ABSTRACT Chromatin structure regulates both genome expression and dynamics in eukaryotes, where large heterochromatic regions are epigenetically silenced through the methylation of histone H3K9, histone deacetylation, and the assembly of repressive complexes. Previous genetic screens with the fission yeast Schizosaccharomyces pombe have led to the identification of key enzymatic activities and structural constituents of heterochromatin. We report here on additional factors discovered by screening a library of deletion mutants for silencing defects at the edge of a heterochromatic domain bound by its natural boundary—the IR-R+ element—or by ectopic boundaries. We found that several components of the DNA replication progression complex (RPC), including Mrc1/Claspin, Mcl1/Ctf4, Swi1/Timeless, Swi3/Tipin, and the FACT subunit Pob3, are essential for robust heterochromatic silencing, as are the ubiquitin ligase components Pof3 and Def1, which have been implicated in the removal of stalled DNA and RNA polymerases from chromatin. Moreover, the search identified the cohesin release factor Wpl1 and the forkhead protein Fkh2, both likely to function through genome organization, the Ssz1 chaperone, the Fkbp39 proline cis-trans isomerase, which acts on histone H3P30 and P38 in Saccharomyces cerevisiae, and the chromatin remodeler Fft3. In addition to their effects in the mating-type region, to varying extents, these factors take part in heterochromatic silencing in pericentromeric regions and telomeres, revealing for many a general effect in heterochromatin. This list of factors provides precious new clues with which to study the spatio-temporal organization and dynamics of heterochromatic regions in connection with DNA replication.

KEYWORDS chromatin remodeling cohesins DNA replication progression complex fission yeast gene silencing genetic screen heterochromatin mating-type region nuclear organization proline isomerase

The various chromatin states found in eukaryotes fall into two histologically distinct types: euchromatin, which sustains gene expression, and heterochromatin, with repressive functions. While numerous forms of euchromatin can be distinguished based on histone modifications, heterochromatin is more homogenously characterized by the methylation of histone H3 at lysine 9 (H3K9me). H3K9me silences repeats and transposable elements that together constitute more than half of the human genome (Gregory 2005), and recent investigations of embryonic stem cells and cell reprogramming have further shown the importance of H3K9me in maintaining cell identity in differentiated cells through the formation of facultative heterochromatin (Becker et al. 2016). Beyond the control of gene expression, chromatin fulfills structural roles and participates in DNA recombination, and in the repair, replication, and condensation of chromosomes. How these various functions are coordinated to accommodate each other at the chromatin level is an important aspect of eukaryotic genome biology.

Much knowledge of chromatin structure and function stems from studies of the fission yeast Schizosaccharomyces pombe. Genetic screens in this organism produced mutants of the H3K9 methyltransferase Clr4 (Ekwall and Ruusala 1994; Thon et al. 1994), which together with its metazoan homolog SUVAR39 was the first identified histone methyltransferase (Rea et al. 2000). Clr4 and SUVAR39 establish large heterochromatobic domains. The genetic screens that identified the clr4 locus relied on derepression of the silent mating-type loci and nearby reporters. Not only do clr4 mutants express these normally silent genes due to loss of H3K9me heterochromatin, but several aspects of mitotic
and meiotic recombination are also altered in the mutants (Thon et al.
1994; Ellermeier et al. 2010). Thus, the system provides an example
where chromatin structure coordinately controls gene expression and
recombination through H3K9me. In addition to Clr4, genetic screens
have produced mutants in: the HP1-like protein Swi6 (Gutz and
Schmidt 1983; Lorenz et al. 1994); the Clr7 (a.k.a. Rafl, Cmc2, and
Dos2), Clr8 (a.k.a. Raf1, Cmc1, and Dos1), and Rik1 subunits of the
Clr4-associated complex CLR4 (Li et al. 2005; Thon et al. 2005); the
Clr1, Clr2, and Clr3 subunits of the SHREC histone deacetylase com-
plex (Thon and Klar 1992; Ekwall and Ruusala 1994; Thon et al. 1994;
Sugiyama et al. 2007; Job et al. 2016); Clr5 (Hansen et al. 2011); the
Clr6 histone deacetylase (Grewal et al. 1998); and the Ubc4 E2 ubiquitin
ligase (Irvine et al. 2009). This mutant assortment mirrors mutants
isolated in Drosophila (Elgin and Reuter 2013) and mouse (Blewitt
et al. 2005), and emphasizes the evolutionarily conserved properties
of heterochromatin, such as H3K9me and histone hypoacetylation.

