Abstract

The purpose of this work is to compare the environmental impacts of spring barley cultivation in Denmark under current (year 2010) and future (year 2050) climatic conditions. Therefore, a Life Cycle Assessment was carried out for the production of 1 kg of spring barley in Denmark, at farm gate. Both under 2010 and 2050 climatic conditions, four subscenarios were modelled, based on a combination of two soil types and two climates. Included in the assessment were seed production, soil preparation, fertilization, pesticide application, and harvest. When processes in the life cycle resulted in co-products, the resulting environmental impacts were allocated between the main product and their respective by-products using economic allocation. Impact assessment was done using the ReCiPe (H) methodology, except for toxicity impacts, which were assessed using USEtox. The results show that the impacts for all impact categories, except human and freshwater eco-toxicity, are higher when the barley is produced under climatic circumstances representative for 2050. Comparison of the 2010 and 2050 climatic scenarios indicates that a predicted decrease in barley yields under the 2050 climatic conditions is the main driver for the increased impacts. This finding was confirmed by the sensitivity analysis. Because this study focused solely on the impacts of climate change, technological improvements and political measures to reduce impacts in the 2050 scenario are not taken into account. Options to mitigate the environmental impacts are discussed.

Keywords: Life Cycle Assessment, attributional LCA, barley, climate change, future climate

Introduction

Life Cycle Assessment (LCA) seeks to identify the potential environmental impacts of a product over the course of its life cycle (ISO, 2006) by assessing all inputs from and outputs to the environment from the so-called product system. However, environmental impacts may work as a 'feedback' mechanism and in turn have consequences for future product systems. In LCA the focus usually is on how human activities affect the environment, but it must be realized that (man-made) changes to the environment also have an effect on human activities. The burdens mankind has exerted and momentarily exerts on the environment will influence future product systems. The effects of climate change on agriculture can be considered as an example of this feedback on product systems.

As a first consequence of this feedback, increasing levels of atmospheric CO₂ concentrations (hereafter referred to as [CO₂]) are known to increase grain yields (Clausen *et al.*, 2011), resulting in lower inputs per mass unit of harvested crop. In case of barley cultivation in Denmark, yields were estimated to increase up to 20% (Saxe, 2013). As a second consequence, a predicted temperature increase, at least under Danish circumstances, has been shown to decrease grain yields as the grain filling time is reduced (Børgesen & Olesen, 2011). An illustration of the combination of these two effects for barley grown in Denmark was provided by Clausen *et al.* (2011), who compared grain yields under different environmental circumstances. Comparing grain yields under ambient and elevated (700 ppm) atmospheric [CO₂], an increase of 7.6 g/plant to 12.0 g/plant (+56%) was observed. In contrast, barley grown under elevated (+5°C) day and night temperatures showed a significantly lower yield (-27%) compared to barley grown under ambient temperatures. When barley was grown under both elevated atmospheric [CO₂] and temperature, the yield decreased 14% compared to barley grown under ambient conditions. A third example of the effect of climate change on agriculture is that changes in the rainfall patterns, for example caused by man-made climate change (Cook *et al.*, 2013) are expected to result in alterations in the nutrient flows from arable land, as well as to force limitations in some regions to the use of water for irrigation (Jeppesen *et al.*, 2011). As a fourth consequence, changes in temperature and rainfall patterns may change pest populations, leaving some regions unsuitable for certain pests already present in these regions undergoing climate change, whilst new species move in to fill this ecological niche (Gregory *et al.*, 2009). Changes in the pest species prevailing in a certain region will inevitably influence the pest management needed to maintain yields. Therefore the type and amount of pesticides applied to the arable land will be affected by climatic changes.

Changes in atmospheric [CO₂], temperature, rainfall and pest prevalence, each alone or combined will change the environmental impacts of agricultural product systems. The question is to what extent. Even though LCA is a suitable methodology to answer that question, it has, to the best of our knowledge, rarely been applied to do so. Niero *et al.*

(2015) studied the environmental impacts of Danish spring barley under changing climate circumstances. In contrast to these authors' approach, the assumptions for the future climatic circumstances on which this paper is based, are more moderate. We worked with an atmospheric [CO₂] of 530 ppm, and an average temperature increase of 2°C, whereas Niero *et al.* (2015) assume a worst-case scenario of 700 ppm and a temperature increase of 5°C. In addition, this study considers different soils and local climates.

This paper is thus a comparative case study of barley produced in Denmark under current and future climatic circumstances aiming at answering the following question: How do the environmental impacts of barley cultivation in Denmark change when going from the current (400 ppm) to a future (2050, 530 ppm CO₂) atmospheric [CO₂] with the accompanying changes in the climatic conditions?

2. Methods

Life Cycle Assessment (LCA) is a comprehensive methodology to assess the environmental impacts of a product, service, or system over its entire life cycle. As defined in ISO 14040 (ISO, 2006), LCA consists of 4 phases:

1. Goal & Scope definition, in which the product is described, and the assessment aim and method are defined;
2. Life Cycle Inventory (LCI), in which all flows between the product system and the environment are mapped and quantified,
3. Life Cycle Impact Assessment (LCIA), in which the flows quantified in the LCI are classified and characterized, and possibly normalized.
4. Interpretation, done parallel to the first three phases, in which these phases are critically reflected on, leading to changes in the goal and scope, LCI, or LCIA.

In this paper, the current section covers the goal and scope definition, as well as the LCI. The results of the LCIA are presented in section 3 and discussed in section 4.

