14 **ABSTRACT:** With the increased numbers of nuclear power plants constructed along the east coast of
15 China, improved knowledge of radioactive sources and transport through different pathways between
16 land and sea is needed. ^{129}I and ^{127}I in two sediment cores from the East China Sea were analyzed. The
17 chronology by excess ^{210}Pb from two sediment cores was determined to cover the range of 1959-2010.
18 Significantly increased levels ($^{129}\text{I}/^{127}\text{I} = (15.0-75.0) \times 10^{-12}$) compared to the pre-nuclear value ($^{129}\text{I}/^{127}\text{I}$
19 $= 1.5 \times 10^{-12}$) were observed, with peaks in layers of 1959, 1966, 1971 and 1976 (1977) corresponding
20 to the atmospheric nuclear weapon tests at Pacific Proving Grounds and Lop Nor, and with high values
21 after the late 1970s related to the European reprocessing plants releases, of which the reprocessing

releases dominate the total amount of ^{129}I . In addition to ocean current transport, the combined action of Westerlies with Monsoon is an important driving force of large-scale pollutant dispersion from high latitude West Europe to middle latitude East Asia. Riverine input is the main pathway for the transport of radioactive pollutants from Lop Nor to the sea.

Capsule:

The sources and transportation pathway of anthropogenic ^{129}I in the ECS was investigated to evaluate the impact of the human nuclear activities and improve the understanding of pollutant dispersion.

Keywords: Iodine-129; sediment; Environmental dispersion; human nuclear activities; Lop Nor;

1. Introduction

Anthropogenic pollutants released into the environment can be preserved in terrestrial and marine system through atmospheric dispersion and deposition, precipitation leaching and riverine input, and sea currents transport. Enhancing knowledge on sources and transport pathways of pollutants is crucial. A large amount of radioactive substances have been released from human nuclear activities through atmospheric nuclear weapon tests (NWTs), nuclear accidents (NA) and the reprocessing of spent nuclear fuel (NFRPs) (UNSCEAR 2000). ^{129}I as a fission product of ^{235}U and ^{239}Pu has already entered the environment (Hou et al., 2013). Up to 2013, over 6500 kg of ^{129}I has been released from NFRPs mainly in Sellafield, La Hague and Marcoule, 150 kg from NWTs and 7.2 kg from NA (totality of Chernobyl and Fukushima), which highly overwhelmed the natural inventory of ^{129}I in surface environment (180 kg in hydrosphere, 60 kg in lithosphere, most exists in the ocean, with a natural $^{129}\text{I}/^{127}\text{I}$ atomic ratio of 1.5×10^{-12}) (Moren et al., 1998). Owing to the long half-life (15.7 Ma) of ^{129}I , high volatility and water solubility, conservative feature in the ocean, biophile characteristics and redox sensitivity of iodine, ^{129}I entered into both terrestrial and marine systems and can now be used as an environmental tracer in investigation of atmospheric dispersion of European NFRPs originated

47 pollutant (Moran et al., 1999), re-emission of ^{129}I from the contaminated seawater by NFRPs (Sellafield
48 and La Hague) to the atmosphere (Hou et al., 2009a), dispersion of Fukushima pollutants in North
49 Pacific Ocean (Stan-Sion et al., 2015; Chang, 2016), the circulation of California Current System and
50 the background value under the influence of Hanford site (Chang, 2016), and the long-term transfer
51 process of radioiodine from soil to the plant and translocation within soil in Chernobyl contaminated
52 surface (Handl et al., 1990).

53 Sediments can be ideal integrated archives of sequential environment signals from atmosphere,
54 biosphere, pedosphere and hydrosphere, which could supply radioactive sources information and trace
55 the relative transportation processes based on the temporal distributions of ^{129}I in both marine and
56 terrestrial environment. The marine current circulation from North Sea to Baltic Sea through the
57 Skagerrak and Kattegat was identified by liquid discharges from Sellafield and La Hague, and the
58 variation trend was constructed by analyzing the temporal distribution of ^{129}I in Baltic Sea sediment
59 (Aldahan et al., 2007). The process of close-in tropospheric bomb fallout from Nevada site that eroded
60 from drainage basin was traced based on the vertical profile of $^{129}\text{I}/^{127}\text{I}$ in Mississippi Delta sediments
61 (Oktay et al., 2000). The low-latitude gaseous pollutant transportation from PPG to the central
62 Philippines through trade winds was determined from the ^{129}I distribution in a lake sediment core
63 collected in the Philippines (Zhang et al., 2018). However, the transport and pathway of radioactive
64 pollution between the terrestrial and marine system is still not well known, especially the transport
65 pathway of atmospheric deposition on the ground into the marine system. Sediment cores from
66 epicontinental seas are the ideal choices for the study of the dynamics of transport from the land to the
67 sea. Our previous investigation on ^{129}I in a sediment core collected in Jiaozhou Bay, located in the
68 margin sea of the Yellow Sea, clearly showed signals from different nuclear activities (Fan et al., 2016).
69 Such kinds of investigations were not undertaken in the East China Sea (ECS) margin until April 2018,
70 although the most important area for pollutant dispersion research, since 39 nuclear power reactors are
71 installed nearby.

72 This work aims to investigate the sources and pathways of radioactive pollution in the margin of the
73 ECS by determination of ^{129}I distribution in two sediment cores collected there in 2010. The results will

74 also provide important data for evaluation the impact of different types of human nuclear activities on
75 the marine environment, and for understanding pollutant dispersion model in the case of accidents.