Major players in S. pombe heterochromatin formation were identi-
cified by the screens mentioned above, although not all players. This
is partly because some requirements for heterochromatin formation are
location-specific. At centromeres, heterochromatin is strongly driven
by RNA interference (RNAi), whereas this is less the case in the mating-
type region (Ekwall and Ruusala 1994; Thon et al. 1994; Sugiyama et al.
2007; Job et al. 2016). The formation of telomeric heterochromatin depends
on RNAi and on the Shelterin protein Tax1 (Kanoh et al. 2005; Hansen et al. 2006). Small heterochro-
matin islands dispersed in the genome depend on Red1 or Shelterin
components (Hiriart et al. 2012; Zofall et al. 2016). In addition, some
factors possibly eluded original screens due to their relatively small
contribution to heterochromatic gene silencing; this would be the case
for the Swi6 paralog Chp2 (Thon and Verhein-Hansen 2000), the
impaired growth of the mutants, as for the Pcu4 cullin (Thon et al.
2005), or to functional redundancy, as for Atf1/Pcr1 redundant with
RNAi to establish heterochromatin in the mating-type region (Jia et al.
2004). Also, the screens were not saturated, as some loci appeared as
mutational hotspots while others were underrepresented. Other loci
affecting heterochromatin formation or function were subsequently
identified in candidate approaches (references in Table 1). Recently, a
screen of the Bioneer deletion library recapitulated some of these find-
ings for pericentromeric silencing by isolating factors required for the
silencing of an ade6 reporter placed in a dg repeat of centromere 1
(Bayne et al. 2014).

Comprehensive models for heterochromatin formation and main-
tenance have been derived from the phenotypes of S. pombe mutants,
with noncoding RNAs, RNAi, and DNA-binding proteins participating
in the establishment of heterochromatic domains whose subsequent
maintenance invokes epigenetic components. Domains in the 20–
100 kb range are formed at centromeres, telomeres, and the mating-
type region. Smaller heterochromatin patches are formed at internal
chromosomal locations, some of which participate in the repression of
meiotic genes during vegetative growth.

The new screens reported here build on our recent identification of
dNA elements capable of functionally replacing the natural chromatin
boundary, IR-R+, at the edge of the mating-type region (Jakociunas
et al. 2013; Toteva et al. 2017). IR-R+ deletion leads to reduced hetero-
chromatic silencing (Thon et al. 2002) that can be restored by artificial
boundaries. Thus, five genomic elements, whose boundary activity
requires the regulators of replication origin firing Tax1 and Rif1, can
substitute for IR-R+ (STAR1-5, for Sensitive to Tax1 and Rif1), as well as
another uncharacterized element originating from a unique chromo-
somal location, BTH1 (Boundary To Heterochromatin 1) (Toteva et
al. 2017). At their endogenous chromosomal locations, STAR elements are
adjacent to late replication origins. They are physically bound by Tax1,
which, together with Rif1, delays origin firing (Hayano et al. 2012;
Tazumi et al. 2012). The effects of Tax1, Rif1, and STAR elements on
replication and chromatin structure appear to be mechanistically con-
nected, perhaps through protein phosphatase 1 (Toteva et al. 2017).
DNA repeats can also form ectopic boundaries, in this case highlight-
ing the essential role of the replication-blocking protein Reb1 in bound-
ary formation (Jakociunas et al. 2013). Additional phenotypes suggest
coordinated control of DNA replication and boundary positioning. In
particular, the heterochromatic part of the mating-type region repli-
cates early in S phase in contrast to the flanking euchromatin. Deletion
of the IR-R+ boundary perturbs the replication pattern at the edge of
the domain in addition to perturbing heterochromatin (Toteva et al. 2017).

Our new screens confirm and extend these previous observations by
showing that multiple proteins associated with the replisome partici-
pate in heterochromatic gene silencing. This is in addition to several
other factors with hitherto undocumented roles in heterochromatin,
whose identification further increases our understanding of the inter-
play between genome organization and gene expression.

MATERIALS AND METHODS

Strains, genetic manipulations, media, and oligonucleotides

The S. pombe strains used in this study are listed in Supplemental
Material, Table S3 in File S1. Oligonucleotide sequences are provided
in Table S4 in File S1. Media and yeast handling were conducted
according to Ekwall and Thon (2017). NBA medium (Yeast Nitrogen
Base) is identical to Saccharomyces cerevisiae SC medium.

