Abstract

Synchronisation between supply of plant available nutrients to crops’ needs and uptake is a major challenge in Sub-Saharan Africa. Experiments were set to evaluate release patterns and availability of nutrients by leguminous green manures in soil. Mucuna and greengram materials were buried 10 cm in mesh bags. Replicated bags removed weekly and analysed to determine decomposition rates and quantities of nutrients released into soil. Mucuna decomposition was faster compared to greengram, from third to twelve week of incubation. This implies that greengram has relatively more resistant materials to decomposition compared to mucuna. Maximum effect on soil nutrient content occurred in sixth and seventh weeks after application of green manures. Total organic C in soils increased by a factor of 2.3 to 3.2. Total N increased significantly from 1.28% to 2.64% at sixth week in soil with greengram and 2.83% at seventh week in soil with mucuna. Available P content of soil increased from 0.03 to 0.39 and 0.37 mg kg⁻¹ in soil treated with greengram and mucuna. Optimum microbial population was attained from fifth to seventh week after manure application, with 2.3 x 10⁸ in soil with greengram and 3.08 x 10⁸ with mucuna, significantly improved compared to original population.

Key words: green manure, soil fertility, incubation period, cover crop.
Introduction

Poor soil fertility has been one among the major problems in agriculture in Sub-Saharan Africa, leading to poor crop productivity (Camara and Heinemann 2006). Agriculture in many African countries is subjected to poor nutrient replenishment in soils, leading to soil degradation and hence poor productivity (Kimetu et al. 2008; Abate et al. 2006; Shepherd 2007). However, the use of inorganic fertilisers alone cannot be a long term solution for soil fertility management among poor African farmers, and thus integrated soil fertility management has been proposed (Sanginga and Woomer 2009). The synchronisation between sufficient supply of plant available nutrients like phosphorus (P), potassium (K) and nitrogen (N) to the crops needs and uptake is a major challenge (Edmeades 2003; Sharma et al. 2008; Mafongoya et al. 2006). However, the use of leguminous plants as green manure can be a good alternative for replenishing soil fertility and diversify farm productivity in intensive production because legumes generally are nutrient rich (Diacono et al. 2010; Mafongoya et al. 2006).

Therefore, agriculture intensification in poor fertility soils can be supported through natural means of improving and sustaining the soil fertility (Vanlauwe et al. 2014). Cover crops, which are used for pests control in organic agriculture, can be a good source of nutrients as green manure (Mulvaney et al. 2008; Sarwar et al. 2010), and also increase soil organic matter content which can support soil microbial activity (Lundquist et al. 1999). The use of cover crops as green manure and for weed control was adopted as strategy for replenishing soil nitrogen that had been taken up by crops and to provide organic matter for maintaining soil’s fertility and improving its properties (Mulvaney et al. 2008; Ganry et al. 2001). Marandu et al. (2011) observed an increase of about 12.4 mg mineral N kg\(^{-1}\) soil when maize was grown in rotation with greengram. There is evidence on the ability of *Mucuna spp* green
manure to influence soils’ physical and biological and chemical properties (Djigal et al. 2012; Elfstrand et al. 2007). However, lack of synchrony between mineralization of organic N from green manure and plant N requirements of a subsequent crop is a major challenge (Palm et al. 1997; Mafongoya et al. 1998). Understanding the nutrient release patterns of the green manure applied is thus a prerequisite to optimize an efficient use of the green manure and to sustain a high value vegetable crop (Baijukya et al. 2006; Möller 2009).

The objective of the current study consequently was to determine relative decomposition patterns, nutrient release rates and microorganism proliferation as influenced by two leguminous green manure crops, mucuna (Mucuna pruriens) and greengram (Vigna radiata (L.)), that were incorporated into the soil under field conditions in Morogoro, Tanzania, using the mesh bag approach.

**MATERIALS AND METHODS**

**Experimental site**

The field decomposition study was carried out at Sokoine University of Agriculture (SUA) Crop Museum in Morogoro region (06° 50’ 34.4” S and 6° 82’ S, 37° 38’ 50.3” ) lying at an average elevation of 534 m.a.s.l. The location has bimodal rainfall of 800-1000 mm annually with the short rains in November to January and the longest from March to May. Rainfall patterns for the twelve weeks at the experimental area during the experiment are presented in Figure 1.

