Abstract

This article confirms the superior performance of topology optimized heat sinks compared to lattice designs and suggests simpler manufacturable pin-fin design interpretations. The development is driven by the wide adoption of light-emitting-diode (LED) lamps for industrial and residential lighting. Even for advanced lighting technology as LEDs, a large fraction of the input power is still converted to heat. Thus, efficient thermal control lowers energy waste, increases lifetime and reduces maintenance costs of this rapidly growing, expectedly soon to be governing, illumination technology. The presented heat sink solutions are generated by topology optimization, a computational morphogenesis approach with ultimate design freedom, relying on high-performance computing and simulation. Optimized devices exhibit complex and organic-looking topologies which are realized with the help of additive manufacturing. To reduce manufacturing cost, a simplified interpretation of the optimized design is produced and validated as well. Numerical and experimental results agree well and indicate that the obtained designs outperform lattice geometries by more than 21\%, resulting in a doubling of life expectancy and 50\% decrease in operational cost.

Keywords:...

1. Introduction

Lighting in residential and commercial sectors accounts for up to 7\% of the total US electricity consumption in 2016\textsuperscript{2} and accounts for a significant share (14-60\%) of the electricity bill in retail and office buildings [1, 2, 3]. Over the last decade, initiatives supported by governments around the world have accelerated development and adoption of light-emitting diode (LED) products as a replacement for century-old incandescent technologies and newer high-intensity discharge and fluorescent lamps. LED technologies are estimated to comprise anywhere from 25\% to upwards of 80\% of lighting by 2020, and their rapid development and improved efficiency will result in a 75\% reduction in energy consumption for lighting by 2035 [2]. Other main positive factors are light output, longevity, light distribution, dimensions, chromaticity, control, stability, environmental impact, durability and cost.

Despite their efficiency compared to other lighting technologies, LEDs still only convert 25\% to 35\% of the input energy to light [4], the rest is lost as heat generated in a relatively small area of the light-emitting semiconductor. This contrasts incandescent and fluorescent lamps, where heat generated in voluminous bulbs is easily conducted through bulb walls and subsequently radiated and convected through the surroundings. Increased temperature or overheating results in a shift of emission wavelength, lower lumen output and lifetime reduction of LEDs. Large LEDs produce more light per unit area and generate a significant amount of heat, thus requiring external heat exchangers which impacts size, reliability and cost. The excess heat must be removed either by active forced convection (fans) or by passive heat sinks relying on natural convection.

Fans are energy consuming, noisy and subject to mechanical failure, whereas natural convection needs careful design of heat sink geometries to ensure adequate cooling performance. A typical off-the-shelf fan, compatible with the dimensions of the presented coolers, consumes between 0.4W and 1.2W, increasing the en-
ergy consumption with 8% to 24% compared to a passively cooled solution for a 5W LED illuminator\(^3\).

Natural convection, on the other hand, is a heat transport mechanism which accelerates fluids based on differences in fluid densities due to temperature gradients. Figure 1 visualizes the process, where a sink attached to a heat source conducts heat to its surface, and the temperature difference between sink surface and ambient air generates a fluid motion which transfers the heat to the surroundings. The performance of the heat sink depends on a delicate balance between its ability to conduct heat away from the semiconductor and the excitation of a fluid motion strong enough to remove the heat by natural convection. The process continues to draw a lot of attention and has been studied extensively using experimental and numerical techniques, leading to a set of simple design rules utilized by designers and engineers. However, the simplicity of these rules, as well as the complexity of the physical phenomena may easily result in sub-optimal solutions leaving many opportunities for improvements [5, 6, 7].

We use state-of-the-art computing techniques and algorithms to design efficient passive heat sinks and validate the resulting structures experimentally. We find that topology-optimized natural convection coolers outperform traditional designs. The computational morphogenesis approach results in coral-like branching topologies resembling plants and organisms found in nature. The complex topologies can be manufactured using additive manufacturing technologies, or may inspire simplified and more easily manufacturable designs with a minor loss in performance. The process is verified by numerical simulations and confirmed experimentally. Methodology and findings may be further utilized and extended to cooling of electronic equipment, industrial machines, and processes, where robustness, low-maintenance cost and performance are of vital importance.

