Production of molecular scale palladium (Pd) nanoparticles (NPs) is important due to their catalytic function in electrochemical oxidation of a number of core fuel molecules in fuel cells. Biogenetic methods offer an economic and environmentally friendly synthesis route. In this work, the electrochemically active bacterium *Shewanella oneidensis* MR-1 is employed as a reducing agent to generate PdNPs as well as a support for immobilization of the PdNPs. The synthesis was carried out at 28 °C and pH 7.0, and completed within one hour. The PdNPs are monodisperse (6.2 nm) and located on the bacterial membrane surface. Mapping by conductive atomic force microscopy shows that the presence of these PdNPs promotes electron transfer and enhances the electric conductivity of the cells. Compared to electrodeposited PdNPs, PdNPs generated by *S. oneidensis* MR-1 catalyzes electrochemically the oxidation of formate with 200 mV less over potential. Notably they show unique selective activity toward electrochemical oxidation of formate, whereas no electrochemical catalysis was found for oxidation of ethanol, methanol, acetate, and formate. This work demonstrates a sustainable and low-cost method for producing efficient PdNPs catalysts with high catalytic selectivity.

Introduction

Noble metals such as Palladium (Pd) and platinum (Pt), are important catalysts in energy conversion, chemical reactions and abiotic electrochemical processes^{1,2}. Nanoparticles (NPs) provide a large specific surface area, favourable electron density distribution, and reactive surface sites. They have been shown to assist effectively reduction/oxidation reactions of organic molecules³. Particularly, noble metal NPs are the most successful electrocatalysts for oxidation of small bio-organic molecules⁴, such as formic acid, ethanol, methanol, acetate and oxalate^{5,6}. These cost friendly molecules can be used as fuels in fuel cells to convert chemical energy into electricity by electrochemical reactions⁷⁻⁹. Formation of PdNPs from inorganic Pd salt is a redox process and 50–150 nm PdNPs can

be prepared by electrodeposition in 3 M HCl¹⁰ or chemical synthesis¹¹⁻¹². However, only few of such PdNPs can catalyze selectively specific reactions¹³.

Biosynthesis of metal NPs was emerged in late last century using *Pseudomonas stutzeri* for synthesis of silver-based crystalline nanoparticles¹⁴. The method is developing fast due to sustainability and environmentally friendly reaction conditions¹⁵⁻¹⁶. Microorganisms such as *Shewanella* and *Geobacter* have been found to be highly reactive towards binding of metal ions¹⁷ and to induce precipitation of nanomaterials under mild conditions¹⁸. So far, the ability of producing PdNPs has been reported using a number of microbes such as *Desulfovibrio desulfuricans*¹⁹ and *Escherichia coli*²⁰. The cells were exposed to Pd(II) aqueous solution with dihydrogen, formate, or acetate as the electron donors. Notably, biogenic palladium nanostructures have been demonstrated to catalyze various reduction reactions including perchlorate degradation, chromate reduction, chlorophenol dehalogenation¹⁹⁻²², and reductive dehalogenation of polychlorinated biphenyl congeners in sediment and aqueous matrices²³. In addition, biogenic PdNPs were reported to serve as effective catalysts in the synthesis of organic compounds^{19,24}. Due to poor intrinsic conductivity of the bacterial cells, carbonization of the cells was employed so that the PdNPs could be used as electrocatalysts. A binder such as Nafion also had to be employed to fix the PdNPs firmly on the electrode surface²⁵.

Shewanella oneidensis MR-1 belongs to a class of Gram-negative bacteria and is chosen as a target microorganism in the present work due to its unique electrochemical activity²⁶⁻²⁷. *S. oneidensis* MR-1 can transfer electrons from the inner to the outer membrane, and eventually to exogenous electron acceptors²⁸, resulting in the reduction of metal ions. While cytochrome *c* plays an important role in the reduction of iron and silver, several studies have demonstrated that hydrogenases play a leading role in microbial Pd(II) reduction^{29,30}. Specifically, the hydrogenases but not cytochrome *c*, are mainly responsible for Pd(II) reduction in *S. oneidensis* MR-1³¹. In addition, extracellular polymeric substances (EPS) of *Shewanella* biofilm contain over 20 redox active proteins^{32,33}. Our recent work showed that EPS in this strain were transient media for microbial extracellular electron transfer³⁴.

