Abstract

1 Arsenic (As) release and mobility in groundwater is coupled to the iron (Fe) cycling and the

2 associated transformation of Fe-oxides present in sediments. Recent in-situ experiments have

3 provided observations on arsenic mobilization and co-occurring reductive mineral transformation

4 when placing As-loaded ferrihydrite-coated sand for 80 days in wells of an As-contaminated

5 aquifer of Northern China. However, the complex temporal change in solid-associated arsenic

6 and the multiple geochemical processes occurring when the flowing groundwater contacts the

7 As-loaded ferrihydrite-coated sand hamper a detailed evaluation of the experimental dataset. In

8 this study, we develop a modeling approach that allows a quantitative interpretation of arsenic

9 release and ferrihydrite transformation observed during the in-situ experiments. The model

10 accounts for the interplay of abiotic and biotic geochemical processes (i.e., surface complexation,

11 reductive dissolution, formation of secondary iron minerals and arsenic sequestration into the

12 newly formed minerals) involved in the transformation of Fe-oxides and controlling arsenic

13 mobility. The results show the capability of the proposed approach to reproduce the temporal

14 trends of solid arsenic and ferrihydrite concentrations, as well as the spatial variability of mineral

15 transformation, observed in different wells using a common set of surface complexation

16 parameters and kinetic rate constants. The simulation outcomes allowed us to disentangle the

17 specific contribution of the different mechanisms controlling the release of arsenic. It was

18 possible to identify an initial rapid but minor release of As (13-23% of the initial surface

19 concentration) due to desorption from ferrihydrite, as well as the reduction of adsorbed As(V) to

20 As(III) upon contact with the flowing anoxic groundwater. Successively, reductive dissolution of

21 ferrihydrite caused the decrease of the amount of the Fe mineral phase and led to a major

22 depletion of solid-associated arsenic. The produced Fe(II) catalyzed the ferrihydrite conversion

23   into more crystalline Fe(III) oxides (i.e., lepidocrocite and goethite) through Ostwald ripening,

24   and resulted in the formation of siderite and mackinawite upon reaction with carbonates and

25   sulfides naturally present in the groundwater. The model results also showed that, whereas the

26   decrease in surface sites during reductive dissolution of ferrihydrite promoted arsenic

27   mobilization, the mineral transformation limited As release through its sequestration into the

28   newly formed secondary mineral phases.

29

Introduction

Prolonged exposure to arsenic (As) contaminated groundwater affects the health of millions of individuals in various parts of the world *(1-3)*. This problem is particularly severe in South East Asia *(4)* where arsenic contamination primarily results from the reducing conditions prevailing in the aquifers, triggering the dissolution of iron oxides present in the sediments and the simultaneous release of As *(5-8)*. The mobility of arsenic in groundwater is controlled by iron minerals through sorption onto the mineral surfaces *(9-13)*. Other important processes, such as the reduction of arsenate to arsenite, can change the affinity for mineral surfaces and affect arsenic mobility *(14-16)*.

Significant effort has been devoted to the investigation of the cycling of iron oxides and its fundamental implications on arsenic release and transport. Ferrihydrite, which has a high capacity in hosting arsenic *(17)*, has been detected in sediments of Bangladesh *(18-19)* and near-surface sediments in the Mekong Delta *(20)* where groundwater arsenic contamination occurred. This poorly crystalline oxide is reactive and can undergo microbially-mediated reductive dissolution *(21-22)*. Furthermore, ferrihydrite can adopt, over time, a more crystalline structure (e.g., goethite), which causes a decrease in the As sequestration potential of the sediments *(13)*. The ferrous iron produced during the reductive dissolution of ferrihydrite can (i) abiotically catalyze the crystallization of the Fe(III) oxide phases *(23-26)* and/or (ii) precipitate into Fe(II)-bearing mineral phases such as siderite, mackinawite, vivianite *(12, 21, 27)*. Depending on the type of secondary mineral phases, significant amount of arsenic can be sequestered through adsorption and reincorporation leading to a disparity between the disintegration of ferrihydrite and the arsenic release *(28-32)*.

52 The interpretation and prediction of arsenic fate in the subsurface is particularly challenging as it

53 requires the consideration of the complex interplay between flow, reactive transport processes

54 and the hydrochemistry of the groundwater. Despite the large number of studies on arsenic

55 release and transport mechanisms an apparent research gap still exists between the level of

56 understanding of arsenic mobility under controlled laboratory conditions and under natural field

57 conditions. Laboratory studies typically limit the number of geochemical processes under

58 investigation using simplified aqueous composition and mineral assemblage. In contrast, natural

59 systems have a higher level of complexity due to the large number of geochemical factors and

60 co-occurring mechanisms. Hence, pilot-scale experiments, directly conducted in aquifer systems,

61 are of primary importance to bridge such knowledge gap between simplified laboratory setups

62 and complex field investigations. Recently performed pilot-scale experiments, injecting reactive

63 organic compounds to stimulate microbial activity in the subsurface, have provided insights on

64 the transformation of naturally-occurring mineral phases and their interactions with arsenic *(33-*

65 *34)*. Another experimental approach that has been adopted in pilot scale experiments consists in

66 assessing the change of known mineral phases exposed to natural groundwater conditions *(33,*

67 *36-38)*. Furthermore, important insights and quantitative understanding of arsenic release and

68 transport processes are obtained when experimental observations are interpreted with numerical

69 modelling both at laboratory *(39-42)* and at field scales *(34, 43-45)*.

70 In this study, we develop a model to simulate the reductive transformation of synthetic

71 ferrihydrite and concomitant release of pre-loaded arsenic exposed to natural groundwater

72 conditions during in-situ experiments performed in an As-contaminated sedimentary aquifer of

73 Northern China *(37)*. Such experiments have shown complex dynamics between arsenic release

74 from ferrihydrite-coated sand and ferrihydrite dissolution/transformation at different spatial

5

75 locations. Using the implemented modeling framework, we provide a quantitative interpretation

76 of the experimental datasets comprising (i) time series of total Fe and As solid-associated

77 concentrations, (ii) mineral composition at the end of the experiments and (iii) groundwater

78 hydrochemical data. The modeling outcomes highlight the distinct contribution and the

79 interactions of different geochemical processes controlling the mobilization of arsenic at the field

80 site. Such processes include surface complexation reactions, microbially-mediated reductive

81 dissolution, mineral transformation through Ostwald ripening, formation of secondary mineral

82 phases and As sequestration in the newly formed minerals, and determine the complex trends of

83 arsenic and iron observed at the field site.

