Abstract

The polymorphism of two-dimensional (2D) transition metal dichalcogenides (TMDs) and different electronic properties of the polymorphs make TMDs particularly promising materials in the context of the applications in electronics. Recently, local transformations from the semi-conducting trigonal prismatic H phase to the metallic octahedral T phase in 2D MoS₂ have been induced by electron irradiation [Nat. Nanotech. 9 (2014) 391], but the mechanism of the transformations remains elusive. Using density functional theory calculations, we study the energetics of the stable and metastable phases of 2D MoS₂ when additional charge, mechanical strain and vacancies are present. We also investigate the role of finite temperatures, which appear to be critical for the transformations. Based on the results of our calculations, we propose an explanation for the beam-induced transformations which are likely promoted

by charge redistribution in the monolayer due to electronic excitations combined with formation of vacancies under electron beam and build-up of the associated mechanical strain in the sample. As this mechanism should be relevant to other 2D TMDs, our results provide hints for further development and optimization of electron-beam-mediated engineering of the atomic structure and electronic properties of 2D TMDs with sub-nanometer resolution.

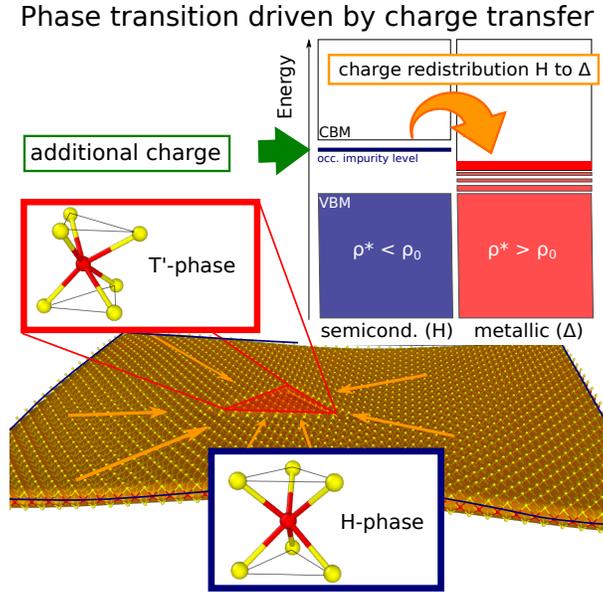

Figure 1: **TOC**

In the rapidly growing family of two-dimensional (2D) materials, monolayers of transition metal dichalcogenides (TMDs)^{1,2} are of particular interest, as many of them exist as several polymorphs with drastically different electronic characteristics. Specifically, 2D TMDs can have the stable trigonal prismatic (H), octahedral (T), and distorted octahedral (T' or T'') atomic configurations¹, and exhibit semiconductor, metal or topological insulator properties.^{3,4} Moreover, controllable transformations from one phase to another induced by either electron beam⁵ or Li-treatment^{6,7} or laser irradiation⁸ have been reported. Nanomaterials, in which phase transitions are associated with minute changes in the arrangement of atoms without altering material stoichiometry, not only exhibit rich physical behavior, but also open unique opportunities for the fabrication of

¹Since in this work we consider monolayers only, we omit the numbers used to denote phases of the bulk TMD systems, e.g., 2H or 1T.

electronic and optoelectronic devices. Indeed, metallic T' regions embedded into semiconducting H matrix in MoS₂⁷ and MoTe₂⁸ have been used as low-resistance contacts or to design MoS₂-FET transistors with sub 10 nm channel length.⁹

The energetics of the phases of various 2D TMDs and their alloys has extensively been studied by first-principles methods.^{10–13} As for MoS₂, the most widely used and correspondingly explored material among 2D TMD, ab initio calculations revealed that the pristine T-phase is unstable¹¹ and spontaneously relaxes to T', while the metastable T'-phase (T'-phase is 0.55 eV higher in energy than the H phase per formula unit, f.u.) returns to H after annealing, as experimentally observed.^{14,15} Normally, the transformations are mediated by strong electron doping of the system. Charge transfer upon alkaline (e.g., Li) atom intercalation leads to the transition from H to T' phase.^{14,16–21} The transformation from H to T' phase has also been attributed to electron transfer from Au or Ag substrate.²² The calculations^{13,15,23–27} showed that the T'-phase becomes energetically favorable over H-phase when the system is strongly n-type doped, which naturally occurs under alkali metal intercalation. Calculations with Li/Na adsorption demonstrated that about 0.4 alkali atoms per f.u. are needed to induce a transition to T' phase.^{25,26,28} The estimates obtained from calculations involving direct charging give a wider range of 0.08–0.8 e/f.u.^{25,29} Once alkaline atoms are removed, e.g., during exfoliation to produce single sheets, the barrier between the phases is apparently high enough to preserve the metastable T' phase under ambient conditions.