S. oneidensis has shown its ability to biosynthesize metallic (Fe, Au) nanomaterials by reduction or adsorption of metal ions or complexes from the surrounding medium^{35,36}. Recently, highly-porous heteroatom-doped carbon with well-dispersed 150 nm PdNPs has been developed through biogenic reduction on *S. oneidensis* and activation at 420 °C in KOH and found to electrocatalyze strongly the electrochemical dioxygen reduction reaction⁹. Furthermore, formic acid (HCOOH) is an organic biomolecule widely used in chemical industry and a byproduct in the manufacture of other chemicals. Electrochemical oxidation of formic acid (FA) is another core anodic reaction in FA fuel cells.

In this work we develop a method for synthesizing small PdNPs as electrocatalysts under mild conditions using *S. oneidensis* MR-1. Here the bacterial cells serve as electron donors (as reducing agent) and supporting materials for immobilization of the formed PdNPs. Microscopic techniques such as transmission electron (TEM), atomic force microscopy (AFM) and particularly current sensing AFM are employed to map the structures and compositions of *S. oneidensis* MR-1 and PdNPs. We find that the presence of the PdNPs increases significantly the electric conductivity of the biological cells. The PdNPs prepared and immobilized on *S. oneidensis* MR-1 show strong electrochemical catalysis specifically toward oxidation of formic acid, but no catalysis for other small organic fuel molecules, ethanol, methanol, and acetate. Such selectivity is unique and important for development of FA fuel cells.

Experimental section

Chemicals

Sodium tetrachloropalladate (98%, Sigma-Aldrich), sodium lactate (98%, Sigma-Aldrich L7022), sodium formate (99.0%, Fluka), sodium acetate (99.0%, Sigma-Aldrich), methanol (99.9%, Sigma-Aldrich), ethanol (99.9 %, Uvasol), Luria-Bertani (LB) Broth (L3022, Sigma-Aldrich) were used without further purification. Phosphate buffer solution (PBS) was prepared from potassium phosphate salts (KH₂PO₄, 99.995%; K₂HPO₄, 99.999%; Fluka). The precise pH was measured by pH meter.

All solutions were prepared with ultrapure water (18.2 MΩ·cm).

Bacterial growth and Pd(II) bioreduction assay

Shewanella oneidensis MR-1 from ATCC (USA) was grown aerobically in LB medium overnight at 28 °C. The cells were then harvested and transferred into sterile 50 ml centrifuge tubes by centrifuging at 4000 rpm for 10 min, followed by washing three times with phosphate buffer (50 mM, pH 7.0). The washed cells were resuspended with 40 ml lactate medium in glass serum bottles. Serum bottles were capped with inert viton stoppers. A control reactor containing no cells was set up in parallel. Bioreduction assays that excluded dioxygen were flushed with N₂ for 30 min. Finally, 0.20 mM sodium tetra-chloropalladate(II) was added to the bioreduction assay. The serum bottles were then incubated overnight at 28 °C. pH in all assays remained 7.0 ± 0.1 and all assays were performed in triplicates.

UV-vis spectroscopy

Ultraviolet-visible (UV-vis) absorption spectra were recorded for different bacterial and chemical solutions using quartz cells and an Agilent 8453 UV-vis spectrophotometer.

Transmission electron microscopy (TEM)

Samples for TEM were prepared by transferring the cells from sealed batch cultures and immediately fixing the cells by glutaraldehyde solution (2.5 % final concentration). Samples were then subjected to a serial dehydration protocol using increasing concentrations of ethanol and placed onto a carbon coated copper grid. After drying at 60 °C for 24 h, the desiccated samples were imaged by a transmission electron microscope (Tecnai G2 F30, Philips-FEI, Netherlands).

X-ray diffraction (XRD) and sample preparation

After the exposure to sodium tetrachloropalladate, *S. oneidensis* MR-1 was collected by centrifugation at 8000 xg for 10 min, and washed three times with ultrapure water. The cells were then dried at 60 °C. A X-ray diffractometer (X'Pert PRO, PANalytical) was employed for XRD analysis to determine the composition of the nanoparticles. Each sample was scanned in the θ -range of 5-90 °.