84 **Materials and Methods**

85 **Experiments and datasets description**

86 The in-situ experiments were conducted in monitoring wells screened in a shallow reducing As-

87 contaminated aquifer in the Hetao Basin (Inner Mongolia, China) and consisted in placing As-

88 loaded synthetic iron mineral phases at screen depth (i.e., [18.5 - 26.2] m) for 80 days in order to

89 observe the effect of the continuous groundwater flow on the As retention and iron mineral

90 transformation. The ferrihydrite coated sand was synthetized according to the method of

91 Schwertmann and Cornell *(46)* and the As loading was performed in the laboratory by using a

92 solid-to-solution ratio of 50 g/L and equilibrating the solid phase with a 500 mg/L As(V)

93 solution. The As-loaded coated sand had a porosity of 0.5, a Fe content of 2.71 mg/g coated sand

94 (i.e., 27 g ferrihydrite/L) and an As content of 213 µg/g coated sand.

6

95   The coated sand was divided into amounts of 0.5 g before being deployed in the field, where

96   water could flow homogeneously through the highly permeable porous medium. Periodic

97   sampling of the solid phase allowed measuring the temporal change in solid-associated As and

98   total Fe content after total digestion of the sample, using the microwave-assisted method of Link

99   et al. *(47)*. Reductive dissolution of ferrihydrite and release of arsenic occurred incongruently in

100   all wells as shown by the monitored transient decrease in Fe and As. Synchrotron X-Ray

101   diffraction (XRD) indicated that goethite formation occurred in all wells whereas presence of

102   lepidocrocite was less pronounced and differed among the wells. The difference in mineral phase

103   composition was confirmed by the scanning electron microscopy (SEM) exhibiting varying

104   degree of crystallization. In order to characterize the mineral phase composition and the As

105   oxidation at the end of the experiments, Fe and As K-edge X-Ray absorption spectroscopy

106   (XANES) was conducted at the BL14W beamline of the Shanghai Synchrotron Radiation

107   Facility (SSRF) operated in the energy range [-50 ; 150 eV] with a Si(111) monochromator. Fe

108   K-edge XANES indicated significant formation of siderite and mackinawite during the

109   experiments. As K-edge XANES showed that the oxidation state of As adsorbed onto the

110   ferrihydrite surface partially changed from As(V) to As(III). During the in-situ experiments, the

111   chemical composition of the groundwater was measured at 0, 30 and 80 days in each well. In this

112   study, we consider the datasets collected in 3 wells placed along the main groundwater flow

113   direction and separated by a distance of 2.5 km. The datasets include the average groundwater

114   composition for each well, the temporal change in solid-associated As and Fe, as well as the

115   quantification of the secondary mineral phases at the end of the experiments. Details about the

116   monitoring wells and field data are provided in the Supporting Information, whereas an extensive

117   description of the in-situ experiments is given by Zhang et al. *(37)*.

118   **Modeling approach**

119   The model simulates the groundwater flow through the ferrihydrite-coated sand leading to a

120   change from aerobic to anaerobic conditions, the continuous supply of dissolved groundwater

121   species, the mineral transformation, and the As release/sequestration. Figure 1 displays the

122   location of the 3 considered wells, and a visual representation of the conceptual framework for

123   the proposed approach and of the key biogeochemical processes. The model accounts for a series

124   of processes triggered by the dynamic change in the hydrochemistry: the microbially-driven

125   reductive dissolution of ferrihydrite, the formation of secondary Fe(II) and Fe(III) oxides mineral

126   phases, the change in As redox state, as well as the uptake of As through sorption onto iron oxide

127   surfaces and sequestration into secondary mineral phases.
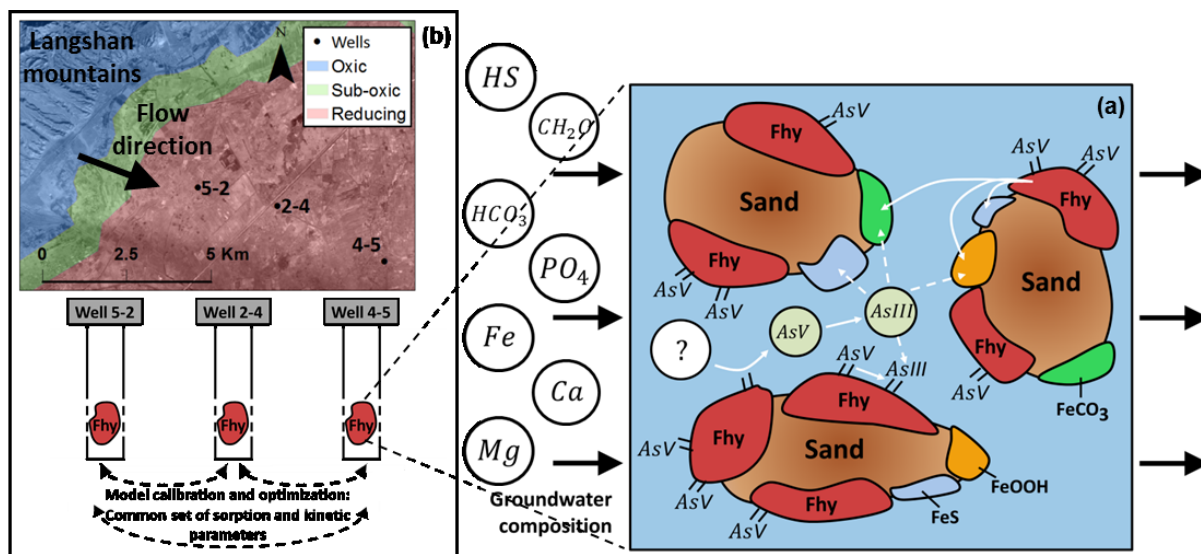

128

129   Figure 1. Illustration of the modeling approach for reductive transformation of ferrihydrite and

130   As mobilization/sequestration during the in-situ experiments: (a) conceptual model; (b) location

131   of the observation wells and simultaneous calibration approach through parallelization of

132   simulations with a common set of parameters for the different spatial locations.