Figure 2a) shows a commercial LED bulb developed as a direct replacement for an incandescent one. Due to the small size of the semiconductor, designers have extensive freedom to propose aesthetically pleasing, and at the same time efficient, cooling solutions. The design is monolithic and includes the heat sink implemented as a ring with several straight fins along the body. The implementation targets a vertical orientation of the bulb, where the fins become parallel to the gravity vector and accelerate the air through a chimney effect. On the other hand, LEDs are strictly directional light sources, requiring different orientations for delivering light where needed. Thus, for positions different from vertical, the heat sink will perform inefficiently [8, 9, 10]. The presented experimental results confirm this effect as well.

Most research works investigate different variants of pin- or straight-fin heat sinks [11, 12, 13, 14, 15] due to their easy parametrization and simplified geometry. Various combinations of these primitives are often utilized for improving performance and building more complex products realizing designers’ visions. Figures 2.b) and 3.a) show expert industrial design solutions for larger industrial LEDs, designed by a project partner\(^4\). The intricate lattice-like sinks conduct the heat away from their base and transfer it to the surrounding air ensuring redundancy of conduction and flow pathways with the aim of achieving orientation insensitive performance. The complex topologies are realized in an aluminum alloy using metal 3D printing and provide the starting point for this study. Their performance is compared numerically and experimentally to the topologically-optimized designs. The optimization methodology with numerical studies on the influence of different symmetries on the design process is presented in [16]. In the present study we focus on the experimental validation of the designs complementing the numerical results in [16] and closing for the first time the design-validation-manufacturing loop for topology optimization of passive heat sinks. The experimental comparison outline the advantages of optimized designs. Detailed numerical simulations, validated experimentally, explain the physics in the presented geometries. The gained knowledge and understanding is utilized in the design of a simplified sink, with geometry modified for cost reduction and inspired by the optimized topology.

2. Topology optimization

Topology optimization [17, 18] is an iterative process, which distributes a material in a prescribed design domain by optimizing a selected performance measure; i.e. in the presented examples minimizing the average temperature of the sink base plate [19, 7]. The result of the optimization is a voxel-based spatial distribution of zeros representing void regions and ones representing solid regions. This binary optimization problem is relaxed to a continuous density distribution in turn allowing for the use of efficient, gradient-based optimization

\(^3\) The power consumption is estimated by the authors using several commercial catalogs. The estimates are for fans matching the geometries of the heat sinks utilized in the article.

techniques. A repetitive sequence of numerical simulations, regularization steps and design updates by mathematical programming complete the process. The topology optimization technology is now extensively utilized in the automotive and aerospace industries for solid mechanics applications, reducing weight and improving stiffness of mechanical parts with reported savings from 20% to 40% [20]. The methodology has been extended to extreme material design [21], optimized nanophotonic and acoustic devices [22, 23], electromagnetic antennas [24], and recently to thermoelectric and heat thermal energy storage devices [25, 26]. Topology optimization was first applied to fluid mechanics problems more than a decade ago [27], and only recently extended to fully-coupled conjugate heat transfer problems [19, 7], which provide the computational basis for the obtained results.

The optimization problem is formulated as

$$\min_{\rho} J(\rho, u)$$

s.t. $r(\rho, u) = 0$, $u \in U_{ad}$

$$g(\rho) \leq 0$$

$$\rho \in D_{ad}$$

where the objective functional $J(\cdot)$ depends on the system response $u$ and the material distribution $\rho$. The so-called density field $\rho$ takes value one in the fluid part of the computational domain and zero in the solid. The considered constraint $g(\cdot)$ imposes an upper bound on the volume of the conductive material. The density field $\rho$ is required to belong to the set of admissible solutions $D_{ad}$ to ensure an existence of a solution to the optimization problem. This is achieved by filtering [28].

The physics is represented by the residual $r(\rho, u)$ of the Navier-Stokes equations combined with a convection-diffusion equation. The response vector $u = [u_x, u_y, u_z, p, t]$ consists of the fluid velocities $u(x,y,z)$ and the temperature distributions, respectively. The optimization utilizes a steady laminar incompressible fluid model coupled with heat transfer through the advection-diffusion equation. The formulation models the natural convection effect with the help of the Boussinesq approximation with details provided in [19, 7].