Screens of Bioneer deletion library

An S. pombe deletion library of haploid strains (Bioneer, version 3) was
screened in an arrayed format with the help of a ROTOR HDA robot
(Singer Instruments), as described in Toteva et al. (2017) and based on
Baryshnikova et al. (2010). Compared to Toteva et al. (2017), where the
B6 and B7 strains were used as query strains, the following additional
strains were mated here to the library: B14, B15, B16, B17, B18, and
B19. In all cases, recombinant progeny of the crosses were selected for
G418 resistance, conferred by the ORF deletions, and uracil prototro-
phy, conferred by the mating-type region of the query strains. (EcoRV): ade6 derepression was tested by growth in the absence of adenine, first
in two rounds of high-throughput screening and subsequently by
spot tests of a ten-fold dilution series for potential hits. Isolated colonies
for the best-looking hits were obtained by streaking Bioneer library
strains. The purified strains were then checked by PCR to confirm the
expected ORF deletions, using Taq polymerase and primer Cp-N10 or
Cp-C3, which anneal within the kanR cassette (Kim et al. 2010), in combination with loci-specific primers. Cp-N10 was used with Cp5
loci-specific primers and Cp-C3 with Cp3 loci-specific primers.
Once confirmed, the purified strains were crossed again with the query
strains to test the resulting Ade phenotype in ade6-DN/N progeny.
ade6-DN/N was identified by PCR on genomic DNA with primers
GTO-232 and GTO-233.

Construction of mcl1, wpl1, and dpb4 deletion strains

To retest the phenotypes of mcl1::kanR (SPAPB1E7.02cΔ), wpl1::
kanR (SPBC428.17cΔ), and dpb4::kanR (SPBC3D6.09Δ), deletion cas-
ettes were amplified from the corresponding Bioneer deletion library
strains, respectively: V3-P19-76, V3-3P77, and V3-P102-69, with the
oligonucleotide pairs GTO-1332 and GTO-1333, GTO-1365 and
GTO-1366, and GTO-1363 and GTO-1364, and Phusion HF DNA
polymerase (Thermo Fisher Scientific). The mcl1::kanR amplicon

was cloned into the EcoRV site of plasmid pJET1.2 (Thermo Fisher Scientific), generating plasmid pPA7. This plasmid was digested with BglII to release the mcl1A::kanR insert for S. pombe transformation, while the purified ampiclons for wpl1A::kanR and dpb4A::kanR were used directly. Each deletion was introduced into the S. pombe strains PG9350, PC152, PT600, and PG3947, and transformants were selected on YES plates with G418. Gene replacements were confirmed by PCR with primers Cp-N10 or Cp-C3 (Kim et al. 2010) was used as above with locus-specific primers: Cp5-mcl1D, Cp5-wpl1D, and Cp5-dpb4D were used with Cp-N10, and Cp3-mc1D, Cp3-wpl1D, and Cp3-dpb4D were used with Cp-C3. The PG9350, PC152, PT600, and PG3947 transformants with mcl1A::kanR were named PA71, PA72, PA73, and PA74; those with dpb4A::kanR were named PA77, PA78, PA79, PA80, and PA81; and those with wpl1A::kanR were named PA82, PA83, PA84, and PA85. During the construction of these strains, transformants were replica-plated onto medium with limited adenine (YE) and medium lacking adenine (AA-ade) at several steps, including following the original G418 selection of transformants, during the colony purification of multiple candidates to gauge effects on (EcoRV)::ade6 expression, and to ensure that the phenotypes of the strains saved in the collection were representative.

RNA preparation and RT-QPCR

(EcoRV)::ade6 RNA levels were monitored as described previously (Hansen et al. 2005; Jakociunas et al. 2013). Briefly, for each strain to be examined, three isolated colonies were first patched on YES and subsequently propagated overnight in 50 ml EMM2 cultures supplemented with adenine, leucine, and uracil, to an OD600 of 0.4. Cell pellets were flash frozen in liquid nitrogen and stored at −80°C. Following RNA extraction, 2 μg RNA were treated with RNase-free DNase I (Promega), diluted with DEPC-treated H2O to a final volume of 200 μl, and stored at −20°C. QPCR was set up with 7.5 μl DNase-treated RNA samples in 25 μl reactions using a QuantiFast Multiplex RT-PCR kit (QIAGEN) and two primers at 1 μM each. Three technical replicates were set up for each reaction. The reactions were performed as suggested by the manufacturer: 10 min at 50°C, followed by 5 min at 95°C and 39 cycles of 10 sec at 95°C, and 30 sec at 60°C, with data capture at each cycle, in a Bio-Rad CFX96 Thermal Cycler. Melting curves were produced on the final products and no RT controls were included. Reactions were set up with the primer pairs GTO-218 and GTO-219 (ade6+), and TJO-55 and TJO-58 (act1+). Data were analyzed using Bio-Rad CFX Manager and Microsoft Excel, normalizing ade6+ expression to act1+ in all samples.

