Abstract

Low-carbon martensitic stainless steels with 11.5 – 16 wt.% Cr, 4 – 8 wt.% Ni and low interstitial content, C < 0.07 wt.% and N < 0.06 wt.% are characterised by their outstanding property combination of high corrosion resistance, strength, ductility and impact toughness, obtained by formation and stabilisation of fine-grained reverted austenite from lath martensite upon annealing in the inter-critical region. This review reflects on the mechanisms that govern the formation and stabilisation of reverted austenite and the early stage of austenite reversion close to A₁ with focus on the role of residual stresses in martensite. The review is assisted by the computation of phase equilibria. Literature data on Cr and Ni concentrations of the reverted austenite/martensite dual-phase microstructure are assessed with respect to predicted concentrations obtained from phase equilibria. Reasonable agreement was found for concentrations in martensite. Systematic excess of Cr in austenite of approx. 2 wt.% relative to calculations was suspected to originate from the growth of M₂₃C₆ with a coherent interface to austenite. Within large scatter, measured values of Ni in austenite were on average 2 wt.% below predictions. Complex equilibration of the microstructure and experimental error are discussed as possible origins of the discrepancies.

Keywords: austenite reversion; microstructure evolution; solute partitioning; thermodynamics; CALPHAD; diffusion; martensite formation; residual stress;

1. Introduction

Low-carbon martensitic stainless steels comprise the group of supermartensitic stainless steels, soft martensitic stainless steels and precipitation-hardening versions. While the individual alloy groups are optimised towards different application fields such as weldability, corrosion resistance or hardenability, all contain a nano-lamellar dual-phase microstructure of reverted austenite and tempered martensite through inter-critical annealing, i.e. annealing in the temperature region in which both ferrite and austenite are thermodynamically stable. The obtained ‘reverted austenite’ is distinguished from ‘retained austenite’, i.e. that is untransformed during cooling to room temperature [1]. Stabilisation of reverted austenite against martensite formation occurs primarily by the partitioning of austenite stabilising elements during diffusional reversion. The resulting fine-grained dual-phase microstructure lowers the yield strength, ultimate tensile strength and hardness, while ductility and impact toughness are significantly enhanced [2–4].

The mechanisms leading to the reversion of austenite and the analysis of the stability of reverted austenite against martensite formation to thermal or mechanical treatments are the subject of numerous research articles published within the last decades. Newly emerging experimental and modelling methods enabled the progressive transition from a processing-property based approach to a microstructure-property based understanding of these materials. It therefore appears timely to review the present understanding of the reverse martensite-to-austenite phase transformation. As the title suggests, this review includes phase equilibrium calculations (so-called CALPHAD approach) to support the discussion.

The microstructure-property based characterization of the alloys in recent years has led to a wealth of quantitative literature data on the partitioning of Ni and Cr after partial reversion of austenite during inter-critical annealing of martensite. As reported data concerns different alloy systems and annealing parameters, and as discussion of the data is generally limited to the scope of the specific work, a collective representation of the data is established here to reveal underlying trends. As austenite reversion during isothermal annealing is accompanied by diffusion, it is of interest to verify whether the experimentally determined concentrations can be predicted by phase equilibria from thermodynamics modelling. Finally, the early stage of austenite reversion close to A_1

and the findings from the analysis of compositional data from literature are critically discussed.

Scope

The present review is limited to low-carbon martensitic stainless steels with 11.5 – 16 wt.% Cr, 4 – 8 wt.% Ni and low interstitial content, C < 0.07 wt.% and N < 0.06 wt.%, for which a fine-grained dual-phase structure of reverted austenite and tempered martensite forms by a diffusional mechanism during inter-critical annealing. In some steels austenite stability is sufficiently high for austenite reversion to occur by a displacive mechanism at temperatures where a diffusion controlled transformation is kinetically suppressed [5,6], which is not treated in this review. Austenite reversion and stabilisation by a diffusional mechanism is not limited to the alloys discussed here and can also be found in other alloy groups, as for example in medium manganese steels [7,8]. The mechanisms discussed in the present work can readily be transferred to other alloy systems, but that is beyond the scope of this review. The focus of this review lies on phase transformations rather than alloy properties. Only a short section is dedicated to the effect of reverted austenite on microstructure properties, including references for further reading.

