Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

On the Activity – or Lack Thereof – of RuO₂ Based Electrodes in the Electrocatalytic Reduction of CO₂

ABSTRACT

RuO₂-based electrodes have been extensively studied for several electrochemical reactions. Earlier literature works claim RuO₂-based catalysts to be active also for the electrocatalytic conversion of CO₂ to methanol with high selectivity at very low overpotentials. Here we report a thorough investigation of RuO₂ films and particles for the electrocatalytic reduction of CO₂. The different experimental configurations explored in our work showed that H₂ is basically the only reaction product under CO₂ reduction conditions in contrast to earlier reports. In situ surface enhanced infrared absorption spectroscopy (SEIRAS) measurements revealed that CO bound to the RuO₂ surface, albeit acting solely as spectator species. Our experiments indicated that adsorbed CO cannot be reduced further to methanol or other CO₂ reduction products.

INTRODUCTION

The electrocatalytic reduction of CO₂ is a promising strategy to synthesize commodity chemicals and fuels exploiting renewable energy resources. Major breakthroughs are necessary to discover efficient catalysts capable to maximize the production of high-value products.¹⁻³ Copper is the most efficient known, monometallic catalyst capable to reduce CO₂ and CO to multi-carbon hydrocarbons and oxygenates like ethylene and ethanol.⁴⁻⁶ The electrochemical synthesis of methanol from CO₂ is more difficult and, to the best of our knowledge, with monometallic catalysts, this product has been observed only in minute amounts at high overpotentials.⁷ While the activity of mono and (bi)metallic transition metals have been largely mapped out,^{4,8} stable conductive oxides remain largely unexplored catalysts.

RuO_x-based materials have been extensively studied as electrodes for supercapacitors⁹ and as catalysts for the hydrogen evolution reaction,¹⁰ chlorine evolution reaction¹¹ and oxygen evolution

reaction.¹² Several earlier literature works claim RuO₂-based oxides to be active catalysts for the electrocatalytic reduction of CO₂ to methanol with high selectivity at very low overpotentials. To our knowledge, Bandi and co-workers are the first to explore this class of materials. They studied binary RuO₂/TiO₂ and multi-components RuO₂/TiO₂/SnO₂/MoO₂ mixtures reporting Faradaic efficiency for CH₃OH up to 24 % at ~ -0.15 V_{RHE} in 0.05 M H₂SO₄ (pH 1.2). They reported a Faradaic efficiency of 74 % by operating the RuO₂/TiO₂ catalysts in a phosphate buffer (pH 4) at an undefined potential labelled as “near water reduction potential”.^{13,14} They found that the performance of RuO₂/TiO₂ mixed oxides can be further improved by adding Cu species on the surface (up to $\sim 30\%$ Faradaic efficiency for a Cu-doped 75:25 Ru:Ti electrode).¹⁴ Faradaic efficiency towards CH₃OH up to 30% at -0.15 V_{RHE} were reported also with Cd and Cu modified RuO₂ electrodes in 0.5 M KHCO₃.¹⁵ Qu et al. studied RuO₂ particles supported on TiO₂ nanotubes and registered a selectivity towards CH₃OH up to 60% at -0.15 V_{RHE}.¹⁶ By comparing the performance of RuO₂ particles deposited on boron-doped diamond and TiO₂ substrates, Spataru et al. later postulated that the interaction between RuO₂ and the TiO₂ substrate is instrumental to achieve high yield of CH₃OH.¹⁶ More recently, Ullah et al. investigated Ir_{0.8}Ru_{0.2} films and reported the formation of a variety of oxygenates at -0.7 V_{RHE} in an organic buffer solution.¹⁷ Ab initio calculations have rationalized the aforementioned experimental findings by identifying possible reaction paths for the production of CH₃OH and CHOO⁻ with RuO₂, doped-RuO₂ and Ru-Ir catalysts.^{18–21}

Motivated by the preliminary studies presented above, we aimed at inspecting this class of materials for the electrocatalytic CO₂ reduction more in depth. The interest towards RuO₂ and other oxides is well motivated by their rich chemistry, which offers plenty of scope to tune their textural and electronic surface features.^{22–24} Indeed, this flexibility is potentially a strong asset for

tuning their electrocatalytic behavior, thus maximizing the production of desired compounds. Here we report a thorough investigation of RuO₂ films and particles for the electrocatalytic reduction of RuO₂. The electrochemical performance of this class of materials was thoroughly assessed, with particular attention to the formation of methanol or other oxygenates. We discuss the stark contrast between our results and prior literature reports.