Within LCA, two modelling approaches are generally recognized: attributional LCA (aLCA) and consequential LCA (cLCA). aLCA focuses on modeling all environmentally relevant flows of energy and materials to and from the life cycle of a product (i.e. barley), whilst the aim of cLCA is to model only those environmentally relevant flows that change as a consequence of a possible decision (Finnveden *et al.*, 2009). aLCA was chosen as the assessment methodology. Since the primary focus of this paper is on how climate change affects the impacts of barley cultivation, and not on how the wider agricultural system changes as a consequence of changes in barley production, aLCA is the most appropriate methodology in this context.

2.1 Goals and scope

The functional unit used here to compare barley cultivation in Denmark under current and future atmospheric CO₂ concentrations (“atmospheric [CO₂]”) is 1 kg of spring barley at farm gate (i.e. cradle-to-gate LCA).

The assessed product system includes all activities specifically required to produce barley: production of seeds, soil preparation (ploughing and harrowing), fertilizer and pesticide application, harvesting and drying of the harvested grains. The boundary between the product system and the environment was set as described in Dijkman *et al.* (2012): the field in which barley is cultivated is part of the product system, including 1 meter of soil below and the air column above the field up to 100 meters. Once a substance crosses this system border it is considered an emission to the environment.

Process multi-functionalities in the foreground system are resolved using economic allocation. We deviate from the ISO 14040 standard (ISO, 2006) recommendation of system expansion and substitution, because an important by-product of barley production, straw, has different uses, for some of which a substitute is not easily found. Moreover, relying on allocation instead allows for a straightforward sensitivity check of the product system model. There are good arguments to be made both in favor of and against economic allocation (Ardente & Cellura, 2012). Here, it is used for two reasons. Firstly, economic data is available for all co-products to be allocated (barley and straw, pig meat and manure, and various feed crops and meals for pig production), allowing for allocation to be done consistently throughout the study. Secondly, allocating on the basis of properties such as mass and energy content do, in our opinion not reflect the motivation for production of one or more of the co-products to be allocated. Another option for allocation of agricultural products, the Cereal Unit (Brankatschk & Finkbeiner, 2014), could not be applied for all co-products and was therefore excluded.

The product system was modelled in GaBi 4.4.142.1 (PE-LBP, 2008) using the ecoinvent 2.2 database (Ecoinvent centre, 2007).

2.2 Scenarios

Two scenarios were defined: a 2010 scenario representing current climatic conditions and a scenario with climatic circumstances as they are projected for Denmark by 2050. These scenarios will be referred to as the 2010 and 2050 scenarios.

In the 2010 climate scenario, the average annual temperature is 10.3°C, with monthly averages between 2.4°C and 19.1°C. Annual precipitation is 660-950 mm, depending on the scenario (see Table 1), with June, July and August being the months with most rainfall. In the 2050 scenario it was assumed that the atmospheric [CO₂] has increased from ~400

ppm in 2010 to ~530 ppm in 2050. This is in line with the IPCC A1B scenario (IPCC, 2007), based on economic and cultural globalization, rapid economic growth and a population size which peaks in the middle of the 21st century and decreases hereafter. In the A1B scenario, the focus is on rapid introduction of new technologies. Energy provision in these scenarios is based on a combination of fossil, non-fossil and renewable energy sources. In terms of greenhouse gas emissions, the A1B scenario falls in the middle of the range of IPCC scenarios (IPCC, 2007) used for the third and fourth assessment reports. In the fifth assessment report, published after the research reported here was designed, new scenarios were defined which could not be included. Apart from higher atmospheric [CO₂], the 2050 scenario operates with higher temperatures and an altered rainfall distribution. The temperature and rainfall distributions used were based on a Northern French temperate maritime climate dataset included in PestLCI 2.0 (Dijkman *et al.*, 2012), under the assumption that the current climate in Northern France and Central Germany is comparable to the climate conditions expected in Denmark in 2050 (Henriksen *et al.*, 2013). In this scenario, the average temperature is 12.3°C (monthly averages between 4.8°C and 20.2°C), which is 2°C higher than the 2010 scenario. Moreover, more precipitation occurs in winter, and less in summer compared to the 2010 scenario: November, December and February now are the months with most precipitation. Changes in atmospheric ozone concentrations have not been included in this study.

Within both the 2010 and 2050 scenarios four sub-scenarios were defined (see Table 1). These sub-scenarios are combinations of two different soil types present in Denmark (sandy and sandy loam) and two local climates with different amounts of precipitation. The sandy soil, modelled after the Danish soil type classification numbers JB-3 and JB-4, consists of 75 % sand and 10 % clay, a pH of 5.1 and 1.0 % organic carbon. The sandy loam soil (JB-5 and JB-6) consists of 60 % sand, 11 % clay and has a pH of 5.4 and contains 2.1 % organic carbon. These soil types were selected, because they are the most frequently occurring soils in Denmark. Together these soils represent more than half of the Danish surface area: JB-3 and JB-4 soils cover 28 % of the Danish surface area, JB-5 and JB-6 cover 24.5 % (Mortensen, 1986). Sandy soils are found mostly in northern and western Jutland, sandy loam soils are found in eastern Jutland and on the islands (Mortensen, 1986). The main difference between the climates is the annual amount of precipitation: 650 mm/y and 950 mm/y in the dry and wet scenario respectively.

Table 1: Scenarios for barley cultivation

Main scenario	Subscenario							
	1		2		3		4	
	soil	climate	soil	climate	soil	climate	soil	climate
2010	sandy	wet	sandy	dry	sandy	wet	sandy	dry
2050					loam		loam	

2.3 Life Cycle Inventory Analysis

2.3.1 Yield

Danish spring barley grain yields in the 2010 main scenarios were approximately 4250 kg dry material (DM)/ha on a sandy soil and 4850 kg DM/ha on sandy loam soils. The crop was assumed to be grown in combination with a catch crop on both soils (Hamelin *et al.*, 2012). Yields in the 2050 main scenarios are assumed to be 10% lower, based on interpolations from the data by Doltra *et al.* (2012). This decrease reflects the combined effects of increased atmospheric [CO₂] and temperature.