2. Current view on austenite reversion

Historical aspects and alloy design of low-carbon martensitic stainless steels

These alloys are built on the Fe-Cr-Ni ternary system with additions of Mn, Mo, Si and particularly low contents of the interstitial elements C and N. In 1960, Irvine et al. [9] comprehensively described aspects of designing transformable 12% Cr steels to obtain a strong and corrosion resistant material. A major challenge consisted of finding alloy compositions that could be solution treated without forming δ -ferrite, maintained A_1 above 700 °C during 5 h isothermal tempering to avoid re-austenitisation during tempering, and kept M_s above 200 °C to ensure complete transformation to martensite during cooling [9]. An Fe-0.1C-12Cr-2Ni-1.5Mo-0.3V (wt.%) alloy was found most promising with respect to strength and impact toughness [9] (Table 1).

Additional stabilisation of austenite was necessary to maintain a transformable steel when increasing the Cr content for enhanced corrosion performance. As further

addition of C, one of the most effective austenite stabilising elements, would lead to $M_{23}C_6$ precipitation and thus deplete Cr, other substitutional solutes needed to be considered instead [10]. Ni proved to be the most effective element, and substitution of C with Ni further led to a useful softening of virgin martensite, which manifests as increased impact toughness [10–12].

Following this paradigm, the Swedish steel manufacturers Bofors and Avesta reduced the C content to 0.06 wt.% to develop soft martensitic stainless steels with good corrosion resistance, high strength and high impact toughness for pressure vessel applications in the mid 60's of the last century [3,18–20] (Table 1). These steels

contained small amounts of retained austenite and formed reverted austenite upon inter-critical annealing. Precipitation-hardening steels are designed with a similar base alloy composition, but solutes such as Cu, Mo and Nb enable precipitation hardening [4,21,22].

Further advances in steelmaking enabled the development of modern supermartensitic stainless steels in the 90's of the last century, which generally consist of 10.5 – 13.5 wt.% of Cr to enable passivation, very low C content (preferably <0.01 wt.%) to enhance weldability and impact toughness, around 4 – 6 wt.% Ni to enable martensite formation, and increased Mo content (0.5 – 2.5 wt.%) to enhance resistance to localised corrosion and sulphide stress cracking [10–12,23–25] (c.f. overview in Table 1).

Solution treatment, martensite formation and tempering of martensite

Before austenite reversion from martensite is obtained by inter-critical annealing, low-carbon martensitic stainless steels are solution treated in the austenite single-phase region to obtain homogeneous austenite as a parent phase for lath martensite. Some alloys contain micro-alloying elements, such as Ti, Nb or V, to form carbides and nitrides that pin the austenite grain boundaries during solution treatment to limit grain growth [23,26]. Austenite transforms to martensite during cooling over a narrow transformation range, with martensite formation starting at a relatively low temperature ($M_s \approx 260 - 130$ °C) and finishing just above [27–32], or in exceptional cases even below [2,33], room temperature. Martensite forms with less than $\sim 2^\circ$ deviation [34] from a Kurdjumow-Sachs orientation relationship with austenite, $(111)_\gamma \parallel (011)_{\alpha'}, [10\bar{1}]_\gamma \parallel [\bar{1}\bar{1}1]_{\alpha'}$ [35]. Even though the exact nature of the interface associated with the orientation relationship is still subject of current research [36,37], it has to be semi-coherent, consisting of periodic steps with coherent patches [38,39]. The low-carbon martensitic stainless steels have a high hardenability and are insensitive to the applied quenching rate [4,11,17]. Recent work showed that, as a consequence of the low M_s temperature and interstitial content, no interstitial segregation by auto-tempering or 6 months of room temperature aging was observed [40]. In contrast, clustering of carbon at room temperature was reported in Ref. [41], without specifying the aging time. Martensitic transformation leads to transformation strains, which may be partially accommodated by retained austenite. During the

transformation, martensite initially experiences high tensile stress, which then gradually decreases towards the end of the transformation (down to ~ 40 MPa), while retained austenite experiences significant compressive stress towards the end of the transformation (up to ~ -900 MPa) [42].

Lath martensite shows very high dislocation densities, similar to heavily cold-worked alloys [43]. Quantitative studies on dislocation densities revealed $\sim 4 \times 10^{15} \text{ m}^{-2}$ in an Fe-0.03C-15.5Cr-5Ni (wt.%) precipitation hardening steel [44] and $\sim 7 \times 10^{14} \text{ m}^{-2}$ in an Fe-0.04C-15.5Cr-5Ni (wt.%) soft martensitic stainless steel [45] in as-quenched conditions.

When the dislocation-rich microstructure is reheated to the inter-critical region, C and N partition from solid solution and diffuse to lattice defects in order to minimize local strain fields [27]. Because of the low interstitial content, no transition carbides are formed during the tempering of martensite [21,46]. Tempering of Mo-containing steels at 400°C [21] and Cu-containing steels at 450 to 480°C [29,47–50] leads to secondary hardening by precipitation of Mo_2C and Cu precipitates, respectively. Generally, the kinetics and magnitude of secondary hardening in specific alloys is sensitive to the amount of available interstitial elements and the content of precipitate forming substitutional alloying elements. During further heating, concurrent recovery of the martensite matrix and austenite reversion at grain boundaries commence at approx. 500 to 550°C [45,51], leading to a reduction in dislocation density by approx. an order of magnitude [45].