EXPERIMENTAL METHODS

Electrodes Preparation

RuO₂ films were prepared by thermal decomposition of metal precursors (Ru(NO)NO₃ and RuCl₃) drop-casted onto etched Ti substrates. Ru-Ti and Ru-Sn mixed oxides were prepared starting from RuCl₃, TiCl₄ (attention, compounds reacts violently with water) and SnCl₂ solutions (0.15 M, 0.15 M and 0.5 M, respectively) using isopropanol as solvent. Once dried (room temperature), the electrodes were calcined at 450 °C (30 min at 90 °C, 3 °Cmin⁻¹ ramp to 450 °C, 1 h dwell time) in a tubular furnace under static air. Copper-doped Ru-Ti oxides were prepared following the procedure electrodeposition procedure reported by Bandi et al.¹⁴ RuO₂ particles (99.9% trace metals basis) were purchased from Sigma Aldrich and used as received. More information about the electrodes preparation can be found in the Supporting Information.

Electrochemical Measurements

CO₂ electrolysis experiments were carried out in a custom-made three electrode glass H-cell. The working electrode (WE) and CE compartments were separated by a Nafion® 117 proton conducting membrane. A gold mesh (GoodFellow 99.9%) was used as counter electrode (CE). The volume of the electrolyte in the WE compartment was 12 mL. The working electrode potential (E_{WE}) was referenced against a Hg/HgSO₄/sat. K₂SO₄ reference electrode (SI analytics) and converted to the reversible hydrogen (RHE) scale according to:

$$E_{\text{RHE}} (\text{V}) = E_{\text{WE}} + E_{\text{MSE}} + 0.059 * \text{pH}$$

Where E_{WE} and E_{MSE} are the set potential at the WE (vs. Hg/HgSO₄/sat. K₂SO₄) and the reference electrode potential (typically 0.664 V ± 5mV vs. E_{SHE}), respectively. The reference electrode potential (E_{MSE}) was regularly checked by measuring the equilibrium potential against a Pt|H₂(1 atm)|H⁺(0.1 M) electrode in 0.1 M HClO₄. Electrochemical measurements were conducted using

a BioLogic VMP2 potentiostat controlled through the EC -Lab software. CO₂ electrolysis experiments were carried out potentiostatically (chronoamperometry) in a CO₂ saturated 0.1 M KHCO₃ solution (pH 6.8), prepared by bubbling CO₂ in a 0.1 M KOH aqueous solution (Merk, Potassium hydroxide hydrate 99.995 Suprapur®, solid pellets). The Ohmic resistance (R_{Ω}) was measured via electrochemical impedance spectroscopy (EIS) and the iR Ohmic drop was compensated for via positive feedback. The pressure in the working electrode (WE) compartment was kept at 1.1 bar. More details about the electrochemical characterization are reported in the Supplementary Information.

Products analysis

Gaseous reaction products were detected and quantified via in-line gas chromatography (GC). Liquid products were detected and quantified via head-space gas chromatography (HS-GC) and via high performance liquid chromatography (HPLC). External standards were used for the calibration of the HS-GC and HPLC analyses. Full details about the GC, HS-GC and HPLC analyses are given in the Supplementary Information.

CO and CO₂ dosing experiments

CO and CO₂ dosing experiments were conducted in a one-compartment three-electrodes glass cell equipped with a Lugging capillary connected to a Hg/HgSO₄/sat. K₂SO₄ reference electrode. A gold mesh was used as counter electrode. Prior to each measurement, the Ohmic drop was determined via EIS and compensated for via positive feedback. A 0.1 M HClO₄ (Merck Suprapur 70%) electrolyte was used for the experiments. The electrode (RuO₂ film prepared using RuCl₃) was held at constant potential ($-0.2 V_{RHE}$, $-0.5 V_{RHE}$ and $-0.75 V_{RHE}$) while monitoring the current.