2.3.2 Fertilization and nutrient emissions

In this study, nitrogen, phosphorous and potassium fertilization were taken into account, assuming that half the crop's N demand was fulfilled by application of pig manure. The composition of this manure was based on Hamelin (2013). Based on sales statistics for fertilizers in Denmark (Nielsen *et al.*, 2011), the amount of P and K not met with manure were modelled to be supplied by application of diammonium phosphate and potassium chloride. Calcium ammonium nitrate (CAN) was modelled to supplement manure and diammonium phosphate as N fertilizer.

The fertilizer inputs per hectare for the 2050 scenarios were assumed to be the same as those for the 2010 scenarios. The level of N fertilization is currently not determined by the plant's need, but rather by the levels of N emissions that are considered acceptable in terms of freshwater emissions (Olesen, personal communication, 9 April 2013). The fertilization level is therefore mainly a political decision, and hence outside this paper's scope. Table 2 shows the amounts of fertilizer applied to each of the soil types modeled in the sub-scenarios presented in Table 1. It was assumed that the synthetic fertilizer is transported 50 km by truck from a regional storehouse to the farmer.

Table 2: Fertilizer recommendations and amounts applied

Fertilizer demand and sources	Soil type					
	sandy			sandy loam		
	N	P	K	N	P	K
Fertilizer requirements ¹	109	22	45	97	22	45
<i>Fertilizer sources:</i>						
Manure	54.5 (72.7) ²	17.2	40.9	48.5 (64.7) ²	15.3	35.4
Diammonium phosphate	4.3	4.8	-	6.0	6.7	-
Calcium ammonium nitrate	50.2	-	-	42.5	-	-
Potassium chloride	-	-	4.1	-	-	8.6

1: Danish Ministry of Food, Agriculture and Fisheries (2009).

2: Danish farmers are allowed to apply an estimated 75% efficiency of pig manure in replacing mineral fertilizer, and can hence apply 133% of the recommended dose (Danish Ministry of Food, Agriculture and Fisheries (2009)).

Lime (850 kg/ha) was assumed to be applied once every 5 years in order to maintain soil pH and yields (Hamelin, 2013). An application of 170 kg/ha annually was hence allocated to the barley production for all scenarios. Here, an estimated 200 km transport from plant to farm was assumed.

Emissions of nitrogen-containing gaseous conversion products of both mineral fertilizers and manure were calculated using the emission factors given in Hamelin (2013). Leaching of nitrate to water was modelled by Hamelin (personal communication, 19 April 2013). In accordance with the emission factors presented by this author, it was assumed that 5 % of P surpluses and 0 % of K surpluses are emitted to surface freshwater recipients. K emissions are set to 0 % of the surplus since these do not contribute to any of the impact categories considered. A fertilizer surplus is here defined as the difference between the amount of mineral applied and the amount of mineral contained in the parts of the crop removed from the field. The applied emission factors are summarized in Table 3.

For the 2050 scenarios the 2010 emissions factors were considered representative and hence applied. Nitrate leaching to water was based on interpolation of N leaching results from Doltra *et al.* (2012), showing that as a consequence of the predicted change in precipitation patterns, emissions will increase with 2 % and 50 % in 2050 for sandy and sandy loam soils, respectively.

Table 3: Emission flows from fertilizer during barley cultivation, 2010 scenario

N flows		
NH ₃ to air (kg NH ₃ -N/kg N applied)		
- from mineral fertilizers	0.020	
- from manure	0.12	
	0.004	during application, manure only
N ₂ O to air (kg N ₂ O-N/kg N applied)		
- from mineral fertilizers	0.01	
- from manure	0.01	
- from decaying crops	0.01	
NO _x to air (only NO) (kg NO-N/kg N)		
- from fertilizer	0.011	per kg N applied
- from decaying crop residues	0.007	per kg N present
NO ₃ ⁻ to water (kg NO ₃ ⁻ -N/ha/y)		
- wet climate	31/26	on sand resp. sandy loam soil
- dry climate	25/21	on sand resp. sandy loam soil
P flows		
P to water	5 % of surplus	
K flows		
K to water	0 % of surplus	

2.3.3 Manure

Manure was modelled as a by-product from pig farming. The inputs to the pig production considered are feed, and heat, electricity and tap water for pig farm operation. These inputs are presented in Table 4. The amount of feed is based on a feed conversion ratio (i.e. the ratio between food consumed and weight gain) of 1.92 for weaners (0-30 kg) and 2.82 for finishers (30-100 kg, Danish Agriculture and Food Council, 2011). The feed composition for the 2010 and 2050 scenarios were obtained from Saxe (personal communication, 6 May 2013). The feed composition under the 2050 climatic scenarios is based on forecasted changes in feed crop composition that alter the applicability of the crop as a pig feed ingredient. The most marked changes were the decrease in wheat (-5 % compared to 2010), and the increased use of soy meal (+23 %). Feed constituents making up less than 0.6 % of the feed mass were cut off, resulting in 97.4 % of the feed mass being included.