At the same time, local phase transitions from the H to T-phase have also been observed to occur in MoS₂ under in-situ electron beam irradiation in the transmission electron microscope (TEM).⁵ Specifically, formations of triangular regions of the T phase embedded into the H matrix have been reported in MoS₂ flakes. This is a surprising result, as it is unlikely that the exposure to the electron beam of atomically thin samples in the TEM will give rise to negative charging: the other way around, the sample may acquire positive charge, especially in wide-gap semiconductors with defects, due to emission of secondary electrons,³⁰ as convincingly demonstrated for BN nanotubes.³¹

Several other factors may be responsible for the phase transition. Re doping of the MoS₂ sheets

was necessary to observe the transformations. Moreover, the transitions were usually initiated by the formation of extended defects ("alpha stripes") located close to Re impurities.⁵ The transformed area depended exponentially on the electron dose, but not on temperature. However, temperatures above 400 °C were needed for the transformation to occur, and it is not clear what actual role the temperature played.

Defects, in particular S vacancies, were produced by the electron beam in the samples, which may have played an important role, as in MoTe₂.⁸ Vacancies in MoS₂ are known to cluster and form lines³² giving rise to substantial strain in the atomic network, so strain should also be taken into consideration.

In this work, using first-principles calculations, we carefully study the factors that may be responsible for the transformations under electron beam as observed in Ref. 5, namely (i) mechanical strain, (ii) finite concentration of vacancies, (iii) Re impurities and local charge transfer, (iv) electronic excitations and (v) temperature. Based on the results of our analysis, we propose a possible mechanism for the phase transition from the H to T' phase in MoS₂ under electron beam. We show that while all these factors decrease the energy difference between the H and T phases, it is most likely a combination of these that gives rise to the stabilization of the metastable T phase.

Details of calculations. To get insight into the energetics of the system, we performed density functional theory (DFT) calculations aimed at determining the energetically most favorable atomic configurations (phases) of MoS₂ and the corresponding electronic structures under different conditions. Plane wave basis set and projector augmented wave (PAW) description of the core regions were used, as implemented in the Vienna *ab initio* simulation Package (VASP) code.^{33,34} The exchange and correlations were described within the Perdew-Burke-Ernzerhof (PBE) generalized gradient approximation.³⁵ The structure relaxations were carried out with 600 eV plane wave cutoff. The convergence criterion for forces was set to 5 meV / Å. At minimum 10 Å of vacuum perpendicular to the monolayer MoS₂ was added to avoid spurious interaction between the periodic images of the sheets. The lattice parameters of the H, T, and T' pristine phases obtained in our calculations proved to be in a good agreement with the results of previous studies.^{15,25,27,36} While

the T phase was reported to appear under electron beam in Ref. 5, we found the T phase to be unstable with regard to the reconstruction to the T' phase, in accordance with Refs.^{15,25,27,36} We therefore concentrate on the T' phase. The DFT calculations, however, were carried out at zero temperature, while the experiments were done at 400-700 °C, and this may account for the difference in behavior. In any case, the mechanism of transformation from the H phase we propose is relevant for both T and T' phases. To account for the effects of temperature on the calculated energies, vibrational free energy was determined within harmonic approximation as implemented in the code Phonopy.³⁷ We employed 6×6 supercell and 2×2 k-point mesh for the H phase and 4×4 k-point mesh with Methfessel-Paxton smearing for the T' phase.

To investigate MoS₂ monolayers with different concentrations of impurities and co-existing different phases, we used super cells of different sizes. The largest supercell consisted of 20 × 20 unit cells corresponding to 1200 atoms. For these calculations, 300 eV plane wave cutoff and 10 meV/Å force convergence criterion were chosen. Test calculations with a cutoff of 400 eV gave essentially the same results for the energy difference between the configurations we considered. Such large supercells were necessary to include a large enough triangle-shaped metallic region into the semiconducting matrix in order to investigate charge transfer.