Surface enhanced infrared absorption spectroscopy (SEIRAS) experiments

For the *in situ* SEIRA measurements, we used a Pt working electrode composed of a thin (*ca.* 50 nm) Pt film deposited on the Si prism (radius 22 mm, Pier optics) via an electroless deposition method.²⁵ Magnetron sputtering was used to deposit the RuO₂ electrocatalysts. The film was sputtered on the electroless deposited Pt layer at a deposition rate of ~ 0.7 Å/s under Ar:O₂=7:5 sccm, total pressure 3 mTorr, at 450°C, result in a thickness of *ca.* 30 nm, as measured by an electrochemical quartz crystal microbalance. The SEIRA spectra were recorded using a single reflection ATR accessory (Pike Vee-Max II, Pike Technologies) with the Si prism at an incident angle of 68 degrees. Before every experiment, Ar was bubbled through the electrolyte for 15 minutes in order to remove air from the solution. The prism surface was then cleaned by cycling

the potential between 0.05 and 0.90 V vs. RHE. Details of *in situ* SEIRAS measuring procedure were described elsewhere^{26,27} and in the Supplementary Information.

RESULTS AND DISCUSSION

Electrodes Characterization. Three different forms of RuO₂ electrodes were investigated: RuO₂ films prepared via thermal decomposition of RuCl₃ and Ru(NO)(NO)₃ as well as commercial RuO₂ particles. Figure 1b shows representative scanning electron microscopy (SEM) images of RuO₂ films prepared via thermal decomposition of RuCl₃. The Ti substrate is covered by a rough nanocrystalline RuO₂ layer, which forms a homogenous film for high catalyst loadings while it fragments in patches for lower loadings. Similar structures were observed with films prepared starting from Ru(NO)NO₃. The commercial RuO₂ particles (Figure 1c) display an agglomerated nanocrystalline structure with primary units of ~ 50-100 nm in size. The X-ray diffraction patterns (Figure 1a) confirm the catalysts have a rutile crystalline structure and the XPS spectra agree with a typical RuO₂ core-level profile (Figure S1).

The physical and electrochemical characterization of Ti supported RuO₂ films prepared via the thermal decomposition of metal precursors has been the subject of numerous studies, particularly in relation to supercapacitors⁹ and dimensionally stable anodes.^{28–30} The initial electrochemical surface area was monitored via cyclic voltammetry (CV) in CO₂ saturated 0.1 M KHCO₃ (Figure S2 and S3 for detailed discussion). The charge derived from the integration of the CVs recorded with films and RuO₂ particles at increasing loadings is shown in Figure 2a. We note how the measured capacitance decreases with increasing scan rates (Figure S 3). The concept of inner/outer surfaces is recalled to explain this behavior.^{31,32} A scan rate of 20 mVs⁻¹ and an average surface

specific charge of $100 \mu\text{FcmRuO}_2^{-2}$ was used for the calculations in this work.³¹ As expected for nanostructured electrodes having an increasing catalyst loading with fully accessible active surface area, a linear behavior is visible for RuO_2 particles.

Figure 1. (a) X-ray diffraction patterns of commercial RuO_2 particles and RuO_2 film (from RuCl_3) deposited on etched Ti electrode. The expected reflections for rutile RuO_2 (star symbol) and the Ti hcp (square symbol) phases are reported at the bottom of the plot and on top of the diffraction pattern for the RuO_2 film. Rutile RuO_2 Powder Diffraction File (PDF): 01-088-0285; hcp Ti PDF: 01-077-0447 41-1445. (b) and (c) Scanning Electron Microscopy images of RuO_2 film and particles, respectively. The insets report magnified details of the structures.

In contrast, the charge measured with RuO_2 films prepared from RuCl_3 approaches a plateau at high loadings, indicating the formation of a thick film and resulting in a poor utilization of the catalyst. The extrapolated electrochemical active surface area (ECSA) corresponds to ca. $14 \text{ m}^2\text{g}^{-1}$ for films with low loadings and to $2 \text{ m}^2\text{g}^{-1}$ for thicker films (Figure 2b). For RuO_2 particles, the measured specific surface area ($\sim 10 \text{ m}^2\text{g}^{-1}$) is independent of the loading. This value is in good

agreement with the specific surface area measured via N_2 physisorption and with simple geometrical considerations (primary units of 50-100 nm in size). At identical loadings, the charge measured with RuO_2 films prepared from $Ru(NO)NO_3$ consistently showed higher capacitance. It is suggested that the lower decomposition temperature of $RuCl_3$ precursors leads to electrodes with a higher degree of crystallinity and, in turn, with a lower electrochemical surface area.³⁰

Figure 2. (a) Charge derived from the integration of the cyclic voltammograms recorded with RuO_2 films and particles in CO_2 sat. $0.1M KHCO_3$ ($0.3-1 V_{RHE}$, $20 mVs^{-1}$) and varying catalyst loadings. See Figure S2 for an example of cyclic voltammogram (b) Corresponding electrochemical active surface area. An average surface specific charge of $100 \mu F cm RuO_2^{-2}$ was used for the calculations.³¹ The surface area measured for RuO_2 nanoparticles via N_2 physisorption (BET) is indicated.

