Abstract

This paper is concerned with evaporation of moderately volatile liquids, gasoline in particular, due to spray generation, liquid fragmentation and fountain effects following accidental puncture of a pressurized pipeline. Hazard analysis predicts that extensive evaporation will take place. The paper examines a typical fuel depot receiving gasoline from a ship at a nearby port via an above-ground pipeline. For comparative purposes, two types of accidental release during import are considered: 1) The receiving tank overflows in a worst-case Buncefield-type event (baseline). 2) The import pipeline is punctured and a jet of liquid discharges upwards.

The paper examines pipeline import of three substances, hexane, octane and winter gasoline. Hazard analysis using the PHAST software suite indicates that the amount of fuel evaporated from the pipeline puncture scenarios greatly exceeds the amount evaporated in a tank overfill event for all three substances, gasoline in particular. Proper modelling of evaporation of wide-range multi-component mixtures such as gasoline is challenging however. PHAST's simplified thermodynamic modelling of properties of mixtures may be a source of error. A PHAST-based stand-alone spray evaporation model with advanced thermodynamic capability is developed. Results indicate that PHAST does

indeed overestimate evaporation of mixtures. Still, model output shows that evaporation following pipeline puncture may exceed the evaporation from a Buncefield-type tank overfill event by a factor of two or more. This finding is significant as evaporation from pipeline puncture scenarios appear largely overlooked in hazard analysis. The finding may lead to a fundamental re-appraisal of the hazard potential of fuel depots and pipelines.

1 Introduction

Before 2005, the storage of gasoline in large above-ground tanks was thought to present rather limited risks to neighbours. The worst design event associated with a tank farm was believed to be a large pool fire following tank failure. Predicted hazard distances rarely exceeded 200 m [1], [2].

In 2005, an incident at the UK Buncefield fuel depot fundamentally changed the perceived hazard potential of gasoline fuel depots – the worst event became a vapour cloud explosion. The sequence of events at Buncefield can be summarized as follows: During a fuel import, a gasoline tank overfilled. Large amounts of gasoline flowed from breather openings in the tank roof and fell (cascaded) into the bund area. The volatile components in the gasoline vaporized rapidly and mixed with air to form a flammable mixture that subsequently exploded with devastating force.

The Buncefield explosion took place early Sunday morning, the area was quiet and there were no fatalities. While nobody was killed, the potential for a mass-casualty event is obvious. Property damage was extensive. The fuel depot was close to some 630 businesses employing about 16,500 people. The premises of 20 businesses employing 500 people were destroyed and the premises of 60 businesses employing 3,500 people were severely damaged [3]. Buildings as far as 8 kilometres from the depot, suffered lesser damage, such as broken windows, and damaged walls and ceilings. Costs were estimated at about £1 billion [2].

The Buncefield incident had major implications for hazard analysis of fuel depots. The new insights can be summarized as: 1) An unforeseen release mechanism (overflow and cascading), leading to extensive evaporation of the lighter components of gasoline; and 2) An unforeseen explosion mechanism, producing destructive blast pressures even though the area around the depot was considered rather open and uncongested. The Buncefield incident led to a worldwide re-appreciation of the major hazard potential of fuel depots. The concern now became a Buncefield-type tank overfill event, late ignition and a so-called Open Flammable Cloud Explosion (OFCE) [2], [4]–[6]. The term Unconfined Vapour Cloud Explosion (UVCE) has been used extensively in the past but may give way to the term Open Flammable Cloud Explosion (OFCE). It has been argued that the word ‘unconfined’ should be dropped in favour of ‘open’ to emphasise that for many past UVCE incidents there was in fact some degree of confinement provided by obstacles which prevented the unhindered movement of the flammable cloud ahead of the flame as the combustion process developed [2].

This paper draws attention to another release mechanism capable of producing a large vapour cloud, which to the best of our knowledge has received little attention in the literature: Puncture of an import pipeline results in a jet spray of liquid gasoline that discharges upwards and forms a fountain with many droplets, which leads to extensive evaporation of the lighter components of gasoline. We present evidence to suggest that this spray scenario may evaporate more fuel than a Buncefield-type overfill event. Hence, it may

constitute a worst-case scenario in fuel depot hazard analysis that is currently overlooked.

We are of the opinion that the pipeline puncture scenario is particularly relevant for hazard analysis of fuel depots at marine terminals. Import or export pipelines are often located above ground and may be vulnerable to external impact, e.g. dropped objects, or for pipe bridges above road crossings, collision impact by heavy vehicle.

A gasoline pipeline risk analysis approach published in 1999 [7] considered a pipeline leak or rupture forming a pool of gasoline from which evaporation and ignition resulted in a flash fire which burned back to produce a pool fire. The study assumed that soil permeability determined the size of the unignited pool and hence the rate of evaporation feeding a vapour cloud. Gasoline was assumed to be absorbed into the ground after which it presented no safety risk. Estimated pools were rather small, for a rupture with a release rate of 205 kg/s and delayed ignition, the maximum pool diameter was 100 m. Evaporation from spray and fountain effects were not considered.

Another pipeline risk analysis approach also published in 1999 [8] considered the length of throw of a jet of gasoline, which could douse occupied buildings and later engulf them in flames. Spray formation was briefly mentioned but evaporation was not addressed. In 2002, the UK HSE published a large set of pipeline incident reports [9]. For non-flashing liquids only pool fires were considered although the study suggested that spray releases appeared to be significantly more hazardous. A risk analysis of a Polish gasoline cross country pipeline published in 2006 [10] did not consider spray evaporation either.

More recent oil and gas pipeline risk studies in 2015 and 2016 [11], [12] do not address spray evaporation of liquids with volatile components. A 2017 study on pipeline accidents and land-use planning [13] does not appear to rule out an explosion following the accidental release of "volatile liquid materials" but the discussion lacks precision, as the study is based on analysis of historical data and struggles with incomplete information and other limitations of (often discontinued) accident databases. The work of [14] presents an exception to this general picture, as they briefly attempt to extend their models of tank overfill events to cover spray releases also.

In conclusion, rapid evaporation of large quantities of flammable vapours from puncture of a gasoline pipeline due to spray and fountain effects is a scenario currently given little or no consideration in pipeline risk analysis studies.