76 **2. Material and methods**

77 **2.1 Study area**

78 The ECS is a broad and shallow epicontinental sea between mainland China in the west, the Taiwan
79 Strait in the south, and the Yellow Sea in the north. Water circulation in the ECS is dominated by
80 oceanic intrusions of the northward Kuroshio Current (KC) and Taiwan Warm Current (TWC),
81 southward flow of the Yellow Sea Coastal Current (YSCC)) and mostly eastward flow of the
82 Changjiang Dilute Water (CDW) (northeastward in summer and southward or southeastward in winter
83 under the control of East Asian Monsoon) (Sasaki et al., 2008) (Fig. 1). The TWC after entering the
84 ECS is divided into two branches, with one to the southeast and another mingling with CDW. The CDW
85 with low salinity moves along the surface 10 m, carries large amount of fresh water (mean: 9.05×10^{11}
86 $\text{m}^3 \text{y}^{-1}$) and sediment (mean: $2.4 \times 10^8 \text{ ton y}^{-1}$) to the ECS from the Changjiang (Yangtze) River (Liu et
87 al., 2007). In the north of the Changjiang Estuary, there is the southeastwards Yellow Sea Coastal
88 Current (YSCC) driven by the winter monsoon to penetrate into the northern ECS, which remains steady
89 from October to next July, and disappears in August and September (Li et al., 2006). The north part of
90 YSCC water consists of the Liaonan Coastal Current and Lubei Coastal Current, which takes in the
91 fresh water input mainly from nearby Liao River and Yellow River to transport them out of the Bohai
92 Sea, and then moves southwards after crossing the east most of Shandong Peninsula to the south of 30°
93 N (Wei et al., 2011). The YSCC meets the CDW in the border (30° N) of the Yellow Sea and ECS with
94 loading material to ECS (Li et al., 2006), and formatting a converging zone around 30° N , 126° E (Fig.
95 1).

Fig. 1. Sampling site of two sediment cores with possible sources, the major sea currents in the East China Sea and the dominant wind direction in China (Wang et al. 2017, Chen et al., 2009). NA, Nuclear Accident; NWT, Nuclear Weapon Test; NFRPs, Nuclear Fuel Reprocessing Plants; EASM, East Asian summer monsoon; EAWM, East Asian winter monsoon; NEC, North Equatorial Current; KC, Kuroshio Current; YSCC, Yellow Sea Coastal Current; YSWC, Yellow Sea Warm Current; CDW, Changjiang Dilute Water. TWC, Taiwan Warm Current; The dashed-line boundary stands for the dividing line of monsoon region and westerly area. Sampling sites mainly receive fresh water from Yangtze River, Yellow River and Liao River through CDW and YSCC, and sea water from TWC, also is controlled by East Asian Monsoon.

The ECS shelf is located in the intense region of the East Asia Monsoon. The year prevailing wind direction is from the southeast with strong rainfall in summer and from the northwest featured with dry and cold in winter. The total riverine input would go further into the middle and outer shelf of ECS during stronger dry northwest winter monsoons, leading more sediment is moved towards the southeast (Fig. 1).

2.2 Material and core chronology

The two sediment cores, CORE-1 of 19 cm (31.5° N, 124.51° E) and CORE-2 of 22 cm (30.99° N, 124.99° E), were sampled near the 50m depth contour in the ECS (Fig.1) in Jun 2010. The sampling sites were situated in the converging region formed by YSCC, CDW and TWC (Wang et al., 2017). The sediment cores were sampled with 10-cm diameter Plexiglas Core Tubes and were sliced into 1-cm interval and then stored at 4 °C until laboratory analysis. The sliced sediment samples were first freeze-dried, and then ground and sieved through a 200-mesh sieve. After weighing and transferring the samples to a plastic counting container, the activities of ^{210}Pb were measured using HPGe gamma spectrometry (Canberra Be3830) with 35% relative counting efficiency to determine the accumulation

rate of CORE-1 is 0.37 ± 0.01 cm/a and CORE-2 is 0.42 ± 0.01 cm/a, and the detail of dating method was described in the Supplementary Information 1 (Wang et al., 2017). Both accumulation rates fall in the similar level with reported values in this area (Wang et al., 2017), which corresponds to the pattern that high accumulation rate is found in the southeast, driven by strong northwest winter monsoons, as discussed above. 19 samples of CORE-1 from depth of 0-19 cm corresponding to 1960-2010, and 22 samples of CORE-2 from depth of 0-22 cm corresponding to 1959-2010 were selected for iodine isotopes analysis. The time range of 1cm is 2.7 years for CORE-1 and 2.4 years for CORE-2, which suggests the age uncertainty for the entire profiles might be up to 3 years.

2.3 Determination method of iodine isotopes in the sediment

All the details of chemical reagents used here are described in the Supplementary Information 2. The iodine in the sediment was separated by combusting at 800 °C for 3 hours in a tube furnace (Catalytic Pyrolyser-4 Trio™ furnace, Raddec LTD, Southampton, UK). The detail analytical method has been reported elsewhere and is summarized in the Supplementary Information 2 (Hou et al., 2010). The measurement of $^{129}\text{I}/^{127}\text{I}$ atomic ratios was conducted using a 3 MV Tandem AMS system (HVEE) at Xi'an AMS Center, China, and the details of AMS system and measurement method for ^{129}I have also been reported elsewhere (Hou et al., 2010). The measured $^{129}\text{I}/^{127}\text{I}$ ratios in procedure blank were below 2×10^{-13} , which was at least 2 orders of magnitude lower than that in samples. The $^{129}\text{I}/^{127}\text{I}$ ratios in the samples were corrected by subtracting the blank. The stable iodine was measured using ICP-MS (Agilent 8800 ICP-MS) at the Xi'an AMS Center. Cs^+ was added as internal standard, 0.15 mol/L $\text{NH}_3 \cdot \text{H}_2\text{O}$ is used as wash solution between samples. The detection limit of this method is lower than 0.02 ng/L, which is more than 10 times higher than the procedure blank and at least 3 orders of magnitude lower than the samples.