133   The first modeling steps consist in loading the arsenic onto the mineral surface by equilibrating

134   ferrihydrite with the As concentrated solution used for the preparation of the reactive samples,

135   and defining the hydrochemical composition of the groundwater according to the field

136   measurements. Subsequently, the solution in contact with the As-loaded ferrihydrite is iteratively

137   replaced by the groundwater solution to simulate the flushing of the pores due to groundwater

138   advection. The flow rates defined through the advective time steps were based on values found in

139   Stolze et al. *(45)* showing decreasing flow velocity along the flow line from the mountains

140   towards the flat plain (Supplementary Information, Table SI7). Following the transport step, the

141   surface complexation reactions and aqueous speciation are calculated assuming local equilibrium,

142   whereas the reductive dissolution of ferrihydrite, the transformation and precipitation of mineral

143   phases, and the change in As speciation were described as kinetic processes. Therefore, the

144   feedback/interaction of the flow and transport processes with the reaction network is directly

145   taken into account in the description of the flow-through system.

146   The model was implemented by coupling the geochemical code PHREEQC-3 *(48)* with the

147   software MATLAB$^{®}$ *(49-50)* using the IPhreeqc model *(51-52)*. Such coupling results in a

148   flexible modeling approach that combines the capabilities of PHREEQC to model solute

149   transport, kinetic and equilibrium reactions with the advanced capability and functions of

150   MATLAB$^{®}$ for data analysis, model calibration and optimization. We used the WATEQ4F

151   thermodynamic aqueous reactions database, amended with the aqueous speciation reactions of

152   arsenic from Dixit and Hering *(17)* (Table 1).

153

154 **Reaction network**

155 The model includes a series of abiotic and microbially-mediated reactions that aimed at

156 describing the geochemical transformations taking place during the in-situ experiments. Table 1

157 lists the key reactions considered in the model. Ferrihydrite was represented with its simplified

158 stoichiometry $Fe(OH)_3$ for computational ease *(21)*. Secondary Fe(III) phases (i.e., goethite and

159 lepidocrocite) were represented as a generic Fe(III) oxide (FeOOH).

160 Table 1: Aqueous speciation and geochemical reactions included in the reactive transport model

Aqueous speciation		log K
$AsO_4^{3-} + 3H^+ = H_3AsO_4$		20.06[a]
$AsO_4^{3-} + 2H^+ = H_2AsO_4^-$		18.35[a]
$AsO_4^{3-} + H^+ = HAsO_4^{2-}$		11.60[a]
$AsO_3^{3-} + 3H^+ = H_3AsO_3$		34.74[a]
$AsO_3^{3-} + 2H^+ = H_2AsO_3^-$		25.52[a]
$AsO_3^{3-} + H^+ = HAsO_3^{2-}$		13.41[a]
Reactive minerals	**Name**	**log K**
$Fe(OH)_3 + 3H^+ = Fe^{3+} + 3H_2O$	Ferrihydrite	4.891[b]
$FeOOH + 3H^+ = Fe^{3+} + 2H_2O$	Fe(III) oxide	-1[c]
$FeS + H^+ = Fe^{2+} + HS^-$	Mackinawite	-2.95[d]
$FeCO_3 = Fe^{2+} + CO_3^{2-}$	Siderite	-10.89[c]
Reductive dissolution of ferrihydrite		
$CH_2O + 4Fe(OH)_3 + 7H^+ \rightarrow HCO_3^- + 4Fe^{2+} + 10H_2O$		
Redox change in As speciation		
$0.5CH_2O + HAsO_4^{2-} + 1.5H^+ \rightarrow H_3AsO_3 + 0.5HCO_3^-$		
$0.5CH_2O + Hfo_wAsO_4^{-2} + 1.5H^+ \rightarrow Hfo_wH_2AsO_3 + 0.5HCO_3^-$		

[a]*(17)*, based on MINEQL+ database *(53)*; [b] *(54)*, [c]*(55)*, [d]*(56)*

161 ***Dissolution and precipitation kinetics.*** The mineral transformation reactions were controlled by

162 kinetics rate expressions defined by means of thermodynamic constraints and hydrochemical

163 composition *(57)*. We considered the dissimilatory reductive dissolution of ferrihydrite by

164 oxidation of organic matter leading to the release of Fe(II) and HCO_3^- *(2, 21, 23)*. The kinetic rate

165 of the reaction was expressed as function of the abundance of the electron acceptor (i.e., the

166 ferrihydrite) with a Monod type rate equation *(41, 57, 58)*. Additional terms allowed us to

167 account for: (i) the decrease in accessibility for reactive surface sites during ferrihydrite

168 dissolution *(59)*, and (ii) the passivation of ferrihydrite via the adsorption of charged species *(60-*

169 *61)*.

$$R_{ferri} = -k_{ferri}\left(\frac{[Fe(OH)_3]}{K_m^{ferri\text{-}org} + [Fe(OH)_3]}\right)\left(\frac{A_{Fe(OH)_3}}{A_{0,\,Fe(OH)_3}}\right)\left(\frac{S_{tot}\text{-}S_{occupied}}{S_{tot}}\right)L(t) \quad \begin{cases} L\left(t{<}t_{i,\,ferri}\right){=}0 \\ L\left(t{\geq}t_{i,\,ferri}\right){=}1 \end{cases} \quad (1)$$

170 where k_{ferri} is the rate constant, $K_m^{ferri\text{-}org}$ is the half-saturation constant, $A_{Fe(OH)_3}$ and $A_{0,\,Fe(OH)_3}$

171 are the total surface areas of ferrihydrite at time t and t=0, respectively, S_{tot} is the total amount of

172 ferrihydrite surface sites, and $S_{occupied}$ is the amount of ferrihydrite surface sites occupied by

173 Fe(II) *(60)*, phosphate *(61)*, As(V) *(14, 16)*, silicates, and carbonates. As(III) was not included in

174 the surface site passivation term since it rather favors ferrihydrite dissimilatory reduction *(14)*.

175 Quantities in brackets, [ ], represent the molar concentration of the indicated species. $K_m^{ferri\text{-}org}$

176 was defined proportional to the amount of Fe(III) crystalline oxide formed during the in-situ

177 experiment, since this can limit ferrihydrite reactivity *(23)*:

$$K_m^{ferri\text{-}org} = K_{m,0}^{ferri\text{-}org}\ \frac{[FeOOH]}{[Fe(OH)_3] + [FeOOH]} \quad (2)$$

178 where $K_{m,0}^{ferri\text{-}org}$ is a calibrated variable.