Atomic Force Microscopy (AFM), sample preparation, and image acquisition.

Bacterial cells were collected by centrifugation (8000 xg, 10 min), and washed three times with ultrapure water. The cell resuspension was dropped on a platinum sheet (1.0 × 1.0 cm²) and dried at room temperature. A PicoScan 5500 instrument (Agilent Technologies, Chandler, AZ, USA) with an 80 μm scanner and cantilevers (NP-S) from Veeco (Camarillo, CA, USA) were used to obtain the AFM images. Contact mode was used to record all the signals. All AFM images shown are representative of a large number of images under the same conditions. The contact mode AFM (Pico View, Agilent) with a

current-sensing module, known as current sensing AFM (CS-AFM), was utilized to obtain simultaneously topography, deflection and current images. Chromium-platinum (Cr/Pt) coated cantilevers (spring constant, 0.2 N/m) were from Budget Sensors (Sofia, Bulgaria). The load force applied was less than 10 nN to avoid damage of samples and the conductive tip. The bias voltage between conductive cantilever and substrate (Pt) was 50 mV in all imaging experiments.

Electrode preparation and electrochemical measurements

Cells of *S. oneidensis* MR-1 were collected by centrifugation at 8000 xg for 5 min, and washed three times with phosphate buffer (50 mM, pH 7.0). 5 μ L of cell pellet was transferred to the surface of a glassy carbon (GC) electrode and dried at room temperature.

A three-electrode glass cell with the prepared GC working electrode, a saturated calomel (SCE) reference electrode and a Pt wire counter electrode confined in a Faraday cage was used for the electrochemical measurements. Cyclic voltammetry was carried out using an Autolab potentiostat (The Netherlands). The scan rate was 10 mV/s. All electrochemical tests were repeated at least 5 times and all measured potentials are reported vs SCE. Phosphate buffer (50 mM, pH 7.0) was used as electrolyte. Argon (5.0 N) was used to deoxygenate all solutions for at least 30 min and an argon stream was kept flowing over the solutions.

Results and discussion

Biosynthesis of PdNPs

Scheme 1. Illustration of the biosynthesis of PdNPs on *S. oneidensis* MR-1.

The process of biogenic synthesis of PdNPs using *S. oneidensis* MR-1 is presented schematically in Scheme 1. The bacterial cells serve as reducing agents for reduction of $[\text{PdCl}_4]^{2-}$ to PdNPs as well as a support for immobilization of the freshly formed PdNPs. The colour of the *S. oneidensis* MR-1 containing medium changed from light yellow into dark brown within 10 min (Figure 1, A and B) after the injection of aqueous $\text{Na}_2[\text{PdCl}_4]$. The rapid formation of PdNPs on *S. oneidensis* cells is due to high hydrogenase content in the cells³⁷. A series of UV-vis spectra indicate that the synthesis is complete (Figure 1C). Aqueous $\text{Na}_2[\text{PdCl}_4]$ solution itself showed a distinct absorption peak at 411 nm. When the solution colour changed into dark brown, the $[\text{PdCl}_4]^{2-}$ absorption peak disappears totally. Bacteria-free solution still showed the 411 nm absorption peak in the same time interval, though the peak became narrower. This shows clearly that the reduction was conducted due to *S. oneidensis* MR-1 rather than any chemical component in the medium.

Figure 1. Photos of the solutions (A) before and (B) after the reaction of bacteria with $\text{Na}_2[\text{PdCl}_4]$; (C) UV-vis spectra of $\text{Na}_2[\text{PdCl}_4]$ (black line), control experiment without bacteria (red line), and supernatant of the bacterial solution after reaction (blue line). OD_{600} of the bacterial solution was 0.6 and the final concentration of $\text{Na}_2[\text{PdCl}_4]$ was 0.10 mM.