Table 4: Inputs for pig farming, per kg pig live weight at the farm gate

Input	Mass	
Feed (kg)	2.55	
Feed composition	(2010)	(2050)
wheat	0.48	0.46
barley	0.25	0.25
soy meal	0.092	0.11
rape meal	0.068	0.068
sunflower meal	0.042	0.042
beet molasses	0.017	0.020
PFAD oil	0.013	0.013
Lime	0.012	0.012
Electricity (MJ) ¹	0.42	
Heat (MJ) ¹	0.47	
Tap water (MJ) ¹	0.35	

1: Data from Reckmann (2013)

2.3.4 Pesticide application and emissions

Pesticides used and application dates for spring barley production in the 2010 and 2050 scenarios were taken from Henriksen *et al.* (2013). These authors based their 2050 scenarios on current crop management practice in Central Germany and Northern France, because these areas currently have a climate similar to the climate modelled for Denmark in 2050 in terms of temperature conditions. In this study, we follow the assumption made in Henriksen *et al.* (2013) that the occurrence and intensity of pests in Central Germany and Northern France is a good approximation of the situation in Denmark in similar climatic circumstances. Table 5 lists the pesticides used in this study, as well as their application dates. Based on the current practice in Germany and France, an application of insecticide on loamy soil is omitted in the 2050 scenarios (Henriksen *et al.*, 2013). Since the season for crop growth in Denmark is expected to start earlier under future climate conditions, the pesticides used for spring barley production will also be applied earlier.

Table 5: Pesticides applied for spring barley cultivation

Product name	Active ingredient	Dose g a.i./ha ¹		Application date	
		2010	2050	2010	2050
Oxirtil (herbicide)	Thifensulfuron methyl	2.64	2.64	May 1	April 20
	Tribenuron methyl	1.34	1.34		
Comet (fungicide)	Pyraclostrobin	62.5	62.5	May 10	May 5
Opus (fungicide)	Epoxiconazole	31.3	31.3	May 10	May 5
Karate (insecticide) ²	λ -cyhalotrin	3.75	-	June 1	-

1: Calculated from the volumes listed by Henriksen *et al.* (2013) and product labels

2: Only applied on loamy soils in current practice (Henriksen *et al.*, 2013)

Pesticide emissions to air and surface water were calculated using PestLCI 2.1, a modified version of PestLCI 2.0 (Dijkman *et al.*, 2012). This model is suitable for our purposes because it allows for soil and climate-specific pesticide emission patterns. Modifications of the PestLCI model include a reworked approach towards macropore flow as described in Dijkman *et al.* (2014) and new soil profiles of typical Danish sandy (JB-3 and JB-4) and sandy loam (JB-5 and JB-6) soils (Greve & Breuning-Madsen, 1999). A Danish climate profile present in the model was customized to arrive at annual precipitation amounts of 660 and 950 mm/year, representative for the dry and wet climate sub-scenarios. For the 2050 scenarios, a climate data set from a French weather station in a temperate maritime climate was modified so that the annual total amount of precipitation matches the wet and dry Danish climate scenarios, thereby yielding a climate profile considered representative for the expected climatic conditions in Denmark in 2050.

2.3.5 Other agricultural activities

The soil preparation steps accounted for by the product system model are similar to those described in Hamelin *et al.* (2012) and will not be described in detail here. In a nutshell, the soil preparation steps accounted for cover ploughing, harrowing, and seedbed harrowing followed by rolling. Harrowing was modeled as spring tine harrowing on a sandy soil, and a rotary harrowing on sandy loam soil. The diesel consumption of these activities was adjusted to reflect Danish conditions according to Damgaard *et al.* (2001). For sandy soils, a diesel consumption adjustment factor of 0.9 was used in accordance with Hamelin *et al.* (2012). The same procedure was followed for the other agricultural machinery-related processes: sowing and application of pesticides. Mineral fertilizer was assumed to be applied with a broadcaster and manure was spread using a vacuum tank.

2.3.6 Allocation

Allocation was applied to split impacts of processes that result in more than one outputs: growing barley also produces straw, and the manure used as a fertilizer is a side-product of pig farming.

The average price of 1 kg of barley grains between 2006 and 2010 was DKK 1.11 (Statistics Denmark, 2013). The price for straw in Denmark is typically between DKK 0.15 and 0.25 per kg (Erfaland.dk, 2011), even though prices below DKK ~0.40 per kg are discouraged when the straw is sold for energy generation purposes (Hinge & Maegaard, 2005). Here a straw price of DKK 0.20 per kg was applied. Combined with a mass ratio for harvested grains:harvestable straw of 1.82, the allocation factor for barley grains was calculated to be 0.91 while the straw allocation factor amounts to 0.09. These allocation factors were used for both the 2010 and 2050 scenarios. Pig manure, here used as a fertilizer, is a by-product from pig production. The market price of a finisher pig with an assumed weight of 100 kg is DKK 400 (Danish Agriculture and Food Council, 2011). The price of pig slurry is DKK 70 per tonne (Hansen & Tersbøl, 2009), and a pig produces 470 kg slurry over its lifetime (Hamelin, 2012). Therefore the resulting allocation factor for pig slurry was 0.076.

2.3.7 Overview of processes

An overview of the processes used in this study is found in Supplementary Information 1.

2.4 Impact Assessment

Classification and characterization were done at midpoint level using the ReCiPe (H) methodology for the following impact categories: climate change, ozone depletion, terrestrial acidification, freshwater and marine eutrophication, ionizing radiation, particulate matter formation, photochemical oxidant formation, freshwater ecotoxicity, human toxicity, fossil depletion, metal depletion, water depletion, agricultural land occupation, natural land transformation, and urban land occupation. Human and freshwater ecotoxicity impacts from pesticide emissions to air and freshwater were characterized using the consensus model USEtox (Rosenbaum *et al.*, 2008), rather than the toxicity impact categories included in ReCiPe (H). This was done because we found USEtox to be better suited for inclusion of new chemicals. USEtox characterization factors for the pesticides applied in barley cultivation are listed in Table 6. It was assumed that the ReCiPe (H) and USEtox characterization factors can be applied under both 2010 and 2050 climatic circumstances.