The partial differential equations are discretized using the Finite Element Method (FEM) on a regular grid of size $384 \times 384 \times 640$ (half domain) and $192 \times 192 \times 640$ (quarter domain) for the horizontal and the vertical optimization case, respectively. The fine resolution is necessary for accurate modeling and allowing small features to appear in the optimized design. The material distribution (the density field) is represented as a constant within each element, and the discrete values are updated iteratively using gradient-based optimization techniques, i.e., a parallel version of the Method of Moving Asymptotes [29, 30]. A detailed description of the discretization and the optimization process can be found in [7, 16]. Thus, further implementation details are omitted.

In topology optimization the voxel representation provides ultimate freedom for the design process. However, finer discretizations necessary for better topological representation lead to large discrete numerical models imposing severe requirements to the computational power. Thus, applications to full assemblies, with giga-voxel resolution requirements, like an airplane wing, have only recently been demonstrated with the help of supercomputers [20]. High resolution is also required to resolve the topology and the physics in the natural convection case. The nonlinear nature of the fully-coupled Navier-Stokes and heat transfer equations further challenge the computational cost. The presented topologically-optimized designs require two to five full days of computing time running on 1000-2500 cores on a high-performance computing (HPC) cluster equipped with Intel e5-2680v2 Ivy Bridge processors. This significant computational cost is, however, surpassed by the potential savings in material and life-time costs.

Compared to parametric optimizations, regularly utilized for improving heat sink performance [11, 12, 31, 32], topology optimization possesses the ultimate freedom in distributing material, in turn resulting in organic-like topologies sharing similarities with natural plants and organisms. In contrast to natural evolution requiring millions of years, however, the use of efficient gradient-based solution methods speed up the generative process resulting in highly efficient solutions within hours or days. The resulting organic shapes may provide challenges for traditional subtractive manufacturing technologies or casting technologies. However, such issues may be resolved using the freedom provided by additive manufacturing, where the design is built layer-by-layer by either deposition or melting of material powder at specified points [33]. The present main restriction is the requirement for self-support, i.e., upper parts should be sufficiently supported by lower parts [34, 35]. As this constraint was not enforced during the optimization, the obtained designs require additional supporting structure which must be removed manually in a post-processing step. Recent research advances [36, 37] provide the necessary algorithmic modifications. Such amendments, in combination with a requirement for robustness to exploitation and manufacturing uncertain-
ties, will allow for complete digitalization of the design process [21, 28] and will remove the need for any human intervention. However, any restriction on the design freedom will come at the cost of performance loss. Hence, in this paper the ultimate cooling capability is pursued with no additional restrictions imposed.

3. Experimental setup

The performance of the coolers is verified experimentally using the setup shown in Figure 4. A heat sink is positioned in space with the help of thin threads to avoid flow disturbance. This setup allows for detailed comparison with the numerical optimization model but does not necessarily reflect a practical use situation. Heat is supplied by a resistor encased in a SikaBoom S isolation foam and connected to a digitally controllable Tenma 72-10480 power supply. A thermocouple 5TC-TT-KI-30-1M, type K with wire diameter 0.25mm, manufactured by OMEGA Engineering is positioned between the power source and the attached sink. A second thermocouple measures the ambient temperature near the setup. An additional digital thermometer offers independent measurements. Both thermocouples are attached to an isothermal terminal block TB-9214, produced by National Instruments Corporation, with measurement uncertainty ±0.45°C and sensitivity 0.02°C according to the specifications. Data control, timing, synchronization, and transfer to a computer are provided by cDAQ-9171. A thin layer of Dow Corning 340 heat sink compound is utilized to prevent air pockets and to maximize heat transfer between the heat source and the attached sink.

Each measurement is obtained by first setting the supplied power and recording the temperature, with a sampling frequency of 1Hz, for 5400s. All systems reached steady state in less than an hour, and the first 3600 samples are excluded from the data analysis. The rest of the record is visually inspected for abnormal variations, e.g. in ambient temperature. Only 600 sequential samples, corresponding to 10 min of measurement time, are extracted, and the average temperature is reported in Table 1 and Figure 7. The estimated standard deviation for all measurements is less than 0.1°C. All measurements were obtained for ambient temperatures between 22.5°C and 24.3°C.