Properties of bio-PdNPs

The presence and composition of PdNPs were further mapped by scanning transmission electron microscopy (STEM). Representative images of bacterial cells and the biosynthetic PdNPs at a $\text{Na}_2[\text{PdCl}_4]$ concentration of 0.4 mM are shown in Figure 2. When the cells were exposed to $\text{Na}_2[\text{PdCl}_4]$ solution, highly dispersed NPs were observed on the bacterial cell surface. The size of the PdNPs was determined to be in the 3–10 nm range with an average diameter of 6.2 nm (Figure S1). The size and distribution of PdNPs are highly reproducible both within a single sample and among different samples with the same treatment. Compared with the High-Angle-Annular-Dark-Field (HAADF) micrograph, the single cell can be distinguished by the presence of biologically common chemical elements such as carbon, nitrogen and phosphorous. After formation, the composition of the nanoparticles was determined and the Pd element distribution found to match well the shape of the bacterial cell (Figure 2E and F). X-ray diffraction (XRD) was employed to further determine the valence state of the biogenetic PdNPs (Figure S2). Five new peaks occurred after the cells had been exposed to 1 mM $\text{Na}_2[\text{PdCl}_4]$ solution. By comparing with standard PDF card [JCPDS file no. 03-05-6174.], these emerging peaks at $2\theta = 40.230^\circ$, 46.651° , 68.119° , 82.050° and 86.672° , are assigned to Pd(111), Pd(200), Pd(220), Pd(311) and Pd(222) reflections, respectively. These results confirm that PdNPs had been formed on the *S. oneidensis* MR-1 surface.

Figure 2. TEM images of a *S. oneidensis* MR-1 cell (A, B) before and (C, D) after the bio-reduction of Pd(II); (E) HAADF image of a *S. oneidensis* MR-1 cell after PdNP formation and (F) EDS mapping of the red box area in E showing clusters mainly composed of palladium (blue points).

Dynamics of the biogenic PdNP synthesis

The formation of PdNPs is a redox process when palladium salt is in contact with reducing agents in the solution. The redox potential of the solution therefore changes during consumption of the oxidation agent and can be measured by chronopotentiometry. $\text{Na}_2[\text{PdCl}_4]$ solution with a yellow colour was reduced to palladium atoms, which further underwent nucleation and growth to develop into PdNPs with a deep brown colour. The reduction process can be described by equation 1.

The reaction was accompanied by equilibrium potential changes in the solution. The time-dependent potential represents the development of the ratio between the oxidized and reduced forms, thus reflecting the dynamics of the reduction process³⁸. The time dependence of the potential was dominated by reduction of $\text{Na}_2[\text{PdCl}_4]$. The potential value of $\text{Na}_2[\text{PdCl}_4]$ is different from that of the buffer and bacterial cells, and equilibrates much faster.

To investigate the biosynthesis process, indium tin oxide (ITO) and saturated calomel electrode (SCE) were used as working and reference electrode. Anaerobic condition was achieved by bubbling Ar gas for 40 min. Bare ITO or bacteria coated ITO

was initially inserted into the phosphate buffer (lactate, 5 mM), followed by recording the open circuit potential (OCP) between the working and reference electrode during the reaction. When the potential reached a stable value, a certain amount of 0.20 mM $\text{Na}_2[\text{PdCl}_4]$ solution (final concentration) was injected in 10 ml medium solution. Figure 3 shows several examples of time-dependent potential evolution at different $\text{Na}_2[\text{PdCl}_4]$ concentrations. The time evolution of the OCP is complex, and several kinetic phases can be clearly distinguished, as reported for AuNP formation via $[\text{AuCl}_4]^-$ reduction by 2-(N-morpholino)ethanesulfonic acid (MES)³⁸. The OCP for bare ITO increased from 0.01V to 0.31V immediately after $\text{Na}_2[\text{PdCl}_4]$ addition and kept at a relatively stable value (0.29 V) for a long time. The slight decrease in potential right after addition was caused by diffusion of $\text{Na}_2[\text{PdCl}_4]$ in the bacteria-free medium. For bacteria coated ITO, the potential rose steeply after adding $\text{Na}_2[\text{PdCl}_4]$. At lower $\text{Na}_2[\text{PdCl}_4]$ concentration (0.1 mM, 0.2 mM), the OCP increased less and reached a maximum in 100-150 seconds, while at higher $\text{Na}_2[\text{PdCl}_4]$ concentrations (0.3 mM, 0.4 mM), the OCP increased rapidly and reached its maximum in about 50 seconds followed by a decay. The potential decay was slow and changed slightly at low $\text{Na}_2[\text{PdCl}_4]$ concentration, but was much faster at a higher concentration with a slower further decay appearing after 250 s.