Table 6: Characterization factors for pesticides used in barley cultivation

Emission compartment	Freshwater ecotoxicity (PAF m ³ day kg _{emitted} ⁻¹)		Human toxicity (cases kg _{emitted} ⁻¹)	
	Continental rural air	Continental freshwater	Continental rural air	Continental freshwater
Active ingredient				
Thifensulfuron methyl	3.56·10 ⁴	1.29·10 ⁵	9.44·10 ⁶	1.15·10 ⁵
Tribenuron methyl	1.55·10 ²	6.80·10 ²	5.34·10 ⁶	6.66·10 ⁶
Pyraclostrobin	1.33·10 ¹	2.40·10 ³	3.07·10 ⁷	1.89·10 ⁶
Epoxiconazole	4.43·10 ²	2.30·10 ⁴	8.43·10 ⁶	4.39·10 ⁵
λ-cyhalotrin	5.76·10 ⁵	1.39·10 ⁸	6.78·10 ⁶	5.89·10 ⁵

Thus, the choice of ReCiPe (H) supplemented with USEtox allows us to conduct a broad assessment of the impacts under current and future climatic circumstances, instead of a selection of impact categories that are selected because these are considered important for agricultural LCA: acidification, climate change, eutrophication, photochemical oxidant formation and resource depletion (see for example Torellas *et al.*, 2012), sometimes supplemented by toxicity impacts (see for example Nemecek *et al.*, 2011). However, environmental impacts that occur as a consequence of agriculture, such as changes in soil quality and biodiversity (Meier *et al.*, 2015), have not been included since no suitable LCIA methodologies capable of accounting for these impacts are available. Moreover, in the case of soil quality, the field is included in the technosphere. As a consequence, changes in soil quality are not environmental impacts affecting the ecosphere.

The characterized results were not normalized. The main purpose of normalization is supporting a further comparison of impacts across impact categories. This is not among the aims of this paper, removing the need for normalization.

2.5 Sensitivity Analyses

In the sensitivity analysis, a number of model parameters were tested to determine if, or how, changes in these would affect the conclusions.

First of all, the allocation factors for barley grains and straw for the 2050 scenarios were analyzed. Grain prices in Denmark have shown an increasing trend in the recent decades (Statistics Denmark, 2013). Meanwhile, focus on increasing the share of sustainable energy in the Danish electricity consumption has also led to an increased use of agricultural by-products for electricity generation (Bentsen, 2012). Because the Danish government aims at a fossil fuel free energy system in 2050 (Danish government, 2011) prices for biomass may increase more than grain prices. However, for both grain and straw the price increase cannot be foreseen. Since the relative increase determines the allocation factor of the impacts of barley cultivation, a ‘break-even’ point was calculated for the scenarios 2050-1 and

2050-3. 'Break-even' is defined as the allocation factor that would make the environmental impacts of the 2050 climatic circumstances equal those of 2010.

Other model parameters, selected on the basis of their large contribution to the environmental impacts observed from the model results, were increased by 10 % in order to determine how the environmental impacts, would respond to such changes. The following parameters were investigated: yield, share of pig manure in fertilization, and on-farm fuel consumption.

3. Results

The potential environmental impacts for the 4 scenarios for barley cultivation in 2010 are presented in Table 7. To ease the comparison across scenarios, the four rightmost columns show the relative results for each impact category, setting the impact with the highest score to 1. Figure 1 presents the relative impacts for the four 2050 scenarios, which are in this figure compared to the results for the 2010 scenarios.

Table 7: Characterized impacts for 1 kg of spring barley at farm gate for the four scenarios modelling the climate of 2010. See Table 1 for the scenario definitions

Environmental impact category	Abbreviation	Unit	Environmental impact, characterized				Environmental impact, relative ¹			
			Scenario				Scenario

1: For the relative results, the highest impact in each category was set to 1, and the other impacts in that category were expressed as a fraction of the highest impact.