4. Design parameters, assumptions and simplifications

For experimental and simulation purposes the LED element is replaced by a heat-generating element attached to a 3mm thick aluminum plate and encased in foam to direct the heat towards the sink. Due to the high computational cost necessary for obtaining optimized topologies, designs are generated for a controllable power source of 1.08W, and later their performances are numerically and experimentally tested for input powers up to 5.27W. The Grashof number, which is lower than 7.3 × 10^5 based on the heat sink diameter, is smaller than the transition limit for horizontal cylinders, and hence, verifies the steady laminar flow assumption. Two different orientations are considered, horizontal (Figure 5) and vertical (Figure 6), with designs shown in Figure 3. The horizontal designs are optimized with 1/2 and 1/8 symmetries and the vertical with 1/8 symmetry. Increased symmetry means reduced sensitivity to rotation. The optimized topology for horizontal orientation with 1/8 symmetry is manufactured and tested against several custom designed, off-the-shelf and simplified pin-fin designs with results shown in Table 1.

For the considered optimization case a prescribed volume of aluminum is distributed in a design domain occupied by air. The design domain is embedded in a simulation domain which has the form of a rectangular parallelepiped with a square base and dimensions 150mm × 150mm × 250mm. The design domain is a cylinder with diameter of 65mm and height of 60mm. The central axis of the cylinder is either parallel to (vertical) or perpendicular (horizontal) to the gravity direction. The design domain is connected to a heat source element encased in a foam insulation to direct the heat towards the sink. The heat is generated by a resistor which is attached to a 5mm thick round aluminum plate, with diameter 52mm, in order to distribute the heat supplied to the design domain more evenly. The total thickness of the foam encasement is 25mm.

During the optimization, the whole setup, which consists of a design domain and the attached heat source part, is positioned centrally in the simulation domain. The conductivity of the aluminum alloy distributed in the design domain is \( k = 175\text{W} \cdot \text{m}^{-1} \cdot \text{K}^{-1} \), the heat capacity is \( c_p = 9033\text{J} \cdot \text{kg}^{-1} \cdot \text{K}^{-1} \), and mass density \( \rho = 2702\text{kg} \cdot \text{m}^{-3} \). The considered physical properties of air are \( k = 0.026\text{W} \cdot \text{m}^{-1} \cdot \text{K}^{-1} \), \( c_p = 10033\text{J} \cdot \text{kg}^{-1} \cdot \text{K}^{-1} \), and \( \rho = 1.2\text{kg} \cdot \text{m}^{-3} \). The dynamic viscosity of air is \( \mu = 1.86 \times 10^{-5}\text{Pa} \cdot \text{s} \) and the coefficient of volumetric expansion is \( \beta = 3.34 \times 10^{-3}\text{K}^{-1} \). The insulation is manufactured using SikaBoom S foam with properties \( k = 0.026\text{W} \cdot \text{m}^{-1} \cdot \text{K}^{-1} \), and \( c_p = 10033\text{J} \cdot \text{kg}^{-1} \cdot \text{K}^{-1} \). The copper wires connecting the resistor to the power supply are considered in the simulation as well. Their thickness is 3mm with thermal properties \( k = 287\text{Wm}^{-1} \cdot \text{K}^{-1} \),
Figure 4: Setup for experimental verification of a heat sink: a) 3D printed heat sink in horizontal position, b) a heat sink attached to a heat source, c) a heat source element without heat sink. Each heat sink is oriented and positioned with the help of thin threads. During the experiment, any of the sinks is attached to a heat source. The heat source element consists of a resistor encased in an insulation foam and connected with two copper wires to a power source. The thin channel is utilized to position a thermocouple between the heat sink and the heat distribution plate.

\[ c_p = 376 \text{J} \cdot \text{kg}^{-1} \cdot \text{K}^{-1}, \text{ and } \rho = 8800 \text{kg} \cdot \text{m}^{-3}. \]

A simplified traditional pin-fin heat sink, inspired by the optimized result, is constructed to lower the manufacturing cost. The design is shown in Figure 3. The base plate dimensions of the pin-fin cooler are kept the same as the topology optimized one. The rest of the material is distributed in two circular layers of aluminum rods mimicking the optimized material distribution. The diameter of the rods is 5.98 mm. The outer layer with a diameter of 53 mm consists of 12 rods and the inner layer with a diameter of 37 mm consists of 4 rods.

