Highlights

- 11-year study of monitored natural attenuation in a 2 km PCE plume
- *In-situ* chlorinated ethene degradation rates calculated over time and distance
- Dual C-Cl isotope development through time and field-based enrichment factors
- Community sequencing and *Dehalococcoides* and *Dehalogenimonas* spp. quantification
- Biotic and abiotic cDCE reductive dechlorination mechanisms

Key words

Stable isotopes, molecular biology, *Dehalogenimonas* spp., biodegradation, abiotic degradation, multiple lines of evidence

Abstract

The extent, mechanism(s), and rate of chlorinated ethene degradation in a large tetrachloroethene (PCE) plume were investigated in an extensive sampling campaign. Multiple lines of evidence for this degradation were explored, including compound-specific isotope analysis (CSIA), dual C-Cl isotope analysis, and quantitative real-time polymerase chain reaction (qPCR) analysis targeting the genera *Dehalococcoides* and *Dehalogenimonas* and the genes *vcrA*, *bvcA*, and *cerA*. A decade prior to this sampling campaign, the plume source was thermally remediated by steam injection. This released dissolved organic carbon (DOC) that stimulated microbial activity and created reduced conditions within the plume. Based on an inclusive analysis of minor and major sampling campaigns since the initial site characterization, it was estimated that reduced conditions peaked four years after the remediation event. At the time of this study, 11 years after the remediation event, the redox conditions in the aquifer are returning to their original state. However, the DOC released from the remediated source zone matches levels measured three years prior and plume conditions are still suitable for biotic reductive dechlorination. *Dehalococcoides* spp.,

44 *Dehalogenimonas* spp., and *vcrA*, *bvcA*, and *cerA* reductive dehalogenase genes were detected close
45 to the source, and suggest that complete, biotic PCE degradation occurs here. Further downgradient,
46 qPCR analysis and enriched $\delta^{13}\text{C}$ values for *cis*-dichloroethene (cDCE) suggest that cDCE is
47 biodegraded in a sulfate-reducing zone in the plume. In the most downgradient portion of the
48 plume, lower levels of specific degraders supported by dual C-Cl analysis indicate that the
49 biodegradation occurs in combination with abiotic degradation. Additionally, 16S rRNA gene
50 amplicon sequencing shows that organizational taxonomic units known to contain organohalide-
51 respiring bacteria are relatively abundant throughout the plume. Hydraulic conductivity testing was
52 also conducted, and local degradation rates for PCE and cDCE were determined at various locations
53 throughout the plume. PCE degradation rates from sampling campaigns after the thermal
54 remediation event ranged from 0.11-0.35 yr⁻¹. PCE and cDCE degradation rates from the second to
55 the third sampling campaigns range from 0.08-0.10 yr⁻¹ and 0.01-0.07 yr⁻¹, respectively. This is
56 consistent with cDCE as the dominant daughter product in the majority of the plume and cDCE
57 degradation as the time-limiting step. The extensive temporal and spatial analysis allowed for
58 tracking the evolution of the plume and the lasting impact of the source remediation and illustrates
59 that the multiple lines of evidence approach is essential to elucidate the primary degradation
60 mechanisms in a plume of such size and complexity.

61 **1. Introduction**

62 Chlorinated ethenes such as tetrachloroethene (PCE) are toxic pollutants commonly found in
63 groundwater. Because chlorinated ethenes can be transported with groundwater over long distances
64 and deep into aquifers, remediation is challenging. Natural attenuation is preferred whenever
65 possible, and other intensive methods, such as thermal remediation, are used to remove chlorinated
66 ethenes in plume source zones where the concentration is highest (Friis et al., 2005). Thermal
67 remediation by steam enhanced extraction releases dissolved organic carbon (DOC) from the soil

68 and aquifer material. The released DOC promotes microbial activity downgradient from the
 69 remediation site and can stimulate chlorinated ethene degradation by organohalide-respiring
 70 bacteria (OHRB) without additional engineering intervention; e.g. via biostimulation or
 71 bioaugmentation (Badin et al., 2016; Friis et al., 2005).

72 Just like naturally occurring SO_4^{2-} and Fe(III), chlorinated ethenes can serve as electron acceptors in
 73 the subsurface (Holliger et al., 1993). The use of PCE as an electron acceptor by OHRB
 74 sequentially yields trichloroethene (TCE), *cis*-dichloroethene (cDCE), vinyl chloride (VC), and
 75 ultimately the harmless ethene. More reduced conditions are needed as the chlorinated ethenes
 76 become further degraded, and it is not uncommon for degradation of these compounds to slow or
 77 halt partway through the sequence and cause accumulation of cDCE and potentially the daughter
 78 product VC (Bradley, 2000; Shani et al., 2013). Degradation of these contaminants is also
 79 dependent on the presence of electron donors, typically H_2 , and the presence of bacteria capable of
 80 chlorinated ethene degradation. OHRB represent various bacterial genera, such as *Sulfurospirillum*,
 81 *Dehalobacter*, *Desulfitobacterium*, and *Desulfuromonas*, but these OHRB can only facilitate
 82 degradation to cDCE (Hug et al., 2013). Until recently, only the genus *Dehalococcoides* was
 83 identified as capable of degrading cDCE and VC to ethene via the VC dehalogenases VcrA and
 84 BvcA (Löffler et al., 2013; Yargicoglu and Reddy, 2015), though it had been posited that other as
 85 yet unidentified bacteria may also possess the capability (Maphosa et al., 2010). Recently, the genus
 86 *Dehalogenimonas* was identified as capable of VC reduction to ethene via the VC dehalogenase
 87 CerA (Yang et al., 2017). This discovery has shifted the paradigm that complete biotic degradation
 88 of chlorinated ethenes is only possible when *Dehalococcoides* is a main player in a groundwater
 89 microbial community. Further, it is also possible for cDCE and VC to be degraded by microbial
 90 oxidation, including microaerophilic oxidation, cometabolic oxidation by methanotrophs and
 91 etheneotrophs, or anaerobic oxidation (Bradley et al., 1998; Bradley and Chapelle, 2000; Liang et

92 al., 2017; Smits et al., 2011). Chlorinated ethene degradation may also proceed abiotically in iron-
93 and sulfate-reducing conditions when mediated by reactive iron minerals such as iron sulfides,
94 magnetite, and green rust (He et al., 2015). For instance, the iron sulfide mineral pyrite is capable of
95 degrading all chlorinated ethene compounds via β -elimination, where the main product is acetylene
96 (Lee and Batchelor, 2002a).