3. Result

3.1 ^{127}I and ^{129}I level in the sediment cores from the ECS

The analytical results of ^{127}I and ^{129}I in the two sediment cores show that the ^{127}I concentrations are 5.0-37.2 $\mu\text{g/g}$ in CORE-1 and 15.0-42.5 $\mu\text{g/g}$ in CORE-2 (Fig. 2). The iodine in marine sediment mainly originates from decomposition of biota debris with high iodine content (marine algae: 10-6000 $\mu\text{g/g}$, most values: 200-300 $\mu\text{g/g}$, mineral < 1 $\mu\text{g/g}$), which absorbs and concentrates iodine from seawater (around 50 $\mu\text{g/L}$) (Hou et al., 2010; Hou et al., 1998; Price and Calvert, 1973). The ^{127}I concentrations in CORE-1 (5.0-37.0 $\mu\text{g/g}$) and CORE-2 (15.0-42.5 $\mu\text{g/g}$) is lower than that in most marine sediments, including those from Oregon (98-243 $\mu\text{g/g}$), Kattegat (100-200 $\mu\text{g/g}$) and Baltic Sea (42.7-75.9 $\mu\text{g/g}$) (Moran et al. 1998; López-Gutiérrez et al., 2004; Aldahan et al., 2007), but higher than most values of lake sediments collected from Sweden (5.0-10.0 $\mu\text{g/g}$) and Philippines (2.97-20 $\mu\text{g/g}$) (Englund et al., 2008; Zhang et al., 2018). The values are in the similar level with that in the mixed zone of river and ocean, such as Jiaozhou Bay (20-36 $\mu\text{g/g}$) and the Mississippi River Delta (5.7-34.3 $\mu\text{g/g}$) (Fan et al., 2016; Oktay et al., 2000) (Table SI2). This indicates that the sampling sites are located in the mixed zone of river and ocean input.

Large variation of ^{129}I concentrations were observed in the two sediment cores, i.e. $(0.05-1.2) \times 10^7$ atoms/g in CORE-1 and $(0.13-1.2) \times 10^7$ atoms/g in CORE-2 (Fig. 2). More than one order of magnitude differences in ^{129}I concentrations in the two depth profiles should be attributed to the different sources of ^{129}I accumulated in the sediment cores. The high variation might also result from the variation of iodine into the sediment in different period. To overcome the influence of different input and integration of iodine, the $^{129}\text{I}/^{127}\text{I}$ atomic ratio is often used to investigate the source of ^{129}I . The $^{129}\text{I}/^{127}\text{I}$ atomic ratios of $(17-65) \times 10^{-12}$ for CORE-1, and $(15-66) \times 10^{-12}$ for CORE-2 are more than one order of magnitude higher than the pre-nuclear level of $^{129}\text{I}/^{127}\text{I}$ ratios in marine system (1.5×10^{-12}) (Moran et al., 1998), indicating the ^{129}I in the sediment cores is mainly due to anthropogenic sources. However, this level is more than 2 orders of magnitude lower than that in marine sediments collected from directly affected area by reprocessing releases in Europe (10^{-8} - 10^{-9}) (López-Gutiérrez., 2004; Aldahan et al.,

2007), and also at least 2 orders of magnitude lower than that in terrestrial sediments collected from Sweden (10^{-9} - 10^{-8}) and Spain (10^{-11} - 10^{-9}) (Englund et al., 2008; Santos et al., 2007). This result is comparable to the $^{129}\text{I}/^{127}\text{I}$ ratios reported in sediment cores from East Asia, such as Jiaozhou Bay in Yellow Sea (10^{-12} - 10^{-10}) and Taal lake in Philippines (10^{-12} - 10^{-10}) (Fan et al., 2016; Zhang et al., 2018), indicating it falls to the present background level without direct influence from the nuclear facilities (Table SI2).

3.2 Distributions of ^{127}I and ^{129}I concentrations in the two sediment cores

Fig. 2. Depth profiles of ^{127}I and ^{129}I concentrations and in sediment CORE-1 and CORE-2 from the ECS (a). Depth profiles of $^{129}\text{I}/^{127}\text{I}$ atomic ratios within time in CORE-1 and CORE-2 collected in ECS (b). More drastically decreased ^{127}I along depth occurs in CORE-1. There is a less positive correlation between ^{129}I and ^{127}I concentrations in CORE-2 than CORE-1. Two synchronous peaks show in two cores around 1972 and 1976/1977, and a separate peak in 1966 found in CORE-1 and a distinct small high value around 1959 in CORE-2.