CO₂ electrolysis with RuO₂ electrodes

CO₂ electrolysis experiments were carried out with the three types of RuO₂-based catalysts, always using fresh electrodes. The tests were performed in chronoamperometric mode at potentials ranging from -0.1 V_{RHE} to -0.9 V_{RHE}. A total charge of 15 C was passed in each experiment. The accumulated reaction products were quantified by gas and liquid chromatography at the end of each experiment. Figure 3 summarizes the Faradic efficiency measured with RuO₂ electrodes prepared via thermal decomposition of RuCl₃.

Figure 3. Faradaic Efficiency (FE) measured during CO₂ electrolysis experiments with RuO₂ electrodes (prepared from thermal decomposition of RuCl₃) in CO₂ saturated 0.1 M KHCO₃. A total charge of 15C was passed through the electrode for each experiment. See the Experimental Methods and the Supporting Information for more details concerning the electrochemical and analytical procedures.

At potentials more anodic than -0.75 V_{RHE}, H₂ was the only product detected. We note that the charge balance is close to 100% in all the cases: this indicates that the totality of the electrons

being transferred at the electrochemical interface was accounted for. At $-0.1 V_{\text{RHE}}$, because of the low current densities (typically below 0.5 mAcm^{-2}), long chronoamperometric measurements ($> 15 \text{ h}$) were required to transfer a total of 15 C . Consequently, a small fraction of the produced H_2 escaped the cell, causing the charge balance to drop below 95% . At potentials more cathodic than $-0.75 V_{\text{RHE}}$ traces of CO and CHOO^- (Faradaic efficiencies of $\sim 0.05\%$ and $\sim 0.2\%$, respectively) were detected. Similar results were obtained with RuO_2 films prepared from $\text{Ru}(\text{NO})(\text{NO})_3$ and with commercial RuO_2 particles (Figure S4). Methanol was not detected under any conditions. We note that the presence of oxygenates or other CO_2 reduction products was carefully monitored for each experiment via head space gas chromatography and HPLC. Based on the detection limit for CH_3OH ($\sim 10 \mu\text{M}$, Figure S5), the volume of the electrolyte (12 mL) and a total charge of 15 C , we were able to detect the formation of CH_3OH down to $\sim 0.5\%$ in Faradaic efficiency. The contribution of the substrates (Ti/TiO_2 for RuO_2 films and glassy carbon for RuO_2 particles) in the tested potential window is negligible compared to the current registered with the RuO_2 catalysts (Figure S6). Because of the generation of bubbles (H_2), the formation of localized pH gradients and the non-negligible contribution of the substrates, it was not possible to test the catalysts at potential more cathodic than $-1 V_{\text{RHE}}$.

Surface adsorbates under CO_2 reduction conditions

In order to understand whether CO_2 and CO interact with the RuO_2 surface, a series of chronoamperometry experiments were carried out with RuO_2 films in 0.1 M HClO_4 . The electrolyte, initially saturated with Ar , was purged with CO_2 (or CO) after 300 s while keeping the electrode under potential control (Figure 4). The use of an acidic media allowed us switching from Ar to CO_2 (or CO) saturated electrolytes without changing the pH of the electrolyte. In parallel, we performed a series of *in situ* surface enhanced infrared absorption spectroscopy (SEIRAS)

measurements on a RuO_2 nanofilm sputtered on a roughened Pt surface using a similar measuring protocol (Figure S7). When the electrolyte was saturated with Ar, the registered current is completely ascribed to the hydrogen evolution reaction (HER) and no detectable adsorbates were observed in the SEIRA spectra. Immediately after the introduction of CO (or CO_2), the total current density decreased drastically. The current drop was more pronounced with CO at mild cathodic potentials (-0.2 to $-0.5 \text{ V}_{\text{RHE}}$), while it was less severe at $-0.75 \text{ V}_{\text{RHE}}$. SEIRAS measurements at $-0.5 \text{ V}_{\text{RHE}}$ showed two distinct peaks at ca. 1870 cm^{-1} and ca. 1660 cm^{-1} appearing upon the introduction of CO, which correspond to linear-bound CO adsorbates³³ and interfacial water,³⁴ respectively.