When comparing the energy of the phase patterned system (island of the T' phase embedded into H phase) to the reference system, the number of atoms (and electrons) need to match. However, the H/T interface is S deficient, and therefore the reference system is taken to contain a suitable S-vacancy line, since this has been found to be the lowest energy configuration for S deficient MoS₂.^{32,38}

The comparison of the energetics of these two systems yielded the energetically preferable configuration for different conditions, e.g., different concentrations of Re impurities.

Effects of strain. We started our analysis by addressing the role of mechanical strain. S vacancies produced by the electron beam in MoS₂ tend to cluster and form lines,³² which may give rise to substantial strain in the atomic network. Figure 2 presents strain defined as a difference in Mo-Mo atom separation near vacancy lines in comparison to that in pristine MoS₂. It is evident that

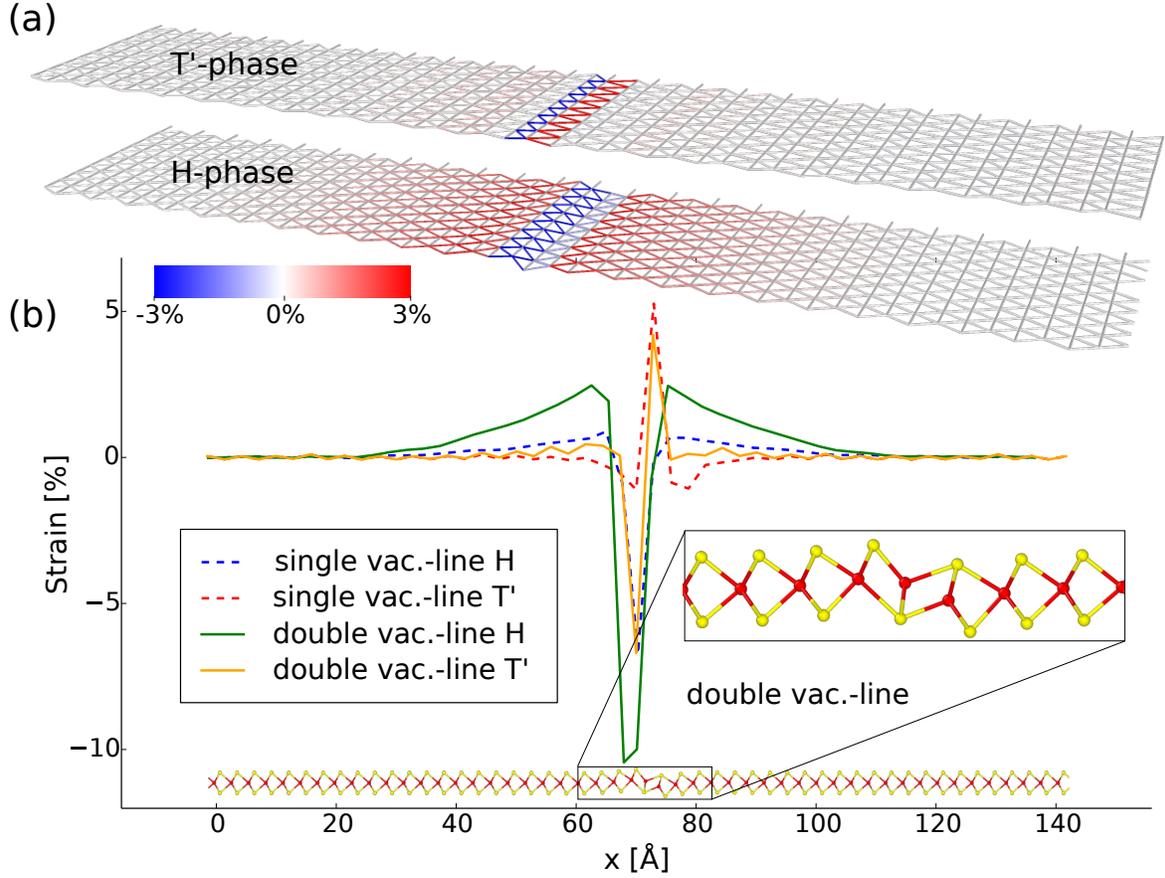

Figure 2: **Strain distribution along vacancy lines.** Line defects formed due to the coalescence of electron-beam created vacancies induce strain in 2D MoS₂. Panel (a) illustrates the strain distribution near a double vacancy line in the T'- and H-phases, respectively. (b) Strain along the x -axis oriented perpendicular to the vacancy line calculated for single and double vacancy lines in both phases. While vacancy lines in the T' phase give rise to local strain only, the long-ranged strain appears in the H phase.