The main thrust of this work relates to hazard analysis of evaporation from a spray release of gasoline. We examine the generation of vapour following a puncture of a pressurized gasoline import pipeline to a fuel depot. For perspective, we compare the results with the amount evaporated in case the same import pipeline would result in a Buncefield-type overfill scenario. The purpose is to examine the relevance of the spray release scenario as major hazard scenario and potential worst design event to be considered in hazard analysis of fuel depots. To our knowledge, no previous work has addressed this topic.

A representation of the composition of gasoline is required before modelling and process hazard analysis can take place. This is no trivial task as gasoline is a complex mixture of hundreds of hydrocarbons with very different boiling points. Earlier experimental and simulation work, see e.g. the comprehensive research program on vapour cloud formation reported in [15], used hexane to represent gasoline in order to simplify analysis, or at best used a four-component mixture of butane, pentane, hexane and decane. A second thrust of this paper is to define a generic wide-range multi-component hydrocarbon composition with properties similar to a typical winter gasoline for use in consequence modelling. To our knowledge, this contribution is also novel.

There are a variety of consequence modelling software suites available [16]. This work uses the commercially available software suite for process hazard analysis PHAST developed by DNV GL. PHAST is referred to in international peer-reviewed journals, in model benchmark analysis [17], in post-accident comparative analysis [18] and in consequence model validation studies [19], [20]. Specifically, we point to articles on validation of PHAST's models for spray releases [21], [22].

We have certain a priori reservations regarding the ability of well-established hazard analysis software suites to handle wide-range multi-component mixtures such as gasoline. The approach taken in PHAST to thermodynamic modelling of mixture properties is simplified, essentially a mixture is represented by a "pseudo-pure component". A third thrust of this work is therefore to construct a stand-alone spray evaporation model faithful to the one implemented in PHAST and then enhance this model with advanced thermodynamic modelling capability. The purpose is to examine the effect of improved thermodynamic modelling of mixtures on the estimated amount of evaporation for spray releases.

It is true that PHAST provides a multi-component version with more advanced thermodynamic modelling. The multi-component version does not model rain-out however. The model is therefore not suitable for estimation of evaporation of moderately volatile liquids for which the rainout fraction is significant. A custom model is required.

There are numerous theoretical and practical challenges associated with extracting a single stand-alone model from a suite of integrated models. Juxtaposition of the results from PHAST and the PHAST-based Stand-Alone Model (SAM) will provide a crude but nonetheless essential indication of the magnitude of any errors potentially caused by simplified thermodynamic modelling. To our knowledge, no previous study has attempted advanced thermodynamic modelling of spray evaporation of wide-range multi-component mixtures for accidental loss of containment events.

2 Material and methods

2.1 Overview

The research methodology is summarized in Figure 1. Accordingly, the work reported here comprises the following steps:

- 1 Definition of release scenarios, input parameters and substance property models
 - 1.1 Description of a generic fuel depot configuration and a typical gasoline import situation
 - 1.2 Specification of two types loss of containment (LOC) events during the gasoline import: 1) a Buncefield-type tank overfill scenario (baseline), and 2) puncture of the pressurized import pipeline
 - 1.3 Definition of a generic multi-component hydrocarbon composition to represent a typical winter gasoline
- 2 Estimation of evaporation from a Buncefield-type over-fill scenario based on large-scale experimental work reported by HSE/HSL and FABIG
- 3 Estimation of evaporation from pipeline puncture scenarios, using:
 - 3.1 The PHAST software suite's (ver. 8.0) recommended settings, i.e. the default release rate and spray evaporation models and the available thermodynamic package for multi-component mixtures
 - 3.2 A stand-alone PHAST-like spray evaporation model faithful to the one in PHAST but enhanced with advanced thermodynamic modelling of multi-component mixtures, implemented in MATLAB software.

Figure 1. Methodology and purpose of this study

2.2 Step 1: Definition of model scenarios and input parameters

2.2.1 Configuration of generic fuel depot and a typical gasoline import situation

Fuel depots typically receive gasoline from a marine tanker at a nearby port or from a distant tank farm via a cross-country pipeline. This study considers imports of gasoline from tankers at ports only. Typically, import pipelines at ports are a few kilometres long and pressures are in the 10-15 barg range, whereas the length of cross-country pipelines are measured in hundreds of kilometres and pressures often exceed 100 barg. Hence, if spray effects are relevant for pipelines at port terminals, they are even more so for cross-country pipelines with much higher internal pressures.

We have assumed a typical import rate of 1,000 m³/h. For perspective, the import rate (via cross-country pipeline) to the overflowing tank at Buncefield was 550 m³/h, increasing to 890 m³/h [1].

A fuel terminal informed the authors, that certain refineries ship warm gasoline, which even after a 2-3 day Atlantic Sea voyage during wintertime can be warm upon arrival. We have assumed a liquid temperature of 20 °C for winter gasoline. For details, refer to Table 1, section A.

2.2.2 Specification of tank overfill and pipeline puncture scenarios

The Buncefield-type tank overfill scenario is assumed to result from a failure of the receiving tank's level indication and overfill protection systems. The entire import flow rate runs from openings in the tank roof and forms a free cascade that is projected away from the tank wall. The cascade and splashing at the base lead to extensive evaporation of the lighter components of gasoline. For details, refer to Table 1, section B.

The pipeline puncture scenario is assumed to result from some external impact, e.g. truck driver forgets to lower the crane arm and collides with a pipe bridge (road overpass) about 100 m from the ship. A jet of liquid discharges upwards through an orifice, forming a fountain with many droplets, which leads to extensive evaporation of the lighter components of gasoline. Four hole sizes are considered for which the combination of hole size and pipeline back-pressure (orifice pressure) allows the release of 95%, 75%, 50% and 25% of the nominal import flow rate. Two pipeline lengths are considered. Their different friction loss profiles result in different orifice pressures at the puncture location. For details, refer to Table 1, section C.

Liquid not evaporated while airborne will rain-out on the ground and form a pool from which further evaporation will take place. The rate of evaporation is a function of the pool area, which is unknown. To simplify analysis, pool evaporation is ignored. Effects of wind on evaporation while droplets are airborne are also ignored, only calm conditions are considered.

2.3 Step 2: Estimation of evaporation from Buncefield-type tank overfill scenario

Our modelling of the amount evaporated in a Buncefield-type overfill event is based on the results of large-scale experimental work carried out by the UK HSE/HSL [15], in particular the empirical correlations reported by the Fire and Blast Information Group (FABIG) Technical Note 12 [14], [23]. The FABIG source provides empirical correlations for hexane and winter grade gasoline.