The depth profiles of ^{127}I and ^{129}I concentrations in the two sediment cores shows a gradually decreasing ^{127}I concentration from the top to about 12 cm in CORE-1 and then remaining at a constant low value of about 5.5 $\mu\text{g/g}$ in 13-21 cm (Fig. 2 a). A different distribution was observed in CORE-2 with a relative constant and high ^{127}I concentration of 27-42 $\mu\text{g/g}$ occurring in depth 0-15 cm, and then slightly decreasing to 15-32 $\mu\text{g/g}$ in the depth of 16-22 cm, which is still higher than that in the deeper part of CORE-1 (Fig. 2 a). The difference of ^{127}I depth profile between two cores might be induced by different deposition environments that often take place due to the rugged sea floor. Then the fluctuation of ^{127}I concentration along profile probably indicates the material source changing with time in a convergent zone comprised of CDW, YSCC and some TWC origin.

The significantly positive correlation between ^{129}I and ^{127}I concentrations in CORE-1 ($r = 0.97$, $P < 0.01$) indicates that ^{129}I and ^{127}I in the sediment have the same sources. However, the correlation between

¹²⁹I and ¹²⁷I in CORE-2 is less significant as that in CORE-1, especially in the deep layer of the sediment core (top 16 cm: $r = 0.81$, $P < 0.01$, 16-22 cm: $r = 0.50$, $P < 0.01$). This discrepancy might imply different sources of ¹²⁹I and ¹²⁷I. Apart from directly atmospheric deposition, ¹²⁹I in marine sediment is also derived from marine organisms, which absorb ¹²⁹I (iodine) from seawater during their lifetime. CORE-1 is located at the area with high concentration of riverine input from CDW and YSCC, which could supply both ¹²⁷I and ¹²⁹I, causing a significantly positive correlation between ¹²⁹I and ¹²⁷I in CORE-1. Due to the longer distance to the coast, a relative constant and high ¹²⁷I concentration was found in CORE-2 that implied more seawater input, while ¹²⁹I in this estuary area with the depth of only 50 m is mainly from riverine input as demonstrated by the declined trend of ¹²⁹I levels in surface seawater from the Changjiang River estuary towards the ECS shelf (Liu et al., 2016).

Although the depth profiles of ¹²⁷I and ¹²⁹I concentrations show differences in the two cores, the ¹²⁹I/¹²⁷I atomic ratios profiles in the two cores (Fig. 2 b) are similar, with relatively high and constant ¹²⁹I/¹²⁷I ratios ($(50-70) \times 10^{-12}$) in the upper 11-13 cm, followed by a dramatically decreased ratios down to 15×10^{-12} at the bottom. Meanwhile, several peaks in the lower part of two cores (before 1980) can be observed, which correspond to the years 1966, 1971, 1977 respectively in CORE-1, and 1959, 1971, 1976 in CORE-2. The slight time discrepancy between the two cores might be ascribed to the uncertainty of chronology. The missing peak around 1958-1961 in CORE-1 is attributed to the short length of 19 cm in CORE-1. The lack of a peak around 1966 in CORE-2 possibly is caused by the doubled ¹²⁷I concentration (Fig. 2 b). It is obvious that the deepest layers of both cores do not reach to the pre-nuclear age (before 1945), which restricts the discussion about pre-nuclear level of ¹²⁹I level in the ECS.

4. Discussion

4.1 Sources and pathways of ¹²⁹I in the sediment in the ECS

The anthropogenic ¹²⁹I in the ECS can potentially originate from (1) fallout of the atmospheric nuclear weapon tests (NWT) in 1945-1980; (2) releases of the Chernobyl nuclear accidents in 1986 and Fukushima accident in 2011; (3) releases of nuclear fuel reprocessing plants (NFRPs) and nuclear power

plants (NPPs) operating in 1959-2010. The profiles of $^{129}\text{I}/^{127}\text{I}$ ratios in the two sediment cores (CORE-1: 1960-2010, CORE-2: 1959-2010) are compared with the time distribution of atmospheric nuclear weapons tests and the annual discharges of ^{129}I from the nuclear fuel reprocessing plants at La Hague, Sellafield and Marcoule (Fig. 3) in order to understand the sources of ^{129}I in these sediment cores.

220

Fig. 3. Comparison of measured $^{129}\text{I}/^{127}\text{I}$ ratios in the sediment cores from ECS (a) with that from Jiaozhou Bay sediment (b) (Fan et al., 2016), NWT fission yield (c) (UNSCEAR 2000), marine discharges and air discharges of ^{129}I from NFRPs (d) (Hou et al., 2009b). The first 1959 peak in CORE-2 and Jiaozhou Bay corresponds to the NWTs around 1958; The second peak equals to the NWTs in 1961-1962; The next two peaks relate to two periods of Chinese NWTs; The high $^{129}\text{I}/^{127}\text{I}$ ratios since late 1970s correspond to NFRPs release.

4.1.1 ^{129}I from PPG (Pacific Proving Grounds) by ocean current

The first high $^{129}\text{I}/^{127}\text{I}$ value (19.2×10^{-12}) at 22 cm (1959) compared to the nearby values (15×10^{-12}) in 18-21 cm from CORE-2 might indicate ^{129}I input from atmospheric NWTs. Due to a global atmospheric fallout lag of about 1-2 years (Zhang et al., 2018), the hysteresis quality of marine sediment record and the uncertainty of chronology (maximum ± 3 years), the NWTs during 1956-1958 (1959-1960 is the moratorium period) should be considered (Fig. 3 c). Since the 2-times higher fission yield at PPG (27.63 Mt) than the total yield (14.78 Mt) of other tests (Nevada, Novaya Zemlya and Semipalatinsk) during this period and the relatively short distance (4700 km) to the sampling sites, the first high value is ascribed to the atmospheric nuclear weapons tests at PPG (1956-1958) (UNSCEAR

2000). Apart from global fallout of the NWTs at PPG, the high water soluble ^{129}I from relatively high local deposition could enter into the seawater and then be transported to the ECS through the North Equatorial Current (NEC) and then the Kuroshio (Fig. 1 North Pacific Gyre). Many observations on anthropogenic radionuclides in the West Pacific have indicated sources from the NWTs at PPG, such as ^{129}I peak in 1959 in coral samples collected in the South China Sea (Chang et al., 2016; Bautista et al., 2016), plutonium isotopes in sediment cores collected from the ECS (Wang et al., 2017), Pearl River Estuary (Wu et al., 2014), and even a peak of ^{129}I in 1957 in sediment from Jiaozhou Bay (Yellow Sea, China), further north of the study area (Fan et al., 2016).