while vacancy lines in the T' phase give rise to local strain only, long-ranged strain appears in the H phase, especially near double vacancy lines: the strain distribution spreads several nanometers into the pristine region.

In order to understand how strain affects the energetics of the system, we calculated the total energy per f.u. of the H and T' phases as a function of biaxial external strain, Figure 3(a). Figure 3(b) presents the energy difference ΔE between the phases. ΔE decreases with strain, but it is evident that about 14% of strain is required to make the T' phases energetically favorable. This value appears to be too high to be achieved in practice, especially taking into account that the

experimentally measured fracture strain for MoS₂ is reported to be 6% – 11%.³⁹ Thus strain alone cannot explain the observed transformations.

Role of vacancies. In our analysis, we assumed that strain originates from the extended line defects which have appeared due to the agglomeration of electron-irradiation-induced vacancies. As isolated vacancies can still be present in the system, we also repeated the calculations for H and T' phases with a single vacancy concentration of 3.1%. The results of calculations are also shown in Figure 3. When vacancies are present, ΔE decreases even in the unstrained system. Similar trend was reported⁸ for MoTe₂. As ΔE for the pristine system is much less in MoTe₂ (40 meV) than in MoS₂ (550 meV), only about 3% of vacancies were sufficient to make T' phase energetically favorable. Here, although vacancies decrease the energy difference between the phases, we can exclude them as the main reason for the transition from H to T' phase.

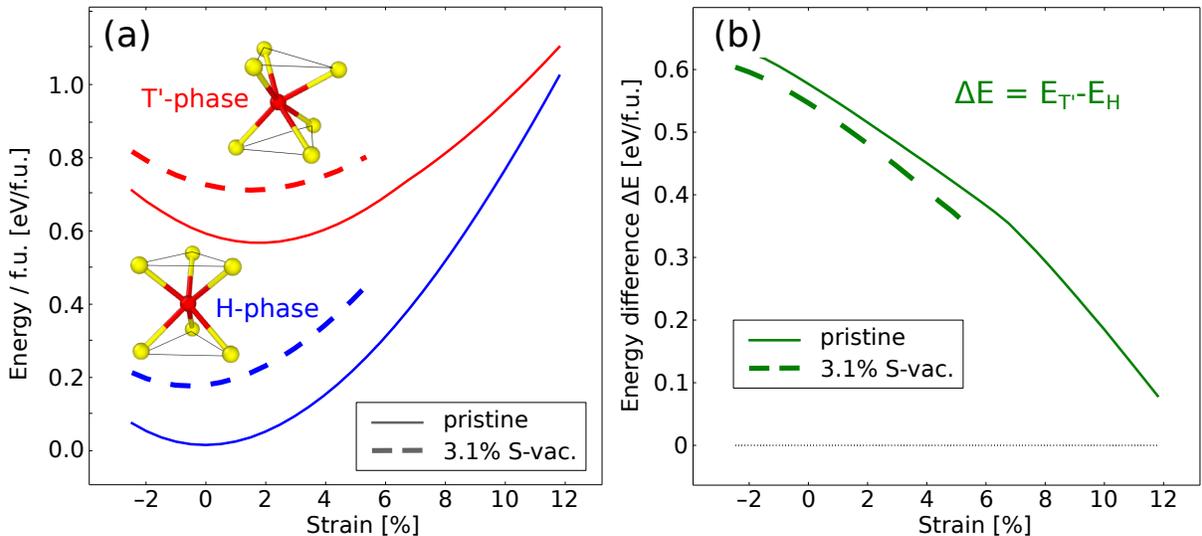

Figure 3: **Effects of mechanical strain on the energetics of the H and T' phases.** (a) Total energy per formula unit vs. biaxial strain for the semiconducting stable H-phase (blue) and the metallic metastable T'-phase (red). Solid lines stand for the pristine system, dashed lines for that with defects. Zero energy corresponds to the most stable H polymorph of MoS₂. (b) Energy difference between the phases $\Delta E = E_{T'} - E_H$ as a function of strain. Strain decreases ΔE , but unrealistically high values (about 14%) are required to make the T' phase energetically preferable over H phase ($\Delta E < 0$) either for the pristine system or that with vacancies.