An examination of the background study [15] reveals that the correlation for hexane is based on experiments with commercial hexane, i.e. a mixture of several hexane isomers. The correlation for winter grade gasoline is based on experiments with commercial hexane and supplementary experiments with other mixtures. We consider the results from this ambitious research program to provide the best guidance currently available for estimation of worst-case evaporation resulting from a tank overfill event.

Table 1. Definition of loss-of-containment (LOC) scenarios

A) Import pipeline and fuel transfer

Nominal import flow rate	1,000 m ³ / h
Pipeline lengths considered	1,000 m and 2,000 m
Pressure source	Pump at marine tanker
Temperature of imported liquid	20 °C
Pipeline internal diameter	250 mm
Armatures in pipeline	50 bends, 8 valves

B) Tank overflow scenarios

Liquids considered	Commercial hexane ^a , winter grade gasoline ^{a,b}
Flow rate of overtopping liquid	1,000 m ³ / h
Temperature of liquid	20 °C
Tank diameter	29 m
Tank height	20 m
Ambient conditions	Calm wind, 10 °C
Evaporation from rainout fraction	Ignored

^a The compositions used in large-scale experimental work [15]

^b Referred to as gasoline 1

C) Pipeline puncture scenarios

Liquids considered	n-hexane, n-octane, winter gasoline ^a
Release rate (expressed as fraction of nominal import flow rate)	25%, 50%, 75% and 95%
Pipeline length	1,000 m and 2,000 m

Angle of jet from horizontal	45° and 80°
Temperature of liquid	20 °C
Ambient conditions	Calm wind, 10 °C
Evaporation from rainout fraction	Ignored

^a Wide-range multi-component mixture with properties similar to a typical winter gasoline. This composition is referred to as gasoline 2.

2.4 Estimation of evaporation from of pipeline puncture scenarios

2.4.1 Spray evaporation using PHAST

PHAST modelling of evaporation from a pipeline puncture and spray release is described in the PHAST technical documentation [24].

It comprises three steps:

- 1 A discharge model based on Bernoulli's equation for incompressible fluids.
- 2 A droplet formation model based on an aerodynamic break-up mechanism. The Sauter mean droplet diameter is calculated based on the work of [25]
- 3 An aerosol jet dispersion and evaporation model-based on the work of [26].

The core of the droplet evaporation model is the solution of differential equations describing droplet mass and temperature change due to droplet evaporation. Evaporation terminates when the droplet trajectory intercepts with ground level, known as droplet rainout. For spray releases of mixtures such as gasoline, PHAST represents the mixture with a pseudo-pure component. The PHAST thermodynamic property model for the mixture is based on the AIChE DIPPR database for which details are available in [27].

2.4.2 Spray evaporation using PHAST-based stand-alone model

A Stand-Alone Model (SAM) for spray release evaporation from pipeline puncture has been implemented in MATLAB, a computing environment provided by MathWorks [28]. The SAM shares the same theoretical foundation and takes the same approach as PHAST. SAM output is tuned to PHAST output for selected scenarios with pure substances. The aim has been to provide an as faithful representation of the PHAST model as possible, within the time and budget constraints of this project, which gives similar results when applied to spray releases of pure substances.

The SAM is then enhanced with advanced thermodynamic modelling capability for mixtures, a capability PHAST has not. The advanced thermodynamic modelling of mixture compositions is based on the GERG-2008 multi-parameter wide-range Equation of State (EoS) for natural gases and mixtures [29]. GERG-2008 widely known to be one of the most accurate and reliable property models for fuel mixtures. It has been used to calculate mixture properties for various technical applications. In particular, it is used to model liquid hydrocarbon mixtures in industrial chemical processes and thermodynamic cycles. GERG-2008 is based on an explicit formulation of the Helmholtz free energy as function of density, temperature and composition. It allows calculating real mixture properties such as liquid phase and vapour phase pressures, densities, enthalpies, entropies as well as heat capacities. For details, refer to Appendix A.

A major challenge for the PHAST-based Stand-Alone Model arises because some of PHAST's computations of energy balance, mechanical turbulent mixing with ambient air and droplet trajectory take place in the Unified Dispersion Model (UDM) module [22], [30] of the PHAST software suite, not in the spray module. A stand-alone model of the UDM module is beyond the scope of the present work however.

3 Generic multi-component hydrocarbon composition similar to a typical winter gasoline

Commercial gasoline is a mixture of a large number of hydrocarbons with different boiling points. The exact composition of gasoline is unknown and varies according to the crude oils from which it is produced, the type of processing units present at the refinery, how those units are operated and which hydrocarbon streams (blendstocks) the refinery opts to use when blending the final product.

In Europe, gasolines must meet the requirements set forth in EN 228 [31]. Important specifications relate to volatility and Research Octane Number (RON). The fuel volatility requirement, measured as Reid Vapour Pressure (RVP) at 37.8 °C (100 °F), reflects a compromise; on the ability to start a cold engine while at the same time avoid excessive evaporative losses of volatile organic compounds (VOCs), which are unwanted air pollutants. The fuel volatility specification varies according to geographical area and season, with higher volatility during winter. In Denmark, the maximum RVP is 70 kPa summer and 95 kPa winter. Refiners typically adjust the vapour pressure by adding butane (C4) to the gasoline blend. Because the price of butane is lower than that of gasoline, refiners have an economic incentive in meeting the maximum permitted RVP.

At the refinery, the heavy virgin naphtha (HVN) fraction (mainly C7-C9) from crude oil distillation is processed in a reformer unit, which converts cyclic alkanes (naphthenes) and other hydrocarbons to unsaturated and ring-shaped aromatic compounds (e.g. benzene, toluene, ethyl-benzene, xylenes), which have much higher octane numbers. Refiners avoid feeding C6 to the reformer unit, in particular cyclohexane, as this would be converted to benzene, for which EN 228 sets a maximum content of one percent volume fraction due to its adverse health effects. The stream leaving the reformer unit is known as reformate. Refiners typically adjust the octane number of the gasoline blend by adding reformate.

The light virgin naphtha (LVN) fraction (mainly C5-C6) has a high content of straight chain alkanes with low octane numbers. Some refineries have an isomerization unit, which convert them into branched isomers, which have higher octane numbers. The stream leaving the isomerization units is known as isomerate. Refiners can use the rather volatile isomerate as a base blendstock in gasoline blending.

The description above is highly simplified. There are many other options, and the economic performance of the refinery depends much on its ability to optimize gasoline blending operations.