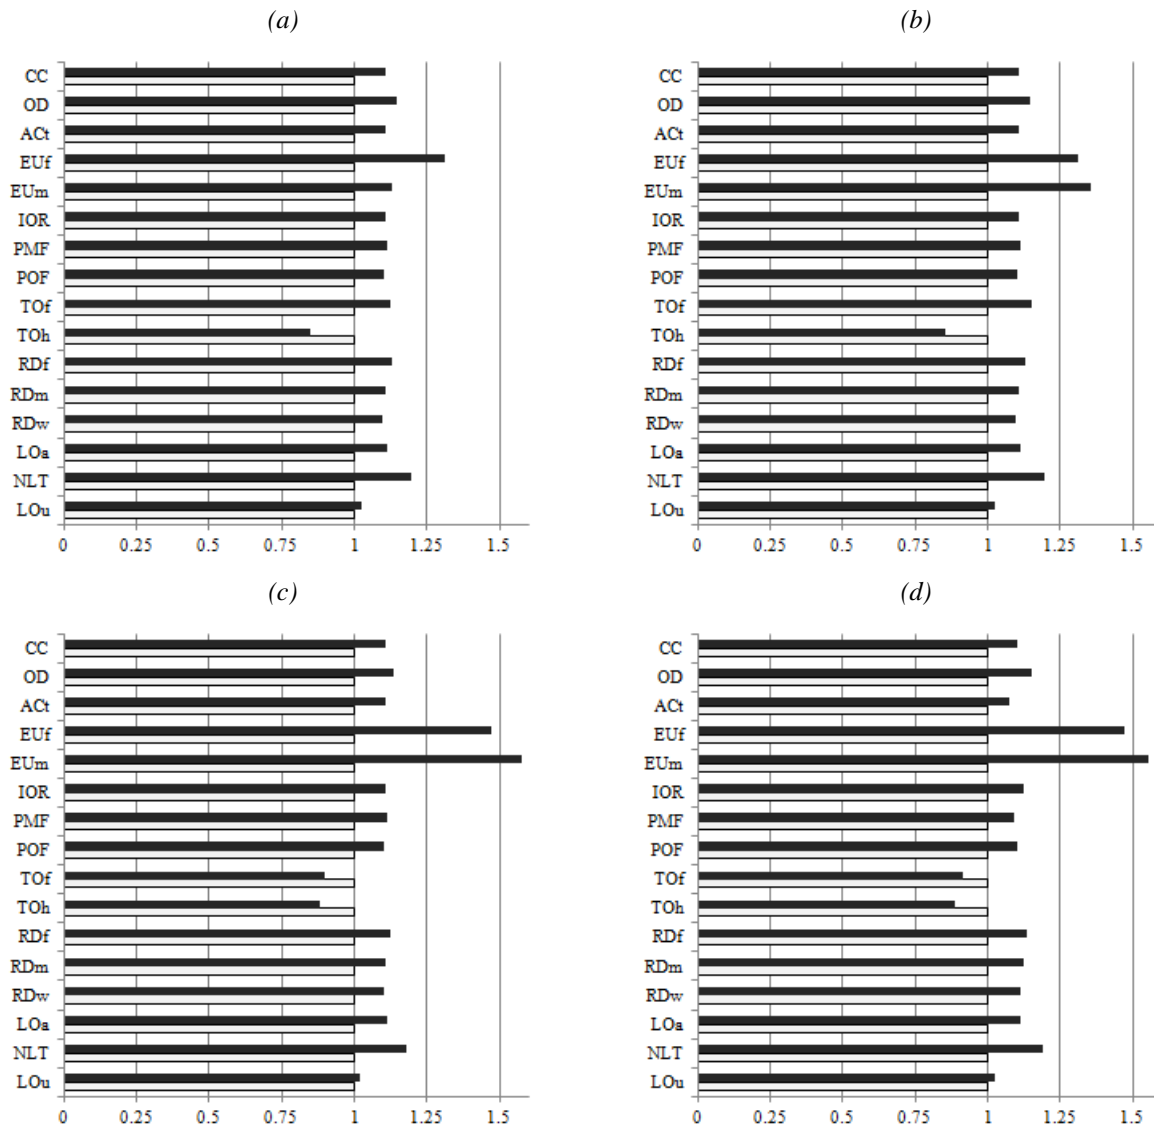

Figure 1: Comparison of characterized impacts between 2010 (white) and 2050 (black) scenarios, with 2010 results indexed at 1. Figure (a) presents subscenario 1, (b) subscenario 2, (c) subscenario 3, (d) subscenario 4. An overview of the scenarios is presented in Table 1, the acronyms are given in Table 7.

4. Discussion

4.1 Impacts under 2010 climate scenarios

Looking at Table 7, it can be concluded that the variation in environmental burdens arising from the cultivation of barley in Denmark is small, with minimal dependencies on soil and local climate. For the majority of impact categories the larger environmental burden is found for sub-scenarios 1 and 2 (sandy soil), compared to sub-scenarios 3 and 4 (sandy loam soil). This does not come as a surprise: barley cultivation on sandy soil produces lower yields, despite higher fertilizer inputs per hectare. However, for the impact categories ozone depletion, ionizing radiation and those

related to resource depletion, the higher environmental impacts are observed for sandy loam soils. In these cases, the use of heavier machinery and/or higher diesel combustion results in larger impacts.

4.2 Impacts under 2050 climate scenarios

Overall, the differences between 2010 and 2050 scenarios are in the order of up to 10 %, reflecting the changes in the input data for the 2010 and the 2050 scenarios, which typically were in the same order of magnitude. Looking at climate change, the driver for the changes we studied, a positive feedback mechanism is observed: the changes to crop production induced by climate change lead to additional climate change impacts.

The Figures 1a and 1b, barley cultivation on sandy soils, show that all impacts except human toxicity in the 2050 scenarios are higher than in the corresponding 2010 scenarios. In fact, most impacts are approximately 10 % higher in the 2050 scenario compared to the corresponding 2010 scenario, reflecting the predicted 10 % yield decrease in the 2050 scenarios. As a consequence of this yield decrease, more inputs are required to produce 1 kg of barley. Grain yield is thus an important parameter for explaining the increased level of impacts in 2050 for most of the impact categories.

The explanation for the >10 % increase in freshwater eutrophication is that while the fertilizer inputs are assumed to remain unchanged, the predicted reduction in biomass yields in 2050 results in an increased P surplus. As P run-off was modelled as a fixed fraction of this surplus, P emissions thus increase resulting in higher freshwater eutrophication impacts. For human toxicity, a reduced impact is observed in 2050. The human toxicity impact is, surprisingly, largely driven by clopyralid emissions during rapeseed cultivation for pig feed. PestLCI 2.0 modelling results showed that these emissions are lower under the 2050 climatic circumstances. This observation is explained by more frequent rainfall in the 2050 climatic circumstances: an assumption in PestLCI 2.0 is that all pesticide washes off from leaf surfaces to soil during the first rainfall event after pesticide application. Thus, more frequent rainfall reduces the air emissions due to volatilization from plant surfaces of clopyralid.