97 It is recommended for risk management of monitored natural attenuation to assess the extent,
98 mechanism, and rate of degradation of chlorinated ethenes in the subsurface (Yargicoglu and
99 Reddy, 2015) in what can be called the multiple lines of evidence approach. In this approach,
100 various analyses are used in combination to yield a comprehensive picture of the state of a
101 contaminant plume (Wilson, 2010), and it has been used successfully over the past decade (Courbet
102 et al., 2011; Damgaard et al., 2013; Imfeld et al., 2008; Nijenhuis et al., 2007). New chemical and
103 biological tools are available that can aid in this endeavor. One such tool is compound specific
104 isotopic analysis (CSIA), which has been used over the last decades to determine in situ degradation
105 of chlorinated ethenes (Braeckevelt et al., 2012). Additionally, dual C-Cl analysis can assist in
106 distinguishing between degradation pathways (Elsner et al., 2012). The database of laboratory
107 determined C-Cl isotope slopes has continued to expand in recent years, though there are still
108 limitations that render this method best used along with other lines of evidence (Badin et al., 2016;
109 Doğan-Subaşı et al., 2017; Gafni et al., 2018). Bio-molecular approaches can also assist in assessing
110 the likelihood that biotic degradation occurs. Quantitative real-time polymerase chain reaction
111 (qPCR) analyses can be used to identify whether specific genera and reductive dehalogenase (*rdhA*)
112 genes are present in the plume, and Illumina sequencing analysis can be used to screen the entire
113 microbial community (Imfeld et al., 2011; Paes et al., 2015; Yargicoglu and Reddy, 2015).
114 Moreover, when the mechanism and extent of degradation are quantified and combined with
115 knowledge of the aquifer hydrogeology, the rate of degradation can be estimated. This is essential

116 knowledge for accurate risk assessment of a polluted site – yet few of the rates published in the
117 literature are determined at the field scale, and for chlorinated ethenes, published rates span multiple
118 orders of magnitude (Ottosen et al., 2019).

119 The aim of the current study is to use the new tools and knowledge available, including knowledge
120 about *Dehalogenimonas* spp. and dual C-Cl isotope analysis, to investigate the degradation
121 mechanism(s) that occur in a chlorinated ethene plume and to quantify the rate at which degradation
122 proceeds. Furthermore, we aim to assess the long-term impact of source thermal remediation on a
123 chlorinated ethene plume. Use of the multiple lines of evidence approach is essential because little
124 VC is measured in the plume, and thus the fate of cDCE is unclear (Damgaard et al., 2013). The
125 new tools can in particular advance our understanding of the fate of cDCE.

126 Two previous comprehensive sampling campaigns have been conducted on the plume, one prior to
127 thermal remediation and one eight years later. The current study has been carried out 11 years post-
128 remediation. A comprehensive sampling campaign was conducted that involved measurement of
129 hydraulic conductivity, redox parameters, and chlorinated ethene concentrations and isotopic
130 composition; qPCR analysis of selected OHRB and VC *rdhA* genes, including the newly reported
131 *cerA*; and bacterial community analysis by 16S rRNA gene amplicon sequencing. This extensive
132 characterization of the Rødekro plume, through time and with numerous lines of evidence, allows
133 for both localized and broad interpretation of the degradation mechanisms that occur throughout the
134 plume. In this study, we first present each line of evidence and its interpretation individually and
135 then discuss process understanding of each section of the plume based on review of all lines of
136 evidence. We conclude by evaluating the spatial and temporal evolution of the plume as a whole
137 and give some prospective remarks as to possible further development.

2. Study site description

The study site is located in the town of Rødekro, in southern Denmark, and has previously been described by Hunkeler et al., 2011 and Badin et al., 2016. A dry-cleaning facility was in operation at the site from 1964 to 2001, and is the origin of the PCE contamination. The subsurface material is primarily sand, interspersed with gravel and clay lenses (Hunkeler et al., 2011). A PCE plume originates from the decommissioned dry-cleaning facility and extends ~2 km downgradient toward the south; after 1 km the plume bends slightly toward the southeast, in accordance with the flowfield depicted in Figure 1.

146

147 Figure 1: Sampling scheme for the 2017 sampling campaign, groundwater equipotential lines from
 148 2017 (light blue), and approximate plume flowline (dashed dark blue). All well locations indicated
 149 with a color (both green and orange) were sounded; well locations indicated in green also
 150 sampled. Map insert shows the source zone and sampled wells (F2, F3, and F4) that are

151 immediately downgradient from the source. Detailed information about which analyses were
152 conducted at each sampled location is included in Table S1.

153 Thermal remediation via steam injection was conducted at the source zone in 2006, which
154 effectively removed the main dense non-aqueous phase liquid source. The initial state of the plume
155 is presented in Hunkeler et al., 2011, and the effect of the thermal remediation event after eight
156 years, in 2014, is described by (Badin et al., 2016). Chlorinated ethene concentrations measured in
157 the plume from close to the source zone to 750 m from the source were 85% lower in 2014 than in
158 2006. A main impact of the source remediation event was a DOC release from the soil and aquifer
159 material, which stimulated microbial activity and reduced the redox conditions in the aquifer, such
160 that a zone 1050 to 1400 m from the source were suitable for reductive dechlorination of cDCE and
161 VC. It was determined from the first and second major sampling campaigns that PCE and TCE
162 underwent biotic degradation in the first 400 m of the plume before remediation and in the first
163 1000 m of the plume after remediation. It was also determined that cDCE did not undergo
164 degradation in the first 1050 m from the source zone, before the remediation event, but eight years
165 later did undergo biotic degradation within 1000 m from the source zone. Degradation of cDCE and
166 VC in the plume was documented; it was not possible to ascertain the exact mechanism of cDCE
167 (and VC) degradation from 1400 m until the plume front, but in both 2006 and 2014, there is
168 evidence that a combination of reductive dechlorination and abiotic degradation was responsible.

169 Since 2014, five new wells have been drilled, these are B75, B76, B77, B78, and B79 (Figure 1).
170 Wells B76 through B79 are located directly north and south of well B64 and form a 100 m transect
171 across the plume near the front, at 1900 m from the source. Wells B36, B35, B29, B34, B33, and
172 B38 form another transect across the plume at 1050 m from the source. The flow line of the plume
173 was determined based on measurements taken in these transects, and it was determined that the

174 flowline was the same as in the previous two studies. More information on the new transect can be
175 found in the Supplementary Information.