Because winter gasolines contain more volatiles, we select a typical Danish 95 octane winter gasoline composition for our study. We have communicated (personal communication) with a refinery on gasoline blending operations and the blendstocks used, and with a large laboratory which undertakes certification

work that commercial gasolines meet specifications. The refinery and the laboratory have kindly supplied relevant information for our gasoline composition work, but both wish not to be named.

The refinery informs that the typical main blendstocks for gasoline formulation are isomerate, reformate and butane. Refer to Table 3 for stream properties. Isomerate is rather volatile with 85 %-vol evaporated at 70 °C, while only 4%-vol of the reformate has evaporated at this temperature. The laboratory provided analysis results of two typical 95 RON winter gasoline formulations, here shown as Blend1 and Blend2 in Table 3. Blend1 contains much isomerate. Blend2 has less isomerate and some low-RON straight chain LVN paraffins, which the refinery likely had in surplus. Hence, Blend2 has a higher content of reformate to meet the RON specification, and a higher butane content to meet the upper RVP limit. The two blends are typical and both meet the 95 RON winter gasoline specification but because of different formulations, their C4-C11 distributions differ. The two blends illustrate the inherent compositional variability of "commercial gasoline" and the practical challenges associated with defining a model composition based on pure substances.

The isomerate is too volatile for the RON to be determined experimentally. Instead, the RON is computed based on gas chromatograph analysis which provides detailed information on the composition. Based on this information and an additional iso-pentane blendstock, we define a wide-range multi-component mixture to represent a generic European winter gasoline, named Gen13 in Table 2.

The initial Buncefield report [1] grouped butanes, pentanes and hexanes as the 'lighter components' in gasoline. Our a-priori expectation is therefore that the most relevant compounds to consider for spray and fountain evaporation are in the C4-C6 range. While there is little doubt that the highly volatile C4 fraction will evaporate with ease, good modelling of evaporation of the moderately volatile C5 and C6 fractions appears essential. The isomers of these fractions have a wide range of boiling points, e.g. 28-49 °C for C5 alkanes and 50-81 °C for C6 alkanes. An accurate representation of these compounds, in particular the most volatile alkane isomers, may therefore be important. The Gen13 model composition attempts to do this. The composition is modelled on Blend1, which had the highest content of C4-C6 volatiles. Due to unavailability of thermodynamic interaction parameters in the NIST REFPROP database [32] for several isomers, this study uses a simplified composition, Sim10, to represent 95 RON winter gasoline, henceforth referred to as gasoline 2.

Table 2. Two example compositions to represent a generic European RON95 winter gasoline. This paper uses the simplified 10-component mixture (Sim10), also referred to as gasoline 2

Component	CAS	BP °C	Gen13 %-vol	Sim10 %-vol
Iso-Butane	75-28-5	-12	3.58	3.58
n-Butane	106-97-8	-1	6.58	6.58

iso-Pentane	78-78-4	28	17.88	17.88
Cyclopentane	287-92-3	49	-	9.44
2,2-Dimethylbutane	75-83-2	50	4.23	-
2-Methylpentane	107-83-5	60	10.42	-
n-Hexane	110-54-3	69	-	8.94
Methylcyclopentane	96-37-7	72	3.73	-
CycloHexane	110-82-7	81	5.82	5.82
2-Methylhexane	591-76-4	92	3.26	-
n-Heptane	142-82-5	98	-	3.26
Toluene	108-88-3	111	18.41	25.00
n-Octane	111-65-9	126	3.45	10.00
m-Xylene	108-38-3	139	15.06	-
n-Nonane	111-84-2	151	5.44	9.49
Decane	124-18-5	174	2.12	-

Table 3. Characteristic properties of typical gasoline blendstocks and two typical commercial 95 RON winter gasoline blends. For comparison, the properties of two suggested generic compositions are also shown.

		Typical blendstock			Commercial 95 RON raw ^a winter gasoline		Multi-component model mixtures	
		Isomerate	Reformate	Butane	Blend 1	Blend 2	Gen13	Simple10
Density at 15 °C	kg/m3	677	810	577	738	745		
Evaporated at 70 °C	%-vol	84.6	3.6		35-37	35-37		
Evaporated at 100 °C	%-vol	97.3	13.6		58-59	58-59		
Final Boiling Point	°C		192		188-190	188-190		
Reid Vapour Pressure	kPa	73.5	29.4	315.0	85-88 ^a	85-88 ^a	91.4	90.2

Total C10	%-vol		2.0	2.0	2.1
Total C11+	%-vol		0.4	0.5	

^a Raw gasoline refers to qualities handled at depots. Ethanol (5 %-vol) is added later in the distribution chain, raising the octane number to 95 RON and the RVP to just below 95 kPa at the pump.

4 Results

FABIG estimation of evaporation for a Buncefield-type tank overfill scenario is shown in Table 4.

Table 4. Vapour generation in case of Buncefield-type tank overfill event (baseline), import rate 1,000 m³/h

Model substance	Import rate [kg/s]	Evaporation rate ^a [kg/s]	Fraction of import rate evaporated [-]
Hexane ^b	182	35.8	0.197
Winter grade gasoline ^c	206	40.7	0.198
Heavy reformat ^d	225	9.53	0.042

^a Estimates based on experimental and theoretical work [15] and correlations [14]

^b Based on experimental work with commercial hexane (mixture of hexane isomers).

^c Also referred to in this article as "gasoline 1". Correlation is likely based on experimental work with model mixture of butane, pentane, hexane and decane.

^d Example of low-volatility substance, correlation is available but experimental basis and composition are unclear.

The results of the PHAST modelling of pipeline puncture scenarios are shown in Table 5. Beside the evaporation rate and the fraction evaporated, also the orifice diameter, the release rate, the estimated back-pressure in the pipeline required to attain the scenario release rate, and the initial droplet diameter are tabulated. Unsurprisingly, a reduction in the orifice diameter gives a smaller release rate and a higher orifice back-pressure, which in turn gives a more efficient droplet atomization (smaller droplet diameter) and a more pronounced droplet evaporation. It is noteworthy that for relatively modest orifice back-pressures, say larger than 4 barg, the model predicts almost complete evaporation of spray releases of moderately volatile liquids such as hexane and winter gasoline.

Table 5. Vapour generation for pipeline puncture scenarios, estimated using PHAST. Release rate is the total liquid release rate before evaporation.