Re impurities and local charge redistribution. So far we have considered separate phases, tacitly assuming that the transformation happens in the whole system. No interaction or charge

transfer was possible between the phases. In the experiment, however, the transformations were local, and only a small part of the system was converted to the T phase. Now we address a more realistic situation by considering a large supercell representing a T' phase triangle embedded in the H matrix, as in the experiment,⁵ see Figure 4. The energy of the system with the island is compared to that of a system with single vacancy line, which has the same number of atoms. We note that the energy cost of forming an interface is small and thus it does not prevent formation of the T'-triangle. We stress that substitutional Re impurities were present in the MoS₂ flakes used in the experiment.⁵ Re atom has an extra electron, as compared to Mo, so that such impurities⁴⁰ are perfect n-type dopants, giving rise to an occupied shallow state close to the conduction band minimum (CBM).⁴¹

At elevated temperatures these states should also result in considerable electron density at CBM. In this work, we assume that each Re atom donates one electron. The defect states associated with vacancies are lower than those impurity states, so that partial charge redistribution is possible, as schematically shown in Figure 4. Charge redistribution, in its turn, may affect the energetics.

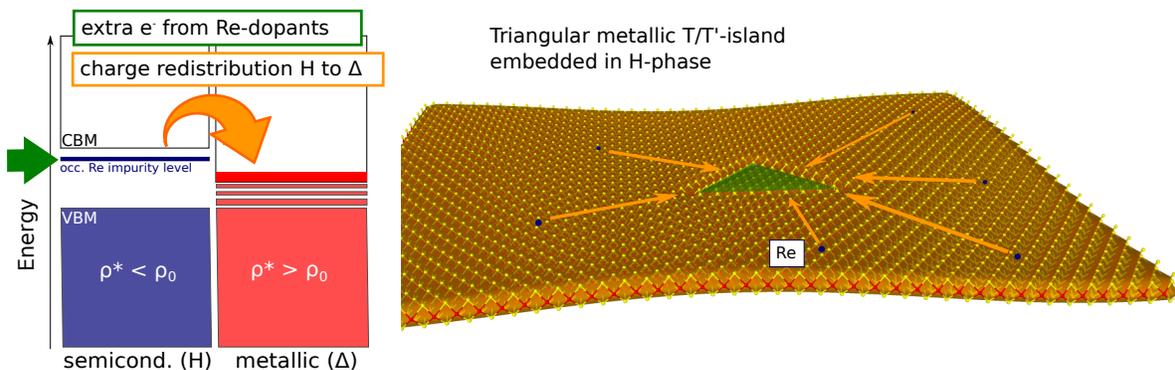

Figure 4: **Schematic representation of the charge redistribution model:** Electronic charge in the conduction band minimum originating from Re-impurities can partially go into the vacancy related states and triangle region of the metallic T' phase, so that T' phase island may get extra charge and become energetically favorable over the reference configuration with the vacancy line.

Our calculations showed that the vacancy line presented in Figure 4 has defect states in the band gap of MoS₂ which are higher in energy than the CBM of the metallic phase. To study possible redistribution of the charge, we carried out two sets of calculations. In the first approach we added

extra electrons to the supercell along with the positive background to fulfil the neutrality conditions required in the plane-wave calculations. We stress that the total energy depends on the amount of vacuum and other details of calculations in this case, and it is meaningless, as discussed previously,^{42,43} but the energy difference between the two configurations is a physically valid quantity. In the second approach we substantially increased the concentration of Re impurities well above the experimental values.

Within the first approach, our calculations showed that when extra electron charge is added to the system, the energy difference between the phases (normalized to the area of the T' island) decreases, Figure 5. The analysis of charge distribution indicates that extra electrons indeed go into the T' phase island, being localized close to its borders, as evident from the inset in Figure 5. Overall electron excess of +22% could be determined for the T'-triangle as compared to the uniform charge distribution. It is also evident, however, that considerable extra charge is required to make the T' phase energetically favorable.