For the previous three seasons the field was used for cultivating various annual crops. The initial soil analysis of the experimental site within SUA crop museum was done for a composite soil sampled diagonally diagonal across the site within the 0-20 cm depth. The area is characterized by kaolinitic clay soils which are well drained. The physiographic
features of the area are characteristically an undulating convex land and the slope is about 4% (Kisetu and Mtankimwa 2013). The sample was air dried and ground to pass through a 2 mm sieve.

**Experimental layout and sampling**

Mucuna (*Mucuna pruriens*) and greengram (*Vigna radiata* (L.)) were grown adjacent to the experimental site to the 50% flowering stage. The crops were harvested just above the soil surface, chopped and 500 g fresh weight filled into polyethylene plastic mesh bags (20 x 20 cm) of 2 mm mesh size. The litter-bags were buried 5-10 cm deep into the soil in four replicates. For twelve consecutive weeks, with exact intervals of 7 days, four replicated mesh bags were sampled for decomposition analysis. The 5 cm soil located directly below the mesh bags was collected. The plant and soil samples were air dried in a screen house for 72 hours and then oven dried for 24 hours at 70°C to constant weight. The samples were ground ready for analysis to determine their decomposition patterns.

**Plant analysis**

**Total nitrogen:** 0.2 g of the sample of green manure was transferred to a 500 ml Kjeldahl tube and two grams of mixed salts catalyst (K$_2$SO$_4$ + CuSO$_4$ + selenium powder, in the ratio of 10: 10: 1 by weight) was added. Ten ml of H$_2$SO$_4$ were added. The mixture digested for one hour at 360°C. After cooling, 50 ml of water were added, followed by 25 ml of H$_3$BO$_3$ and 50 mls of 40% NaOH. The mixture was distilled and about 200 ml of distillate collected. The distillate was titrated using 0.05N H$_2$SO$_4$ (Horneck and Miller 1998).

**Phosphorus content:** extractable P was determined using the Bray 1 method (Sims 2000). A sample of three grams was taken in to the extraction bottle, 20 ml of extraction solution and shaken thoroughly. Then the mixture was filtered through filter paper. Five millilitres aliquot
of the sample mixture was transferred to 50 ml volumetric flask and 10 ml of water added. Two millilitres of phosphate reagent was added and the volume was made to 50 ml, the colour was allowed to develop in 15 minutes. Then phosphorus content in solution was determined in a spectrophotometer at 882 nm.

**Soil analysis**

**Organic soil carbon:** Organic carbon analysis of the green manure was done using the Walkely-Black method (Yeomans and Bremner1988). Duplicate samples of 1 g were weighed in an Erlenmeyer flask, 10 ml of 1N K₂Cr₂O₇ was added followed immediately by 20 ml concentrated H₂SO₄ and hand shaken for about a minute to oxidize the soil’s organic carbon. Then the mixture was allowed to stand on asbestos plates for 30 minutes. About 100 ml of water were added followed by 10 ml orthophosphoric acid and 10 drops of diphenylamine indicator. The solution was titrated with FeSO₄ to determine the organic carbon.

**Total soil nitrogen and Phosphorus:** these elements were also determined using the same methods used for the analysis of the plant materials.

**Ca and Mg content:** the exchangeable Ca and Mg were determined from the same solution used to determine P using atomic absorption spectrophotometer (Cheng 1951).

**Cation exchange capacity:** the soil remained after exchangeable bases extraction filtration was washed using 100 ml of ethanol and then placed into plastic bottles. 50 mls of 4% KCL were added and shaken for 30 minutes, distilled and the distillate collected over Boric acid. Then the distillate was titrated with 0.1N H₂SO₄ and the titre value was used to calculate the CEC (Rhoades 1982).
**Total microbial count:** Microbial count was done by determining moisture content of the sample. Ten grams sample was placed in 90 ml water and shaken vigorously to uniform suspension to detach microbial cells from soil particles in to the suspension. One ml of the suspension was transferred to 9 ml water, and similarly the dilution was continued up to a dilution of $10^7$. Then the $10^3$ to $10^7$ dilutions were plated into petri dishes with nutrient agar and spread evenly. The plates were incubated 21°C for four days and then plates with 30-300 colonies were selected for microbial population counting and calculation of microbial populations. The microbial population per gram of soil was calculated using the formula:

\[
\text{Microbial population} = \frac{\text{colony count} \times \text{dilution counted}}{\text{Weight of soil}}
\]

**Data analysis**

Data were subjected to analysis of variance using GENSTAT statistical program (Genstat release 6.1 Lawes Agricultural Trust). Treatment means were ranked using Duncan’s Multiple Range Test at $P \leq 0.05$.