Juxtaposition of the fraction evaporated from Buncefield-type tank overfill events (Table 4) and pipeline puncture events (Table 5) are shown in Figure 2. For moderately volatile liquids such as hexane and winter gasoline, the worst-case pipeline puncture event appears to be a combination of hole size and pipeline back-pressure that leads to the release about 50 percent of the import rate. The amount of fuel vaporized then exceeds that of a worst-case tank overfill event by a factor two or more. Although smaller hole sizes lead to higher orifice back-pressures and more efficient spray evaporation, the release rate also lowers, leading to an overall decrease in the amount of fuel evaporated.

Table 6 presents the results of using PHAST and the more advanced property model in the PHAST-based Stand-Alone Model (SAM). Figure 3 presents results for winter grade gasoline evaporation (the two spray angle cases averaged). SAM predicts less evaporation than PHAST but still significantly more than the baseline tank overfill scenario.

Figure 2. Evaporation following pipeline puncture event due to spray effects estimated using PHAST (vertical bars) compared with evaporation for Buncefield-type tank overfill event estimated using FABIG correlations (horizontal line). Evaporation is expressed as fraction of import rate.

5 Discussion

5.1 Early work

In risk consultancy work of a fuel depot in 2008, COWI reported (confidential and unpublished) that PHAST output suggested that spray evaporation following pipeline puncture could produce very large vapour clouds. The implications were not fully realized however, as generally accepted models of evaporation from tank overfill events were not available and overfill events were generally believed to be the worst-case scenario.

In 2016, the issue resurfaced (confidential and unpublished), in part because an import pipeline to a fuel depot was severely deformed when the raised crane of a passing truck struck a pipeline road overpass. Hazard analysis using PHAST clearly showed that major pipeline damage produced the largest hazard range of all the loss of containment scenarios considered for the fuel depot. Key inputs to some models were approaching the limits of the recommended range of application however, in particular low orifice back-pressures. An additional concern was that the findings, while technically defensible and correct, might be an artefact of PHAST's simplified modelling of properties of wide-range multi-component mixtures. Although the software developer did not advise against the computational procedure, doubts remained. Those doubts eventually led to this work.

5.2 Improved thermodynamic modelling

The work reported here largely supports those doubts. Advanced thermodynamic modelling indicates that PHAST does overestimate evaporation from spray releases of mixtures. The main finding stands however: Modelling shows that spray evaporation following puncture of an import gasoline pipeline can evaporate large quantities of fuel, perhaps exceeding the evaporation from a Buncefield-type tank overfill event by a factor two or more.

There are many challenges associated with extracting a single stand-alone model from a suite of integrated models. PHAST modelling of the behavior of airborne droplet in a moving mass of entrained air takes place in the complex UDM module, not the spray module. Stand-alone modelling of the UDM module is outside the scope of this project however, and the issue was managed through model tuning, details are provided in the appendix. As a result, we can only state that PHAST likely overestimates spray evaporation for wide-range multicomponent mixtures. We cannot state how much.

5.3 Mixing with air

The main concern in hazard analysis of fuel depots is a loss of containment event leading to an Open Flammable Cloud Explosion (OFCE). An OFCE has three principal characteristics: 1) A release of a large quantity of flammable vapour. 2) Good mixing with air to produce a large volume within the

flammability limits, since rapid flame propagation and blast effects will only occur through those premixed explosive regions. Moreover, there must 3) be a delay, of undefined duration, before ignition, to build up a large cloud [2]. Calm conditions represent a worst case [23], [33], [34]

This paper only considers the first step, the quantity evaporated. It has been argued however, that good mixing with air may be the critical step in OFCE hazard analysis [2]. The cascade and splash evaporation at Buncefield likely led to near-optimal (stoichiometric) mixing [14].

More research is needed to determine whether spray and fountain evaporation from a puncture event will also lead to near- stoichiometric mixing with air. We hypothesize however, that the freefall stage of a fountain release may indeed be comparable to a cascade release. We find it noteworthy that the authors of a recent review of past large vapour cloud explosions conclude that "smaller" vapour release rates, a term the authors reserve to rates lower than 100 kg/s, i.e. similar to those considered in this paper, seem to have a propensity to produce an OFCE rather than a flash fire [33].

5.4 Re-appraisal of the hazard potential of fuel depots

As stated in the introduction, the Buncefield explosion in 2005 fundamentally changed the perceived hazard potential of gasoline fuel depots. Immediately following the accident, the Buncefield Major Incident Investigation Board accepted what appeared to be the view commonly held by the industry and the relevant expert community in Britain: that this was an unprecedented event [2].

Failures should be valued as unique learning opportunities. Evidently, it makes good sense to share the lessons learned from unwanted outcomes in order to minimize the number of times the same lessons have to be learned [35]. It is therefore remarkable that a number of overfill-related gasoline vapour cloud explosions had occurred on earlier occasions, e.g. Houston, TX, USA, 1962; Baytown, TX, USA, 1977; California, USA, 1981; Newark, NJ, USA, 1983; Naples, Italy, 1985; and Sri Racha, Laem Chabang, Thailand, 1999 [1], [4], [6], [36], [37]. Some 20 years before Buncefield, authors had discussed the hazard potential [38]. In this light, the Buncefield incident may well stand out as exceptional, not that it took place, but that it was thoroughly studied and lessons shared.

Johnson reflects on whether the Buncefield incident was foreseeable. The answer is largely affirmative: All the elements of the incident were recognised as being possible [6]. Mannan arrives at a similar conclusion: There was nothing new or unforeseeable about what happened at Buncefield [36], [39]. Despite availability of evidence, there was limited appreciation of the hazard.

An analogous situation may currently exist for spray releases following pipeline puncture. Previous incidents have taken place. In Saint Herblain, France, 1991, a release of gasoline from a transfer pipe inside a bund produced a vapour cloud which upon ignition produced extensive explosion damage [40]. At a terminal in Jaipur, India, 2009, a large leak occurred from a valve on a

tank outlet. The leak resulted in a fountain or spray of gasoline directed upwards from the valve driven by the hydrostatic pressure in the tank only, i.e. a very modest overpressure. The leak produced a very large cloud which exploded with devastating force [41].