Mean normalized expression (MNE) values were calculated according to the following equation: $MNE = \frac{E_{act1, mean}C>T_{act1}}{E_{ade6, mean}C>T_{ade6}}$, where $E_{act1}$ is the efficiency of act1+ DNA amplification determined on 10-fold serial dilutions of genomic DNA, $C>T_{act1, mean}$ is the mean cycle threshold for act1+ RNA amplification, $E_{ade6}$ is the efficiency of amplification of the target of interest (ade6+) determined on 10-fold serial dilutions of genomic DNA, and $C>T_{ade6, mean}$ is the mean cycle threshold for ade6+ RNA amplification.

Data availability

Strains are available upon request. All Supplemental Tables and Figures are regrouped in File S1. Table S1 in File S1 presents a list of Bioneer deletion strains selected for the second and third mutant screens and Table S2 in File S1 gives a list of potential false positives. Figures S1–S8 in File S1 show the phenotypes of mutants examined in the second screen, while Figures S9–S11 in File S1 show the phenotypes of mutants examined in the third screen. Table S3 in File S1 contains a list of strains and their genotypes, while Table S4 in File S1 contains oligonucleotide sequences.

RESULTS AND DISCUSSION

Screen for factors required for heterochromatin integrity close to domain boundaries

An arrayed library of 3308 S. pombe ORF deletion strains (Kim et al. 2010) was used to determine the requirements for heterochromatic gene silencing at the edge of the mating-type region in eight strains: a strain with the wild-type IR-R+ boundary and strains with, respectively: STAR1-4, BTH1, an rDNA repeat, or the edge of cent1 in the place of IR-R+ (Figure 1A). The eight query strains contained the (EcoRV)::ade6+ reporter gene close to the edge of the heterochromatic domain to provide a readout for gene silencing (Thon et al. 1999), and a euchromatic urad4+ gene tightly linked to the mating-type region to allow for its selection ((Xmml)::urad4+). The query strains were crossed with the deletion library in parallel large-scale experiments. Progeny combining the mating-type region of interest with each ORF deletion were selected according to the scheme in Figure 1B and tested for (EcoRV)::ade6+ expression. Candidate factors whose deletions appeared to permit the expression of (EcoRV)::ade6+ were identified. At this stage, even deletions with a dubious phenotype were chosen for further examination alongside deletions with a potentially strong effect. The corresponding 196 strains from the Bioneer library were rearrayed on a single plate.

(191 strains) or processed individually (five strains) and retested by genetic crosses against all query strains, leading to a shorter list of 48 factors potentially required for (EcoRV)::ade6+ repression (Figures S1–S8 and Table S1 in File S1). Factors with extensively documented effects on heterochromatin formation were not tested further, and we focused instead on factors whose effects on heterochromatin had not been documented before, or not tested in the mating-type region. Recombinant Ura+ G418-resistant progeny were colony-purified and spotted on indicator and selective plates to better evaluate (EcoRV)::ade6+ expression, leading to a short list of 33 candidate genes with a heterochromatic silencing defect in at least one of the queried mating-type regions. For these candidates, single colonies were isolated from the Bioneer collection, the ORF deletions were verified by PCR using locus-specific primers, and we obtained recombinant progeny combining the mating-type regions of interest with each ORF deletion in an ade6-DN/N background. The ade6-DN/N background is well suited to the monitoring of ade6+ expression by colony color on a limiting concentration of adenine or by RT-QPCR with primers that specifically recognize ade6+. In addition to Bioneer strains, three deletion strains that were not present in the library were added to the analysis (abo2Δ is shown for comparison with the deletion of its paralog abo1Δ). A different reporter, (EcoRV)::ura4+, was affected in the same way. In particular, mrc1Δ, pof3Δ, def1Δ, szc1Δ, fkhp39Δ, and fft3Δ cells grew better in the absence of uracil than in the presence of fluoroorotic acid (FOA), unlike the parental wild-type strain for which (EcoRV)::ura4+ repression leads to the opposite growth pattern (Figure 6).