4.1.2 ^{129}I source from NWTs during 1960-1980

The maximum $^{129}\text{I}/^{127}\text{I}$ peak (93.0×10^{-12}) appears at the depth of 17 cm in CORE-1 corresponding to 1966, and the same peak of ^{129}I concentration (2.3×10^6 atoms/g) is presented in 19 cm corresponding to 1966 in CORE-2 even without a $^{129}\text{I}/^{127}\text{I}$ peak which is obscured by the almost twofold of ^{127}I concentration ($31.8 \mu\text{g/g}$) than the adjacent ones ($19.4 \mu\text{g/g}$) (Fig. 2 a). The global fallout of the largest numbers of atmospheric NWTs in 1961-1962 should response for this peak (Fig. 3 c), and the 4 years' lag is explained by the uncertainty of chronology, the long sweep time from stratosphere and the hysteresis quality of marine sediment record. A similar ^{129}I peak at this period was also observed in sediment from Jiaozhou Bay in Yellow Sea (Fan et al., 2016) and coral samples from South China Sea (Chang et al., 2016). In addition, the signal was recorded by a ^{137}Cs peak in surrounding lake and marine sediments (Zheng et al., 2008; Su C and Huh C, 2002).

Two successive $^{129}\text{I}/^{127}\text{I}$ peaks along both sediment cores occurred in 1971-1977, at 15 cm depth (corresponding to 1971) and 13 cm depth (corresponding to 1977) in CORE-1, and at 17 cm depth (corresponding to 1971) and 15 cm (corresponding to 1976) in CORE-2. Although the 1976/1977 peaks are not significant and are followed by higher values after that (Fig. 3 a), the contribution of the elevated air release from Marcoule (France) since 1977 for these peaks could be excluded out due to the long distance and hysteresis quality of marine sediment record. Since the Partial Test Ban Treaty was signed in 1963, only some atmospheric testing was undertaken by China and France (Zheng et al., 2008). The low fission yields (mostly < 0.5 Mt, only one high yield bomb was 1.3 Mt in Aug 1968) and long

distance (in the south of 21° S) by French atmospheric NWTs in 1960-1974 makes the only possible origin for these two peaks to be from Lop Nor site, which conducted 22 atmospheric NWTs in 1964-1980. The relative high fission yield tests were made in 1967-1970, 1973, and 1976 respectively (Fig. 3 c), which correspond well with the $^{129}\text{I}/^{127}\text{I}$ peaks in the sediment cores (Fig. 3 a) with just 2-3 years lag. The first peak in 1971 should be attributed to the first extensive tests interval during 1967-1970 with 3 years' time lag. The second peak in 1976/1976 might be the result of the combinative signal of the two high fission yield tests in 1973 (1.5 Mt) and 1976 (2.3 Mt). The 2-3 years' time discrepancy can result from the hysteresis quality leading by transportation process. The specific transportation process is singled out to discuss in section 4.2 due to the scarce reports on the specified transportation of Chinese NWTs in mainland China.

4.1.3 Nuclear accidents

No significantly elevated ^{129}I concentrations or $^{129}\text{I}/^{127}\text{I}$ ratios were observed around 1986 and 2011 in the two cores indicating no significant contribution from the accidents at Chernobyl and Fukushima. The Chernobyl accident in 1986 released about 1.3-6 kg ^{129}I to the environment (Aldahan et al., 2007; Hou et al., 2009b). The main radioactive plume dispersed and deposited in Europe by means of the dominant east wind. Only a total deposition of 7.8-36 g ^{129}I mainly in north China is estimated according to the yield of 0.5-0.7% of the total ^{131}I that transported to China (Fan et al., 2016). The relatively small deposition and the high ^{129}I background from NFRPs since 1980 makes the Chernobyl accident a negligible contribution of ^{129}I in the ECS. It was estimated that Fukushima accident released about 1.2 kg ^{129}I (including 0.35 kg direct marine discharge) to the environment (Hou et al., 2013). However, the atmospheric releases dispersed eastwards and mostly deposited in the North Pacific Ocean, and the radioactive substances discharges to the sea including ^{129}I were mainly transported eastwards too as reported before (Tang et al., 2016), and the investigation on ^{129}I in the seawater from the ECS has also showed no detection signal of Fukushima nuclear accident even in August 2013 (Liu, et al., 2016).