176 **3. Materials and methods**

177 **3.1 Hydraulic testing: slug tests and pump tests**

178 Vacuum slug tests were conducted in duplicate on 25 screens in six boreholes (Table S2) during the
179 2017 field investigation. Pump tests were also conducted on nine of these screens in three
180 boreholes. Data was collected using Slug Test Acquisition® software (Geoprobe Systems®) and
181 analyzed with AQTESOLV Pro® software (HydroSOLVE, Inc.); the Springer-Gelhar and Kansas
182 Geological Survey models were used to interpret the slug test data and determine the hydraulic
183 conductivity for the sandy, underdamped and clayey, overdamped portions of the Rødekro aquifer,
184 respectively. Pump test data were analyzed with the Theis solution (Theis, 1935).

185 **3.2 Groundwater sampling**

186 In the 2017 sampling campaign, which spanned four weeks in March-April, 52 screens from 24
187 boreholes were sampled (Figure 1, Table S1). Boreholes not on the flowline that formed the two
188 transects were sampled at a later date (Figure 1, Table S1). Sampled boreholes are indicated in
189 green in Figure 1. An additional nine boreholes were sounded during the campaign, indicated in
190 orange in Figure 1. Sampling procedures were the same as those used in the previous two
191 campaigns (Badin et al., 2016; Hunkeler et al., 2011) except for the following minor differences.
192 Sampling materials for nitrate (NO_3^-), sulfate (SO_4^{2-}), ferrous iron (Fe(II)), manganese (Mn^{2+}), and
193 methane (CH_4) were provided by Eurofins (Eurofins Miljø A/S, Denmark). Samples for chlorinated
194 ethene isotope analysis were acidified with HCl; 40 mL samples were collected in quadruplicate,
195 and 1 L samples were collected in duplicate. Samples for analysis by Microbial Insights were taken
196 with Sterivex™ filters and fastenings provided by Microbial Insights, Inc. (Knoxville, TN, USA)
197 and were stored in 50 mL Falcon tubes at -10 °C until shipment to Microbial Insights (Microbial

198 Insights Europe, Wondelgem, Belgium) for analysis. Samples for 16S rRNA amplicon sequencing
199 and *rdhA* analysis were collected by passing 0.93-3 L of groundwater through a 0.22 µm Sterivex™
200 filter (Millipore Corporation Billerica, MA, USA) via vacuum pump and were flash frozen in the
201 field in liquid N₂. Samples were stored at -80 °C before analysis at Aarhus University (AU) in
202 Roskilde, Denmark or shipment on dry ice to Ecole Polytechnique Fédérale de Lausanne (EPFL) in
203 Switzerland. Samples for rRNA analysis were collected by passing 4-5 L of groundwater through a
204 0.2 µm MicroFunnel™ filter (Pall Corporation, Port Washington, NY, USA) via vacuum pump,
205 stored in a CryoTube (Nunc A/S, Roskilde, Denmark), and were flash frozen in the field in liquid
206 N₂ and stored at -80 °C before analysis at AU in Roskilde, Denmark.

207 **3.3 Analyses**

208 **3.3.1 Chemical analysis**

209 All sampled well screens were analyzed for aqueous redox relevant chemical parameters as well as
210 for PCE and its degradation products. Of these, 37 well screens were also analyzed for the gases
211 methane, ethene, ethane, and acetylene (Figure 1, Table S1). Analyses for aqueous NO₃⁻, Mn²⁺,
212 Fe(II), SO₄²⁻, and DOC were conducted by the accredited (DANAK, ISO/IEC 17025) laboratory
213 Eurofins in Veen, Denmark (Package AAG, Eurofins Miljø A/S, Denmark) with detection limits of
214 0.3 mg L⁻¹, 0.005 mg L⁻¹, 0.01 mg L⁻¹, 0.5 mg L⁻¹, and 0.1 mg L⁻¹ respectively. PCE, TCE, cDCE,
215 and VC were also analyzed by Eurofins with a gas chromatography-mass spectrometer (GC-MS)
216 and a detection limit of 0.02 µg L⁻¹ for all compounds. Methane, ethene, ethane, and acetylene were
217 measured at the Technical University of Denmark (DTU, Kongens Lyngby, Denmark) using a
218 headspace gas chromatograph with a flame ionization detector (GC-FID) (Thermo Scientific
219 TRACE 1300 GC with HP-plot Q capillary column 8 m x 0.32 mm / I.D. 0.02 mm, Agilent
220 Technologies). The detection limit was 0.05 µg L⁻¹ for methane and 0.25 µg L⁻¹ for ethene, ethane,
221 and acetylene and the results were processed with Chromeleon software (Thermo Scientific).

3.3.2 Isotopic analysis

Samples from 37 well screens (Table S1) were collected for compound specific isotope analysis (CSIA) for carbon and chlorine. Carbon isotope ratios ($^{13}\text{C}/^{12}\text{C}$) were measured with an isotope ratio mass spectrometer coupled to a gas chromatograph by a combustion interface (GC-C-IRMS) at the University of Neuchâtel (CHYN, Switzerland) using the method described by (Badin et al., 2016) with detection limits of $30\ \mu\text{g L}^{-1}$, $30\ \mu\text{g L}^{-1}$, $25\ \mu\text{g L}^{-1}$, and $7\ \mu\text{g L}^{-1}$ for PCE, TCE, cDCE, and VC, respectively. Sets of Vienna Pee Dee Belemnite (VPDB) referenced standards of PCE, TCE, and cDCE were prepared and analyzed in the same manner as the samples to correct for isotope fractionation which may occur during sample preparation and analysis. A purge and trap system was applied, with a purge volume of 25 mL. For samples with chlorinated ethene concentrations lower than these detection limits, a purge volume of 1 L was applied (Badin et al., 2016), and detection limits for carbon isotope fractionation were $1.3\ \mu\text{g L}^{-1}$, $1.1\ \mu\text{g L}^{-1}$, $0.8\ \mu\text{g L}^{-1}$, $0.6\ \mu\text{g L}^{-1}$ for PCE, TCE, cDCE, and VC, respectively. Chlorine isotope ratios ($^{37}\text{Cl}/^{35}\text{Cl}$) were also measured as previously described by Badin et al., 2016 for PCE and TCE, with minimum required concentrations for analysis of $30\ \mu\text{g L}^{-1}$ and $5\ \mu\text{g L}^{-1}$, respectively. Chlorine isotope ratios were obtained by measuring pairs of ion fragments using a quadrupole mass spectrometer following separation with a gas chromatograph. During each measuring sequence the samples were bracketed with two external standards referenced to the Standard Mean Ocean Chloride (SMOC) in order to allow reporting of sample isotope ratios relative to SMOC using a two-point calibration.