In the second approach, randomly distributed (over the whole system) substitutional Re impurities were added to the systems. The calculated energy difference decreased similarly with increasing concentration of Re atoms, as evident from Figure 5. However, the necessary Re concentration to shift the energy balance towards T' proved to be unrealistically high, about 15%. As mentioned above, additional negative charge is not expected during the exposure of atomically thin samples to the high-energy electron beam in TEM experiments, so that although the extra negative charge should give rise to local transformation to the T' phase from the H phase with a vacancy line according to our results, this mechanism alone cannot explain the observations.

Effects of electronic excitations. The impacts of high-energy electrons onto the sample on a TEM grid give rise to core and valence electron excitations, as evident from electron energy loss spectra. Several mechanisms, including optical transitions, Auger-type processes, electron-electron and electron-phonon interactions are responsible for de-excitations. The typical times for non-radiative electron-hole recombination in the T' phase island with lateral size L should be considerably shorter than that for optical recombination in the H phase, indicating that de-

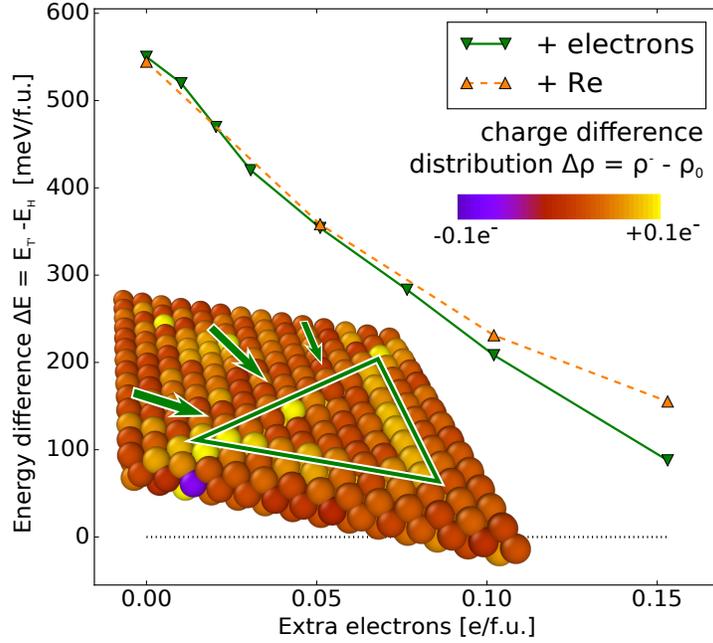

Figure 5: **Effects of local charging on the energetics of the phases.** Energy difference between the island of metallic T' phase embedded into H phase and the semiconducting reference system (H phase with a line defect). In the first computational approach we used, the number of electrons in the system is increased (solid green). In the second approach (dashed orange curve), substitutional Re impurities were introduced. The abscissa corresponds to the maximum transferable number of electrons in this case. Both curves clearly indicate that additional electrons decrease the energy difference between the systems. The inset illustrating the charge difference which corresponds to the calculation with increased electron number proves that charge transfer into the triangular metallic region (more precisely into the borders) indeed takes place. Bader analysis reveals an increase in the number of valence electrons in this region of +22% as compared to the situation with the uniformly distributed charge.

excitations occur mostly in the island after the localization of the excited electrons in this area. At the same time, the non-radiative recombination time should be much larger than in bulk metallic systems due to size quantization, as in semiconductor quantum dots,⁴⁴ provided that the energy difference Δ_e between the size-quantization-defined energy levels is larger than the optical phonon energies. This condition should be fulfilled in this case for L up to about 10 nm, as $\Delta_e \sim \hbar v_F/L$ is larger than 50 meV, characteristic optical phonon energies in MoS_2 ,⁴⁵ with $v_F \sim 10^6$ m/sec being the typical Fermi velocity in metallic systems. Taking the above considerations into account, one can assume that the electronic charge associated with the electrons excited in the H phase will be

localized in the T'-phase area, followed by electron-hole recombinations after several electron-phonon and electron-electron scattering events, as schematically illustrated in Figure 6(a).