179 L(t) expresses the inhibition of the reductive dissolution of ferrihydrite for each well over a time

180 period $t_{i,\,ferri}$, as the dataset indicated a lag phase preceding the decrease in the solid-associated Fe

181 content. The abiotic reduction of ferrihydrite by sulfide was not considered in the model as it was

182 not possible to distinguish its effect from the microbial reductive dissolution of ferrihydrite. The

11

183 consumption of organic carbon was simulated according to the reactions and stoichiometry

184 reported in Table 1. Organic carbon was not considered as limiting factor for the reaction

185 kinetics due to its abundance in the flowing groundwater and to its reactivity in the area of the in-

186 situ experiment *(62)*.

187 The Fe(II)-catalyzed conversion of ferrihydrite into a more crystalline Fe(III) oxide phase

188 (comprising goethite and lepidocrocite) occurs via Ostwald ripening *(16, 24, 63-64)*. The kinetic

189 rate, $R_{Ostwald}$ considers the Fe(II) surface coverage *(21, 30, 65-67)*, the dissolved Fe(II)

190 concentration *(25-26, 68)*, and the effect of chloride, sulfate, and bicarbonate concentrations

191 since these ions have been shown to significantly slow down the crystallization of ferrihydrite

192 *(69)*:

$$R_{Ostwald}= -\left(k_1\left(\frac{S_{Fe(II)}}{S_{tot}}\right) + k_2\frac{[Fe^{2+}]}{[Fe(OH)_3]}\right)\left(\frac{[Fe(OH)_3]}{K_m^{ferri-ost} + [Fe(OH)_3]}\right)\left(\frac{1}{[Cl^-] + [SO_4^{2-}]+[HCO_3^-]}\right)^x \quad (3)$$

193 where k_1 and k_2 are rate constants, $S_{Fe(II)}$ is the amount of ferrihydrite surface sites occupied by

194 Fe(II), and x is a calibrated exponent. The abiotic dissolution of ferrihydrite resulting from

195 electron transfer from aqueous Fe(II) is inhibited when the electrochemical potential of the redox

196 couple Fe(II)/Fe(III) exceeds the absolute energy of the conduction band of ferrihydrite (i.e.,

197 $E_{Fe(OH)_3}$ = -5.00 eV) *(25-26, 68)*. All produced Fe^{3+} was turned into a single Fe(III) crystalline

198 phase. Furthermore, the formation of magnetite was not considered as this mineral was not

199 detected during the in-situ experiments.

200 Siderite and mackinawite were allowed to precipitate as products of the reaction of Fe(II) from

201 the reactive dissolution of ferrihydrite and dissolved carbonate and sulfide species present in the

202 flowing groundwater. The precipitation of these secondary minerals was controlled by the kinetic

203 rate expressions:

$$R_{sid\text{-}pptn}=k_{sid\text{-}pptn}\max\left(0,\left[1-\frac{K_{sp(sid)}}{IAP_{sid}}\right]\right) \qquad (4)$$

$$R_{mack\text{-}pptn}=k_{mack\text{-}pptn}\max\left(0,\left[1-\frac{K_{sp(mack)}}{IAP_{mack}}\right]\right) \qquad (5)$$

204 where K_{sp} is the solubility product and IAP is the ion activity product.

205 ***Arsenic release and sequestration.*** The change in speciation of arsenic, from As(V) to As(III),

206 occurring when the reduced groundwater contacted the As-loaded ferrihydrite-coated sand, was

207 described as a linear kinetically-controlled mechanisms with a rate coefficient k_{As}. Sorption

208 reactions were assumed to be instantaneous and were modeled for ferrihydrite and the secondary

209 Fe(III) oxide using the diffuse double layer (DDL) model *(70)*. Ferrihydrite was defined with a

210 specific surface area of 600 m^2/g and with weak and strong adsorption sites (i.e., Hfo_w and Hfo_s,

211 respectively) *(70)*. The secondary Fe(III) oxide was assumed to have the surface complexation

212 properties of goethite and was represented with a specific surface area of 54 m^2/g and a single

213 type of surface sites (i.e., Goe) *(71)*. The densities of surface sites Hfo_w and Goe were calibrated

214 within the range [0.05 – 0.31] mol/mol Fe *(17, 72)* and [0.011 - 0.018] mol/mol Fe *(71)*,

215 respectively. The density of Hfo_s sites was set to 0.005 mol/mol Fe *(70)*. Since the number of

216 surface sites are stoichiometrically linked to the mol of mineral phases, reductive transformation

217 of the mineral phases lead to a change in sorption capacity. The set of surface reactions for

218 ferrihydrite was taken from the *(70)* database and amended with arsenic *(17, 73)*, silica *(74)*,

219 carbonates, and ferrous iron *(75)* surface reactions. Ferrihydrite and goethite surface reactions

13

220   included in the model with respective equilibrium constants are listed in Tables SI4 and SI5 of

221   the Supplementary Information. The affinity constants for ferrihydrite were re-optimized through

222   calibration using their 95% confidence intervals reported in the literature.

223   In addition to complexation onto Fe(III) mineral phases, As reincorporation into the crystalline

224   oxides *(32, 76)* and/or adsorption onto siderite *(29)* were considered. These mechanisms were

225   described through the uptake of total aqueous As (i.e., considering the relative proportion of

226   As(III) and As(V)) by a linear sequestration rate stoichiometrically proportional to the amount of

227   produced siderite and secondary Fe(III) oxide defined as:

$$R_{As\text{-}seq} = \alpha \left(R_{sid\text{-}pptn} + R_{Ostwald} \right) \qquad\qquad (6)$$

228   where α is the molar ratio of As sequestration. We assumed that no significant amount of As was

229   sequestered by mackinawite *(56, 77-78)*.

230   ***Calibration strategy.*** The modeling framework aimed at describing the reductive mineral

231   transformations and the As release at different spatial locations during the in-situ experiments.