Other pipeline incidents with extensive evaporation of gasoline appear to have taken place elsewhere. An anonymous reviewer pointed to four incidents in USA: Bellingham (WA) on 10 June 1999, Allentown (PA) on 1 February 2005, Pasadena (TX) on 23 September 2008 and Colon (MO) on 5 December 2008. Available information is sparse however. In the Bellingham case, for example, the official investigation [42] merely provides sporadic mention of a large vapour cloud travelling down a creek: A young man fishing was overcome by hydrocarbon fumes, lost consciousness and drowned; a resident reported that odours were overwhelming and his dog was convulsing, but the investigation does not mention an explosion upon ignition, only fire. Another source [43] says that vapour clouds were reported visible to 10 feet over city streets, probably in downtown Bellingham, well over a mile from the rupture location, and provides vague reference to a "bomb-like blast" at the rupture location. More work is necessary to evaluate the relevance and significance of these incidents.

More recently, authors [14], [23] have argued that many of the physical processes that apply in a spray release are common with the overfilling problem. Yet, there appears to be limited appreciation of the spray evaporation hazard.

5.5 Future research

Before Buncefield, only the release of superheated liquids (e.g. propane and butane) were thought to be capable of producing large vapour clouds [2], [5]. Early spray modelling work is largely concerned with releases of flashing liquids, e.g. [25], [44]. The literature on spray releases of moderately volatile liquids appears sparse.

An experimental study on rainout data for spray releases of non-flashing water and xylene [21] showed that droplet behaviour in the jet is more complex than PHAST assumes. The spray is initially dominated by a small number of large non-spherical droplets that undergo secondary break-up further downstream the nozzle. Another experimental study [22] suggested that the current UDM model implemented in PHAST under-predicts the droplet size, in particular for gasoline releases. The prediction of an overly small initial droplet size will tend to produce too much evaporation, although droplets will subsequently reduce in size due to secondary droplet breakup and so the net effect of the model's poor prediction of the initial droplet size may be limited. More research is clearly needed.

A better understanding of the effects of the different input parameters to the estimation procedure is needed. A detailed sensitivity and uncertainty analysis using global methods such as variance based decomposition techniques [45], [46] and Monte Carlo techniques [47] will help quantify the contribution of the

inputs to predicted evaporation rates. Commercial gasoline is manufactured to meet engine requirements and its exact chemical composition is inherently ill-defined and variable. This should also be accounted for in sensitivity analysis.

Above all, however, future research should rectify the scarcity of large-scale experimental data for spray releases of moderately-volatile liquids to aid model verification.

6 Conclusion

Hazard analysis using PHAST predicts that extensive evaporation will take place due to spray and fountain effects following a pipeline puncture. To evaluate the significance of the spray release mechanism in hazard analysis of fuel depots, the quantity evaporated is compared against the quantity evaporated in a Buncefield type overfill event, which is currently considered to be the worst-case event for fuel depots.

This paper examines releases of two pure substances and a mixture: Moderately volatile hexane, low-volatility octane and winter gasoline. PHAST modelling consistently shows that a spray release can evaporate more fuel than an overfill event, in particular for gasoline, the substance of key interest to this paper due to the ubiquity of gasoline storage sites in society.

Proper modelling of evaporation of wide-range multi-component mixtures such as gasoline is challenging. For calculation of thermodynamic properties, PHAST represents the mixture with a pseudo-pure component, a simplification which may introduce errors. We develop a stand-alone spray model with advanced thermodynamic capability. Results suggest that PHAST does overestimate evaporation of mixtures. Still, this paper finds that evaporation following pipeline puncture may exceed the evaporation from a Buncefield-type tank overfill event by a factor two or more. The finding may lead to a re-appraisal of the hazard potential of pipelines and fuel depots.

This leads to the overall conclusion that pipeline punctures may be the worst-case scenario in hazard analysis of fuel depots. This is a novel proposition, which runs counter to established hazard analysis practice. While the incident at Jaipur, India, may provide some empirical support for this proposition, more research is clearly necessary, in particular large-scale experimental work for model verification, before conclusions of a more confident nature can be stated. In the meantime, a cautious approach in hazard analysis would be to include scenarios with spray evaporation from pipeline punctures.

7 Software

This study used Phast Risk (Version 8.0) from DNV GL software. MATLAB [28] was used for the PHAST-based model using an advanced multi-component mixture model.

8 Conflicts of interest

The authors declare that they have no conflicts of interests

9 Contributorship

This paper uses the first-last-author-emphasis approach and lists other authors in the order of importance of their contributions. The main authors of this work are F. Hedlund and J. Frutiger. F. Hedlund generated the idea, designed and initiated the project, coordinated tasks and drafted the article. J. Frutiger developed the PHAST-based model with real mixture properties, carried out all MATLAB model computations, drafted parts of the article and wrote the appendix. J. Boier Pedersen defined accident scenarios and carried out all PHAST computations. G. Sin provided technical and academic overview and guidance. F. Garde and E. Kragh were first to identify the significance of the pipeline puncture scenario. All authors have revised and contributed significantly to the final version.

11 Appendix A: Model for spray release evaporation from pipe damage

A stand-alone model for spray release evaporation from pipeline puncture has been implemented in MATLAB [28]. The model is independent from but faithful to PHAST as the stand-alone model mimics the approach taken in PHAST and is based on the same theoretical foundation. The aim has been to provide an as faithful representation of the PHAST model as possible, within the time and budget constraints of this project. The stand-alone model is then enhanced with advanced thermodynamic modelling capability for mixtures, a capability PHAST has not. The purpose is to examine the effect of improved thermodynamic modelling of mixtures on the estimated amount of evaporation for spray releases.

It is true that PHAST provides a multi-component version with advanced thermodynamic modeling. This version does not model rain-out however. The model retains droplets suspended in air until they are fully evaporated or the flammable concentration is below the cut-off concentration. The model is therefore not suitable for estimation of evaporation of moderately volatile liquids for which the rainout fraction is significant. The following scenario is considered: A gasoline pipe is ruptured forming an orifice. The liquid gasoline discharges and expands into the atmosphere, forming a stream of droplets, where gasoline evaporates and forms a vapour cloud. The stream of droplets subsequently touches the ground and forms a pool.

The model consists of 3 parts:

- 1) A discharge due to rupture
- 2) Droplet formation
- 3) Droplet evaporation

Input specification

The model can be solved through the following input specification.

Static pressure and temperature of the gasoline pipe: P_{st} and T_{st}

Orifice (hole) diameter: d_{hole}

Average droplet trajectory angle: θ

Atmospheric pressure and temperature: P_a and T_a

Furthermore, the following gasoline properties need to be calculated through a suitable equation of state [29] or obtained from a tabulated database [48], [49].