Figures 1c and 1d present the comparison of impact between the 2010 and 2050 climatic scenarios for barley cultivation on sandy loam soils. The trends for these two sub-scenarios are largely the same as observed in the sub-scenarios 2050-1 and 2050-2, with two exceptions: marine eutrophication and freshwater ecotoxicity impacts. The considerable increase in marine eutrophication is caused by higher N-emissions from sandy loam soils under the 2050 climatic circumstances. The increase on sandy loam soils (50 % increase) is more pronounced than on sandy soils, where emissions were 2 % higher. Freshwater toxicity impacts showed a decrease for the sandy loam soils in the 2050 scenario compared to the 2010 scenario, which contrasts with the increasing impacts on sandy soils (sub-scenarios 1

and 2). The explanation is the removal of a λ -cyhalotrin application in the 2050 scenario for the sandy loam soils (see Table 5). However, Henriksen *et al.* (2013) noted that a warmer climate and the resulting consequences for the crop composition is expected to improve conditions for aphids. Depending on the timing of barley cultivation and the effects of climate change on aphid predators, one can therefore speculate about the continuation of λ -cyhalotrin application in an altered climate. If this pesticide is applied in scenarios 2050-3 and 2050-4, the freshwater ecotoxicity impacts increase approximately 30 % in the 2050 scenarios, ending up 4.7 % and 6.9 % higher than the corresponding 2010 scenarios.

For modelling of the application of pesticides, we followed the approach outlined in Henriksen *et al.* (2013) and assumed that the presence and intensity of pests under future climatic circumstances in Denmark is similar to the current situation in regions where the climate currently is similar to the expected future climatic circumstances. However, given the difficulties in modelling the response of pests to climate change (Juroszek & Von Tiedemann, 2011), other assumptions can be made about the future pests and pesticide use. For example, Niero *et al.* (2015) assume a 25 % increase in the amount of pesticides used in barley production under future climatic circumstances. Had that approach been followed here for (a) barley cultivation alone or (b) for all crops in the product system, larger toxicity impacts would have been calculated. In case (a), the freshwater ecotoxicity and human toxicity results would increase 1.2-4.5 %, thus not changing the observations made regarding toxicity in the 2050 climatic scenarios. In case (b), the picture would change: in all scenarios, the human toxicity and freshwater ecotoxicity impacts would now be larger under 2050 climatic circumstances than under their 2010 equivalents.

From the results presented in Figure 1, we conclude that the impacts for barley cultivation are higher when the barley is produced under the climatic conditions representative for 2050, compared to the impacts from 2010 scenarios. This result is in accordance with Niero *et al.* (2015), who found that environmental impacts of barley cultivation increase under worst case future climatic circumstances, except for an optimistic scenario in which the rate of yield improvements of the past four decades are sustained in the future. As concluded in the present study, Niero *et al.* (2015) found that decreasing yields are the main driver for the increased environmental impacts. The conclusion that the yield has an important role in determining environmental impacts when comparing agricultural products (Cerutti *et al.*, 2013) or production systems (Nemecek *et al.*, 2011, De Backer *et al.*, 2012) when the functional unit is mass-based, is in line with previously published work. In both the current study and the study by Niero *et al.* (2015) on barley production, the same characterization factors are applied for both the 2010 and the 2050 climatic circumstances. It can, however, be

argued that new characterization factors should be calculated for the 2050 scenarios for all impact categories, in order to express changes in the environmental fate and in the effects of emissions as a consequence of altered climatic circumstances. For example, the rates of chemical transformations can be expected to be increased under elevated temperatures. Such a task is extensive and beyond the scope of this study, requiring that the cause-effect chains and all inputs of all models used to calculate the characterization factors are adapted to reflect higher temperatures, an altered rainfall patterns, etc.

4.3 Sensitivity analyses

The calculation of break-even points for share of impacts allocated to the barley grains is shown in Table 8. Since the impacts obtained for the scenarios based on sandy soils (2050-1 and 2050-2) and sandy loam soils (2050-3 and 2050-4) scenarios were found to be similar, break-even points are shown for just one scenario for each soil type.

The break-even point is the value that the allocation factor should have in the 2050 scenarios to reduce the impacts of the grains to the level of the corresponding 2010 scenario for a given impact category. The baseline allocation factor is 0.91, the break-even point for many impact categories in both scenarios assessed is around 0.83. To arrive at that allocation factor, the price of straw would have to double, compared to the price of barley grains. There are different factors that can affect the price of both the barley grains and straw. In a Danish context barley is used for malting and as pig feed, the first use being the most financially beneficial for the farmer. Malting requires grains with low protein content, whilst barley grains were found to have increased protein content under elevated $[CO_2]$ and temperature (Niero *et al.*, 2015). In addition, an increased temperature during grain filling was reported to result in lower fermentable sugar content (DaMatta *et al.*, 2010). Both effects would make barley less suitable for malting, which may result in lower barley grain prices. In contrast, current straw prices are around DKK 0.20/kg, whilst farmers are advised not to sell straw for less than double that price when the straw is to be used for bioenergy purposes. Given that the Danish government aims at having a fossil fuel free energy system in 2050 (Danish government, 2011), prices for straw may increase. Combining both trends, an allocation factor of 0.83 does not seem unrealistic.

In Table 8, some of the impact categories show a break-even point >1 . Since an allocation factor of 1 means that all impacts are allocated to the grains, in cases the allocation factor is >1 the environmental impacts of cultivating barley under 2050 climate circumstances are always lower than in the 2010 climate scenarios.

Table 8: Calculation of break-even points for the allocation factor between straw and barley grains

Impact category		Scenario	
		2050-1	2050-3
Climate change		0.83	0.84
Ozone depletion		0.83	0.83
Acidification	terrestrial	0.82	0.82
Eutrophication	freshwater	0.69	0.62
	marine	0.81	0.58
Ionizing radiation		0.83	0.83
Particulate matter formation		0.82	0.82
Photochemical oxidant formation		0.83	0.83
Toxicity	freshwater ecotoxicity	0.89	>1
	human	>1	>1
Resource depletion	fossil	0.83	0.83
	metal	0.82	0.82
	water	0.83	0.83
Land use related impacts	agricultural land occupation	0.82	0.82
	natural land transformation	0.87	0.86
	urban land occupation	0.89	0.89

Because the sensitivity analysis results were similar for the different scenarios, Table 9 only presents results for scenario 2010-1. In the table, the sensitivity is expressed as the percentage change in output resulting from a 10 % increase in input parameter for all impact categories.