232   We used a common set of parameters between the different spatial locations. Therefore,

233   calibration of the model parameters was performed simultaneously by parallelizing the

234   simulations of the considered observation wells (Figure 1b). The model parameters were

235   calibrated in the MATLAB® environment with an automated procedure minimizing the root

236   mean squared error (RMSE) between simulated and measured solid-associated species (i.e., total

237   As and total Fe) throughout the duration of the experiments. Also the secondary mineral

238   composition representative of the samples at the end of the in-situ experiments and determined

239   by Fe K-edge XANES measurements was included in the calibration. Due to the high number of

240 parameters and the non-linearity of the problem, the heuristic, global-search particle swarm

241 optimization (PSO) method was chosen to minimize the objective function *(41, 79)*.

242

Results and discussion

243

244 *Model-based interpretation of the field observations.* The comparison between modeling results

245 and field datasets, displayed in Figure 2, was performed in the three observation wells by

246 considering the temporal change in total solid-associated arsenic (Figures 2a-c), the temporal

247 change in total Fe content (Figures 2d-f), and the amount of iron oxides present in the mineral

248 assemblage at 80 days (Figures 2g-i).
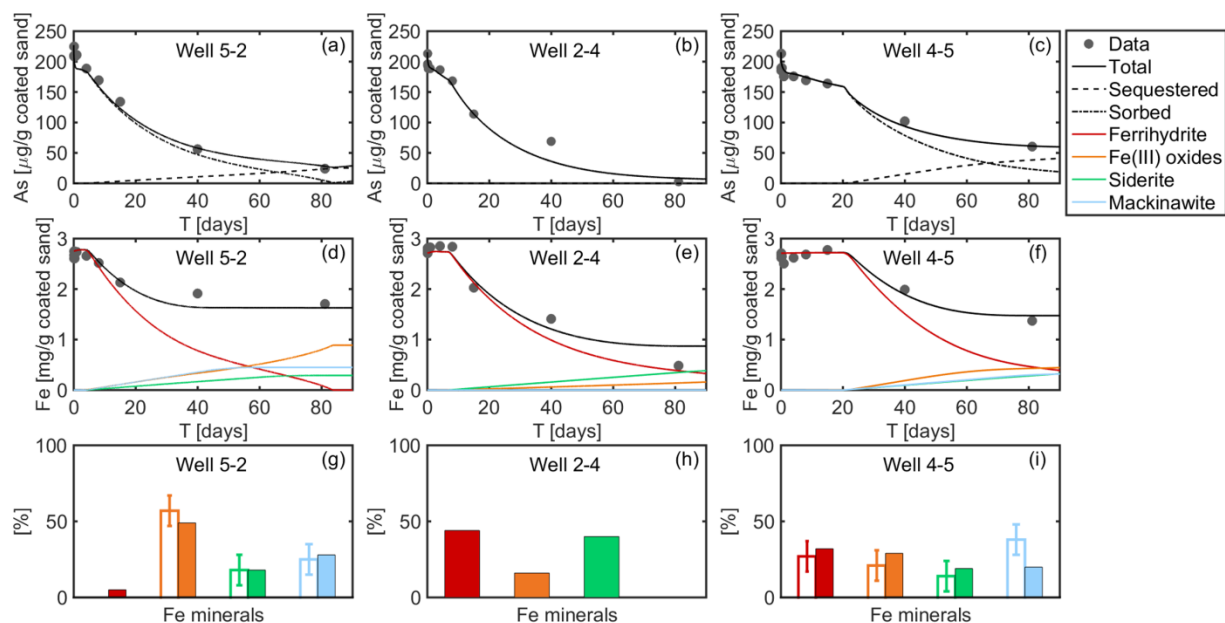

249

250 Figure 2. Comparison between experimental data and simulation results. (a)-(c) Dynamic change

251 in total As (note that no sequestered As was predicted in well 2-4); (d)-(f) dynamic change in

252 total Fe and mineral composition; (g)-(i) mineral composition at the end of the experiment: the

full and empty bars represent simulated and experimental results determined by XANES, respectively. The error bars show 10% uncertainty on quantified mineral fractions for the XANES data available for wells 5-2 and 4-5.

The field data suggest that multiple geochemical processes occurring over different time scales control the As mobilization during the in-situ experiments. Indeed, the solid-associated As concentrations exhibit a complex behavior characterized by a significant and rapid release of arsenic at early time followed by a plateau, particularly visible in wells 2-4 and 4-5, and a subsequent more gradual release. In contrast, decrease in solid-associated Fe did not start when the reactive mineral was exposed to the groundwater but after an initial delay, which was most pronounced in well 4-5. There is a clear consistency between the patterns of As and Fe contents at the different monitoring locations. In particular, the onset of Fe reductive dissolution corresponds to the time at which the arsenic trend shows a change in its slope and starts the gradual decrease which continues throughout the duration of the experiments. The gradual decrease in solid-associated As and the disintegration of the iron mineral phase appears to proceed congruently in wells 2-4 and 4-5. In contrast, in well 5-2 the Fe-content reaches steady state after 40 days whereas the solid-associated As continues to decrease over the whole duration of the in-situ experiments. This difference suggests that the As release cannot be linearly associated with the Fe content. Synchrotron Fe K-edge XANES spectra, available for the samples collected in wells 4-5 and 5-2 at the end of the experiments, show that ferrihydrite was converted into Fe(III) oxide (lepidocrocite, goethite), siderite and mackinawite. In particular, conversion into a more crystalline Fe(III) mineral phase was significantly different in the two wells. Specifically, ferrihydrite was completely consumed and a high amount of Fe(III) oxide

275 was found in well 5-2, whereas high ferrihydrite and a small amount of Fe(III) oxide were

276 observed in 4-5.

277 The existence of multiple surface complexation and mineral transformation mechanisms, which

278 significantly differ among the wells, complicates the interpretation of the processes controlling

279 the As release directly from the experimental datasets. The proposed model allowed us to

280 reproduce the field observations in the three wells with a common set of surface complexation

281 parameters and kinetic parameters for mineral transformation (Tables SI4-6). In particular, the

282 sequential release of As from the solid, occurring at different rates, is captured well by the

283 performed simulations. The modeling results show that the sharp decrease in As at early time is

284 due to desorption as no significant transformation of ferrihydrite was taking place. The duration

285 of the lag phase preceding the reductive microbial dissolution of ferrihydrite (i.e., $t_{i, ferri}$) was

286 found to vary among the wells (Table SI6). This difference could suggest spatial heterogeneity of

287 this reaction in the field *(20, 80)*. Interestingly, the observed lag phase increases along the

288 selected flow line (i.e. from the mountain towards the flat plain). The model calibrated lag phase