4.1.4 ^{129}I source from nuclear fuel repressing plants by atmospheric dispersion

In the two cores, the $^{129}\text{I}/^{127}\text{I}$ ratios rise progressively from late 1970s and remain at a constant high level of $(54.7-75.6) \times 10^{12}$ afterwards, which is more than 2 folds higher than the lower part $((17-32) \times$

10¹²) except the peak value around 1966 layer in CORE-1. This might be attributed to the releases from La Hague (1966-), Sellafield (1951-) and Marcoule (1959-1997) in Europe. The atmospheric release of ¹²⁹I increased from late 1970s (Fig. 3 d) (Reithemier et al., 2006; Hou et al., 2009b), and kept the constant high value of 20 kg/y until 1996, then rapidly decreased to 4.6 kg/y because of the improved reprocessing technologies and the close of NFRP at Marcoule in 1997. However, the ¹²⁹I/¹²⁷I ratios in two sediment cores still remain the high value from the late 1990s. The re-emission of ¹²⁹I in European seawater discharged from the NFRPs might be responsible. The ¹²⁹I/¹²⁷I ratios up to 10⁻⁶ have been observed in the seawater in European seas (North Sea, Baltic Sea and Norwegian Sea) and Arctic Sea due to the increased marine discharges of ¹²⁹I at Sellafield and La Hague from 80 kg/y in 1995 to 350 kg/y in 2000 and this level remains high (Fig. 3 d) (Reithmerier et al., 2006; Hou et al., 2009b). The high level of ¹²⁹I with the similar ¹²⁹I/¹²⁷I ratio of 10⁻⁸-10⁻⁶ was found in aerosols and rainwater samples in the North Europe (Denmark, Germany and Sweden), confirming the re-emission of the marine discharged ¹²⁹I from NFRPs at Sellafield and La Hague to the atmosphere in Europe (Englund et al., 2010; Hou et al., 2009a). Based on the relatively constant high ¹²⁹I/¹²⁷I ratio in both cores from late 1970s, the amount of re-emitted ¹²⁹I from the seawater can be estimated to be about 15 kg/y to compensate for the reduced atmospheric discharges from 20 kg to 4.6 kg after 1997.

Even through the relative transportation of ¹²⁹I by Westerlies from Europe to Asia and even America has been frequently discussed (Fan et al, 2016; Zhang et al., 2018; Moran et al., 1999; Toyama et al., 2012), a typical process to deliver ¹²⁹I to the ECS with monsoon climate will be given below. The Westerlies mainly occupy the belt of 35° N-65° N and occur in the middle troposphere to lower stratosphere (around 1500m-12000m). The ¹²⁹I from NFRPs in Europe could not be directly deposited in study area due to the less influence of Westerlies due to the boundary with Monsoon from the Great Khingan mountain range in a southwesterly direction towards central Tibet around 32° N (Fig. 1) (Chen et al., 2009). The East Asia Winter Monsoon should be the main driving force for the ¹²⁹I moving southwards that carried by the Westerlies. When the East Asia Winter Monsoon (EAWM) prevails across Eurasia in Nov - May, the cold air from Mongolia and Siberia with high ¹²⁹I concentration spills southeastwards to the wide southeastern monsoon area of China. Higher values of ¹²⁹I/¹²⁷I ratios were

measured in rainwater collected in winter and spring from Xi'an (2.5×10^{-8} - 4×10^{-8}) than that in summer and autumn (around 1×10^{-8}), indicating the influence of the EAWM (Jiang, 2017). The two times higher ^{129}I deposition in spring in Tokyo compared to that in autumn is due to the spring prevailing western wind under the EAWM (Toyama et al., 2012). There is also agreement between high levels of ^{129}I level and the enhanced EAWM in Taal Lake (14° N) sediment core from Philippines (Zhang et al., 2018). The combination action of Westerlies with EAWM is the main force for the atmospheric ^{129}I originated from European NFRPs to be delivered to the sampling sites in ECS and the relative drainage basin of input rivers. The transfer process of ^{129}I from drainage basin to the sediment will be discussed in 4.2.2.

4.1.5 Other possible sources of ^{129}I

The influence of nearby operating nuclear power plants and other small reprocessing plants is expected to be negligible here. The ^{129}I produced in nuclear fuel as a fission product is usually well sealed inside the fuel elements, and only a small part of ^{129}I is released to the environment by reprocessing of the spent fuel or accidents of the reactor. The measurement of ^{129}I in sea water from the vicinity area of a Chinese NPPs ($< 7 \text{ km}$) showed no difference in the $^{129}\text{I}/^{127}\text{I}$ atomic ratios (8.29×10^{-11} - 9.45×10^{-10}) compared to that in the background area (He et al., 2011). The investigation on the distribution of ^{129}I in surface soil showed no elevated ^{129}I level nearby the NFRPs in China indicating no obvious contribution (Fan, 2013). There is no extra contribution of ^{129}I from the nearest Tokai NFRP which operating from 1977-2005 with about $1 \text{ kg } ^{129}\text{I}$ released to the environment in total, as demonstrated by the constant low ^{129}I level in the precipitation in Ishigaki-shima (24° N , 124° E) (Toyama et al., 2013) and in surface seawater around Japan (Suzuki et al., 2010) and ECS (Liu et al., 2016) until 2013 (Toyama et al., 2012). The influence from Chinese NFRPs, Guangyuan and Jiuquan reprocessing plants, operating from 1975-1991 and 1968-1984, can be excluded too. Although, the reported $^{129}\text{I}/^{127}\text{I}$ ratios in surface soil near Jiuquan is up to 3.8×10^{-8} , near Guangyuan is 5×10^{-9} , the $^{129}\text{I}/^{127}\text{I}$ ratios in surrounding area and most surface soil in China were 10^{-10} - 10^{-9} , indicating only some local influence (Fan, 2013).