This may give rise to a higher electron density in the T'-phase island, and as long as the sample is under the electron beam, a quasi-stationary state may develop. To investigate the energetics of the T'-island in the H matrix and the reference H system with the line defect, we carried out DFT calculations by setting zero occupancies of the states in a certain energy interval close to the valence band maximum in the combined T'-H system, and putting the corresponding electronic charge into the excited states. Such approximate approach has been previously used to describe excitation-induced semiconductor-to-metal transitions in monolayer MoTe₂. Our calculations showed that only a small fraction of 0.7% of the valence electrons has to be excited in order to tilt the balance towards the T'-phase in the 14 × 14 supercell with 10% T'-phase, which corresponds to ≈ 7% of the T'-valence electrons, Figure 6(b,c). This is comparable to the 5% excited valence electrons reported by Kolobov et. al.⁴⁶ for MoTe₂, where the dynamical pathway was reconstructed using DFT molecular dynamics. Although our approach is by no means rigorous, it indicates that electronic excitations can also decrease the energy difference between the system with and without the T'-phase island. The gain in energetics comes from the difference between the energy required to create an electron-hole pair in a semiconductor (band gap energy minus exciton binding energy) and a metal, which is essentially zero in the latter case. High power excitations (e.g. under laser irradiation) may even be sufficient to give rise to H to T transformations, but it is unlikely that electron beam in TEM under normal imaging conditions can alone give rise to the transformations.

Entropic contributions to the free energy at elevated temperatures. As the experiments were carried out at elevated temperatures, we also studied if entropic contributions can have noticeable effects on the thermodynamics of the system. The difference in the free energy of the T' and H phases can be expressed as

$$\Delta F = F_{T'} - F_H = \Delta U - T\Delta S \quad (1)$$

where ΔU is the difference in the internal energy analyzed previously, and the entropy difference

ΔS consists of two contributions; the vibrational entropy ΔS_{vib} and the electronic entropy ΔS_{elec} . Our DFT calculations of these contributions at a temperature of 1000 K revealed that both lower the energy difference between H-phase and T'-phase further facilitating the phase transition. The vibrational entropy difference between the pristine phases was evaluated to be $T\Delta S_{\text{vib}} \sim 100$ meV/f.u. shifting the free energy balance towards the T'-phase. The electronic entropy term is much smaller, and being of the order of $T\Delta S_{\text{elec}} \sim 10$ meV/f.u. can essentially be neglected.

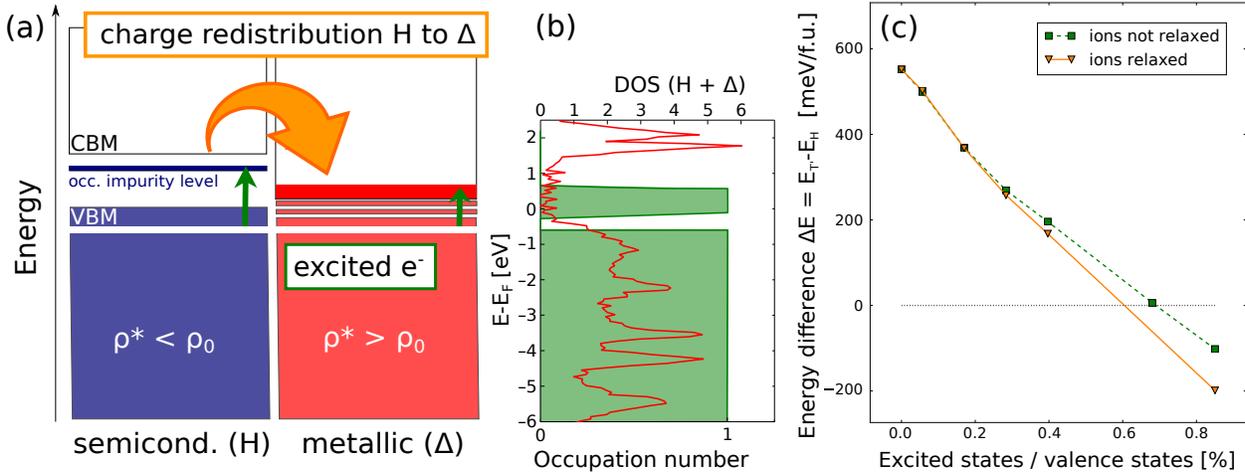

Figure 6: **Electronic excitations as a source for charge build-up.** (a) Schematic representation of the process. The microscope electron beam generates electronic excitations in the sample, with the excited electrons being localized in the T'-phase island prior to their non-radiative recombination with holes. A quasi-stationary state forms as long as the sample is under the electron beam. (b) Electronic density of state of states of the system representing a T'-phase island embedded into H matrix and the occupation numbers of the Kohn-Sham states used to mimic the effects of electron-beam-induced electronic excitations. (c) Energy difference between the metallic T' and the semiconducting H phases as a function of the excited states fraction with and without account for the relaxation of the positions of atoms.