289 appears to scale inversely with the flow velocity and allowed us to reproduce the onset of

290 ferrihydrite disintegration with a similar number (~300) of flushed pore volumes in the three

291 wells. During the reductive dissolution/transformation of ferrihydrite, the solid-associated As

292 concentration becomes function of the As adsorbed onto ferrihydrite and sequestered into the

293 secondary mineral phases. Differences in the calibrated molar ratio of As sequestration α (Table

294 SI6) suggests that this process differs among the wells. In particular, the model predicts that 23,

295 0, and 38 µg As/g coated sand were sequestered at 80 days in wells 5-2, 2-4, 4-5, respectively

296 even though the amount of crystalline Fe oxides is higher in well 5-2 than 4-5. Furthermore, the

297 model allowed us to reproduce the measured mineral composition for the two wells in which

17

298 these measurements were performed. Good agreement was achieved between the observed and

299 simulated amounts of Fe(III) mineral phase, as well as of siderite whereas the model

300 underestimates the amount of mackinawite in well 4-5. The outcomes of the calibrated model are

301 also helpful to visualize the temporal trends of secondary mineral formation and ferrihydrite

302 consumption (Figure 2d-f).

303 ***Processes controlling arsenic release.*** The calibrated model was used to distinguish the

304 contributions of different mechanisms controlling the mobilization of arsenic observed during

305 the in-situ experiments. Here, we assess the effects of arsenic change in speciation, sorption,

306 dissolution of ferrihydrite, and arsenic sequestration into secondary Fe oxides. Figure 3a shows

307 the comparison between simulated solid-associated arsenic for well 4-5 using the calibrated

308 model when individually inhibiting these processes by defining 5 scenarios:

309 • Scenario A: calibrated model including reduction of adsorbed As(V) to As(III), sorption,

310 reductive dissolution of ferrihydrite, Ostwald ripening, precipitation of ferrous oxides,

311 and arsenic sequestration into the newly formed minerals;

312 • Scenario B: only sorption processes and reduction of adsorbed As(V) to As(III);

313 • Scenario C: as Scenario A but without As sequestration into secondary minerals;

314 • Scenario D: as Scenario A but without the reduction of As(V) to As(III);

315 • Scenario E: as Scenario A but the change of As(V) to As(III) occurs in the aqueous

316 phase.

317 Figure 3b displays the simulated temporal change of fractional site occupancy occurring to

318 illustrate the sorption competition mechanism taking place during the in-situ experiments. The

319　analysis for the other wells has yielded similar results and is reported in the Supporting

320　Information (Figure SI1).
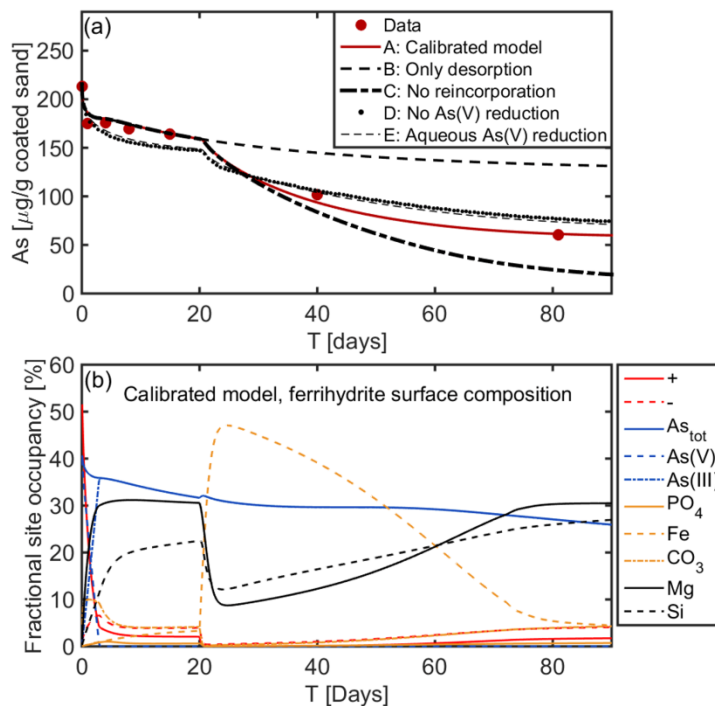

321

322　Figure 3. (a) Temporal change in total solid-associated arsenic concentration predicted for well

323　4-5 when considering different mechanisms of As sequestration and change of speciation. (b)

324　Simulated temporal change in composition of the weak sites (i.e., Hfo_w) of ferrihydrite in well

325　4-5 obtained with the calibrated model.

326　When discarding the iron mineral transformation and only considering As desorption (i.e.

327　Scenario A), the model captures well the first experimental observations but simulates

328　significantly higher As surface concentration after 25 days when ferrihydrite dissolution

329　becomes relevant. This scenario yields a concentration of 133.2 µg As/g coated sand at the end

330　of the experiments that is more than twice the observed value 60.4 µg As/g coated sand (Figure

331　3a). This difference shows that the As release from ferrihydrite surface is primarily determined

332 by the decrease in available sorption sites induced by the disintegration of ferrihydrite whereas

333 sorption competition is of lower importance when reductive dissolution takes place in agreement

334 with the observations of Root et al. *(9)* on artificially deposited ferrihydrite-rich sediments of the

335 North Haiwee Reservoir (Olancha, CA, USA). Conversely, the model scenario that does not

336 include uptake of arsenic into newly formed minerals predicts higher release of arsenic and, thus,

337 lower As concentration at the end of the experiments (i.e., 24.2 µg As/g coated sand at 80 days).

338 These simulation results underpin the importance of As sequestration into secondary minerals for

339 the observed behavior at the field site.

340 Direct microbially-mediated reduction of aqueous and/or adsorbed As(V) has been extensively

341 observed during transition from aerobic to anaerobic conditions *(30-31)*. However, the sequential

342 order in which the biotic reduction of Fe(III) oxide minerals and As(V) occur has been debated

343 *(14, 30, 81-83)*. Furthermore, it remains unclear whether bacteria can directly transform the

344 As(V) into As(III) on the surface or initially requires the desorption of As(V). Here, the

345 speciation change of surface-associated As(V) led to the best agreement with the field dataset. In

346 particular, this mechanism is predicted to limit the release of As from ferrihydrite as a stronger

347 initial As release that is predicted when reduction of surface As(V) is not considered (Scenarios

348 D and E in Figure 3a). When analyzing the simulated temporal change in surface composition

349 (Figure 3b), the adsorbed As(V) becomes As(III) at early times of the in-situ experiments

350 preceding the reductive dissolution of ferrihydrite (e.g., 7 days in well 4-5).