Table 9: Sensitivity analysis for scenario 2010-1, showing the change in impacts (%) in the impact categories when the input parameters (allocation factor assigned to pig manure, fraction of fertilization done with manure, on-farm fuel consumption, yield) are increased 10 %.

Impact category		Allocation	Fertilization	Fuel cons.	Yield
Climate change		0.63	-2.1	1.5	-8.7
Ozone depletion		0.52	-3.5	3.8	-11
Acidification	terrestrial	0.21	5.1	0.1	-9.0
Eutrophication	freshwater	0.13	-0.057	0.0047	-35
	marine	0.22	0.17	0.018	-1.4
Ionizing radiation		0.38	-2.9	0.46	-8.7
Particulate matter formation		0.33	2.8	0.59	-9.1
Photochemical oxidant formation		0.39	-0.59	0.19	-8.3
Toxicity	freshwater ecotoxicity	6.4	0	0	-3.6
	human	9.4	0	0	-0.59
Resource depletion	fossil	0.61	-3.27	3.08	-10
	metal	0.23	-2.41	0.069	-8.7
	water	0.34	-2.23	0.25	-8.1
Land use related impacts	agricultural land occupation	0.18	-0.007	0.0002	-9.0
	natural land transformation	8.6	-1.3	2.8	-7.1
	urban land occupation	0.17	-0.62	0.072	-1.8

Table 9 illustrates again that the results are highly sensitive to changes in yields of barley cultivation. In this study, based on different modelling results presented by Doltra *et al.* (2012), it was assumed that the barley yields will

decrease with 10 % in the climate prevalent in Denmark in 2050. The yield decrease in the scenarios modelled by these authors varied between 4 and 18%, similar to results found by other authors: Borgesen and Olesen (2011) found a decrease in yields for wheat of 10 % , Clausen *et al.* (2012) found a yield reduction of 14 % (which was however not statistically significant). It can be shown that, even when assuming a yield decrease of 4 % in under the climatic circumstances of 2050, the environmental impacts are higher than in the current climate (except human toxicity when using sub-scenario 1 as a basis for this calculation). However, it may very well be that the yield decrease estimates used for this study may be conservative, because the effects of an increased ozone atmospheric concentration have not been included. Clausen *et al.* (2011) suggest that increasing ozone concentrations will reduce yields even more.

4.4 Mitigation options

In this study we assessed the environmental impacts of barley cultivation under 2050 climatic conditions. We have, however, not attempted to model the 2050 society and its policies. The reason for this modelling approach is our intention to study the effects of climate change on barley cultivation rather than the effect of human efforts to mitigate environmental impacts. However, policies can be expected to change in the future, and mitigation actions may be taken. Firstly, because it was found that most environmental impacts increase as a consequence of decreasing yield, changing to other barley cultivars may reduce the impacts under future climatic circumstances. A switch to a barley variety with a longer growing period would result in more biomass being accumulated, as well as in lower nitrogen emissions (Doltra *et al.*, 2012).

Secondly, from Figure 1 it can be seen that eutrophication impacts increase more than the other impact categories for most scenarios under the 2050 climatic circumstances. Eutrophication related to fertilizer use in agriculture already is a prioritized environmental challenge in Denmark (Kaas *et al.*, 1999). Therefore additional measures may be taken in the future, which are not considered in this study. For example, Doltra *et al.* (2012) discuss altered management of catch crops to reduce N leaching, as well as switching to barley cultivars that have a longer growing period. Jeppesen *et al.* (2009) moreover suggested the re-establishment of riparian buffer zones or buffer zones in combination with highly P-adsorbing substrates to prevent P runoff to freshwater. In addition, pesticide consumption may decrease in the future, for example by a more targeted application of herbicides to the individual weed plants instead of the current practice of applying pesticides to an entire field (Djursing, 2013). Toxicity impacts may be reduced further by introducing new pesticides, which are more targeted and have a higher target organism toxicity and lower general (non-target organism) have lower toxicity potentials than the pesticides currently applied.

Conclusion

The potential environmental impacts modeled for the cultivation of 1 kg of barley in the climatic circumstances of 2050, compared to those of 2010, were found to be higher in all impact categories assessed, except toxicity. This increase was found to be driven mainly by a reduction in yield under future climate conditions. Modelling of current and future climatic circumstances was done for four sub-scenarios, showing minor differences between these sub-scenarios. The conclusion that impacts are higher under future climatic circumstances is valid when assuming that the environmental impacts of barley cultivation, producing both grains and straw, are assigned to the grains using an allocation factor of 0.91. A sensitivity analysis showed that a doubling of the straw price relative to the grain price changes the allocation of impacts in such a way that lower impacts are found for the 2050 climate scenario. Effects of technological developments or policy changes were not considered in defining the future climate scenarios, but a switch to higher yielding cultivars could reduce environmental impacts, as would measures to mitigate nutrient leaching and the introduction of new pesticides.

Acknowledgements

The authors would like to thank the project 'Development of genetically modified cereals adapted to the increased CO₂ levels of the future' funded by the Danish Ministry of Food, Agriculture and Fisheries for funding this project. Furthermore, we would like to thank Jørgen E. Olesen, Lorie Hamelin and Maria Nordborg for their help with the inventory analysis, and Peter Fantke and Anders Bjørn for their help in deriving characterization factors for pesticide ingredients needed to complete this study.