3.3.3 Molecular biology analysis

Six samples from wells along the centerline of the plume (F3, F4, B23, B34, B58, B61) and one sample from the outer fringe of the plume (B75-1) were sent to Microbial Insights (Microbial Insights Europe, Wondelgem, Belgium) for QuantArray®-Chlor analysis, which includes quantitative polymerase chain reaction (qPCR) for multiple organohalide-respiring genera

246 (*Dehalococcoides*, *Dehalobacter*, *Dehalogenimonas*, *Desulfitobacterium*, *Dehalobium*, and
 247 *Desulfuromonas*) and *rdhA* genes (*tceA*, *bvcA*, *vcrA*, and the newly identified *cerA*, capable of
 248 degrading VC to ethene (Yang et al., 2017)).

249 DNA and rRNA extraction was conducted at AU for all other microbial samples. Sterivex™ filters
 250 were opened up, and both the Sterivex™ and MicroFunnel™ filters were pulverized. DNA was
 251 then extracted, purified, and in some cases up-concentrated from the Sterivex™ filters and rRNA
 252 from the MicroFunnel™ filters. Analyses for the specific degrader genera *Dehalococcoides* and
 253 *Dehalogenimonas* were conducted via qPCR. Primer and thermocycling information is included in
 254 the SI. Because there is only one 16S rRNA gene per *Dehalococcoides* genome, qPCR results of
 255 copies L⁻¹ are equivalent to cells L⁻¹ (Ritalahti et al., 2006). Sufficient genetic material was obtained
 256 from wells F2, F4, B16, B17, and B23 (Table S1) for specific degrader and gene qPCR analysis.
 257 Sufficient rRNA for activity analysis was collected from wells F4, B17, and B23 (Bead-Beat Total
 258 RNA kit, A&A Biotechnology, Polen). Remaining DNA was removed (DNase I, RNase-free,
 259 Thermo Fisher Scientific, US) and cDNA was produced using a High-Capacity cDNA Reverse
 260 Transcription kit with RNase Inhibitor (Thermo Fisher Scientific, US). The cDNA was analyzed by
 261 qPCR for content of *Dehalococcoides*, *bvcA*, and *vcrA* (Bælum et al., 2013).

262 Eleven of the DNA samples extracted from the Sterivex™ filters were sent to EPFL for community
 263 analysis via 16S rRNA amplicon sequencing (F2, F4, B16, B17, B23, B34, B58, B61, and B64).
 264 DNA samples were amplified by PCR with adapter-containing primers LBE-AS-27F and LBE-AS-
 265 338R with Q5 High-Fidelity polymerase (BioLabs) (see SI for primer and thermocycling
 266 information). PCR products were first purified with Agencourt AMPure XP beads according to the
 267 manufacturer's instructions and quantified with the Fragment Analyser (DNF-473 standard
 268 sensitivity NGS fragment analysis kit, Advanced Analytical Technologies Inc., U.S.A). Addition of
 269 12-nt barcodes, final sample preparation, and sequencing in paired-end mode (2x250bp) were

270 performed by the Genomic Technologies Facility (GTF, University of Lausanne, Switzerland)
 271 following the standard Illumina MiSeq protocol (Illumina, Inc., CA, USA). Analysis of the raw
 272 amplicon sequences was performed using a custom python bioinformatics pipeline developed at the
 273 Laboratory for Environmental Biotechnology at EPFL. First, the sequences were de-multiplexed
 274 and the barcodes were removed. Sequences were then trimmed with Trimmomatic-0.36 and contigs
 275 formed with PEAR version 0.9.11 (Zhang et al., 2014). Clusters were created using CD-HIT-EST
 276 with 97 % identity and n=5 and aligned using Infernal 1.1.2 (Nawrocki and Eddy, 2013) in order to
 277 remove non-16S rRNA sequences. The aligned clusters were blasted against the Greengenes
 278 database (McDonald et al., 2012) to attribute operational taxonomic units (OTUs) to the entire
 279 cluster using similarity thresholds of 75.0 % for phylum, 78.5 % for class, 82.0 % for order, 86.5 %
 280 for family, and 94.5 % for genus (Yarza et al., 2014). OTUs were categorized by functional group
 281 as described in Badin et al., 2016; the category assignments are included in Table S5 in the
 282 Supplementary Information.

283 **3.4 Calculations**

284 **3.4.1 Pore water velocity and contaminant transport**

285 The pore water velocity was calculated for the locations where slug and pump tests were performed
 286 using the Darcy equation (Equation 1), and the distance a particle would move downgradient
 287 without degradation or dispersion was calculated using Equation 2:

$$v_{p,i} = \frac{K_i \cdot I}{\varphi} \quad (1)$$

$$d_i = \frac{v_{p,i} \cdot t}{R} \quad (2)$$

288 where $v_{p,i}$ [m d⁻¹] is the pore water velocity at location i ; K_i [m d⁻¹] is the hydraulic conductivity at
 289 location i ; I [-] is the hydraulic gradient; φ [-] is the porosity; d_i [m] is the distance the aqueous
 290 species moves downgradient in a given time, t [d], given a starting location in the aquifer, i ; and R [-]

291] is the retardation factor, a ratio of the pore water velocity to the velocity of the aqueous species
 292 (Nazaroff and Alvarez-Cohen, 2001) . K_i was determined as described in Section 3.1. I was
 293 calculated from the hydraulic potential map. Typical values for a Danish aquifer were selected for
 294 ϕ , 0.35 for sand and 0.5 for clay (Appelo & Postma, 2005). The distance an aqueous species would
 295 move downgradient was calculated piecewise, where the aquifer was divided into three discrete
 296 flow zones, i , based on the location of clay lenses in the geology. These zones were from 0-700 m
 297 from the source, 700-1200 m from the source, and > 1200 m from the source. Each flow zone was
 298 attributed an average K_i based on the slug test results. When calculating transport of the chlorinated
 299 ethene contamination, a value of 1.2 was selected for R for PCE and TCE based on values
 300 determined empirically from chlorinated ethene transport in sand aquifers with low organic content
 301 (Kret et al., 2015). Because the octanol-water partition coefficient for cDCE is nearly half that of
 302 PCE (Cwierny and Scherer, 2010), R for cDCE was assumed to be 1.