These properties are dependent on temperature T and pressure P .

Vapour phase pressure: $P(T)$

Liquid and vapour density: $\rho_l(T,P)$ and $\rho_v(T,P)$

Liquid and vapour enthalpy: $h_l(T,P)$ and $h_v(T,P)$

Liquid and vapour entropy: $s_l(T,P)$ and $s_v(T,P)$

Liquid phase and vapour phase heat capacity: $C_{p_l}(T,)$ and $C_{p_v}(T,P)$

Discharge due to pipe rupture

When a gasoline pipes ruptures, the pressurized liquid is discharged and expanded through the orifice into the atmosphere. The equations are based on the books of Street et al. on elementary fluid mechanics [50] and Mannan et al. on liquid discharge and loss prevention [51]. The model is based on the following assumptions:

The gasoline flow is in complete liquid state at the orifice.

There are negligible pressure and temperature effects at the orifice.

The velocity at the orifice u_0 is given by Bernoulli's equation for incompressible fluids

$$u_0 = \sqrt{2 \frac{P_{st} - P_a}{\rho_{lst}(T_{st}, P_{st})}} \quad (1)$$

where P_{st} is the static gasoline back-pressure in the pipe, P_a is the atmospheric pressure, ρ_{lst} is the liquid density of gasoline at the static pipe pressure P_{st} and temperature T_{st} . The orifice temperature T_0 and pressure P_0 is set equal to the atmospheric conditions, P_a and T_a :

$$P_0 = P_a \quad (2)$$

$$T_0 = T_a \quad (3)$$

The orifice mass flux G_0 is given then by

$$G_0 = \frac{u_0}{v_0} \quad (4)$$

$$v_0 = \frac{1}{\rho_{l0}(T_0, P_0)} \quad (5)$$

with v_0 being the specific volume ρ_{l0} the liquid density at the orifice. The frictional effect of convergent flow at the orifice reduces the overall mass flow rate. The reduction is expressed through the discharge coefficient C_D . Here, it is assumed $C_D=0.6$. The overall release mass flow Q through the orifice is calculated using the orifice cross-sectional area A_0 through

$$Q = C_D A_0 G_0 \quad (6)$$

$$A_0 = \left(\frac{d_{hole}}{2} \right)^2 \pi \quad (7)$$

After the orifice the gasoline fluid expands into the atmosphere. The final velocity in the atmosphere is given by the following momentum balance:

$$G_0 = \frac{u_0}{v_0} \quad (8)$$

$$v_0 = \frac{1}{\rho_{l0}(T_0, P_0)} \quad (9)$$

Due to negligible pressure effects at the orifice, there is no depressurisation assumed from the orifice pressure to the ambient pressure, hence no atmospheric expansion is calculated. This assumption is reasonable, because there are not large pressure and temperature differences between the pipe and the atmosphere and the gasoline is in liquid state.

Droplet formation

For an aerodynamic break-up mechanism, the mean droplet diameter d_{da} can be calculated using the critical Weber number, which accounts for the liquid-air interface, shear forces and surface tension forces [25]:

$$d_{da} = \frac{\sigma_L We_{crit}}{u_0^2 \rho_a} \quad (10)$$

where σ_L is the surface tension of gasoline, We_{crit} the critical Weber number and ρ_a the atmospheric density. Following the guidelines of Brown et al. [52], it is assumed that $We_{crit}=12$ for low-viscosity fluids. Assuming spherical droplets, the initial droplet mass can be written as

$$m_{d0} = \rho(T_{st}, P_a) \frac{4\pi}{3} \left(\frac{d_{da}}{2} \right)^3 \quad (11)$$

The number of released droplets per second can then be obtained using the total release mass flow rate Q :

$$N_d = \frac{Q}{m_d} \quad (12)$$

Droplet evaporation

The droplet evaporation model is based on the work of Woodward et al. [26]. We would like to explicitly refer to their work for more details on the fundamentals of the model equations.

No droplet size distribution is used. Hence, it is assumed that the larger evaporation due to larger droplets is compensated by the smaller evaporation of smaller droplets. Therefore, all the calculations are performed for an average droplet with an initial droplet diameter equal to the mean droplet diameter.

Woodward et al. [26] assumed the droplets surrounded by a mixture of air and gasoline vapour. In order to obtain the gasoline droplet mass and temperature as function of the distance to the orifice, a system of ordinary differential equations needs to be solved that includes a mass balance, an energy balance and a momentum balance. The change in droplet mass is obtained through the mass transfer equation (see Eq. (11)). The change in the droplet temperature is described using an energy balance taking into account the temperature change due to heat transfer and heat of evaporation (see Eq. (12)). The momentum balance (Eq. (13)) accounts for the change in velocity u_d :

$$\frac{dm_d}{ds} = -\frac{1}{u_d} A_d K_g \rho(P_a, T_d) C \ln \left(\frac{1 - y_g}{1 - \frac{y_s}{T_d / T_{vap}}} \right) \quad (13)$$

$$\frac{dT_d}{ds} = \frac{1}{u_d} \frac{A_d h(T_{vap} - T_d) + u_d \frac{dm_d}{ds} h_{fg}}{m_d C_{pL}} \quad (14)$$

$$\frac{du_d}{ds} = \frac{1}{u_d m_d} \left(u_{dz} u_d \frac{dm_d}{ds} + F_{body} + F_{drag} \right) \quad (15)$$

In Eq. (11) m_d is the droplet mass, s the distance from the orifice, A_d the surface of the spherical droplet, K_g the overall mass transfer coefficient, ρ the droplet density, C' the Stefan flow correction factor, y_g the mole fraction of gasoline in the vapour phase around the droplets, y_s the equilibrium mole fraction of gasoline on the droplet surface, T_d is the droplet temperature, and T_{vap} the vapour phase temperature of the vapour cloud surrounding the droplet. In Eq. (12) h_{fg} is the heat of evaporation, h the overall heat transfer coefficient, and C_{pL} the liquid heat capacity. In Eq. (13) u_{dz} is the vertical components of droplet speed, F_{body} the buoyancy force, F_{drag} the drag force.

The system of system of ordinary differential equations is solved for the following initial conditions:

$$m_d(s=0) = m_{d0} \quad (16)$$

$$T_d(s=0) = T_{st} \quad (17)$$

$$(18)$$

$$T_{vap}(s=0) = T_a \quad (19)$$

Eq. (14) is the initial mass of the droplet derived from the volume of the spherical droplet using the mean droplet diameter. The integration of the differential equations is terminated when the droplets hits the ground, this is approximated using the equation for the projectile motion

$$s_{end} = \frac{(u_0)^2 \sin(\theta)}{2g} \quad (20)$$

where g is the gravitational constant and θ the average droplet's trajectory angle.