**Results**

**Decomposition patterns of the green manures**

The decomposition patterns of the green manures were assessed using decreases of organic carbon (C), total nitrogen (N), phosphorus (P) content and associated changes in nutrient content and total microbial populations in the mesh bags and in the soil just below the mesh bags. Initially the weight of the green manure incubated in the soil decreased with time immediately from the first week throughout the incubation period (Fig. 2) following a first-
order negative exponential curve (mucuna: \( R^2=0.98 \) and greengram \( R^2= 0.98 \)) as commonly found in other studies (Melillo et al. 1989; Palm and Sanchez 1990; Campbell et al. 1995).

The proportion of organic C content in the plant materials was about 40% for mucuna and 35% for greengram. However, the half-life (\( t^{1/2} \)) of the two materials was similar as both attained their half-life at the fifth week of incubation (seen from Fig. 2). Due to the negative exponentially, the decomposition pattern of the two green manures were fast to about the seventh week of incubation which concur with other studies (e.g. Omollo and Abayo 2011; Whitbread et al. 2004). This pattern of decomposition lead to the rapid decrease of the proportion of organic C in the mesh bags in first six to seven weeks of incubation (Fig. 2A). Some of the C is respired but others are eventually added and incorporated in the soil below the mesh bag.

**Decrease in nitrogen in the residual plant materials and nitrogen gains in soil**

For both green manure materials, the trend in the proportion of N in the mesh bag mirrored the trend in the proportion of carbon (Fig. 4A). The net release of N from the mesh bag was evident in the soils below the mesh bag (Fig. 4B) until week 7, after which release rates must have decreased substantially as the microbial biomass started to decrease (Fig. 6), precipitation increases and the content in the soil stabilized (Fig. 4B).

**Phosphorus decrease in decomposed residual plant materials and P gains in soil**

The P content of the degrading green manures followed a linear decline (Fig. 5A) with \( R^2=0.94 \) for mucuna and \( R^2=0.95 \) for greengram. The degradation of P from both types of plant materials did not differ significantly. In both green manures the P release was fast up to the ninth week and then became stagnant. However, the quantity of P in the decomposing
mucuna materials was higher for the first five weeks as compared to that in greengram and then it dropped below that of greengram at the tenth to twelfth weeks of incubation.

Interestingly, the amount extractable inorganic P (Bray 1) accumulation in the soil was faster and higher in the soil under mucuna compared to greengram (Fig. 5B). At the fourth week, soil incubated with mucuna had attained 0.35% of P compared to 0.1% of greengram (Fig. 5B). At the sixth week, the extractable P had reached the same level but green gram had a slower start.

**Decrease in calcium in plant materials and calcium gains in soil**

The trend of Ca release by the green manures and gain by the soil is presented in Figure 7. Calcium release from the plant materials proceeded steadily, with the rate decreasing somewhat in the last three weeks. Throughout the incubation period the residual green manures did not differ in their Ca contents and the release into the soil below it. The faster rate of decomposition and nutrient release by green manure was also observed by Cobo et al. (2002), where mucuna had high release of Ca up to the twentieth week after incorporation in the soil, as revealed by higher accumulation in the soil. This was also observed in the present study where the plant materials continued to release Ca for all the twelve weeks.

In the soil, the Ca gain trend was similar between the two green manures. However, soils incubated with mucuna attained highest total Ca at the sixth week, which was one week later as compared to greengram which attained its peak at the fifth week. The decrease of Ca observed in the present study beyond the fifth and sixth weeks was due to its high immobilisation in the soil. Cobo et al. (2002) observed a similar trend of Ca release from decomposing green manure; however, no consistent trend was found on the Ca accumulation patterns due to its high immobilisation. Other authors reported high ability of Ca
immobilisation in the decomposing materials in different ways and through its accumulation in fungi found in the decomposing materials (Lehmann et al. 1995; Alvarez et al. 2008).