Nucleation and growth close to A_1

A_1 , i.e. the ferrite-to-austenite (α -to- γ) phase transition temperature in thermodynamic equilibrium, may conventionally be obtained from thermodynamics modelling. In the present system, the prediction of extensive partitioning of solute in austenite and ferrite at low temperature leads to a small fraction of stable austenite in thermodynamic equilibrium. In reality, an alloy undergoes martensite formation during cooling, such that austenite forms from an approximately homogeneous distribution of solute during reheating, rendering the prediction of A_1 from thermodynamic equilibrium unfeasible. A_{c1} , the experimentally determined α -to- γ transition temperature during heating, is on the other hand strongly dependent on the heating rate [9,27,52,53] and thus not an explicit quantity. In the present case the phase transition temperatures A_1

and A_3 therefore refer to the phase transition temperatures obtained during very slow heating ($\leq 0.017 \text{ K} \cdot \text{s}^{-1}$). Sufficiently fast heating (approx. $>10 \text{ K} \cdot \text{s}^{-1}$ [54,55]) does not allow enough time for long-range diffusion and thus leads to transformation by a displacive mechanism instead.

Close to A_1 (composition dependent at $\sim 500 - 550 \text{ }^\circ\text{C}$) allotriomorphic reverted austenite with film morphology forms at lath boundaries [55–60] with little or no deviation from the Kurdjumow-Sachs orientation relationship [35,61,62]. All reported micrographs of annealed microstructures in the temperature range 500 to 575 $^\circ\text{C}$ (c.f. reference list in Table 2) reveal that austenite grows from the lath boundary into only one of the laths (Figure 1a) [1,55,60,63]. Above this temperature, austenite films begin to grow into both laths adjacent to a lath boundary (Figure 1b) [55,58,60]. In the case of pre-existing inter-lath retained austenite, immediate growth from retained austenite occurs, as no nucleation is required [59]. For the film morphology, austenite memory, i.e. the tendency of reverted austenite to form in the orientation of the prior austenite grain, is commonly observed [27,59,64]. Further, reverted austenite has been reported to form cooperatively with M_{23}C_6 carbides with a cube-cube orientation relationship, $\{100\}_\gamma \parallel \{100\}_{\text{M}_{23}\text{C}_6}$, $\langle 001 \rangle_\gamma \parallel \langle 001 \rangle_{\text{M}_{23}\text{C}_6}$ [33,41,58,60,65]. According to thermodynamic equilibrium, growth of austenite requires an inward-flux of Ni and outward-flux of Cr [27] (Figure 2), while growth of M_{23}C_6 requires the opposite fluxes. Cooperative growth should thus be facilitated by a gradient in chemical potential and a resulting net flux of Ni and Cr across the interface. It was shown experimentally that M_{23}C_6 can bind sufficient carbon to leave austenite and martensite virtually carbon free [41,66,67].

Figure 2 shows the equilibrium austenite fraction and Cr and Ni concentrations in austenite and ferrite as a function of temperature for a simple Fe-Cr-Ni system with average Ni and Cr concentrations of the analysed literature data in section 0 (c.f. Table 2). At low temperature, enhanced partitioning of Ni is required to form austenite which, together with slow substitutional diffusion kinetics, significantly limits the kinetics of austenite reversion [27,62,68]. Nevertheless, the kinetics of austenite reversion at low temperature were measured to be significantly faster than predicted by modelling of bulk-diffusion, suggesting that grain boundary diffusion and diffusion along dislocations may be important mechanisms that significantly increase the transformation kinetics at these temperatures [27,33,68].

Figure 1. Bright-field micrographs and schematics of the evolution of the reverted austenite morphology with temperature and time in low-C martensitic stainless steels: (a) low temperature film morphology (Ref. [63]); (b) elevated temperature film morphology (Ref.[62]) ; (c) globular morphology at prior austenite grain boundaries (Ref. [1]); (d) globular morphology inside martensite laths (Ref. [58]); reverted austenite is marked with white arrows in the micrographs; Permissions for the use of figures from literature are automatically granted according to the STM signatory guidelines.