4.2 The record of Lop Nor NWTs in the sediment core and its transportation pathway

The releases of the high yield tests in 1967-1970 and 1973-1976 at Lop Nor were well recorded in the sediment cores in the ECS as showed by the $^{129}\text{I}/^{127}\text{I}$ peaks in 1971 and 1976/7. The transportation of released ^{129}I might be carried by directly atmospheric dispersion and deposition and the following riverine input. The transportation processes are firstly discussed below.

4.2.1 Atmospheric transport from Lop Nor

A great amount of radioactive materials including ^{129}I from atmospheric NWTs at Lop Nor was injected to the troposphere at different height and even directly to the stratosphere with high yield due to the main air-drop explosion (except the 28 Dec 1966 by tower explosion) with average height over 500 m above the ground (UNSCEAR 2000), which was then dispersed to a large area due to the temporal atmospheric circulation conditions.

The radioactive substances released to less than 1000 m height mainly dispersed to the Taklimakan Desert and the downwind area with locally prevailing strong ENE winds from March to November, and less frequent WSW wind during winter showed in Fig. 4 a (Yang et al., 2015), and it would be impossible to reach to the sampling site in the ECS with over 5000 km southeast. The forward trajectories by the HYSPLIT model of air mass below 1000 m after most tests at Lop Nor moved southwestwards too (Fig. 4 b). The radioactive substances released to the height of 1000-6000 m, the major part of troposphere with strong westerly wind dominates throughout the year above Lop Nor (41° 30' N, 88° 30' E) mainly moved eastwards to the Pacific as records in Tokyo (Kuroda et al., 1965) and simulated trajectories (Fig. 4 c), with only the plume at 4000 m after the test of Sep. 29, 1969 possibly reaching South China, and not likely reaching the sampling sites (Fig. 4 d). The radioactive substances released to the height above 6000 m, where the Westerlies flows more quickly and straightly in the top of troposphere and bottom of stratosphere (6000-11000 m), moved straightforward to east but scarcely to the south China and the ECS as showed in the forward trajectory analysis by HYSPLIT model (Fig. 4 e and f) and the stratospheric strontium signal detected in north Japan (Kuroda et al., 1965). It can be therefore concluded that the ^{129}I record in the sediment cores in the ECS could not be a result of directly atmospheric transport and deposition to the ECS from Lop Nor.

Fig. 4. The wind rose of maximum wind speed in Ruoqiang County from 1980-2012 (a) (Yang et al., 2015). ENE winds lead most time with less frequent WSW winds; Forward trajectories in 500-1500 m after tests at Lop Nor dispersed to the Taklimakan Desert (b); Forward trajectories of air mass in 1500-6000 m after tests at Lop Nor mainly moved eastwards (c and d); Former trajectories of air mass above 6000 m after tests at Lop Nor moved eastwards (e and f).

4.2.2 Riverine transport of the radioactive substances from Lop Nor

The sampling sites are located in a convergence zone of ocean current (TWC) and terrestrial input through CDW and YSCC, of which the Changjiang River, Yellow River and Liao River might be responsible for the transportation of radioactive substance from Lop Nor to the ECS. Due to the over 7

times larger area of these drainage basins (Changjiang River: 1 800 000 km²; Yellow River: 750 000 km²; Liao River: 219 000 km²) than that of the ECS (353 000 km²) (Su C and Huh C, 2002), the leaching of ¹²⁹I deposited on the catchment from Lop Nor NWTs and European NFRPs through rain water wash-out could be an important pathway. The short residence time and shallow penetration depth of surface 10 cm in drainage basin soil (Hou et al., 2009b) promotes ¹²⁹I prior to leach out than the stable iodine and produce a relative higher ¹²⁹I/¹²⁷I ratio in river water than that in soil.

(1) Changjiang River input

Several southeastwards plumes after tests at Lop Nor (such as that at 1500 m after the test at Jul. 27 1973 in Fig. 4 b, plume at 3000 m and 4000 m after the test at Sep. 29 1969 in Fig. 4 d could bring the radioactive substances to the east edge of Tibet Plateau, where the two most important branches of Changjiang River, Jinsha River and Yalong River, located that covering over 30% of the total Changjiang Basin area. Although no ¹²⁹I data in water sample or soil sample from Jinsha River and Yalong River is available yet, the soluble and exchangeable iodine could be leached out due to the widely developed water erosion and anaerobic soil condition during plum rain season controlled by the monsoon climate (Hou et al., 2009b), and then transported to the ECS. The higher atomic ratios of ¹²⁹I/¹²⁷I in water sample (1000×10^{-12}) from Middle Changjiang River in Chongqing than that in the surface soil (south of 30° N $\leq 100 \times 10^{-12}$) (Fan, 2013; Chen, communication), and a decreasing trend of ¹²⁹I level in surface seawater from the estuary area to southeast along CDW (Liu et al. 2016) was both observed, indicating that ¹²⁹I can be leached out from the Changjiang Basin and therefore be an input source to the ECS. Then the ¹²⁹I can be preserved in study sediment as the death of marine organisms that concentrate iodine from seawater (Price et al., 1973) besides the directly atmospheric and terrestrial material bounded ¹²⁹I.