A few Bioneer strains could not be reliably retested by crossing. Instead, for three of them (mcl1Δ and wpl1Δ, scored as positive in first and second screens, and dpb4Δ, scored as false positive in first screen), the kanMX6 cassette that replaces each deleted ORF (Kim et al. 2010) was comprehensive spot-test analyses assessing silencing by factors that made it through the entire screen are shown in Figures S9–S11 in File S1. A subset of factors are presented in Figure 2 and Figure 3 for their effects on all query strains, and in Figure 4 and Figure 5 for their effects with the wild-type boundary IR-R+. Derepression of (EcoRV)::ade6+ occurs in IR-RΔ and clr4Δ cells, resulting in white or light pink colonies on medium with limiting adenine and improved growth in the absence of adenine. While not as pronounced as for clr4Δ, the phenotypes of the other mutations tested were distinctive and were confirmed by quantification of the (EcoRV)::ade6+ transcript (Figure 5). Increases ranging from 5- to 40-fold over wild-type were measured and normalized to (EcoRV)::ade6+ expression in the IR-RΔ strain in Figure 5. A different reporter, (EcoRV)::ura4+, was affected in the same way. In particular, mrc1Δ, pof3Δ, def1Δ, szc1Δ, fkhp39Δ, and fft3Δ cells grew better in the absence of uracil than in the presence of fluoroorotic acid (FOA), unlike the parental wild-type strain for which (EcoRV)::ura4+ repression leads to the opposite growth pattern (Figure 6).
amplified by PCR, together with 500 bp–1 kb flanking DNA from genomic DNA of the Bioneer deletion strain, and used to transform tester strains to confirm effects suggested by the genetic screens. Little effect was seen in dpb4Δ cells, suggesting that the originally observed phenotype was artifactual, while derepression by mcl1Δ and wpl1Δ was confirmed (Figure 7).

The silencing factors that were retested throughout the whole scheme are listed in Table 1, together with references to prior literature for those that had been described previously. In addition to known components of heterochromatin, the screens identified factors that had eluded all previous screens or that had not been examined for effects in the mating-type region. A few were element-specific, such as Rif1 acting with the STAR elements (Toteva et al. 2017), while others were required for (EcoRV):ade6+ silencing in all or nearly all query strains.

**Figure 2** Factors identified in the screens include histone modifiers and readers, and their regulators. (A) Bulk progeny of crosses combining the indicated boundary elements and ORF deletions, replicated onto medium lacking adenine (NBA [yeast nitrogen base] supplemented with leucine) to assay (EcoRV):ade6+ expression. Light colors reflect (EcoRV):ade6+ expression. Control: an ORF deletion with no effect on (EcoRV):ade6+ expression (V3-P25-45, SPAC15E1.07c). (B) Schematic representation of factors and complexes shown in (A). HDACs remove acetyl groups (in green); CLRC methylates H3K9 (in red); CRL4Cdt2, positively regulated by Csn1, destabilizes the antisilencing factor Epe1. HDACs, histone deacetylases; ORF, open reading frame.

**Requirement for histone deacetylases and methyltransferases**

The sole proteins required for (EcoRV):ade6+ silencing in all configurations of the mating-type region tested were Clr1, Clr2, and Clr3; that is, the deacetylase module of the SHREC complex (Figure 2). Most boundary elements also relied on the chromatin remodeler module of SHREC, Mit1, with the exception of BTH1. Some independence of the deacetylase and remodeler modules of SHREC is predicted by a structure–function analysis of the complex (Job et al. 2016). The histone H3K9 methyltransferase Cfh4, the Cla7, Cla8, and Rik1 subunits of the CLRC complex, and the chromodomain protein Swi6 were also broadly identified, in all screens except for the full-length rDNA repeat (Figure 2A). The rDNA repeat is exceptional in that it silences (EcoRV):ade6+ tightly through
antisense transcription and histone deacetylation, even in the absence of Clr4 (Jakociunas et al. 2013). The Clr6 histone deacetylase-associated PHD protein-1 Cph1 was also identified in several screens, albeit with relatively weak phenotypes (Figure 2). Moreover, deletion of the meu6+ gene adjacent to clr4+ resulted in the same strong derepression as clr4Δ (Figure 2), possibly due to impaired clr4 expression. Altogether, this first set of mutants emphasizes the central roles of deacetylation and methylation in heterochromatic gene silencing, and validates the screening strategy.