In each integration step of the system of ordinary differential equations the temperature, mass and velocity dependent variables and constants that occur in Eq. (11) to (12) need to be updated. In the following the auxiliary equations of these variables are presented that are solved in each iteration step. The following variables are all to be considered at position s , e.g. the surface area of a droplet at position s is written as $A_d(s)$.

The droplet surface area A_d is obtained from the droplet mass m_d , through calculating the droplet density $\rho(T_d, P_a)$, radius r_d and volume V_d .

$$A_d(s) = 4\pi(r_d(s))^2 \quad (21)$$

$$r_d(s) = \left(\frac{V_d(s)}{4/3\pi} \right)^{1/3} \quad (22)$$

$$V_d(s) = \frac{m_d(s)}{\rho(T_d, P_a)} \quad (23)$$

The overall mass transfer coefficient K_g can be calculated using the Sherwood number Sh and the diffusivity of the gasoline in air, D_a .

$$K_g = \frac{Sh D_a (T_d)}{r_d} \quad (24)$$

The mean temperature T_m is the difference between the evaporation temperature T_{vap} and the temperature at the droplet surface T_d :

$$T_m = \frac{T_{vap} + T_d}{2} \quad (25)$$

The Sherwood Sh number is obtained through an empirical correlation of the Schmidt number Sc , the Reynolds number Re and the mass transfer number B_m :

$$Sh = (a + b Re^{1/2} Sc^{1/2}) / (1 + B_m) \quad (26)$$

$$Sc = \frac{\mu_a(T_m)}{\rho_a D_a(T_m)} \quad (27)$$

$$B_m = \frac{C_{pv}(T_m)(T_{vap} - T_d)}{h_{fg}(T_d)} \quad (28)$$

The correlation parameters are set to be $a=1.03$ and $b=0.23$. h_{fg} is the heat of vaporization, C_{pv} is the heat capacity of the gasoline vapour phase.

The correction constant C' is made up of two terms: 1) a term for Stefan flow which accounts for enhanced evaporation at high mass flux, and 2) a correction for the temperature gradient on the diffusion coefficient as described by Barrett and Clement [53], where $\mu=1.8$.

$$C' = \left[1 + \frac{P_v(T_m)}{2P_a} \right] \cdot \left[\frac{(2-\mu)(T_{vap} - T_d)}{T_{vap}^{(\mu-1)}(T_{vap}^{(2-\mu)} - T_d^{(2-\mu)})} \right] \quad (29)$$

The Reynolds number Re is found as follows

$$Re = \frac{2r_d |u_z - u_{dz}| \rho_{\text{cld}}}{\mu_a(T_m)} \quad (30)$$

where $|u_z - u_{dz}|$ is the velocity difference between the cloud and the droplet, ρ_{cld} is the cloud density and cloud and μ_a the dynamic viscosity of gasoline in air.

The drag force, F_{drag} , and the buoyancy force, F_{body} , are obtained as follows

$$F_{\text{drag}} = \frac{1}{2} C_{\text{Dd}} \rho_{\text{cld}} \pi r_d^2 |u_z - u_{dz}| |u_z - u_{dz}| \quad (31)$$

$$F_{\text{body}} = (\rho_{\text{cld}} - \rho_L) g V_d \quad (32)$$

ρ_L is the liquid density of gasoline and g is the gravitational constant.

The drag coefficient C_{Dd} is depending on the Reynolds number:

$$\begin{aligned} C_{\text{Dd}} &= 0.44 \quad \text{for } Re > 985 \\ C_{\text{Dd}} &= 24 \frac{1 + 0.15 Re^{0.687}}{Re} \quad \text{for } 2 < Re < 985 \\ C_{\text{Dd}} &= 24 \frac{1 + \frac{3Re}{16} + \frac{9Re^2 \log(2Re)}{160}}{Re} \quad \text{for } 0.1 < Re < 2 \\ C_{\text{Dd}} &= 24 / Re \quad \text{for } Re < 0.1 \end{aligned} \quad (33)$$

The heat transfer coefficient is obtained from Nusselt (Nu) and Prantl (Pr) number

$$h = \frac{Nu k(T_{\text{vap}})}{r_d} \quad (34)$$

$$Nu = \frac{a + b Re^{1/2} Pr^{1/3}}{1 + B_m} \quad (35)$$

$$Pr = \frac{C_{\text{pv}}(T_m) \mu_a(T_m)}{k(T_m)} \quad (36)$$

where k is the heat conductivity of gasoline.

Modelling was challenging because some of PHAST's computations of energy balance and mechanical turbulent mixing with ambient air takes place in the Unified Dispersion Model (UDM) module of the software package, not in the

spray module. Modelling of the UDM unit module is beyond the scope and budget of the present work however. The issue was managed through model tuning.

When leaving the orifice, a droplet is assumed to be surrounded by a sphere of air, which moves with the droplet. Boundary layer transport of energy and mass takes place between the droplet and the air in the sphere, but not between the sphere and the ambient air. Ideal mixing is assumed the sphere. The mass of air in the sphere is estimated through model tuning. We align the output of the Stand-Alone Model to that of PHAST for the pure component n-hexane. We separate the pure component results into a training set and a test set. The training set is used to determine the mass of air and the test set is used to compare and validate the assumed mass of air.

Pool evaporation ignored

Evaporation is only considered while the material is airborne as droplets in a dispersing jet/fountain, not in pool evaporation after it has rained-out on ground. Similarly, when computing evaporation from a Buncefield-type overfill event, we consider the contributions to evaporation from cascading falling liquid and splashing effects at the tank base only. They contribute more to the source term than diffusive evaporation from a pool [15]. The simplification has additional benefits. Because some of the lighter components evaporate while airborne in the spray/cascade phase, the composition of the material that enters the pool has changed. PHAST is unlikely to take this in account. The simplification also eliminates uncertainties related to how sensitive PHAST's pool evaporation model is to the representation of a mixture by a pseudo-pure component. A more practical argument for ignoring step 4 is to avoid that arbitrary assumptions about drainage and pool area near the pipeline puncture, and similar pool (tank yard) area assumptions for the overfilled tank, influence the comparative analysis.