Decrease in magnesium in plant materials and magnesium gains in soil

The release of Mg from the two green manures and its gain in the soil throughout the incubation period is shown in Figure 8. Mucuna released slightly higher amount of Mg as compared to the greengram.

Soil incubated with mucuna had the highest amount of Mg at the sixth week after incubation, while that with greengram reached its highest level at the seventh week. Thereafter, there was a slight decrease in soil Mg.

Microbial populations in the soils under decomposing green manure materials

The total microbial population following the introduction of the two green manures increased for six weeks, with a subsequent decrease (Fig. 6). The population in the initial soil was about $1.628 \times 10^5$, which increased up to $2.3 \times 10^8$ in the soil with greengram and up to $3.08 \times 10^8$ in the soil with mucuna. Transformed into $\log_{10}$, these values translated to 5.21, 8.05 and 8.50, respectively (Fig. 6).

CEC changes in soil supplemented with mucuna and greengram

The soil treated with mucuna and greengram green manure attained higher CEC in the seventh week, as presented in Figure 9. The CEC in the soil treated by mucuna was 31.5 while that with greengram was 30.6 cmol kg$^{-1}$, respectively, at the seventh week as compared to the original soil whose CEC was 10.8 cmol kg$^{-1}$. 

10
Discussion

The organic C compounds released from the plant materials could be seen accumulating in the soil immediately below the decomposing material in the first six weeks. The accumulation did not continue throughout but reached its optimum at the 6th week and subsequently decreased (Fig. 3B). This dynamic is attributed to the early build-up of the soil microbial population (Fig. 6) that use the organic compounds as substrate and to the fact extensive that leaching has taken place due to excess of precipitation during the last 5-6 weeks of the experiment (Fig. 1).

In accordance with the negative exponential degradation pattern, amounts and rates of C being released from the mesh bags decreased substantially after the seventh week and simultaneously the release rates from the mesh bags most likely also decreased due to the stabilisation of the litter, i.e. the carbon content approaching stability (Fig. 3A) as the C:N ratio of the residual litter approached 8-9 at week 5 after incubation after which the microbial activity may have been slowed down (Manzoni et al. 2008).

For both manure substrates, the C:N ratio decreased from approximately 12 initially to 5 at week 12 after burying the litter bags, following a simple linear pattern (data not shown). This demonstrates the potency of the green manures in the sense that it decomposes very rapidly (Fig. 2) and at the 12th week had reached a structure that resembled soil. The relative low C:N ratio will also lead to a net release of N almost instantly. The apparent linearity agrees with theory (Ågren and Bossata 1996; Manzoni et al. 2008) whereby these substances, as green manures with an initially low C:N ration of approximately 12, must be viewed towards at the late period of the exponential process.
The relatively low C:N ratios is the exact reason for terming these substrates “green manure”. The low C:N ratios indicate that the degradation of the organic materials will not cause a net immobilisation (Ågren and Bosatta 1996) but be able to net release inorganic N into the soil matrix that can benefit crop growth. The rapid decomposition under the current conditions contrast with relatively low mineralisation rates under north European conditions (e.g. Baggs et al. 2000).

The experimental site had been used for cropping the previous cropping during seasons and yet it has a fairly good total N content (1.28%). The inclusion of the green manures however was a high injection of N to the soil such that a high flux of inorganic N must be anticipated (not measured). Other studies (Baggs et al. 2000; Edmeades 2003; Thorup-Kristensen et al. 2003) also observed significant increase of N in different soils treated with different green manures in long term application, explaining the difference in N contribution to the soil by these different green manures. The higher soil N under mucuna may be due to the fact that mucuna had higher leaf:stem ratio than stem materials which accounts for the higher total N (Fig. 4). These results agree with Cobo et al. (2002) who observed mucuna released higher amount of N as compared to the other green manures. In addition to that, in a similar decomposition study, Chikowo (2004) showed prolonged N immobilisation while in under field conditions. After the seventh and eighth weeks, the amount of N in soil started to decrease due to the fact that most of the N released was nitrified and then lost or leached as nitrate upon watering, where it was leached beyond the sampling zone.