Although with clearly distinct kinetic phases as for AuNP formation by MES reduction³⁸, the overall shape of the chronopotentiometric curves are different. Fast and slow potential increases were found on initial stage of AuNP formation followed again by biphasic potential decay³⁸. Such a pattern was attributed to formation of the intermediate $[\text{AuCl}_2]^-$ prior to formation of Au atoms during the early stage of the synthesis process³⁸. Here we conclude that $\text{Na}_2[\text{PdCl}_4]$ reduction occurs due to certain compounds on the *S. oneidensis* MR-1 cell surface. We note that the OCP decrease ends within 250 s and reached a stable value in 1200 s, implying that the reduction reaction is complete. This observation accords with the colour change of the bacterial solution in contact with $\text{Na}_2[\text{PdCl}_4]$. Further, the final OCP value depends on the starting concentration of $\text{Na}_2[\text{PdCl}_4]$, i.e. the OCP using 0.40 mM was higher than that using 0.30 mM, although the net increases were small (0.49 V and 0.51 V, respectively).

Figure 3. Time dependent potential change during the biosynthesis of PdNPs. $\text{Na}_2[\text{PdCl}_4]$ (final concentration 0.2 mM) was injected (0 s) to each solution at room temperature. Addition of a final concentration of 0.2 mM $\text{Na}_2[\text{PdCl}_4]$ to a bare ITO electrode was used as a control experiment (Black line). Bacterial cell coated ITO after addition of 0.1 (Red line), 0.2 (Blue line), 0.3 (Green line), and 0.4 (yellow line) mM $\text{Na}_2[\text{PdCl}_4]$ were recorded. Magnetic stirring was maintained throughout. 50 mM phosphate buffer (pH 7.0) was used as supporting electrolyte.

Enhancement of cell conductivity

Current Sensing-AFM (CS-AFM) provides information on the correlation between the sample morphology and characteristic current pathways³⁹. Herein, CS-AFM (in air) was employed for the study of *S. oneidensis* MR-1 cells before and after PdNPs biosynthesis to investigate changes in cell conductivity. A polished platinum sheet was used as a conductive supporting material. Bacterial cells with or without PdNPs were drop cast on the platinum sheet which was electrically insulated from the sample plate. A copper wire served as an electrode to connect the sample plate and the platinum sheet. A conductive AFM tip coated with Pt/Cr was used to image topography and corresponding currents that flow vertically through the cells by contacting the cells. A small bias voltage (50 mV) between the tip and the substrate was applied when the tip was scanning horizontally over the samples. The vertical currents at each point are relevant in evaluating the electrical properties of the bacterial cells.

Figure 4 shows typical topographic and current images simultaneously obtained for *S. oneidensis* MR-1 cells in the presence/absence of PdNPs. In the topographic images, flat surfaces for Pt sheets were observed and the *S. oneidensis* MR-1 cells feature of were seen clearly. The bacterial cell surface is relatively rough regardless of with or without PdNPs. It is hard to distinguish PdNPs on the cells in topography AFM images due to their small size and the curvature of the bacterial surface, Figure S3. On the other hand, current-sensing AFM (CSAFM) can distinguish clearly different conductivity of the PdNP free and PdNP modified bacterial cells. Bright regions in the CSAFM images represent currents flowing vertically from the tip to the substrate while dark spots show insulating regions. Under the conditions used, these current flow patterns were observed in all samples. Pure bacterial cells

exhibit obvious morphology in topography and appear dark in current images, indicating poor conductivity. The cell height was measured by the AFM cross section profile. In the presence of PdNPs, the bacterial cells showed weak electric currents, demonstrating enhanced electric conductivity, due to enhanced electronic charge transport (tunnelling, or hopping) by PdNPs. CS-AFM images thus show clearly highly conspicuous conductivity increases induced by the PdNPs.