Nucleation and growth towards A_3

At elevated temperature, typically 600 – 700 °C, reverted austenite tends towards a globular morphology, first at prior austenite grain boundaries (Figure 1c) [56,57,59] and at higher temperature within martensite laths (Figure 1d) [55,60,70]. The reversion kinetics are significantly faster, mainly because of lower required partitioning of Ni (Figure 2), accelerated diffusion kinetics and increased prominence of bulk diffusion. Further, the increased driving force for austenite formation in this temperature range renders also incoherent interfaces [56] or the formation of new interfaces energetically favourable [55,60,70], manifested as more nucleation sites. It was found that in an Fe-0.05C-12Cr-4Ni-0.5Mo (wt.%) steel austenite reversion occurred without diffusion during isothermal annealing above 680 °C [67]. Upon further heating grain growth and dissolution of $M_{23}C_6$ carbides continue towards a fully austenitic microstructure, which was reported to recrystallize spontaneously at 900 °C when heating with 0.17 K.s^{-1} , 70 °C above A_{c3} [57].

Stability of reverted austenite against martensite formation

Reverted austenite that is formed close to A_1 is generally more stable against martensite formation upon cooling (or deformation) as compared to reverted austenite formed at higher temperature. There is a consensus that Ni-enrichment in austenite decreases with

Figure 2. Ni and Cr concentration (x) in austenite (fcc) and ferrite (bcc) as well as the molar fraction of austenite (f_γ , grey area) from an equilibrium calculation of a representative Fe-13.3Cr-5.4Ni (wt.%) ternary alloy. Partitioning of Ni increases with lower austenite fraction and temperature. (Allowed phases: liquid, fcc, bcc; software and thermodynamics database: Thermo-Calc 2017a - TCFe6 [69])

increasing annealing temperature [27,29,31,41,55,59,62,63,65–68,71–74], which is in qualitative agreement with the concentrations from thermodynamic equilibrium in Figure 2. The Ni concentration determines mainly the stability of reverted austenite against martensite formation, as more Ni reduces M_s . However, the compositional effect is considered insufficient to explain the stability of reverted austenite alone [41,72]. The increase in grain size [63,65,75,76], the transition to a more globular grain morphology [63,65] and softening of the surrounding martensitic matrix [14,65] with increasing annealing temperature are anticipated to reduce the contribution of strain energy to the critical driving force for martensite nucleation [77], i.e. the stability of austenite. Findings by Zhang et al. [65] are particularly supportive of this mechanism, as inter-critical annealing at 620 °C was found to lead to higher fractions of reverted austenite with annealing time up to a maximum value, after which the fraction decreased again on further annealing. Even though the phase fraction of austenite approached equilibrium content, compositional equilibration (partitioning), carbide growth, recovery of martensite and spheroidisation of austenite continue [65,66], which may affect the stability of reverted austenite.

Bilmes et al. [72] claimed that also a high dislocation density in reverted austenite could contribute to the stability of reverted austenite. This finding is doubtful, as the high dislocation density was identified by the dark appearance of austenite in a bright-field micrograph, which is generally indicative of an orientation contrast when using an objective aperture rather than the presence of dislocations [78]. Further, reverted austenite developed under continued diffusion is known to have low dislocation density [33,79], as opposed to reverted austenite formed by a displacive mechanism [6].

Reverted austenite either remains stable upon cooling, or transforms partially or completely to martensite [30,45,62]. Reverted austenite was reported to even have remained stable after sub-zero treatment at boiling N_2 [2,72,74] and boiling He temperatures [41]. It is critically remarked that martensite formation in lath martensite, especially at sub-zero Celsius temperatures, is time-dependent, i.e. thermally activated, and kinetically suppressed at very low temperature. Transformation generally occurs in the temperature range -150 °C to room temperature, which means that in the referenced cases [2,41,72,74] martensite formation may be fully suppressed if cooling to, or heating from, boiling N_2 temperature is performed sufficiently fast to suppress the

thermally activated phenomena that control the rate of the austenite-to-martensite transformation in steel [80]. In a single case it was claimed that the fraction of austenite increases by applying sub-zero treatment [58], which is in obvious conflict with all above referenced observations.

Reverted austenite may also transform to martensite by strain-induced transformation and in this way enhances the plastic regime [45,71,72,81]. This mechanism known as transformation induced plasticity, has not been treated in depth in low-carbon martensitic stainless steels, but advanced in-situ experiments and modelling of strain-induced martensite formation have been performed in other variations of steels [82–88].

Effect of reverted austenite on microstructure properties

The effect of reverted austenite on the microstructure properties of low-carbon martensitic stainless steels is a broad topic and a proper treatment would exceed the scope of this review. A more detailed overview on the mechanical and corrosion properties of the alloys can be obtained from Refs. [2,4,11,13] and [11,89,90], respectively. Nevertheless, a short summary of the mechanical properties appears necessary to realize the significant property changes induced by formation of reverted austenite.