Despite the delay in enriching the soil in extractable P (Bray-1) for greengram it still reached the same high level as mucuna and its still justified to call them green manures when it comes to supplying plant available P to the crops, which concur with Randhawa et al. (2005). The chemical composition of the source material did not differ (Fig. 5A) so we speculate that
differences may be caused by the morphological differences between the two species, particular the leaf:stem ratio (Albrecht et al. 1987). This has been seen to influence the release rate in other studies (Cobo et al. 2002) and possible interactions between the leaf-stem due to high soluble C contents in the stem (Quemada and Cabrera 1995). The fast decrease of P in the residual of the decomposing plant materials may be due to its soluble nature in the plant cell. Studies by Frossard et al. (1995) and Giacomini et al. (2003) observed that soluble P in plant tissues is also available in the form of diesters (nucleic acids, phospholipids, and phosphoproteins) which can easily be released through microbial decomposition activities. This led to the release of most of the P from the two green manures in the first eight weeks of incubation. The difference P content compared to the N content in the litter is due to the fact that P to a higher degree is organically bound (Hassan, 2013: Randhawa et al. 2005) whereas a higher proportion of the N content initially is soluble (Hättenschwiler and Vitousek 2000).

Mg release from plant materials was almost similar in both green manures. In both plant materials the trend of decomposition was similar, with a somewhat steady rate of decomposition throughout. The difference between the two types of green manures was in the gains of Mg in the soil, whereby the soil incubated with mucuna gained more Mg as compared to that incubated with greengram. Other studies have also observed that soil Mg usually accumulated and became higher mainly in the top soil then decreased with depth (Brar et al. 2002).

The increase in soil microbial the population was a result of increase in the energy and nutrient sources for the microorganisms due to the addition of the green manures. Bakken et al., (2006) and Lavelle and Spain (2001) observed that organic material provided by green manure promotes the activity of soil organisms, as a source of energy and nutrients. Cover crops and mulch increase the populations of macroorganisms and microorganisms, and their
activities in the soil, because they increase the total inputs of organic materials to the soil (Reddy et al. 2003). Increase in total microbial population density in the soil is ascribed to the ability of a green manure to provide conducive environments like increased soil moisture content, ensuring moderate changes in soil temperatures, providing food sources at the soil surface and retention of soil burrows that favour growth and multiplication of macro and microorganisms. A study by Elfstrand et al. (2007) on the responses by soil microbial communities to green manuring detected an increase in soil microbial biomass. Lundquist et al. (1999) also reported an increase of 24 to 52% of active bacteria due to the application of rye green manure. Some studies have revealed the ability of mucuna plants to increase soil organic matter and improve soil moisture regimes (Barthes et al. 2004). Other studies have shown that the increase in microbial population depended on the availability of the organic matter supplied by the soil amendment materials and that the population increase is rather short lived following plant incorporation (Lundquist et al. 1999).

The improvement of CEC was mainly due to the ability of the two green manures to release the bases like Ca and Mg, as well as other cations, upon decomposition. This was also observed by Kimetu et al. (2008) who explained the importance of green manure in the improvement of soil CEC. The soil CEC protects cations from leaching out of the plant root zone and makes them available to plant roots (Orcutt 2000).

The decrease in CEC beyond the seventh week was due to the oxidation of NH$_4^+$ to give NO$_3^-$ which is highly soluble and in turn is leached beyond the sampling zone. Chikowo et al. (2004) observed the accumulation of NO$_3^-$ beyond 40 cm depth of soil just three weeks after the beginning of the rainy season. On the other hand, NH$_4^+$ which is lost from the soil as ammonia gas through the process of volatilization contributes to the decrease in CEC beyond
the seventh week. This was also observed by Zhenghu and Honglang (2000) who found a negative correlation between ammonium volatilization and soil CEC.

Conclusions and perspectives

Using mucuna and greengram as green manure can be of great potential in increasing soil fertility, which can contribute to improving crop production. However, in order to achieve this, the optimal period when the plant can benefit from the nutrients released should be well synchronized with the optimal release of the nutrients from the decomposing green manures. The sixth to eighth weeks after incorporation seem to maximize nutrients release form the green manure, and planting of main crops should target to take advantage of this maximum release period of the green manure. This investigation provides justifiable insights for improving soil fertility and demonstrates the suitability of mucuna and green manures as suitable in the overall scenario of integrated soil fertility management strategy to enhance soil nutrient dynamics and plant nutrition under these tropical soil conditions.
