72 °C for 5 min. PCR products were analysed and cut from 1% agarose gel and purified by QIAEX II Gel Extraction Kit (QIAGEN). Sequencing was applied using the Illumina MiSeq platform at the DTU Multi Assay Core Center (Copenhagen, DK).

9.2 Bioinformatics analysis

The Paired End sequences from the raw fastq files supplied by Illumina Miseq were assembled using the pandaseq software (Masella et al., 2012). All assembled sequences shorter than 200 nts and longer than 500 nts were removed. The primers were also removed from the sequences. Chimeras were removed with UCHIME (Edgar et al., 2011) using default settings. After quality checks, all analyses were performed using QIIME 1.4.0 software (Caporaso et al., 2010). High quality sequences were clustered into OTUs at 97% pairwise identity using the UCLUST algorithm (Edgar et al., 2011) with default settings, and representative sequences from each OTU were aligned against the Greengenes reference alignment (DeSantis et al., 2006) using PyNAST (Coporaso et al., 2010). Taxonomy assignment of each representative sequence was implemented using the BLAST algorithm (Altschul et al., 1997) against the Silva119 curated database. Unassigned sequences were removed from the sequence library and subsampling at depth of 11,800 sequences was performed to equalize sample sizes.

Canonical correspondence analysis (CCA) was used to examine the relationships of microbial communities and system performance variables. Significant correlations between specific taxa and phosphorus removal were confirmed with Pearson's product-moment correlation analysis. All statistical analysis were performed with the vegan package in R (The R Foundation, Vienna, Austria).

9.3 Sulphate reducing bacteria diversity analysis PCR was carried out with primers targeting dissimilatory sulphite reductase subunit-A (dsrA, Ben-Dov et al., 2007) and subunit-B (dsrB, Geets et al., 2006). PCR products were purified, after length verification, via agarose gel electrophoresis and cloned. 96 clones of both dsrA and dsrB PCR products were collected and grown. Finally, the plasmids containing the insert were isolated, purified and sequenced (Macrogen, Amsterdam, Nederland). Sequencing results were processed by locating inserts and eliminating repetitive sequences. Phylogenetic analysis was done using ClustalX multiple alignment software and MEGA phylogenetic tree construction software.

10 Microbial diversity analysis – pyrosequencing

Figure S1: Domain-level taxonomic classification of 16S rRNA amplicons at selected time points of the reactor operation. Taxa abundance is expressed in percentage.

Figure S2: Phylogenetic distances between samples taken at different time points during reactor operation. The dissimilarity matrix was determined using Weighted UniFrac algorithm and plotted via principal coordinate analysis (PCoA). The percentage of variation explained by the principal coordinates is indicated on the axes.

Figure S3: Relative abundance of filamentous bacteria along the operation of the short SRT EBPR. Only the 2 most abundant genera are shown.

Figure S4: Relative abundance of PAO along the operation of the short SRT EBPR.

Figure S5: Relative abundance of *Comamonadaceae* along the operation of the short SRT EBPR.

Figure S6: Relative abundance of GAO along the operation of the short-SRT EBPR.

Figure S7: Relative abundance of SRBs along the operation of the short-SRT EBPR.

Figure S8: Relative abundance of AOB (*Nitrosomonas*) and NOB (*Nitrospira*) along the operation of the short-SRT EBPR.