As an example, Figure 3 shows the mechanical properties of an Fe-16Cr-5Ni-1Mo (wt.%) soft martensitic stainless steel (EN 1.4418) at room temperature after 4 h soaking at various temperatures, adapted from Refs. [13,14]. At first the ultimate tensile strength, the 0.2 % yield strength and the hardness increase by heat-treating up to 475 °C, which is an effect of secondary hardening from precipitation of Mo₂C. Then softening occurs up to 625 °C, mainly due to austenite reversion and recovery of martensite. A new increase in ultimate tensile strength, 0.2 % yield strength and hardness is observed upon heat treatment at 700 °C and above, originating from transformation of reverted austenite to fresh martensite and precipitation of M₂₃C₆ carbides. The elongation and impact toughness develop in inverse relation to the ultimate tensile strength, 0.2 % yield strength and hardness with soaking temperature, i.e. are enhanced by reverted austenite formation and recovery of martensite.

In the presence of reverted austenite, soft martensitic and supermartensitic stainless steels show remarkable impact toughness also at sub-zero Celsius temperature

(> 100 J at -80 °C [11]). Solheim et al. [91] showed that reverted austenite increased the solubility of hydrogen in supermartensitic stainless steel samples dramatically, and that the ductility of such samples was greatly reduced, suggesting that reverted austenite plays an important role in hydrogen embrittlement.

3. Critical assessment of compositional data from literature

All considered references on experimentally determined Cr and Ni contents of partitioning in reverted austenite and tempered martensite are sorted in order of ascending annealing temperature in Table 2. Moreover the sample preparation methods and measurement methods, Energy-dispersive X-ray spectroscopy (EDS) in (scanning) transmission electron microscopy ([S]TEM) and atom probe tomography (APT), are indicated. together with the respective measurement and sample preparation methods.

Figure 3. Fraction austenite and mechanical properties of a 16Cr-5Ni-1Mo stainless steel at room temperature in the hardened condition (HC) and after 4 h soaking at various temperatures: (a) Ultimate tensile strength (UTS), 0.2% yield strength (YS), elongation and fraction austenite (f_γ); (b) Hardness and Charpy V impact toughness; The lines are spline functions of measured data (symbols) and do not represent physical values (adapted from Dawood et al. [13,14])

The reported annealing parameters and alloy compositions were used to determine the equilibrium concentrations of Cr and Ni in austenite and ferrite by computing phase equilibria (Thermo-Calc 2017a [92] with TCFE6 database [69]). For this purpose, the alloying elements Cr, Ni, Mo, Mn, Si, Cu, C and N and the phases fcc, bcc, cementite, M_6C , M_7C_3 and $M_{23}C_6$ were taken into account, representing the most common elements and phases reported in literature [93].

Figure 4 gives reported Ni and Cr concentrations in tempered martensite (a and c) and reverted austenite (b and d) compared with the respective concentrations from computed phase equilibria. Short proximity of data points to the diagonal line indicates good agreement of the measured concentrations with values reflecting thermodynamic equilibrium for the alloy under consideration. Even though different levels of agreement are obtained for different components and phases, experimental data generally seems to agree with calculations from thermodynamics modelling. This supports that austenite reversion occurs mainly by a diffusional mechanism, as potential large strain energies from a displacive transformation are not reflected in the applied thermodynamics model. In tempered martensite, apart from few outliers, both the reported Ni and Cr concentrations are in reasonable agreement with predictions from thermodynamics modelling (Figure 4a and c, respectively). In austenite, apart from a single measurement, all reported Cr concentrations exceed the concentrations for thermodynamic equilibrium (Figure 4d). The reported Ni concentrations of reverted austenite show poor agreement with calculated thermodynamic equilibrium values (Figure 4b). In the latter case, data from APT appeared to agree more convincingly with data from thermodynamic equilibria compared to data from (S)TEM-EDS. Within significant scatter a trend is discernible: Predicted concentrations of Ni in austenite by thermodynamics modelling are approx. 2 wt.% higher than measured concentrations. As the prediction of the Ni concentration in austenite is most relevant for the stability of austenite, the origin of the discrepancy between experimental and predicted Ni content should be investigated. The martensite to austenite phase transformation can be (partly) interface-controlled or local equilibrium may be affected by factors as residual stresses, interfacial segregation and precipitation of carbides. Then the Cr and Ni concentrations can vary with time before the condition of (local) equilibrium is obtained. In order to investigate, whether the discrepancy between Ni concentrations from phase equilibria and measurements decreases with approaching equilibration, a criterion was established