Requirement for Ddb1-Cdt2 and Csn1
Nearly all screens also identified the Ddb1, Cdt2, and Csn1 proteins (Figure 2 and Figure S9 in File S1 for ddb1Δ). Ddb1 and Cdt2 are part of the Cullin 4 ubiquitin ligase CRL4Cdt2 that targets specific proteins for degradation by the proteasome. In Cullin complexes, an adaptor protein, Cdt2 in this case, interacts with cognate substrates to display them to the ubiquitin ligase activity. Three CRL4Cdt2 substrates are known in S. pombe: the putative histone H3K9 demethylase Epe1 (Braun et al. 2011), the licensing factor Cdt1 that is required for the firing of replication origins (Ralph et al. 2006); and the inhibitor of ribonucleotide reductase Spd1 (Liu et al. 2003). According to previous work, stabilization of Epe1 in the cdt2Δ and ddb1Δ mutants and its accumulation in heterochromatin would suffice to derepress (EcoRV)::ade6+ (Braun et al. 2011). Deletion of the COP9 signalosome (CSN) subunit Csn1 also resulted in reduced silencing (Figure 2). Reduced silencing in the csn1Δ mutant might result from CRL4Cdt2 deregulation (Liu et al. 2003), or from the destabilization of other cullin ligases such as SCFPof3, whose F-box component Pof3 is proteolyzed in CSN mutants (Schmidt et al. 2009). Indicative of a general requirement in heterochromatin, Csn1 was also identified in a recent genetic screen for heterochromatic silencing defects at centromeres (Bayne et al. 2014).

Requirement for Def1, Pof3, and Pli1
Further links to ubiquitylation were revealed with the identification of the proposed homolog of S. cerevisiae Def1 and the F-box protein Pof3 (Figure 3, Figure 4, Figure 5, Figure 6, and Figures S9 and S10 in File S1). To our knowledge, this is the first evidence for an effect of Def1 in heterochromatin. In S. cerevisiae, Def1 mediates the ubiquitylation and degradation of the Rpb1 subunit of RNA polymerase II (RNAPII) during transcriptional stress (Wilson et al. 2013), and of Pol3, the catalytic subunit of the replicative DNA polymerase δ, in postreplicative repair (Daraba et al. 2014). In S. pombe, Def1 might control polymerase usage in heterochromatin, remove RNAPII from heterochromatin to promote
checkpoint Mrc1, Pol
the increased stability in Mrc1, Mcl1, Swi1, Swi3, and the Pob3 subunit of FACT were all necessary (Gambus 2013a,b; Maculins et al. 2006). Pof3 associates with the replisome. Its targets, inferred from the increased stability in pof3Δ cells, include the mediator of replication checkpoint Mrc1, Pol e, and subunits of the CMG helicase, each of which could be relevant to the observed effects (see below; Roseaulin et al. 2013a,b; Maculins et al. 2015). Other targets of Pof3 potentially relevant to heterochromatic silencing would be Ams2, a regulator of histone gene transcription (Takayama et al. 2010), or other DNA-binding proteins that might be removed by Pof3 as Pof3 travels with the replication fork.

The screens also detected a small contribution of the SUMO E3 ligase Pli1 to (EcoRV):ade6+ silencing (Figure 3), compatible with previously observed limited derepression of centromeric reporters in pli1Δ cells (Xhemalce et al. 2004).

**Requirement for the RPC**
Mrc1/Clsapin, Mc1 (Cit4 in S. cerevisiae), Sw1 (Timeless in animals or Tof1 in S. cerevisiae), Sw3 (Tipin or Csm3), and the histone chaperone FACT are part of the RPC essential to normal replication fork progression (Gambus et al. 2006; Foltman et al. 2013; Yeeles et al. 2017). Here, Mrc1, Mc1, Sw1, Sw3, and the Pob3 subunit of FACT were all necessary for tight (EcoRV):ade6+ silencing (Figure 4, Figure 7, and Figure S9 in File S1). Mrc1, Mc1, Sw1, and Sw3 also ensure replication fork protection at replication blocks (Noguchi et al. 2004; Shimamoto et al. 2009) and telomeric repeats (Gadaleta et al. 2016). Structurally, Mc1/Cit4 forms a trimer that connects the CMG helicase to the lagging-strand primase Polα, and various accessory factors to the replisome (Williams and McIntosh 2002, 2005; Tsutsui et al. 2005; Simon et al. 2014; Samora et al. 2016; Villà et al. 2016). Pof3/Dia2 in particular, also identified in our screen, is associated with the replisome in an Mc1- and Mrc1-dependent manner (Mammun et al. 2006; Morohashi et al. 2009). Hence, the silencing defect in RPC mutants might be due to a failed association of Pof3 with the fork in these mutants. Since Pof3 is responsible for the short half-life of Mrc1 in wild-type S. pombe cells, and mediates the degradation of DNA polymerases and MCM helicases in the absence of the RPC (Roseaulin et al. 2013a,b), the silencing defect in pof3Δ cells might also result from a misregulated RPC.