Figure 4. AFM images of typical topography and current-sensing AFM (CSAFM) image for natural *S. oneidensis* MR-1 cells (A) and *S. oneidensis* MR-1 cells with PdNPs (B). The scan area was $20 \times 20 \mu\text{m}^2$.

Selective catalysis toward electrochemical oxidation of formate

The electrocatalysis of the electrochemical oxidation reactions of several (bio)fuel molecules with the conducting *S. oneidensis* MR-1 cells with PdNPs on glassy carbon (GC) electrode as heterogeneous catalysts was investigated. Figure 5A shows cyclic voltammograms of electrodeposited Pd on glassy carbon electrode in 0.10 M formate at room temperature. There is a strong anodic peak at 0.15 V as a characteristic feature for catalysis of electrochemical formate oxidation. A dual pathway mechanism for formic acid oxidation with Pd or Pt-based catalyst is commonly accepted^{40,41}. The direct pathway via a dehydrogenation is the more desirable, as a reactive intermediate is formed in this pathway. Another reaction pathway is an indirect path via dehydration in which adsorbed CO as an intermediate catalyst poisoning species is formed. The voltammetric pattern of the electrochemical oxidation of formate is featured by two distinct anodic current peaks, one in the forward potential scan, and the other one in the reverse scan. This one-peak graph is characteristic of the direct formate oxidation pathway, in which HCOOH loses two H-atoms, at the same time generating CO_2 and H^+ , equation (2):

In contrast, there are three peaks in the absence of formate in the forward scan, corresponding to different electrochemical processes at the Pd surface. The redox peaks on Pd at the

potential -0.6V, are caused by the oxidation of adsorbed and desorbed hydrogen⁴¹. The second peak, at -0.4V is attributed to the adsorption of OH^{-42,43}, while the third peak above 0.1V is assigned to the formation of the palladium(II) oxide⁴⁴.

Figure 5. Cyclic voltammograms of (A) electrodeposited Pd on GC electrode; pure *S. oneidensis* MR-1 on GC (B) and (C) *S. oneidensis* MR-1 with bio-PdNPs on GC electrode in 0.10 M formate and 0.10 M pH 7.0 phosphate buffer solution. Scan rate 10 mV/s; and (D) chronoamperometric curve of methanol, ethanol, acetate, and formate oxidation at *S. oneidensis* MR-1 with bio-PdNPs and the potential held at -0.1 V. Final concentrations of methanol, ethanol, acetate, and formate are 0.10 M. Inset figures in (A) and (C) show CVs of electrodeposited Pd and PdNPs-cells on GC in 0.10 M pH 7.0 PBS, respectively.

The CVs in Figure 5B show the redox reaction from the cells and formate. The CV of *S. oneidensis* MR-1 exhibits a pair of electrochemical peaks at +0.05 V and -0.23 V. These are caused by cytochrome *c*. Addition of formate did not generate any strong anodic peak, i.e. electrocatalysis of formate oxidation did not occur with *S. oneidensis* MR-1. The oxidation current was slightly increased probably due to formate oxidation by the respiration of the cells. This result shows that pure *S. oneidensis* MR-1 cells cannot catalyse oxidation of formate electrochemically, but are able to use it as an electron donor.

Scheme 2. Selective catalysis of fuel molecule oxidations on the bio-PdNPs.

Notably, formate oxidation on PdNPs-cell coated GC electrode gives a similar CV pattern as on electrodeposited Pd, but with more than an order of magnitude larger current, Figure 5C. In the forward scan, formate oxidation begins from -0.60 V with one strong anodic peak at -0.10 V. In the cathodic scan, the anodic current started at 0.20 V, and reaches a maximum at -0.10 V. This distinct current peak is related to the removal of carbonaceous substances that were not completely oxidized in the forward scan rather than the oxidation of freshly chemisorbed substance. The high oxidation current observed in the reverse potential sweep is attributed to the regeneration of the active PdNPs surface sites. We note that the anodic formate oxidation peak is 220 mV more negative on biogenetic PdNPs than on electrodeposited Pd, suggesting less activation energy needed and better electrocatalysis on PdNPs-cells achieved.