Table 2: Overview of literature data, x , on measured Ni and Cr concentrations after partitioning in austenite (fcc) and martensite (bcc) compared with data from phase equilibria, x . Figure 4. Comparison of the Ni and Cr concentrations in tempered martensite (a and c), and reverted austenite (b and d) from EDS and APT analysis, x_{meas} , with data from thermodynamics modelling, x_{equ} , under input of the respective alloy compositions and annealing temperatures; the legend is sorted in order of ascending annealing temperature

Figure 5. (a) Kinetics of austenite reversion from kinetics modelling of diffusion of a Fe-13.3Cr-5.4Ni (wt.%) steel (c.f. Figure 2). The broken lines indicate the austenite fractions in equilibrium at the respective temperatures and the open symbols indicate $t_{0.95}$, the time at which 95 % of the equilibrium phase fraction is formed; (b) Fit of $t_{0.95}$ as a function of temperature by an exponential decay function, which is the foundation to assess equilibration of the evaluated heat treatments by the equilibration factor $k_{equ}(T, t)$.

to filter the literature data accordingly (Figure 5). For this purpose, the kinetics of forming reverted austenite from a 200 nm wide martensite lath of an Fe-13.3Cr-5.4Ni alloy (c.f. Figure 2) by bulk-diffusion at temperatures between 600 and 700 °C were assessed in steps of 25 °C by kinetics modelling of diffusion with DICTRA [94] (see Ref. [27] for further details on the kinetics model). Kinetics modelling assumes purely diffusion controlled martensite-to-austenite transformation and local equilibrium at the martensite/austenite interface [95]. While these assumptions, as discussed above, may not be entirely justified in the present case, kinetics modelling should reliably reflect the general kinetics of austenite reversion in low-carbon martensitic stainless steels at different temperatures to establish a qualitative criterion.

The transformation kinetics in Figure 5a reveals that the time to reach 95 % of the equilibrium fraction ($t_{0.95}$) increases from 0.2 h at 700 °C to > 100 h at 600 °C (see open symbols in Fig. 5a and the temperature dependence in Fig. 5b). The dependence of $t_{0.95}$ on the annealing temperature follows an exponential decay function (Fig. 5b):

$$t_{0.95} = A \exp\left(\frac{T_0 - T}{b}\right) + c \quad (1)$$

with $A = 126$ h, $T_0 = 600$ °C, $b = 19.1$ °C and $c = -0.5$ h.

Comparing the time $t_{0.95}$ at reported temperatures with the respective reported annealing times from literature, a factor $k_{equ} = t / t_{0.95}$ is obtained to qualitatively estimate the amount of equilibration for each data point (Table 2).

Figure 6 shows the difference of the measured concentrations with respect to concentrations from thermodynamic equilibrium, ε , in austenite as a function of the equilibration factor k_{equ} . Clearly, the difference between the measured and calculated Ni concentration decreases with increasing equilibration (higher k_{equ}), while a similar trend, if present at all, is less obvious for Cr. Figure 7 shows the data from Figure 4 after filtering with the equilibration criterion $k_{equ} > 0.1$. As expected from Figure 6b, the scatter of the Ni concentration in reverted austenite is reduced, such that the experimental data and data from thermodynamics modelling show reasonable agreement (Figure 7b). Filtering of the data on the Cr concentration in reverted austenite reduces the scatter to a small extent and further confirms that the Cr concentration in

reverted austenite is systematically measured to be 1.0 – 3.5 wt.% higher than predicted by equilibrium thermodynamics (Figure 7d).

4. Discussion

Early stage of reverted austenite formation close to A_1

Microstructure characterization of the initial stage of reverted austenite formation is difficult to conduct and of more fundamental interest. So far, only limited studies have been conducted on the early stage of austenite formation, while the mechanisms during growth in different temperature regimes are fairly well established. Nevertheless, by studying related alloy systems and carefully interpreting related mechanisms, such as martensite formation and austenite memory, an understanding of the early stage of austenite formation can be acquired from the existing literature.

Raabe et al. [8] observed segregation of Mn up to 24 at.% at lath boundaries prior to formation of reverted austenite on tempering an Fe-9Mn (at.%) maraging alloy at 450 °C. The experimentally observed grain boundary enrichment factors, which relate the bulk concentration of an element to the concentration at the grain boundary, were found similar for Mn and Ni [8]. Thus, Ni is likely to segregate to lath boundaries in low-carbon martensitic stainless steel during heating which would locally increase

Figure 6. Difference of measured concentrations with respect to concentrations from thermodynamic equilibrium, ϵ , as a function of the equilibration factor k_{equ} (Figure 5b) of the (a) Cr and (b) Ni concentration in reverted austenite. The symbols correspond to the legend in Figure 4.

the driving force for austenite formation and thereby aid austenite nucleation. So far, no experimental evidence of such mechanisms has been reported that can corroborate this hypothesis.