**Further requirements for DNA replication/genome organization factors**
Other proteins implicated in the control of DNA replication or genome organization identified in the screens were the forkhead protein Fkh2, whose S. cerevisiae homologs Fkh1 and Fkh2 organize the long-range clustering and activation of early-firing origins (Knott et al. 2012) and long-range chromosomal interactions occurring during mating-type switching (Li et al. 2012), and the cohesin release factor Wings apart-like Wpl1 (Figure 3, Figure 7, and Figure S9 in File S1). In the absence of Wpl1, (EcoRV):ade6+ showed a strongly variegated phenotype (Figure 7). In mammals, ΔWAPL cells display altered chromatin loop structure, reduced long-range chromosomal interactions in cis, and decreased nuclear compartmentalization that correlates with gene derepression in normally silent compartments (Haarhuis et al. 2017). These effects might result from the aberrant distribution or accumulation of cohesion, and might be evolutionarily conserved since cohesins participate in S. pombe genome architecture (Mizuguchi et al. 2014) and a rad21 mutation causes heterochromatin loss in subtelomeric regions (Dheur et al. 2011). Furthermore, components of the RPC (including Sw1, Sw3, Mrc1, and Mc1) are required for sister chromatid cohesion (e.g., Williams and McIntosh 2002; Xu et al. 2004; Lengronne et al. 2006; Anschach et al. 2008), hence the effects of the RPC, and Wpl1 might overlap mechanistically.

The screens also confirmed the importance of the iron–sulfur cluster assembly protein Mms19 to heterochromatin (Figure 3). Mms19 co-urifies with the silencing factor Clr7/Dos2 (Li et al. 2011).
**Requirement for chromatin remodelers and chaperones**

In addition to the SHREC subunit Mit1 and the FACT subunit Pob3, the SMARCAD1 family ATP-dependent DNA helicase Fft3 and the ATPase with bromodomain Abo1 were also broadly required for silencing by the various boundary elements used in the screens (Figure 3, Figure 4, Figure 5, Figure 6, and Figure S10 in File S1). In previous studies, Fft3 was found to affect heterochromatic boundaries at centromeres and telomeres (Stralfors et al. 2011), and functions of Abo1 in heterochromatin were recently documented as well (Gal et al. 2016). In our study, deletion of Abo1 conferred relatively modest, albeit distinguishable, phenotypes (Figure 3, Figure 4, Figure 5, Figure 6, and Figure S10 in File S1). The Abo1 paralogue Abo2 was not isolated in the initial screens, but was examined for comparison with Abo1 and displayed more minor effects, if any.

Newly identified factors whose deletion caused a pronounced derepression of (EcoRV)::aden6+ included the predicted peptidyl-prolyl cis-trans isomerase Fkbp39 and the Ssz1 chaperone, an HSP70 family member.

**Figure 7** Effects of Mcl1 and Wpl1 on heterochromatic silencing. (A) The mating-type regions used in this experiment featured two ectopic boundaries, STAR2 and the 85 bp STAR2-S element (Toteva et al. 2017), in addition to wild-type IR-R+. (B) mcl1Δ and wpl1Δ mutants with the indicated boundaries were spotted on low adenine to compare (EcoRV)::aden6+ expression with the wild-type background. mcl1Δ confers a pronounced growth defect; however, the formed (EcoRV)::aden6+ mcl1Δ colonies are Ade+. wpl1Δ induces strong variegation. The strains were wild-type: PG3947, PG3950, PC152, and PT600; mcl1Δ: PA71, PA72, PA73, and PA74; and wpl1Δ: PA82, PA83, PA84, and PA85. YE, medium with limited adenine.

**Figure 8** Effects of selected factors on telomeric and centromeric silencing. Serial dilutions (10-fold) of cell suspensions were spotted. (A) Effects on the m23::ura4+-Tel72 telomeric reporter gene. Derepression of the reporter improves plating efficiency on AA-ura and decreases white colony formation on FOA medium with low adenine concentration (where only cells with a repressed reporter can form white colonies). Strains used: LJ171, FY520, LJ163, LJ172, LJ173, LJ162, LJ174, LJ165, LJ170, LJ168, LJ161, and LJ166. (B) Effects on centromeric otr1(Sphl)::ura4+ reporter gene. Strains used: LJ185, FY648, LJ180, LJ186, LJ190, LJ192, LJ187, LJ183, LJ181, LJ191, and LJ189. AA-ura, medium lacking uracil; ade, adenine; Chr, chromosome; FOA, fluoroorotic acid; WT, wild-type.
protein (Figure 3, Figure 4, and Figure 5 for effects on \(\text{EcoRV}::\text{ade6}^+\) with \(\text{IR-R}^+\); Figure S10 in File S1 for all elements; and Figure 6 for effects on \(\text{EcoRV}::\text{ura4}^+\)). Both Fkbp39 and Ssz1 are predominantly nuclear in \(S.\ pombe\) (Matsuyama et al. 2006), which is compatible with them having effects on chromatin. The Fkbp39 homolog Fpr4 in \(S.\ cerevisiae\) catalyzes P30 and P38 isomerization in histone H3 (Nelson et al. 2006); in this light, our findings indicate a potential importance for this isomerization in heterochromatin.