303 **3.4.2 Isotope balance, extent of degradation, and degradation rates**

304 Carbon isotope results are presented as a fraction of $^{13}\text{C} / ^{12}\text{C}$ relative to the VPDB international
 305 standard in delta notation, where $\delta = (R / R_{\text{std}} - 1) * 1000 \text{ [‰]}$ and R and R_{std} are the ratio of the
 306 heavy isotope to the light isotope in the sample and the standard, respectively (Hunkeler et al.,
 307 2011). Chloride isotopes are presented in the same manner as the ratio of $^{37}\text{Cl} / ^{35}\text{Cl}$ relative to the
 308 SMOC international standard. In order to determine whether degradation to compounds which were
 309 not detected occurred to a significant degree, the $\delta^{13}\text{C}$ balance was calculated as in Badin et al.,
 310 2016.

311 The extent of degradation and the degradation rates were calculated based on the $\delta^{13}\text{C}$ values
 312 relative to the initial relative carbon isotope fraction, $\delta^{13}\text{C}_0$, of the mother compound PCE, which
 313 was determined in (Hunkeler et al., 2011) to be -25 ‰. When all of the mother compound has been
 314 converted to a daughter compound, that daughter compound can be treated as the mother compound

315 for calculation of the degradation rate. The extent of degradation (D) as a fraction was calculated
 316 using Equation 3 (Badin et al., 2016):

$$D = 1 - \exp\left(\frac{\Delta\delta^{13}C}{\varepsilon}\right) \quad (3)$$

317 Where ε [‰] is the enrichment factor. An enrichment factor for carbon, ε_C , of -8.4‰ was found by
 318 using dual C-Cl plots (Section 4.4.1) and was applied to estimate the degradation extent of PCE.
 319 Literature values were applied for cDCE; due to uncertainty of the dominating degradation
 320 pathway, minimum and maximum enrichment values were found from literature ranges for both
 321 biotic and abiotic pathways. For biotic reductive dechlorination of cDCE, the ε_C range is -14.1‰ to
 322 -31.1‰ (Bloom et al., 2000; Lihl et al., 2019). For abiotic dechlorination of cDCE, the ε_C range is -
 323 6.9‰ to -21.7‰ (Elsner et al., 2008; Vanstone et al., 2004). The enrichment factors applied for
 324 estimating the extent of cDCE degradation were thus -6.9‰ and -31.1‰.

325 First order degradation rates for ^{12}C were calculated using Equation 4, modified from (Morrill et al.,
 326 2005) to include the retardation factor, R :

$$k_{CE,i}^{12} = \frac{-\left(\frac{1000}{\varepsilon}\right) \cdot \ln\left(\frac{\delta^{13}C/1000 + 1}{\delta^{13}C_0/1000 + 1}\right)}{R \cdot L/v_{p,i}} \quad (4)$$

327 where $k_{CE,i}^{12}$ [d^{-1}] is the first order degradation rate for ^{12}C in chlorinated ethene CE in location i , and
 328 L [m] is the distance from the location where degradation began. For PCE this is the source, and for
 329 cDCE this is where $\delta^{13}C_{cDCE} = \delta^{13}C_{0,PCE}$. A degradation rate can also be calculated based on
 330 location rather than distance by replacing the denominator in Equation 4 with time between the
 331 measurements. Half-lives, $T_{1/2}$, were calculated by $\ln(2) / k_{CE,i}^{12}$.

332 4. Results & Discussion

333 4.1 Hydraulic conductivity and pore water velocity

334 The hydraulic conductivity determined by the slug and pump tests generally agreed, though the
335 hydraulic conductivity measured by the pump tests was consistently one order of magnitude lower
336 than that measured by the slug tests. The hydraulic conductivity was determined to be $1.97 \times 10^{-3} \text{ m}$
337 s^{-1} (170 m d^{-1}) on average in the underdamped portions of the aquifer and $2.11 \times 10^{-4} \text{ m s}^{-1}$ (18 m d^{-1})
338 in the overdamped portions. Hydraulic conductivity data for both the slug and pump tests is
339 included Table S2 and Figure S2 in the Supplementary Information.

340 The pore water velocity along the central flow line decreases with distance from the source zone
341 (Figure 2). For the first 400 m downgradient from the source, a clay lens at 20 meters below ground
342 surface (mbgs) constricts the groundwater flow; when the lens is no longer present, the pore water
343 velocity slows down. By 1400 m from the source, the pore water velocity is approximately ten
344 times less than the velocity 400 m from the source, with local variations likely due to a few
345 significant clay lenses present in this portion of the aquifer. The pore water velocity from the source
346 zone to 700 m is approximately 300 m yr^{-1} on average. In the transitional section from 700 – 1200
347 m from the source zone, where the plume is no longer confined by the clay lens at 20 mbgs and
348 expands in the vertical direction, the average pore water velocity is 200 m yr^{-1} . From 1200 m to the
349 plume front, the average pore water velocity is approximately 60 m yr^{-1} . Representative, rather than
350 average, pore water velocity values were chosen for each section.

351

352 Figure 2: Pore water velocity along the approximate plume flowline, calculated using hydraulic
 353 conductivity values determined via slug tests conducted in 2017. The arrows represent assumed
 354 pore water velocities for specific distances to assess transport (blue) and for estimation of
 355 degradation rates (green).

356 In 2006, the hydraulic conductivity of the aquifer, based on one pump test, was estimated to be
 357 $6.5 \times 10^{-4} \text{ m s}^{-1}$, corresponding to a groundwater velocity of 0.24 m d^{-1} or 87 m yr^{-1} with parameters
 358 typical for a sandy, Danish aquifer. It was estimated that from 2006 to 2014, chlorinated ethenes
 359 could be expected to be transported 600 m downgradient without degradation. Using local pore
 360 water velocities determined in 2017, the estimated transport of chlorinated ethenes between 2014-
 361 2017 without degradation is as follows: PCE and TCE near the source zone would be transported
 362 approximately 750 m downgradient; cDCE near the longitudinal center of the plume, near B34,
 363 would be transported approximately 600 m downgradient; and cDCE in the last portion of the
 364 plume, near wells B58 to B64, would be transported approximately 150 m downgradient.

365 4.2 Redox conditions

366 The redox conditions in and along the length of the plume are variable, and adds interest to the
 367 continued investigation of the plume. Interpreted redox profiles for all three sampling campaigns
 368 are depicted in Figure 3. Measured concentrations of individual redox sensitive species for the 2006

369 and 2014 sampling campaigns have been published previously (Badin et al., 2016; Hunkeler et al.,
 370 2011), and 2017 redox data for individual parameters are included in Figure S3 in the
 371 Supplementary Information.