351 The solid-associated As at the end of the experiment days was predicted as As(III) whereas the

352 speciation determined by K-edge XANES measurements indicated As(V) as the dominant

353 species (Table SI3). This discrepancy may result from the oxidation of As(III) via interaction

354 and/or sequestration into the formed crystalline iron phases as observed by Amstaetter et al. *(76)*.

355 Indeed, the model indicates that the main part of the solid-associated As (i.e., 80% and 62% in

356 wells 5-2 and 4-5, respectively) is sequestered by the secondary iron oxides at the end of the in-

357 situ experiments.

358 At the beginning of the in-situ experiment, a significant part of the As(V) rapidly desorbs (i.e.,

359 49 to 35 % surface sites occupancy; Figure 3b). A sensitivity analysis assessing the effect of the

360 aqueous species on the surface composition of ferrihydrite indicates that this desorption is

361 induced by the rapid drop in surface charge primarily due to the re-equilibration of the

362 ferrihydrite surface with the groundwater and, to a lower extent, to the competitive sorption

363 effects of dissolved bicarbonate and silica (see Supplementary Information, Figure SI4). Due to

364 the local hydrochemical conditions and the high As(III) concentrations in the groundwater, none

365 of the aqueous species seems able to substantially compete for As(III) sorption sites as shown by

366 the steady As(III) fractional site occupancy (Figure 3b) leading to a plateau regime in the As

367 surface concentration until As(III) mobilization is triggered by the disintegration of ferrihydrite

368 (Figure 3a). In particular, the As(III) surface site occupancy remains steady at the onset of

369 microbial dissolution of ferrihydrite (i.e., 20 days) characterized by an abrupt change in surface

370 composition due to the strong adsorption of Fe(II) concomitant to a sharp desorption in Mg and

371 Si. Similar behavior of As adsorbed onto ferrihydrite is predicted in the other wells even though

372 the sequestration of As into secondary mineral phases spatially differ (Supporting Information,

373 Figure SI1 and Table SI6).

374 ***Reductive transformation of ferrihydrite.*** The reductive transformation of ferrihydrite

375 significantly controls the As release through the dissolution of the solid phase. This leads to a

376   reduction of sorption sites and to the formation of new mineral phases that can potentially

377   sequester arsenic. The model allowed us to assess the relative contribution of the reductive

378   dissolution, Fe(II)-catalyzed transformation, and precipitation of Fe(II)-mineral phases on the

379   change in the total Fe content and in the composition of the mineral assemblage. Figure 4

380   displays the simulation results obtained when considering individually these iron mineral

381   transformation mechanisms through the definition of four different modeling scenarios:

382   • Scenario 1: calibrated model (same as Scenario A above);

383   • Scenario 2: only reductive dissolution of ferrihydrite with no further Fe(II) reactions (i.e.,

384   no Ostwald ripening and no Fe(II) precipitation with carbonate and sulfide);

385   • Scenario 3: as Scenario 2 but including Fe(II) precipitation with carbonate and sulfide;

386   • Scenario 4: Fe(II) allowed to react with ferrihydrite through Ostwald ripening but without

387   reductive dissolution.
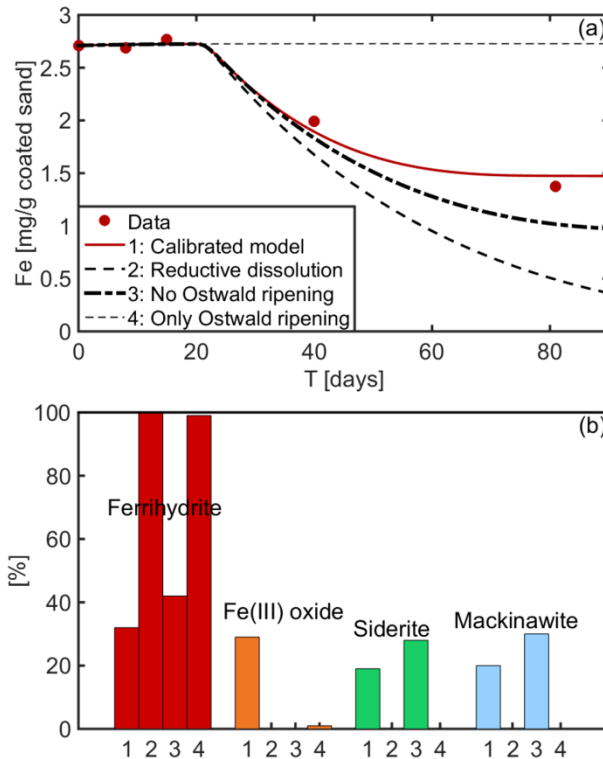

388

389 Figure 4. (a) Temporal change in total Fe content assessed through the different model scenarios;

390 (b) composition of the mineral assemblage at 80 days predicted for well 4-5 using the model and

391 considering the contributions of the different transformation mechanisms studied in Scenario 1-4.

392 Figure 4a shows that the observed pattern of Fe content measured in well 4-5 is captured well by

393 the calibrated model (Scenario 1). When only defining the reductive dissolution of ferrihydrite

394 (Scenario 2) the Fe-content is significantly underestimated (e.g., 0.49 mg Fe/g coated sand

395 compared to the experimental observation of 1.37 mg Fe/g coated sand at 80 days). The

396 formation of ferrous iron minerals limits the decrease in solid-associated Fe and improves the

397 agreement with the field data as illustrated by Scenario 3 (e.g., 1.01 mg Fe/g coated sand at 80

398 days). However, this scenario does not include Ostwald ripening and results in a slight

399 underestimation of the Fe content. Finally, Scenario 4 that only considers the effect of Ostwald

400 ripening does not capture the observed behavior. This scenario predicts a constant Fe content,

401 and only minimal conversion of ferrihydrite into Fe(III) oxide compared to Scenario 1. These

402 results suggest that, under the investigated field conditions, the Fe(II) groundwater

403 concentrations are not sufficient to promote significant recrystallization of ferrihydrite and that

404 the reductive dissolution of ferrihydrite is a prerequisite to generate the local Fe(II)

405 concentrations necessary to substantially convert ferrihydrite into Fe crystalline phases. In

406 particular, the comparison between Scenario 1 and Scenario 3 shows that Ostwald ripening

407 improves the agreement with the experimental data, through the preservation of solid-associated

408 Fe, when it is considered together with the reductive dissolution of ferrihydrite and the formation

409 of Fe(II) secondary minerals.