The production time and cost in additive manufacturing is proportional to the volume/mass of the sinks and the complexity of the layer slices. The weight of the optimized (TO) and the simplified design (PF) is almost the same as the topological complexity for any 2D horizontal slice. Therefore, based on the similarities and excluding the additional support material, it can be concluded that the additive manufacturing cost for both designs will be almost the same. The traditionally manufactured design (PF, Table 1), based on subtractive techniques combined with subsequent assembly, is two orders of magnitude cheaper than the 3D printed one. This fact reveals one of the main weaknesses of the additive manufacturing technology. On the other hand, traditional manufacturing requires a proper organization of supply and distribution chains. Thus, additive manufacturing is still an attractive alternative for unique designs and prototypes where timing and exact reproduction of complexity is of higher priority. It should be pointed out that simplification of the geometry is not directly correlated to a decrease in computational complexity. It affects only the manufacturing process and does not reduce the computational cost. This feature is demonstrated in [16] where the computational cost for parametric studies and optimizations of pin-fin types of heat sinks is similar to the one necessary for full topology optimization. Another manufacturing alternative is the combination of wax 3D printing and investment casting. Wax 3D printing offers cost-effective solutions to mass productions of low-quantity orders. Investment casting utilizes the wax pattern in the formation of a mold, which, in a subsequent step, is employed for producing the actual device. A detailed study of this multi-step process in relation to topology optimization will be presented in a forthcoming paper of the authors [38].

The verifications are performed using COMSOL Multiphysics\textsuperscript{5} with extended simulation domain 300 mm $\times$ 300 mm $\times$ 1050 mm in order to possibly match open space conditions, i.e., to decrease the effect of the boundary conditions on the design response. The axis of the heat sink setup is positioned 125 mm from the bottom of the extended verification domain. All

\textsuperscript{5}Finite element analysis, solver and multiphysics simulation software.
outer boundaries have open flow boundary conditions with an exception applied on the bottom where zero fluid velocity is enforced. For the temperature field all boundaries are set to an ambient air temperature of 23.5°C with an exception applied on the upper side where a zero diffusive flux is enforced.

Often LEDs are embedded in a ceiling panel or mounted close to a wall. These conditions could change the flow around the sinks compared to the idealized situation considered here. More complicated situations require additional simulations and optimizations. Another factor not accounted for in the optimization process is the mount of the lamps. Depending on the orientation as well as on the fixation point, either wall or ceiling, the mount might block the fluid flow. Enforcing rotational symmetry will prevent variations in the flow patterns and decrease the sensitivities of the performance measure with respect to additional obstacles. However, without any imposed symmetries, the design process will result in highly optimized topologies precisely matching the prescribed conditions.

5. Results and discussions

Detailed numerical simulations for horizontal orientation are performed for three of the designs, which are compared to experimental ones in Figure 7. The figure shows temperature differences measured with the help of two thermocouples. For several cases, the numerical estimates fall out of the error bars. The tendency is especially pronounced for the reference heat sink and can be attributed to differences in the simulation assumptions and the actual physical behavior. Examples include discretization error, deviations in the material conductivity, or an undetected draft. The error bars represent the instrument measurement accuracy, and in reality, they could be slightly higher due to the use of two independent thermocouples. The latter will increase the confidence interval leading to an even better agreement with the numerical results. In all cases, however, the general trends agree well and provide confidence in the simulations and a foundation for a deeper investigation of the heat transfer mechanism by using the easy access to the numerically evaluated additional physical fields such as flow velocity, pressure, and temperature distribution. Simulation results for 1.08W power input are shown in Figure 5.