Figure 4 Surface adsorbates under CO_2 reduction conditions. (a) CO_2/CO dosing experiments carried out in 0.1 M HClO_4 with a RuO_2 film prepared from RuCl_3 ($100 \mu\text{g RuO}_2$). (b-c) Surface enhanced infrared absorption (SEIRA) spectra for a RuO_2 nanofilm deposited on a roughened Pt surface at (b) $-0.5 \text{ V}_{\text{RHE}}$, (c) $-0.75 \text{ V}_{\text{RHE}}$ and (d) SEIRAS in CO_2 saturated 0.1 M KHCO_3 . A cathodic potential sweep was applied to the electrode while recording the spectra. The SEIRAS experiment with Ar/ CO_2 in 0.1 M HClO_4 is reported in figure S9.

In our previous experimental work we probed the interaction of CO with a Pt substrate in 0.1 M HClO₄. We observed a distinct couple of sharp peaks of CO species adsorbed in the linear ($>2075\text{ cm}^{-1}$) and bridged ($>1850\text{ cm}^{-1}$) configuration.³⁵ The peaks observed on Pt are distinct from the 1870 cm^{-1} peak observed in this study, confirming that the roughened Pt substrate is not responsible for the adsorbed CO signal in the current study. The relatively thick RuO₂ film (ca. 30 nm) ensures the absence of indirect electronic effects given by the Pt substrate.³⁶ No detectable peaks were observed when the same measurement was performed at more negative potentials ($-0.75\text{ V}_{\text{RHE}}$), suggesting a lower degree of interaction between CO and the RuO₂ surface, in agreement with the chronoamperometric test at $-0.75\text{ V}_{\text{RHE}}$. Furthermore, a similar CO stretching peak was detected when CO₂ was introduced at $-0.5\text{ V}_{\text{RHE}}$, indicating that CO₂ can be reduced to CO in an electrochemical environment (see Figure S8). The interaction of CO₂/CO with RuO₂ was also observed via SEIRAS experiments in CO₂ saturated 0.1 M KHCO₃ electrolyte (Figure 4d, potential is swept cathodically during the scan). However, since H₂ is the only product detected under cathodic potentials, and no other peaks were registered in the SEIRAS measurement, the CO adsorbate can be considered as a spectator species that does not get further reduced.

Mixed RuO₂ oxides

Our results show that RuO₂ electrodes are inactive for the CO₂ electrocatalytic reduction, irrespective of the preparation methods and the applied potential. We further explored the catalytic performance of mixed Ru-Ti and Ru-Sn oxides to elucidate whether the presence of heteroatoms in the lattice structure is key for the formation of CH₃OH or other oxygenates. The mixed oxides were prepared by thermal decomposition of precursors mixtures, exactly reproducing the preparation used by Bandi et al. in their works.^{13,14} It is established that mixed Ru-Sn oxides monophasic solid solutions can be prepared over the whole composition range.³⁷ In contrast, the crystal structure of mixed Ru-Ti oxide is subject of controversy.^{38,39} Several studies on Ru-Ti oxide

prepared via thermal decomposition (same procedure used in our work) postulate the formation of a (meta)stable solid solution for a large compositional window.^{38,40} In contrast, oxides prepared via sol-gel routes tend to result in two separate phases.⁴¹ Our XRD results (Figure S11) showed the formation of a monophasic solid solution for Ru-Sn oxides and for Ru:Ti of 50:50 (at:at), while a biphasic structure was formed increasing the Ti content (Ru:Ti of 25:75).