Stress plays a fundamental role in martensite formation. The strict hierarchy of lath martensite follows the minimisation of the total shape strain [96]. It therefore appears unavoidable to consider the role of stress in the reverted transformation to austenite. The previously mentioned austenite memory effect, the strong tendency of reverted austenite to form in an identical crystallographic orientation to the prior austenite grain, gives important insight into the role of stress in the early stage of reverted austenite formation. Nakada et al. [64] suggested that the reverted austenite variants are theoretically limited to two variants within a martensite packet: the prior austenite and a twin-related orientation variant. The variant restriction originates from crystal symmetry and considerations of interfacial energies and was validated with experiments on a supermartensitic stainless steel with no retained austenite. Indeed, only the two predicted variants formed. Interestingly, the twin-related variant made up

Figure 7. Comparison of the Ni and Cr concentrations in tempered martensite (a and c), and reverted austenite (b and d) with data from thermodynamics modelling from Figure 4 for data with an equilibration factor of $k_{equ} > 0.1$.

less than 5 % area fraction of reverted austenite and could be increased to approx. 40 % by applying a uniaxial tensile stress of 100 MPa during inter-critical annealing. As a consequence, Nakada et al. suggested that also residual stress affects austenite memory in that it favours the prior austenite orientation [64].

Miyamoto et al. [97] provided experimental evidence of the accommodation of transformation strains from lath martensite formation in austenite by measurement of lattice strains (rotations). Sandvik et al. [34] suggested plastic accommodation of transformation strains in martensite laths by characterising the dislocation substructure. Both independently reported that the martensite/austenite interface is relatively straight on one side and irregular on the other side of a lath (Figure 8), which suggests thickening of martensite laths mainly towards the irregular side of the interface. Consequently, transformation strains should accumulate with movement of the martensite/austenite interface and manifest as build-up of residual stress between adjacent laths.

When annealing lath martensite, austenite formation in a crystallographically reverse sense with respect to martensite formation, i.e. an inverse interface movement and orientation relationship, should lead to relaxation of these stresses. Residual stress between adjacent laths may thus act as a mechanical driving force that, in addition to

Figure 8. Footage from literature indicating thickening of lath martensite to primarily one side; (a) Misorientation map of austenite from electron backscatter diffraction (EBSD) after growth of lath martensite (black) in an Fe-20Ni-5Mn (wt.%) alloy indicating strain accommodation of the transformation strain in austenite in primarily one direction of the lath (Ref. [97], permission was automatically granted according to the STM signatory guidelines.); (b) Example of a martensite lath in an Fe-20Ni-6Mn-0.01 (wt.%) alloy, showing a relatively straight (left side) and irregular (right side) martensite/austenite interface (Ref. [34], RightsLink license number 4294080199168.);

the chemical driving force, promotes formation and diffusional growth of austenite in a distinct orientation and growth direction. The observed formation of austenite in only one lath of at lath boundary below 575 °C is consistent with this hypothesis (Figure 1a) [1,55,60,63]. At sufficiently high temperature, recovery of martensite partially relaxes the residual stress and the chemical driving force for austenite formation is higher. Consequently, the contribution of the mechanical driving force is greatly reduced, which gives a consistent explanation for austenite formation in both laths of a lath boundary above 575 °C (Figure 1b) [55,58,60]. Further evidence from experiments and modelling is required to corroborate this hypothesis.

Discrepancy of data on solute partitioning from equilibrium calculations and literature

While reasonable agreement of concentrations from literature data with concentrations from thermodynamic equilibrium was obtained for Cr and Ni in martensite (ferrite), in austenite systematic and more random discrepancies were found for Cr and Ni, respectively. In the following, possible reasons will be discussed.

At first, it is noted that the calculated thermodynamic equilibria originate from a modelling method, which inherently suffers from uncertainties originating from databases [98] and relies on extrapolation from constituent subsystems to multi-component alloy systems [99,100]. In the present case, further uncertainties are expected from treating all alloys with the same list of phases and components, where in some cases not all components were reported or included. Considering these uncertainties, the observed amount of systematic deviation (approx. 2 wt.% for Cr in martensite) appears too excessive to be introduced by the CALPHAD method or the database. The analysed Fe-Cr-Ni alloy system is amongst the best-described systems in thermodynamics modelling and has proven to provide excellent predictions in previous cases [101–103]. Moreover, it appears difficult to explain the more random deviation of Ni in austenite with potential uncertainties in the CALPHAD method. Therefore other reasons for the observed deviation need consideration.