The temperature gradients for all three cases accelerate the air to pass through and to extract heat from the sinks. The flow velocities are higher for the topology-optimized and pin designs resulting in increased mass-flow and convective effects. The air is redirected around the lattice design in contrast to the others, where the flow passes through and accelerates in a low-pressure cavity in the middle of the models. This effect leads to an almost uniform temperature distribution in the lattice sink. Cold air is sucked in and heated to the sink temperature through the lowest elements. The hot air cannot extract additional heat from the upper part, thus, making it redundant. On the other hand, horizontal and vertical temperature variations are observed for both the optimized and the interpreted designs indicating more efficient heat transport both through conduction in the sink and through convection to the moving fluid. Thus, the optimized design achieves 21%-23% lower temperature for 17% smaller amount of material. Interpretation and post-processing of the results (PF, Table 1) move the performance away from the optimal point, however, compared to the original lattice design (AT, Table 1) the temperature is 4% to 6% lower for even higher 19% savings of material. It is interesting to note that the surface areas of the optimized and pin designs, $2.36 \times 10^{-2}$ m² and $2.22 \times 10^{-2}$ m² respectively, are significantly lower than the $2.55 \times 10^{-2}$ m² for the lattice sink (AT). It can be seen that neither the volume, area nor their ratio correlate directly with performance. This fact demonstrates that better performance cannot be achieved just by maximizing the area or the amount of material, but requires delicate balancing between the heat conducted through the material, the temperature gradient necessary for accelerating the flow, the velocity pattern and the contact area between the solid and the fluid. This complex problem, difficult to comprehend even by trained engineers and designers, is captured by the topology optimization, resulting in high performing and at the same time economical optimized solutions.

The above conclusion is also supported by the experimental results in Table 1, where the commercial off-the-shelf cooler (DT, Table 1) performs worse in horizontal orientation than the topology-optimized one (PF, Table 1). Changing the orientation to vertical gives an advantage to the commercial sink allowing it to accelerate the air between the plates and using the large surface to transfer the heat to the flow. For low power input, the topology-optimized design outperforms it slightly indicating that the temperature gradient cannot accelerate the flow enough. It is interesting to note that the sink optimized for horizontal orientation performs better than any of the lattice designs in a vertical test position. The explanation is revealed by the numerical experiments shown in Figure 6. All coolers suck in cold air close to the base plate, however, similar to the horizontal case, the lattice structure prevents the air from accelerating and passing through, thus, heating the air.
Figure 5: Numerical modeling of natural convection around horizontal reference heat sink, topology-optimized heat sink, and a simplified heat sink, obtained by post-interpretation of the topological design and manufactured by traditional techniques. The first row presents the temperature difference to ambient temperature [°C] in the sinks with stream tubes. The second row shows the velocity [m/s] of the cooling air, and the third row provides temperature [°C] distribution in a vertical 2D cross-section of the modeling region perpendicular to the sinks axes. The cross-section is located in the middle of the sink.
Figure 6: Numerical modeling of natural convection around topology-optimized heat sink for vertical orientation, reference heat sink, topology-optimized heat sink for horizontal orientation in a vertical position and a simplified heat sink. The first row presents the temperature difference to ambient temperature [°C] in the sinks with stream tubes. The second row shows the velocity [m/s] of the cooling air, and the third row provides temperature [°C] distribution in a vertical 2D cross-section of the modeling region parallel to the sinks axes.
Figure 7: Comparison of numerically simulated and experimentally measured base temperature difference for reference heat sink (AT), topology-optimized heat sink (TO), and simplified heat sink (PF) shown in Figure 5. Subfigures a) and b) show trends for 1.08W and 5.27W power input and different orientation and twist angles. Subfigure c) demonstrates results for input powers from 1W to 8W.
Table 1: The table presents experimental measurements of the difference between the temperature at the center of the heat sink plate and the ambient temperature for different power inputs, and two orientations. Text coloring between blue (cold) and red (hot) is scaled according to the devices with maximum and minimum performance for each driving power. The topology optimized design (TO) outperforms all other designs for an experimental setup corresponding to the optimization settings, i.e., horizontal orientation. In a vertical position, the optimized design is outperformed only by the twice heavier and much bigger commercial sink (DT) in column 5.

At the bottom, in turn making the upper part of the sink redundant. The topology-optimized sinks use the inner chamber to accelerate the flow and to create a stronger chimney effect. The bent parts at the top of the optimized design for horizontal position increase the drag, resulting in lower flow velocity. The other important difference between the design optimized for horizontal position, the post-processed one, and the one for vertical orientation is the velocity pattern close to the base plate. The latter provides gradually decreasing material distribution towards the center and higher flow velocities capable of extracting heat from the base plate delivered by the solid due to its higher conductivity. A more detailed numerical analysis of the topologies, the orientations, the algorithms, and the procedures for tuning of the solution parameters can be found [16].