410 ***Fe(II)-induced mineralization pathways.*** The type of secondary minerals, as well as the extent

411 and the kinetics of the conversion of ferrihydrite into more crystalline Fe(III) oxides, are

412 primarily controlled by the supply rate and the magnitude of the aqueous Fe(II) concentration *(21,*

413 *84)*. However, significant differences in the crystallization of ferrihydrite can be observed

414 between the wells despite similar surface and aqueous Fe(II) concentrations simulated upon

415 ferrihydrite dissolution (Figure SI3). This suggests that other mechanisms influence the Fe(II)-

416 induced transformation of ferrihydrite and ultimately the As mobility. Adsorbed trace elements

417 and/or the presence of major ions are known to determine the choice of the Fe(II)-induced

418 mineralization pathway from ferrihydrite *(69, 85)*. In particular, the lower crystallization of

419 ferrihydrite predicted in well 2-4 (Figure 2) might be ascribed to the relatively higher chloride,

420 sulfate and bicarbonate concentrations in that well directly considered in the kinetic rate

421 expression controlling the Ostwald ripening reaction (Equation 2, Table SI2), which is in

422 agreement with previous studies *(69)*. Furthermore, the presence of magnetite that forms through

423 topotactic transformation during Fe(II)-induced crystallization of ferrihydrite was not observed

424 during the in-situ experiments. Magnetite is typically observed in presence of high ferrous iron

425 concentrations that impede the release of Fe(II) from the mineral and result in a mix Fe(II)-Fe(III)

426 solid *(23-24, 65, 21, 66, 69)*. Despite relatively low dissolved Fe(II) concentration simulated by

427 the model (always less than 1 mM, Figure SI3), the ratio between ferrous iron and ferrihydrite

428 concentrations at which formation of magnetite is typically observed (i.e., 1 mmol Fe(II)/g Hfo

429 *(39)*) was exceeded upon reductive dissolution of ferrihydrite (i.e., [2 - 10] mmol Fe(II)/g Hfo).

430 However, magnetite was not observed during the in-situ experiments. This result can be

431 explained by the relatively low groundwater concentration of Fe(II) that was maintained during

432 the initial phase preceding the onset of ferrihydrite reduction. Over this initial period,

433 accumulation of small amounts of lepidocrocite and/or goethite favored by the action of Fe(II) on

434 ferrihydrite could have led to surface site passivation preventing the formation of magnetite

435 despite the high concentration of Fe(II) occurring upon ferrihydrite reductive dissolution. A

436 similar effect has been observed in controlled laboratory experiments *(64)*.

437 ***Implications.*** The reductive dissolution of poorly crystalline iron oxides has been recognized as

438 one of the predominant pathways leading to As contamination of groundwater *(7, 20)*. However,

439 the complex interplay of geochemical processes in natural groundwater systems hampers a

440 detailed description of the mechanisms controlling the fate and evolution of mineral phases and

441 As release from the sole analysis of water chemistry and mineral characterization data. This

442 study has highlighted the importance of multiple mechanisms (i.e., surface complexation,

443 reductive dissolution, formation of secondary iron minerals and arsenic sequestration into the

444 newly formed minerals), occurring at different time scales and with significant spatial variability,

445 when groundwater contacts ferrihydrite and triggers the release of arsenic. The model-based

446 interpretation of the in-situ experiments was instrumental to disentangle the roles of the different

447 geochemical processes on the evolution of the mineral assemblage and arsenic in the flow-

448 through system. While part of the arsenic rapidly desorbed from ferrihydrite, most of the

449 mobilization of solid-associated arsenic was controlled by the reductive dissolution of the

450 primary mineral and sequestration (i.e., sorption and reincorporation) into secondary iron oxides

451 in agreement with previous laboratory studies *(30)*. Formation of these more crystalline phases

452 was found to be induced by the Fe(II) generated from the disintegration of ferrihydrite triggering

453 further mineral crystallization. The model highlights important implications of different

454 geochemical mechanisms on the evolution of solid-associated iron and, thus, on the release of

455 arsenic. The kinetics of the transformation of ferrihydrite was particularly influenced by the

456 dissolved groundwater species (e.g., charged solutes) through chemical and electrostatic

457 interactions, and by mineral assemblage composition and transformation. The absence of

458 magnetite formation during the in-situ experiment, despite the high level of generated Fe(II),

459 contrasts with previous laboratory studies which extensively reported magnetite formation upon

460 reductive dissolution of ferrihydrite. This calls for further investigation on the mechanisms

461 controlling the mineralization pathway during Fe(II)-catalyzed transformation of ferrihydrite.

462 The outcomes of this modeling study emphasize the importance of detailed experimental

463 observations able to capture the temporal dynamics and the spatial variability of geochemical

464 controls on arsenic mobilization. The determination of solid-associated arsenic and iron

465 concentrations, together with the microscopic and spectroscopic characterization of primary and

466 secondary minerals and the chemistry of the groundwater, contributed to underpin the model-

467 based interpretation.

468 The performed model-based analysis was carried out using a one-dimensional flow-through

469 approach at specific spatial locations where experimental observations were available. The

470 understanding gained on the temporal dynamics and kinetic parameters for the different

471 geochemical processes could be exported and tested in multidimensional flow-through domains,

472 which have additional degrees of freedom whose effects cannot be easily extrapolated from 1-D

473 setups *(86-87)*. The integration of the knowledge on arsenic release and iron transformation in

474 multidimensional reactive transport models of groundwater flow systems will allow the joint

475 consideration of the geochemical complexity, highlighted in this investigation, with the physical

476 and chemical heterogeneity of groundwater flow system *(88-91)*. This will contribute to improve

477 our capability to describe and predict the release, transport, and fate of arsenic in complex,

478 heterogeneous aquifer systems. Such approach based on mechanistic description of physical and

479 biogeochemical processes also represents a promising design tool for remediation strategies

480 based on amendments injection and enhanced reactive mineral transformation.