Figure 5(a) shows the Faradaic efficiency measured with Ru-Ti oxides at $-0.75 V_{\text{RHE}}$. Overall, the behavior is comparable to that registered with pure RuO_2 electrodes. The selectivity toward CO slightly increases (up to $\sim 1\%$), especially for the Ti rich sample. CH_3OH or other CO_2 reduction products were not detected. Noteworthy, the current densities were smaller than the ones measured with pure RuO_2 films with comparable catalyst loadings, suggesting that the introduction of Ti atoms in the RuO_2 lattice is detrimental for the HER kinetics. No evident reduction of the oxides was observed via electrochemical methods, indicating that the metastability known for RuO_2 is likely to be retained also with Ru-Ti oxides. In their report, Bandi et al.¹⁴ observed an increase in the CH_3OH yield with Cu-decorated Ru-Ti oxides. In order to verify this possibility, we electrodeposited Cu species onto Ru:Ti electrode following the procedure described by Bandi et al.¹⁴ The electrodeposition resulted in the formation of large Cu particles ($> 200\text{nm}$) physically well dispersed on the Ru-Ti surface (Figure S12). At $-0.75 V_{\text{RHE}}$, the as-prepared Cu-decorated electrode showed a selectivity towards of CO and CHOO^- of $\sim 11\%$ and 5% , respectively. Hydrogen remains the most abundant product. Collectively, the electrode operated as a physical mixture of the two constituents (Cu particles and Ru-Ti oxide). Indeed, in this potential window Cu is expected to give small amounts CO and CHOO^- .⁴² In support of this hypothesis, traces of CH_4 (known product of CO_2 reduction with Cu catalysts) were detected when the electrode was tested at $-1 V_{\text{RHE}}$.

Figure 5 (a) Faradaic efficiency measured during CO₂ electrolysis experiments with Ru-Ti and Cu decorated Ru-Ti oxide films in CO₂ saturated 0.1 M KHCO₃ at -0.75 V_{RHE}. (b) Faradaic efficiency measured with Ru-Sn oxide films at different potentials in CO₂ saturated 0.1 M KHCO₃. See the Experimental Methods and the Supporting Information for more details concerning the electrochemical and analytical procedures.

Figure 5b shows the Faradaic efficiency measured with Ru-Sn oxides (Ru:Sn atomic ratio of 25:75 and 10:90) at -0.75 V_{RHE} and -1 V_{RHE}. Sn-rich oxides display a distinct behavior from the Ru:Ti electrodes. Even though H₂ remains the most abundant product and CH₃OH was not formed at any potential, appreciable amounts of CO and CHOO⁻ were detected. With a Ru:Sn (10:90) composition, the total selectivity towards CO₂ reduction products reached ~ 25% at -1 V_{RHE}. At this point, we cannot ascertain the chemical state of the surface under reaction conditions. We cannot exclude a (partial) reduction involving the surface layers and/or the bulk of the oxide, consistent with reports by others on pure SnO₂ catalysts.^{43,44} Overall, besides a purely scientific interest, Ru-Sn oxides do not seem to be promising catalysts for CO₂ reduction.

The evidence presented in the previous sections clearly shows that RuO₂ and mixed RuO₂ catalysts are not active for the conversion of CO₂ to methanol, which is in stark contrast with what highlighted in past literature. While reviewing previous works, we carefully examined the experimental procedures sifting for the decisive detail in the preparation of the electrodes or for the critical measuring conditions. We first hypothesized that the nature of the RuO₂ precursor (i.e. RuCl₃ or RuNO(NO)₃) could have been a decisive factor. However, the concurrent results obtained with different precursors and commercial catalysts clearly indicated that this variable affects the physical features of the catalysts, but not their electrochemical behavior. In addition, this argument rules out the possibility that residual Cl species (from decomposition of RuCl₃) might influence the catalytic events. The impact of the reaction temperature was briefly explored (results not shown). Some of the past works were carried out at temperature below 5°C.^{17,45} At 4°C, we did not observe the formation of CO₂ reduction products and H₂ remained the only gas evolved. Under these conditions we only observed changes in hydrogen evolution current densities, readily explained by intrinsically slower kinetics. We note that it is impossible to pinpoint the reason behind the discrepancy between our findings and past literature data: such a task would go beyond the scope of this manuscript. Moreover, we cannot exclude the notion that RuOx-containing catalysts could be engineered to yield a more favorable performance for CO₂ electroreduction. Nonetheless, it is important to provide some considerations relative to the controversial results reported for RuO₂ electrodes. In hindsight, on a qualitative basis, the reported formation of CH₃OH at potential as low as -0.150 V_{RHE} is challenging to rationalize, especially considering that the thermodynamic potential for CO₂ protonation to CH₃OH is ~ 0 V_{RHE} and an overpotential above 1.0 V is required to produce traces amounts of CH₃OH with pure metal catalysts.⁷ The research effort put in place over the last decade has produced a solid code of practice for experimental work