According to thermodynamic equilibrium, Cr is in all analysed cases supposed to be rejected from austenite and dissolved in carbides and martensite during inter-critical annealing. The difference in concentration between austenite and martensite should in average amount to 2 wt.% (Table 2). From 13 experimental datasets on

partitioning of Cr in austenite and martensite, only three datasets qualitatively confirm such partitioning [73,104,105], while six datasets show no partitioning within 0.5 wt.% of accuracy [1,33,62,66] and four datasets (all originating from the same research group) even show inverse partitioning, i.e. Cr-enrichment in austenite [41,58,65,67]. Even though these inconsistent observations are difficult to interpret, it appears likely that growth of $M_{23}C_6$ carbides affects the local Cr contents of austenite and martensite. $M_{23}C_6$ carbides share a coherent interface with reverted austenite, which is anticipated to facilitate the diffusion flux of Cr and Ni during diffusion accompanied growth of both phases, as also suggested in Ref. [65].

In contrast to the Cr concentration, the Ni concentration in austenite deviated more randomly from thermodynamic equilibrium (Figure 4b). Within large scatter, Ni was in average predicted with 2 wt.% higher concentration than characterized in literature. It appears that two major effects cause the discrepancy: insufficient equilibration of the microstructure and experimental error.

It was found that the Ni concentration in austenite can be predicted with reasonable accuracy by phase equilibria when the microstructure approaches equilibration (higher k_{equ} in Figure 6b). Escobar et al. [66] reported that, even when the equilibrium phase fraction was obtained after annealing for 2.5 h at 625 °C, individual austenite lamellae revealed approx. ± 2 wt.% difference in Ni concentration. Further, gradients of Ni concentration within austenite lamellae in the range of approx. 4 wt.% from interface to bulk were measured with APT. Apparently, the initial composition of reverted austenite is far from equilibrium.

It is noted that martensite itself must be considered as metastable ferrite, as it deviates from ferrite in thermodynamic equilibrium. Nucleation of reverted austenite in equilibrium with martensite (metastable ferrite) may thus occur with different phase compositions as predicted for austenite and ferrite in thermodynamic equilibrium. It is suggested that the phase fractions and compositions of austenite and martensite during continued annealing evolve towards global equilibrium, which appears to be a slow and complex process.

The majority of insufficiently equilibrated microstructures ($k_{equ} < 0.1$) were obtained from annealing below 650 °C. As partitioning of Ni increases with lower temperature (Figure 2), sharp compositional measurements over thin austenite films (40 – 150 nm width) and tempered martensite become more challenging. Figure 4 reveals

that measurements from APT matched the predictions from thermodynamic equilibrium more convincingly than measurements from (S)TEM-EDS. As the spatial resolution (near atomic) and compositional resolution (few ppm) of APT are by far superior to that of standard (S)TEM-EDS [106], this observation appears reasonable. (S)TEM-EDS faces the inherent issue of insufficient counting rate when samples are too thin, leading to insufficient compositional accuracy when applying low counting times and contamination and beam drift when applying high counting times [107]. Increasing the sample thickness on the other hand reduces the spatial resolution and complicates measurement of a sharp austenite/martensite interface. Reliable measurements of fine-grained and partitioned microstructures are certainly possible (good agreement with data from APT was for instance obtained in Refs. [1,66]), but several potential error sources render data from EDS generally less trustworthy. The lower experimentally determined Ni-concentrations, especially at lower temperature, may therefore to a certain extent originate from a higher experimental error of (S)TEM-EDS measurements.

5. Conclusions

The mechanism of austenite reversion in low-carbon martensitic stainless steels was critically reviewed by collating literature on nucleation and growth, stability against martensite formation and the effect on microstructure properties of reverted austenite. Discussion of the morphology of austenite films close to A_1 in the light of austenite memory and the mechanism of martensite formation led to suggest that residual stresses from the martensite microstructure aid nucleation of reverted austenite close to A_1 . It was further investigated whether literature data on the Ni and Cr concentrations in austenite and martensite after inter-critical annealing comply with thermodynamic equilibrium from thermodynamics modelling. In martensite, measured Cr and Ni concentrations matched predictions from thermodynamics modelling with reasonable accuracy. Systematic excess of Cr in austenite by approx. 2 wt.% relative to predictions was suspected to originate from growth of $M_{23}C_6$ with a coherent interface to austenite. Within large scatter, measured values of Ni in austenite were in average 2 wt.% below predictions from thermodynamics modelling. The scatter reduced dramatically when only microstructures with advanced equilibration were considered. Further, APT data matched predictions more convincingly than data from (S)TEM-EDS, indicating better

experimental accuracy for determining concentrations in the partitioned microstructure.