The mechanism of local transformations from the H to T' phase induced by the electron beam.

Our analysis indicates that none of the considered factors such as mechanical strain, vacancies, local charging, Re impurities, electronic excitations, or entropic contributions alone can explain the local phase transitions observed in MoS₂ under electron beam irradiation.⁵ However, our simulations indicate that all these factors lower the energy difference between the T' and H phases, so that their combination may be responsible for the observed transformation. One possible scenario favoring the metallic phase could involve the combination of 4 – 6% local mechanical strain

($\Delta E_{\epsilon=4-6\%} \approx 150 - 300$ meV), 5 – 7% Re impurities ($\Delta E_{\text{Re}=5-7\%} \approx 150 - 200$ meV) and the effect of vibrational entropy $T\Delta S_{\text{vib},T=1000\text{K}} \approx 100$ meV. On the other hand 4 – 5% excited valence electrons in the metallic region would suffice to tilt the balance towards T'-phase ($\Delta E_{\text{exc}} \approx 550 - 650$ meV).

Based on our results, we suggest the following scenario of the transformation: The electron beam creates vacancies through knock-on damage, beam-induced chemical etching and possibly electronic excitations.^{47,48} The vacancies are highly mobile at elevated temperatures⁴⁹ and most of them cluster together into line defects.³² Indeed, the alpha stripes discussed in Ref. 5 appear very similar to the vacancy lines. They naturally give rise to the development of mechanical strain in the MoS₂ flake, as a fraction of atom in the system is lost. At the same time, the emerging vacancy lines are prerequisites for sulfur plane glides⁵ to form the T' phase: S atoms cannot move to the hollow site positions in the H phase unless the neighboring S atoms are removed.³⁸ These factors, together with the extra charge coming not from outside as in case of Li doping, but from Re impurities and quasi-stationary state involving electron excitation by primary high-energy electrons make the T'-phase regions energetically favorable. Moreover, isolated vacancies still present in the system also decrease the energy difference between the phases. High temperature plays several roles. First, it facilitates vacancy agglomeration and makes it easier for the atoms to go over potential barriers, which is required for local atomic reconstructions. Second, it decreases free energy difference between the phases mostly due to the changes in the vibrational degrees of freedom. The created T'-phase remains stable due to finite barriers between the configurations when the beam is switched off.

Our results not only shed light on the mechanism of the beam-induced phase transitions observed in MoS₂, but also, with account for the variations in energy difference between the phases, are relevant to other 2D TMDs, including recently proposed technetium dichalcogenides,⁵⁰ where the natural radioactivity may give rise to a higher concentration of chalcogen vacancies. The details of transitions should, however depend on several factors, like the electronic structure of the system with vacancies, mechanical properties, etc. The mechanism should also work in few-layer

systems, as the long-ranged van der Waals interaction between the layers only weakly depends on the atomic arrangement (trigonal prismatic in the H phase or octahedral in the T phase) of atoms in the sheets.⁵¹ The transformations can depend on the number of layers and the geometry of the sample, though. If we assume that S sputtering and thus vacancy production is more significant in the bottom-most layer, then it could be that the T'-phase is formed first (or only) there. If the whole system is Re-doped, then it could be easier to provide the additional charge required for the transformation and perhaps also electrostatic stability since there are now electrons around the T-domain in three dimensions.

The mechanism we discussed provides hints for further developments and optimization of perhaps most intriguing aspects of 2D materials engineering using electron beam, as the seamless, nanoscale modification of the fundamental physical properties opens for device and circuit design with unparalleled combinations of miniaturization and integration. The possibilities are numerous, and since the phase-transformations are reversible through annealing, TMDs may be used in rewritable electronics. The understanding of the involved mechanisms is essential to develop rational routes to such extreme material modification using scalable techniques, such as for instance high brightness electron beam lithography.