372
 373 Figure 3: Interpreted redox zonation for each major sampling campaign. Information used to create
 374 the 2006 interpretation is from the sampling campaign carried out in both 2006 and 2007. The
 375 dotted line in the 2006 interpretation indicates the approximate location of the pyrite oxidation
 376 front. Blank areas, without redox zonation, in each bottom corner of the figure represent areas with

377 no data, where it is assumed that the original iron/manganese reducing condition of the aquifer
378 remains.

379 From 2014 to 2017, little change was documented in the O₂ and NO₃⁻ reducing zones. The
380 maximum O₂ concentration is 6.12 mg L⁻¹ in 2017, compared to 6.40 mg L⁻¹ in 2014 (Badin et al.,
381 2016). In 2010, O₂ measurements were below detection in the previously oxic part of the plume,
382 presumably due to the DOC release (Badin et al., 2016). In 2017, O₂ and NO₃⁻ concentrations are
383 above 1 mg L⁻¹ at depths above 10-15 mbgs and above 20 mbgs, respectively. While concentrations
384 of O₂ and NO₃⁻ are less than 0.1 mg L⁻¹ below these depths, Fe(II) and SO₄²⁻ appeared at
385 concentrations of 0.36-0.45 mg L⁻¹ and 43-61 mg L⁻¹, respectively, indicating the location of the
386 pyrite oxidation front at approximately 20 mbgs as described in the previous site investigations
387 (Badin et al., 2016; Hunkeler et al., 2011).

388 Mixed redox conditions are still present near the source zone at the local scale, as was also
389 documented in 2014, but not in 2006. As in 2014, O₂ and Fe(II) are sometimes measured
390 simultaneously in some screens within 20 mbgs and 100 m from the source (especially F2, F3 and
391 F4). There are also some screens in this area where NO₃⁻ and Fe(II) are not detected, but methane is
392 detected in low concentrations (<0.01 mg L⁻¹). The DOC released by the thermal remediation (Friis
393 et al., 2005) is still measured at its highest concentration, 6.9 mg L⁻¹, in the mixed area, and is
394 similar to the 6.1 mg L⁻¹ measured in 2014. Mn(II) was not measured in 2014, but in 2017 was
395 measured at low levels of 0.28-0.51 mg L⁻¹ throughout the aquifer and appeared in its highest
396 concentration, 3.9 mg L⁻¹, in the mixed zone. In Badin et al., 2016, it was posited that this mixed
397 zone was the result of local subsurface heterogeneity impacted at different rates by the DOC
398 released by the thermal remediation. Anoxic pockets in mixed redox zones can provide ideal
399 conditions for reductive dechlorination (Wiegert et al., 2012) and it is possible that this process

occurs in this zone. Though the mixed zone has decreased in size, this effect of the thermal remediation is still present in 2017.

Just as the most marked change from 2006 to 2014 was the appearance of an SO_4^{2-} reducing zone, the most marked change from 2014 to 2017 is that the SO_4^{2-} reducing zone has become smaller. In 2014, Fe(II) was not detected from 1050 to 1400 m from the source zone. In 2017, Fe(II) is present throughout the aquifer at depths greater than 20 mbgs. Fe(II) concentrations at 1050 m downgradient in 2017 are 0.25-0.37 mg L⁻¹, which is less than its presence in the remainder of the aquifer, at 0.47-1.2 mg L⁻¹. SO_4^{2-} concentrations in the aquifer at depths greater than 20 mbgs range from 36-50 mg L⁻¹ as in the two previous sampling campaigns, where the lowest concentrations are concurrent with the lowest Fe(II) concentrations, in well B34. This indicates that SO_4^{2-} reduction still occurs in this zone, but to a lesser extent than before – there is no longer enough biogenic sulfide, the product of SO_4^{2-} reduction, to form iron-sulfide precipitates with all Fe(II) produced by pyrite oxidation. However, there is still a decrease in the SO_4^{2-} concentration, which indicates that iron-sulfide precipitates, also referred to as reactive mineral intermediates, are still present at this location (Culpepper et al., 2018; Jeong et al., 2011).

The decrease in size of the SO_4^{2-} reducing zone and the increased concentration of O_2 since 2010 indicate that the redox conditions of the aquifer are returning to their state prior to the thermal remediation and influx of DOC in 2006. However, the conditions in the aquifer are still favorable for microbial respiration of cDCE and VC (Scheutz et al., 2010) in the mixed zone near the source and in the SO_4^{2-} reducing section of the plume, between 1000 and 1200 m from the source.

4.3 Evolution of chlorinated ethene concentrations

The concentrations of PCE and its daughter compounds, TCE, cDCE, and VC, were measured in the plume as in previous sampling campaigns (Badin et al., 2016; Hunkeler et al., 2011) and data

423 for 2017 are presented in Figure 4a. Ethene, ethane, and acetylene were also measured, but as in
424 previous campaigns, were not detected. The plume in general still follows the previously measured
425 centerline.

Figure 4: Chlorinated ethene concentrations (a) and mole fraction contours (b) in the subsurface from the 2017 sampling campaign. Data point labels indicate concentration measurements in (a) and $\delta^{13}\text{C}$ measurements in (b), also from the 2017 sampling campaign. Blank areas, without contour information, in each bottom corner of the figure are areas with no data.

PCE and TCE are still detected in the first 1050 m and 1400 m from the source, respectively, as in 2014, but the concentrations are generally lower than in 2014 and remain substantially lower than before the thermal remediation was conducted. The PCE and TCE centers of mass appear to have moved downgradient since 2014, although the maximum concentrations are found in the same boreholes. PCE still dominates the first 750 m of the plume by mole fraction (Figure 4b), especially at depths greater than 10 mbgs, but unlike in 2014, PCE mole fractions over 85% only occur near the source zone. TCE concentrations within 350 m from the source have also decreased from 2014 to 2017, although the highest concentrations in B28, B34, and B58 have remained relatively constant.

cDCE remains the dominating chlorinated ethene in the plume, and the highest cDCE concentrations are still found in B34, 1050 m from the source, where the plume enters the more reducing zones of the aquifer. In the first 750 m of the plume, the mole fraction of cDCE has decreased since 2014, though it is still the dominating chlorinated ethene in the mixed zone at less than 10 mbgs within 350 m from the source. Concentrations measured near and at the plume front remain similar to those measured in 2014 and remain higher than what was measured before the remediation event in 2006.