(2) Yellow River and Liao River transportation

Most of radioactive substances released from Lop Nor were transported eastward and northeastward and deposited in North China, where the catchment of the Yellow River and Liao River are located. ¹²⁹I deposited on soil tends to be easily leached out because of the dry weather, low vegetation coverage

and concentrated precipitation in the upstream area of Yellow River (Zhang et al., 2013). A higher $^{129}\text{I}/^{127}\text{I}$ ratio of 2000×10^{-12} was measured in the Yellow River water collected in Ningxia Province compared to that in the surface soil of surrounding area ($(100-1000) \times 10^{-12}$) (Fan, 2013; Chen, communication), indicating leaching out of ^{129}I from soil. A distinct $^{129}\text{I}/^{127}\text{I}$ ratio peak in 1970s in the sediment core from Jiaozhou Bay and high level ^{129}I in the coastal seawater in the Bohai Sea clearly recorded the Yellow River and Liao River input of ^{129}I from Lop Nor (Fan et al., 2016; Liu, 2017). The water enriched ^{129}I can then move further to the sampling sites through the YSCC.

The total amount of the annual ^{129}I input in 2013 is estimated to be 6.6×10^{11} atoms/ m^2/y by combining the three river inputs (Changjiang River: 1.5×10^{11} atoms/ m^2/y ; Yellow River: 2.5×10^{11} atoms/ m^2/y ; Liao River: 2.6×10^{11} atoms/ m^2/y for), which exceeds the direct atmospheric deposition (0.36×10^{11} - 4.3×10^{11} atoms/ m^2/y) as reported in Tokyo, that located in northeast 1400 km of study area (Toyama et al., 2012) (Supplementary Information 3), indicating riverine input is the primary source and pathway of ^{129}I derived from Lop Nor and the NFRPs in the sediment from ECS. The overall transit time of the whole processes is estimated to be 0.5-3 years which matches well with the 1-3 years lag in study sediment records (Supplementary Information 4).

5. Conclusion

Based on the results of ^{129}I in two sediment cores collected in the ECS, it can be concluded: (1) The ECS was significantly influenced by human nuclear activities, and the $^{129}\text{I}/^{127}\text{I}$ ratios are in the level of 10^{-11} ; (2) The radioactive substances in the sediment in the ECS mainly originated from the nuclear weapon tests at Pacific Proving Grounds before 1960, global NWTs fallout peak around 1963, Chinese nuclear weapon tests in 1967-1980, and the two European NFRPs from late 1970s; (3) The transportation through ocean currents is of great importance in the dispersing of radioactive substances from the low-latitude tests sites at PPG to middle latitude; (4) The radioactive substance released from the NWTs at Lop Nor and deposited in the downwind drainage basins contributed to the inventory in the sediment in the ECS through rainwater leaching of soil, riverine input and sea current transferring; (5) The constantly high level of ^{129}I in 1979-2010 in the sediment cores mainly resulted from the direct

atmospheric releases in 1979-1997 and the re-emission of the marine discharges in 1997-2010 from the European NFRPs; (6) The combined action of Westerlies with East Asian Winter Monsoon is the mainly driving force in the airborne radionuclides disperse from high latitude in West Europe to low latitude in East Asia.

Figures caption

Fig. 1. Sampling site of two sediment cores with possible sources, the major sea currents in the East China Sea and the dominant wind direction in China (Wang et al. 2017, Chen et al., 2009). NA, Nuclear Accident; NWT, Nuclear Weapon Test; NFRPs, Nuclear Fuel Reprocessing Plants; EASM, East Asian summer monsoon; EAWM, East Asian winter monsoon; NEC, North Equatorial Current; KC, Kuroshio Current; YSCC, Yellow Sea Coastal Current; YSWC, Yellow Sea Warm Current; CDW, Changjiang Dilute Water. TWC, Taiwan Warm Current; Boundry stands for the dividing line of monsoon region and westerly area. Sampling sites mainly receive fresh water from Yangtze River, Yellow River and Liao River through CDW and YSCC, and sea water from TWC, also is controlled by East Asian Monsoon.

Fig. 2. Depth profiles of ^{127}I and ^{129}I concentrations and in sediment CORE-1 and CORE-2 from the ECS (a). Depth profiles of $^{129}\text{I}/^{127}\text{I}$ atomic ratios within time in CORE-1 and CORE-2 collected in ECS (b). More drastically decreased ^{127}I along depth occurs in CORE-1. There is a less positive correlation between ^{129}I and ^{127}I concentrations in CORE-2 than CORE-1. Two synchronous peaks show in two cores around 1972 and 1976/1977, and a separate peak in 1966 found in CORE-1 and a distinct small high value around 1959 in CORE-2.

Fig. 3. Comparison of measured $^{129}\text{I}/^{127}\text{I}$ ratios in the sediment cores from ECS (a) with that from Jiaozhou Bay sediment (b) (Fan et al., 2016), NWT fission yield (c) (UNSCEAR 2000), marine discharges and air discharges of ^{129}I from NFRPs (d) (Hou et al., 2009b). The first 1959 peak in CORE-2 and Jiaozhou Bay corresponds to the NWTs around 1958; The second peak equals to the NWTs in 1961-1962; The next two peaks relate to two periods of Chinese NWTs; The high $^{129}\text{I}/^{127}\text{I}$ ratios since late 1970s correspond to NFRPs release.

Fig. 4. The wind rose of maximum wind speed in Ruoqiang County from 1980-2012 (a) (Yang et al., 2015). ENE winds lead most time with less frequent WSW winds; Forward trajectories in 500-1500 m after tests at Lop Nor dispersed to the Taklimakan Desert (b); Forward trajectories of air mass in 1500-6000 m after tests at Lop Nor mainly moved eastwards (c and d); Former trajectories of air mass above 6000 m after tests at Lop Nor moved eastwards (e and f).