**Requirement for other factors and modifying enzymes**

Finally, Btf3, the Not2 and Rcd1 subunits of the CCR4-Not complex previously implicated in heterochromatic silencing in fission yeast (Gotobal et al. 2015; Bronner et al. 2017), and the histone acetyltransferase Gcn5 were also required, to various degrees, for silencing (Figure 3 and Figure S11 in File S1). Given the strong requirement for histone deacetylation in heterochromatin, a requirement for an opposing activity is intriguing, yet silent chromatin is not altogether deacetylated; Gcn5 might function in concert with Btf3 or Not2, or transient acetylation might facilitate heterochromatin maintenance through effects at the replication fork (Espinosa et al. 2010; Kurat et al. 2017).

**Effects at telomeres and centromeres**

The effects of selected ORF deletions on telomeric silencing was assayed with the m23::\(\text{ura4}^+\)-Tel[72] reporter close to the end of a truncated minichromosome Ch16 ((Nimmo et al. 1994; Figure 8A). In this assay, cells containing the minichromosome are Ade+ due to intragenic complementation between the \(\text{ade6-210}\) allele on chromosome 3 and \(\text{ade6-216}\) on the minichromosome. Several deletions \((\text{mrc1}^{\Delta}, \text{def1}^{\Delta}, \text{szs1}^{\Delta}, \text{fkbp39}^{\Delta}, \text{rif1}^{\Delta}, \text{and} \ \text{rif1}^{\Delta})\) increased growth on medium lacking uracil, indicative of minichromosome. For some strains \((\text{mrc1}^{\Delta}, \text{szs1}^{\Delta}, \text{and} \ \text{ftt3}^{\Delta}\) in Figure 8A), FOA strongly selected for cells that had lost their minichromosome, resulting in red colonies on FOA with limiting adenine. This is expected for mutants in which \(\text{ura4}^+\) cannot be repressed effectively; only cells that have lost the mini-chromosome are phenotypically \(\text{Ura}^-\).

The \(\text{otr1R(Sph1)}::\text{ura4}^+\) insertion in centromere 1 (Allshire et al. 1995) was used to test effects on pericentromeric silencing. These were less pronounced than for the edge of the mating-type region or sub-telomere (Figure 8B), perhaps due to the location of the \(\text{otr1R(Sph1)}::\text{ura4}^+\) reporter, embedded in RNAi-responsive heterochromatin.

**Interplays between replication and heterochromatin**

Physical and functional links between DNA replication and heterochromatin formation have been discovered in numerous organisms, and are proposed to participate in the epigenetic maintenance of heterochromatin during cell division. In \(S.\ pombe\), The Clr7/Dos2 subunit of the H3K9 methyltransferase complex CLRC binds Polo, and Polo mutants with reduced affinity for Dos2/Clr7 exhibit heterochromatin defects (Li et al. 2011). Mutations in the primase Polε (Nakayama et al. 2001; Natsume et al. 2008) or in the Mcm4 helicase (Toteva et al. 2017) also cause heterochromatin defects, as well as mutations in nonessential replication factors (Natsume et al. 2008). Our present results emphasize the tight links between replication and heterochromatin integrity by identifying multiple RPC components and associated chromatin modifiers (Figure 9).

A first mechanism through which RPC components might facilitate the maintenance of heterochromatin is through the stabilization of ongoing replication forks. It has been observed that replisome components are, under some circumstances, degraded upon replication stress (Roseaulin et al. 2013a,b; Daraba et al. 2014); in particular, both Polo and replicative helicases become unstable in \(S.\ pombe\) in the absence of the RPC component Swi1 (Roseaulin et al. 2013a,b). The breakdown of replisomes at replication forks that encounter an impediment in heterochromatin might lead to the dissociation of CLRC from the fork, or to a fork restart using different DNA polymerases that do not interact with CLRC, thereby weakening heterochromatin (Zaratiegui et al. 2011; Lee et al. 2013; Lee and Russell 2013). Similarly, control of homologous recombination, both during and outside S phase, might favor heterochromatin maintenance by preventing the use of polymerases other than Polε (Zaratiegui et al. 2011; Miyabe et al. 2015). A requirement