on the electrocatalytic conversion of CO₂, especially with respect to fundamental research. Several recent manuscripts have highlighted a comprehensive set of testing and analytical aspects that one must consider to avoid experimental artefacts caused by ill-defined experimental conditions, deficient analytical protocols or by the presence of adventitious (metallic) impurities.^{46–48} Many of the preliminary papers reporting the formation of CH₃OH used poorly defined experimental procedures and insufficient analytical methods. Popic et al, for instance relied entirely on infrared spectroscopy and cyclic voltammetry for the detection of reaction products.¹³ In addition, the description of the experimental methods often lacks details (e.g., applied potential defined as “near water reduction potential”).^{13,14} Moreover, a number of works highlighted in the introduction employed buffers containing organic species (i.e., acetic acid for Britton–Robinson buffer solutions) as electrolytes.^{17,45} The presence of organic species may introduce a number of artefacts. In all the past investigations the amount of evolved H₂ was never quantified. The quantification of this by-product is important not only for completeness sake, but also to ensure that the overall charge balance is met, and all the reaction products are accounted for.⁴

Although we could not detect the formation of CH₃OH under any circumstance, the electrochemical and SEIRAS results presented in Figure 4 clearly show that CO and CO₂ do bind to the RuO₂ surface, thus affecting the HER kinetics. The adsorption configurations of CO on RuO₂ in the gas phase have been studied over a wide temperature range and the main findings have been summarized by Over.²² To the best of our knowledge, the interaction between CO and RuO₂ in an electrochemical environment has been investigated only at anodic potentials (electrochemical oxidation of CO).^{49,50} Our SEIRAS measurements confirm the presence of CO adsorbates (bands at ca. 1870 cm⁻¹) also at cathodic potentials. This hypothesis is supported by the existence of the H-O stretching vibration (ca. 3600 cm⁻¹, see Figure S8) and H-O-H bending vibration (ca. 1660

cm⁻¹). These vibrations may be attributed to the isolated water at the interface formed because of the hydrophobic CO adsorbates.⁵¹ Prior vibrational spectroscopy studies suggest the coexistence of a number of adsorption and stretching configurations when a RuO₂ (110) surface is exposed to CO in the gas phase. Three different categories are identified: frequencies between 1850 and 1980 cm⁻¹ and between 1980 and 2100 cm⁻¹ are assigned to CO species binding to the Ru *bridge* site through a symmetric and linear (asymmetric) configuration, respectively. Frequencies between 2100 and 2155 cm⁻¹ are associated to CO species binding to the Ru *cus* site in on-top configuration.³³ Based on the absence of peaks in the 2100-2155 cm⁻¹ region (Figure 4), the latter case (CO adsorbed at Ru *cus* site) can be excluded: we thus infer that under the electrochemical conditions used in our work CO is likely to adsorb on the Ru *bridge* site.

An atomic-scale elucidation of the impact of CO adsorbates on the HER kinetics would require a detailed analysis that goes beyond the scope of this work. The complexity arises because (i) the exact chemical state of the surface under reaction conditions remains elusive and (ii) the HER mechanisms on RuO₂ surfaces is not yet fully understood. Experimental evidence and theoretical calculations have demonstrated that RuO₂ is partially reduced (i.e. protonated to oxyhydroxide) under cathodic conditions,^{22,52–54} albeit the exact chemical state of the surface under reaction conditions remains experimentally undetermined. The extent and degree of crystallinity of the hydrated phase is still matter of debate, as suggested by the different observations reported by *in situ* X-ray diffraction/reflectivity⁵⁵ and XPS studies.^{52,56} Various plausible scenarios have also been predicted by theoretical simulations.⁵⁷ Overall, the heterogeneity of these findings suggests that the chemical and crystalline state of the RuO₂ films under cathodic conditions might depend on subtle experimental variables, such as the procedure used to synthesize the electrodes. The cyclic voltammetry curves we measured after CO₂ reduction (see Figure S13) suggest a partially

1
2
3 irreversible hydration of the RuO₂ films (see discussion in the supplementary information). We
4
5 did not observe evident electrochemical features of a metallic Ru over-layer. The absorption of H⁺
6
7 species within the RuO₂ structure (defined as “catalyst activation”) has been observed in other
8
9 studies.^{56,58}