VC is mostly detected from 1050 m from the source until the front of the plume, and VC concentrations are generally lower than in 2014 and 2006. The highest VC concentration was found in well B34, as was also the case in 2006 and 2014. The VC mole fraction at the plume front has decreased from 40% in 2014 to 16% in 2017. While the maximum concentrations of cDCE and VC in well B34 have moved further downgradient than in 2014, indicating that the plume is moving in the longitudinal direction, there is no indication that the contaminants have moved the 150 to 500 m estimated from the local pore water velocity calculations, which suggests that degradation is occurring.

4.4 Carbon and chlorine isotope composition and evolution

The carbon and chlorine isotope values were measured as in the two previous sampling campaigns (Badin et al., 2016; Hunkeler et al., 2011); the 2017 data is presented in Table S3, and the distribution of carbon isotope values are shown on Figure 4b. The $\delta^{13}\text{C}$ values have not changed remarkably since 2014. The $\delta^{13}\text{C}$ values for PCE are more enriched than the initial value, previously estimated to be -25‰ (Hunkeler et al., 2011), in all but one sampling point. This documents PCE degradation within the first 750 m from the source. The $\delta^{13}\text{C}$ signatures for TCE in this part of the plume indicate that TCE is produced and then even further degraded in some parts above the pyrite oxidation front at approximately 20 mbgs. The most noteworthy degradation of TCE occurs as the plume crosses the pyrite oxidation front at B34, 1050 m downgradient from the source, with $\delta^{13}\text{C}$ values of +11‰ and +7.2‰.

In the mixed redox zone, the first 350 m of the plume, the $\delta^{13}\text{C}$ values for cDCE indicate production followed by degradation, reaching a $\delta^{13}\text{C}$ value of up to -20.4‰. Within 350-750 m downgradient from the source, cDCE production is primarily observed, with the lowest $\delta^{13}\text{C}$ values of -33.6‰ and -37.1‰. As the plume enters the sulfate reducing zone at B34, 1050 m downgradient from the source, cDCE degradation occurs, with $\delta^{13}\text{C}$ values from -20.6‰ to -23.9‰, with the exception of the deepest screen at ~40 mbgs where there is no documentation for degradation. From 1430 m to the plume front, there is also no documentation for cDCE degradation, as the $\delta^{13}\text{C}$ values are close to the initial signature, with the exception of B76 at a distance of 1900m, where the $\delta^{13}\text{C}$ is enriched to -22.4‰. However, a small amount of cDCE degradation could still occur but not be documented if production is the dominant process.

Immediately downgradient from the source zone, a $\delta^{13}\text{C}$ value for VC of -18.1‰ suggests degradation, whereas values of -26.5‰ to -36.7‰ indicate VC production at 100-1050 m. From

1050 m to the plume front, the VC concentrations were too low for isotope analysis; isotope signatures can therefore not be used to assess if the produced VC is further degraded in this part of the plume. As with cDCE, the trend in B76 is an exception in the last part of the plume, where the $\delta^{13}\text{C}$ for VC is enriched and thus indicates further degradation.

Since the contamination originates from one source, an isotopic mass balance can be applied to assess if all degradation products were accounted for (Aeppli et al. 2010; Blázquez-Palli et al. 2019) and was determined for all points with available isotope data (Table S3). Enriched $\delta^{13}\text{C}_{\text{sum}}$ values are found within the first 100 m, at 1050 m (B34), and at 1900 m (B76) from the source. These areas correspond to where cDCE degradation is documented by the $\delta^{13}\text{C}$ values. VC is detected at these locations, and though isotope signatures are not available at all locations to document further dechlorination, it is possible that this enrichment could be due to further degradation of VC. This would indicate that degradation of cDCE is the rate limiting step in the dechlorination process. However, the enrichment could also be an effect of cDCE degradation by a different process without significant VC production, e.g. abiotic degradation by iron minerals below the pyrite oxidation front (Lee and Batchelor, 2002a). End-products of anaerobic reductive dechlorination (ethene and ethane) and of abiotic degradation by e.g. pyrite (acetylene, ethene, and ethane) were not detected and could not be used for clarification. The remaining points have a $\delta^{13}\text{C}_{\text{sum}}$ value close to the initial value, indicating that all contaminants are accounted for and that a limited reduction of the total contaminant mass occurs at 350 m and again from 1450 m to the front of the plume.

The isotope time series data also provide information about areas of the plume between sampling points. As an example, the enrichment in $\delta^{13}\text{C}$ signatures for cDCE observed at 1050 m in 2014 still occurs in 2017, but the enriched signatures are not observed in the downgradient monitoring wells at 1430 m. Given the average pore water velocities (Section 4.1), the transport time between these

496 locations is approximately 4-5 years. Because the less enriched values documented in the sulfate
497 reducing zone in 2014 are not measured at 1430 m from the source in 2017, the zone where cDCE
498 was degraded in 2014 must have been less than 200 m in length. The data also indicate that the
499 degradation zone was not present in 2010, as again, less enriched cDCE isotope signatures would
500 have been detected downgradient in the 2017 sampling campaign. This corresponds well with redox
501 parameters measured in 2010, as Fe(II) was present and the sulfate reducing zone was only
502 beginning to form at well B34, and supports the process understanding of the plume evolution.

503 **4.4.1 Dual C-Cl isotope plots**

504 Dual-isotope plots for all monitored years (2006 (Hunkeler et al., 2011), 2014 (Badin et al., 2016),
505 and 2017) are presented in Figure 5, to provide insight into degradation pathways and changes over
506 time. For the dual-isotope assessment, these slopes are compared to other reported slopes related to
507 different pathways for the individual compounds (Table 1).

508

509 Figure 5: Dual C-Cl isotope slopes for PCE, TCE, and cDCE degradation. Results are included
 510 from the current sampling campaign as well as the two previous sampling campaigns in 2006
 511 (Hunkeler et al., 2011) and 2014 (Badin et al., 2016).

512 Table 1: Dual C-Cl isotope slopes compared with values from the literature for PCE, TCE, and
 513 cDCE degradation at the field and laboratory scales. Some slopes have been converted to ensure the
 514 same ratio and allow for comparison between all data, the original reported slopes are included in
 515 parentheses.

517 ^bCombined biotic anaerobic reductive dechlorination and abiotic degradation by iron minerals, but with the former

518 dominating. ^cMicrobial aerobic oxidation. ^dOxidation by permanganate.

519 The dual C-Cl slope for PCE of 2.2 found in 2017 corresponds well with the slope of 3.0 obtained

520 in 2014. These values are within the range of the reported slopes for microbial reductive

521 dechlorination (0.7 to 3.8), which is one of the most well documented degradation pathways for

522 chlorinated ethenes by the dual C-Cl isotope technique (Table 1). This supports that PCE is

523 degraded by biotic reductive dechlorination within the first 750 m of the plume, however slopes that

524 correspond to other pathways have yet to be defined for PCE. Nonetheless, the likelihood that this
525 pathway occurs is also supported by the high concentration of the intermediate product TCE.