As expected, the lowest base temperature is obtained for the orientation corresponding to the actual optimization conditions. The loss of performance for the horizontally optimized cooler is less than 5% for positions varying from 0 to 90 degrees. An even flatter curve can potentially be realized by optimizing simultaneously for all desired orientations, however, due to the high computational demands, such a study is left for future investigations. The imposed 1/8 symmetry provides negligible sensitivity to rotations around the sink axis demonstrating a computationally cheaper alternative for achieving orientational independence.

5.1. Lifetime expectancy

As the manufacturing processes of LEDs and microelectronic products share many similarities, the methodologies for estimating the lifetime of microelectronic components are applicable for reliability analysis of light-emitting diode products [39]. A 10°C decrease of the operating temperature doubles the life of a product in the semiconductor industry. This rough estimate is based on the empirical Arrhenius model for describing reaction kinetics in chemistry and physics.

\[
k = Ae^{-\frac{E_A}{k_B T}}
\]

The model is often utilized to represent the damage \( k \) of LEDs over time, and depends on the activation energy \( E_A \) associated with the reaction and estimated from experiments, the Boltzmann constant \( (k_B = 8.617 \times 10^{-5} \text{eV/K}) \) and the absolute temperature \( T \). For activation energies varying from \( E_A = 0.4 \text{eV/K} \) to
is required to account for additional physical effects and uncertainties in the input, boundary conditions, manufacturing constraints, and uncertainties are still out of reach for designers and engineers. Another barrier is the cost of 3D printing. The simplified interpretation, obtained from a topology optimized design, is two orders of magnitude cheaper than the 3D printed design. Additive manufacturing provides an acceptable solution for unique prototypes, however, for mass production, traditional manufacturing is still the preferred option. Another alternative for reducing the production cost, without simplifications of the topological details, is the deployment of investment casting in combination with 3D printing. Such results will be reported in a forthcoming paper of the authors [38].

6. Conclusions

The performed experiments demonstrate that our holistic topology optimization approach results in significant material savings and design improvements of passive LED coolers. The possibility to account for several physical fields and their complex interaction provides close to optimal utilization of the heat sink material and moves performance bounds close to the limit. For such broadly applied and well-studied devices, reduction of 17% in material utilization in unison with a 21-23% temperature decrease are still achievable, fully demonstrating the potential of the presented approach. The topology-optimized designs can be produced using 3D printing techniques or can be simplified further making them suitable for traditional manufacturing with a small loss of performance. Higher computational effort is required to account for additional physical effects and practical constraints. The benefits in material savings and decreased temperature justify this cost increase in the design phase. Extensions to more complex multi-physical interactions including heat transfer in turbulent flows, magnetic refrigeration or elastocaloric cooling are still in their infancy, but cater for further future improvements in energy consumption of thermal and other systems.

The current limitation for broader adoption of topology optimization or other systematic design approaches is the high computational cost. The demonstrated designs are obtained for specified power input, assuming laminar flow and open boundary conditions. The experiments show excellent performance under a wider range of powers. However, optimizations taking into account all possible variations in the input, boundary conditions, manufacturing constraints, and uncertainties are still out of reach for designers and engineers. Another barrier is the cost of 3D printing. The simplified interpretation, obtained from a topology optimized design, is two orders of magnitude cheaper than the 3D printed design. Additive manufacturing provides an acceptable solution for unique prototypes, however, for mass production, traditional manufacturing is still the preferred option. Another alternative for reducing the production cost, without simplifications of the topological details, is the deployment of investment casting in combination with 3D printing. Such results will be reported in a forthcoming paper of the authors [38].

Acknowledgements

This work was funded by Innovation Fund Denmark through the HyperCool project, by the Danish Council for Independent Research through the TOpTEn project (DFF-4005-00320), as well as by the Villum Foundation through the NextTop project. The authors would like to thank AT Lighting ApS for their collaboration through the HyperCool project.