High catalytic activity of the biogenetic PdNPs could be caused by the combination of PdNPs with bacterial membrane proteins. Such high catalytic activity is unique and the physical origins of this efficient electrocatalysis is under investigation. We can conjecture that bacterial proteins with multiple electronic and electron transfer systems could affect the three-dimensional electronic PdNP structure, leading to more easily adsorbed formate molecules and dehydration to produce CO₂ on the PdNPs. The proteins may also weaken the adsorption of the CO intermediate on the Pd surface, thus reducing poisoning of the bio-PdNPs. CO is thus a catalytic poison formed and adsorbed on the Pd surface at higher potentials². Our results strongly suggest that the PdNPs formed by *S. oneidensis* MR-1 cells are suitable catalysts with excellent and highly selectivity in formate oxidation. No electrocatalysis was observed for methanol, ethanol, and acetate (Figure S4). This is further confirmed by chronoamperometry. Figure 5D shows that the current is maintained constant after the addition of methanol, ethanol and acetate, but a drastic current increase from 0.08 to 0.22 μA appears after injection of formate. This shows clearly that the bio-PdNPs on *S. oneidensis* MR-1 cells have unique selectivity towards formate oxidation. As a control, experiments using electro-deposited PdNPs, current responses occurred whenever methanol, ethanol, acetate or formate was added (Figure S5), revealing that the electro-deposited PdNPs do not give selective catalysis toward oxidation of formate. The effect of the PdNPs size in formic acid catalytic oxidation has been reported previously. Zhou⁴⁵ showed that 5-7 nm PdNPs offer the best electrocatalysis and that the catalysis mainly follows the direct oxidation mechanism. The current findings indicate that the bio-PdNPs selectively catalyse formate electrochemical oxidation. They offer, therefore a perspective for use as novel electrocatalysts in formate acid fuel cells or formate sensors. A scheme for the selective catalysis of bio-PdNPs that involved preferential binding of

formate but not of methanol, ethanol, and acetate on active sites of *S. oneidensis* bound PdNPs. is shown in Scheme 2.

Conclusions and perspectives

Shewanella oneidensis MR-1 cells provide a facile reduction process for preparing molecular scale PdNPs, and act as a natural support for the biosynthesized PdNPs. The presence of PdNPs on *S. oneidensis* MR-1 cells increase significantly the electronic conductivity of the cells. PdNPs were uniformly dispersed on the bacterial surface and exhibited superior activity for electrochemical oxidation of formate with high selectivity and no activity for the other (bio)fuel molecules methanol, ethanol, and acetate. These findings offer potential applications for metal-reducing bacteria and biosynthetic nanomaterials, and the PdNPs developed in this work could be useful in fields of industrial catalysis, environmental metal remediation and energy conversion. Further studies on the molecular mechanisms of the selective electrocatalysis of these biosynthetic PdNPs are being pursued.

Conflicts of interest

There are no conflicts to declare. The manuscript was written through contributions of all authors. All authors have given approval to the final version of the manuscript.

ARTICLE

Supporting information

Figure S1. Size distribution of the PdNPs biosynthesized on *S. oneidensis* MR-1. Data from TEM images (Fig. 3D).

Figure S2. XRD spectra of *S. oneidensis* MR-1 before (black line) and after (red line) the exposure to 1 mM $\text{Na}_2[\text{PdCl}_4]$. Each sample was scanned in the θ -range of 5-90°.

Figure S3. Tapping mode AFM images of *S. oneidensis* MR-1 cells with PdNPs on Pt sheet (1.0 × 1.0 cm²).

Figure S4. CVs of *S. oneidensis* MR-1 with bio-PdNPs modified GC electrode in 0.10 M pH 7.0 phosphate buffer (solid lines) and in the presence of 100 mM (A) methanol; (B) ethanol and (C) acetate (dotted lines), at a scan rate of 10 mV/s.

Figure S5. Chronoamperometric curve of methanol, ethanol, acetate, and formate oxidation at electro-deposited Pd modified GC electrode. The potential held at 0.10 V in 0.10 M pH 7.0 phosphate buffer solution. Final concentrations of methanol, ethanol, acetate, and formate are 0.10 M.