10
11
12 With respect to HER mechanistic aspects, a series of works published across the 1990s postulate
13
14 that on a partially reduced RuO(OH) surface the HER occurs through a Volmer-Heyrovsky rate
15
16 determining step involving the hydroxyl group in oxygen *bridge* site.^{22,59} In contrast, a direct Ru-
17
18 H (hydride) mechanism limited by a homolytic reaction (i.e., Tafel mechanism) has been recently
19
20 proposed by Pastor et al. through a spectro-electrochemical analysis.⁶⁰ On a theoretical basis, the
21
22 hydride mechanism could occur either at Ru *cus* site or at Ru *bridge* site (via the complete
23
24 reduction of the Ru-OH group). In view of these considerations, one can hypothesize that the
25
26 presence of CO/CO₂ bound on the surface negatively affects the HER performance via (i) a direct
27
28 site-blocking mechanism, most likely to occur on the Ru *bridge* site since we do not have SEIRAS
29
30 evidence for CO adsorbed at Ru *cus* site, and/or (ii) via indirect electronic mechanism, where the
31
32 CO bound at the *bridge* site affects the binding energy of H⁺/H₂O at the adjacent Ru *cus* site. A
33
34 more detailed investigation, ideally coupled with a computational analysis, should be undertaken
35
36 to shed light onto these open questions.
37
38
39
40
41

42
43 It is established that transition metals that bind CO (and/or CO₂) too strongly, such as Pt, Fe and
44
45 Ni,^{4,7,61} are very selective for the HER and inactive for CO₂ reduction. Consequently, at first sight
46
47 one could interpret the lack of CO₂ reduction activity and the detrimental impact of CO adsorbates
48
49 for the HER kinetics as elements that affiliate RuO₂ electrodes to strongly CO-binding surfaces
50
51 such as Pt or Fe. However, one should note that the latter are capable to give minor amounts of
52
53 CH₄ and CH₃OH,^{7,62} despite generally displaying high surface CO coverages under CO₂ reduction
54
55
56
57
58
59
60

conditions.^{35,63,64} In contrast, even though RuO₂ catalysts experience similar CO surface poisoning effects, they are unable to reduce CO further.

CONCLUSIONS

Several past literature reports postulate that RuO₂ catalysts are capable to electrochemically convert CO₂ to methanol with excellent selectivity at low overpotentials. We could not verify these results. All the catalysts tested, and the numerous experimental configurations explored in our work confirmed that H₂ is basically the only product detected under CO₂ reduction conditions. A series of combined electrochemical and SEIRAS experiments showed that CO and CO₂ bind to the RuO₂ surface. However, bound CO acts as spectator species and cannot be converted to methanol or other oxygenates.

SUPPORTING INFORMATION DESCRIPTION

- Additional Experimental Details (electrodes preparation and characterization, SEIRAS experiments)
- Core-level XPS spectra of Ru 3d/ Cls core levels for RuO₂ catalysts; surface area evaluation via electrochemical methods; Faradic Efficiency measured with RuO₂ electrodes prepared from thermal decomposition of RuNO(NO)₃; current density measured with substrates; additional details about analytical sensitivity and SEIRAS experiments; characterization of Cu-doped Ru-TiO_x electrodes.
- Raw data can be accessed on Zenodo: <https://doi.org/10.5281/zenodo.3237389>.

ACKNOWLEDGMENTS

This project has received funding from the European Union's Horizon 2020 research programme under the Marie Skłodowska-Curie grant agreement No. 705230. The support from the VILLUM Center for Science of Sustainable Fuels and Chemicals funded by the VILLUM Fonden research grant (9455) is also acknowledged. AR acknowledges the support from Imperial College London for her Imperial College Research Fellowship. The author would like to thank Dr. A. Bhowmik, Dr. H. A. Hansen and Dr. T. Vegge (DTU Energy) for the fruitful discussions on the project.

Biography

Ifan E. L. Stephens was appointed as Senior Lecturer at the Department of Materials at Imperial College London in 2017. Prior to Imperial, he was Associate Professor and Leader of the Electrocatalysis Group at the Department of Physics at the Technical University of Denmark. In 2015, the Department of Mechanical Engineering at Massachusetts Institute of Technology awarded Ifan the Peabody Visiting Associate Professorship. His team conducts model electrocatalysis experiments to enable the large-scale conversion of renewable energy to fuels and valuable chemicals and vice versa. Ifan has authored or co-authored more than 60 papers in peer-reviewed journals. He is coinventor on two patents and four patent applications. He is cofounder of the spinoff company, HPNow.”