526 At the current knowledge level, the reported slopes (Table 1) are not a strong indicator to determine
527 the degradation pathway for TCE at the field site. First, because recent investigation of slopes
528 related to TCE oxidation (-38 to 1.7) covers a great span, as the investigated strains, *Pseudomonas*
529 *putida* F1 and *Methylosinus trichosporium* OB3b, produce degradation related slopes that are both
530 steeper and more gradual than the slopes of the other pathways. Gafni et al., 2018 does state that
531 further research is required to resolve uncertainties about whether the OB3b strain that led to the 1.7
532 slope is representative of this pathway. If this result is excluded from the range corresponding to
533 TCE oxidation (-38 to ∞), the slopes related to this pathway can be separated from the others.

534 Secondly, Lihl et al., 2019 recently found that cultures precultivated on DCE and VC provided
535 steeper slopes (9.0-18.2) for TCE dechlorination than the commonly reported range (2.3-4.8). Thus,
536 biotic and abiotic slopes for TCE degradation overlap, as the only reported slope for abiotic TCE
537 reduction (5.2) is within the range of biotic reductive dechlorination (2.3-18.2). The dual C-Cl
538 slopes for TCE of 2.4 and 2.7 found at this study site, in 2017 and 2014, respectively, are lower
539 than the reported slope for abiotic degradation, which could indicate that TCE degradation in the
540 first 1050m of the plume is primarily due to biotic reductive dechlorination. This is supported by
541 the significant production of cDCE throughout the plume. However, additional investigation is
542 required to strengthen the applicability of the dual C-Cl isotope approach to assess TCE degradation
543 pathways.

544 For cDCE, it was not possible to obtain $\delta^{37}\text{Cl}$ results in 2017, and it is therefore not possible to
545 evaluate if the observed change in slope from 1.8 to 3.0 in 2006 to 2014 remains. In 2014, it was
546 assessed that cDCE degradation was predominantly abiotic (3.1 to 5.0), as the slopes did not match
547 reported values for microbial reductive dechlorination (11.4-13.7) at the time (Table 1). The same

548 conclusion can be drawn including new slopes reported in the literature: abiotic (3.1 to 5.0),
549 chemical oxidation (-125), microbial oxidation (32.3), and microbial reductive dechlorination (4.5
550 to 17.8) (Table 1). It is notable that the slope range for microbial reductive dechlorination is now
551 closer to the slopes found in the Røddekro site investigations. The slopes found at Røddekro are also
552 comparable to a slope recently reported for combined biotic reductive dechlorination and abiotic
553 dechlorination (1.5) (Table 1). The possibility that both degradation pathways occur in the plume
554 for cDCE should therefore not be dismissed. This is elaborated upon in combination with other
555 lines of evidence in Section 5.

556 Dual C-Cl isotope slopes can provide site specific enrichment factors (ϵ_C). The parallel trend
557 between the PCE and TCE slopes confirms that PCE is the precursor to TCE. The offset of the
558 intercepts on the $\delta^{13}\text{C}$ axis can thus be used to determine the ϵ_C for this degradation step (Hunkeler
559 et al., 2009). This results in an enrichment factor of -8.4‰ in 2017; for comparison it was estimated
560 to be -10.3‰ based on the 2014 dataset. It is viable to apply dual isotope analysis to estimate the
561 enrichment factor at the field scale, as this estimation method is not dependent on concentration and
562 therefore not impacted by dispersion and transport processes. Further, the data used for the ϵ_C
563 estimation is not the same as that used for estimation of the extent of degradation and degradation
564 rates. These site-specific enrichment factors are within the range of earlier reported values of
565 -3.6‰ (Badin et al., 2014), -5.6‰ (Wiegert et al., 2013) and -19.0‰ (Cretnik et al., 2014).

566 **4.4.2 Quantification of degradation by isotope fractionation**

567 The extent of degradation was calculated by Equation 3 for PCE in the first 750 m of the plume and
568 for cDCE from 1050 m to the plume front (Table S3), as this estimation can only be done for
569 compounds that solely are degraded (Badin et al., 2016). This approach has been applied
570 successfully at several field sites (e.g. Aeppli et al., 2010; Lollar et al., 2001) and uncertainties

571 related to this estimation method have been assessed to be relatively low (Abe and Hunkeler, 2006;
572 Thullner et al., 2012).

573 The extent of PCE and cDCE degradation are comparable between 2014 and 2017, as would be
574 expected since the $\delta^{13}\text{C}$ values are similar in both sampling campaigns. The main development is
575 that the extent of PCE degraded at B28-1 (750 m downgradient) has increased from 30% to 52%.
576 The largest proportion of degraded PCE is estimated to be 61% in F3-3 (18 m downgradient), while
577 the average extent of PCE degradation is 29% in the first 750 m of the plume. This demonstrates
578 that degradation varies spatially, and that a significant proportion of PCE must be degraded between
579 750 m and 1050 m downgradient from the source. The estimation of degraded cDCE is more
580 uncertain, since a site-specific enrichment factor related to cDCE degradation could not be
581 obtained. The largest proportion of degraded cDCE is estimated to lie between 13% and 47% and is
582 found in B34-4, 1050 m downgradient from the source zone. In B58, 1430 m downgradient, at most
583 2% of cDCE is estimated to be degraded, which illustrates that cDCE is chiefly degraded in the
584 sulfate reducing zone.

585 The isotope data can also be applied to derive degradation rates, and though there is some
586 uncertainty related to the input parameters, it is still suggested to be a more accurate approach than
587 determining rates from concentrations (Abe and Hunkeler, 2006; Morrill et al., 2005). Local
588 degradation rates were calculated for PCE (Table 2) by dividing the plume into two flow zones
589 from 18-350 m and from 350-750 m downgradient from the source (see Supplementary Information
590 for more information on flow assumptions). The apparent degradation rate for the first 350 m (0.12
591 yr^{-1}) is three times lower than the rate for 350 m to 750 m (0.35 yr^{-1}). The estimated degradation
592 rate (0.25 yr^{-1}) for the entire length (0-750 m) demonstrates that averaging over a longer distance
593 masks the local variation, and it is thus important to determine local pore water velocities if the
594 isotope signatures indicate local degradation zones. The degradation rates between the same

boreholes and screens were also estimated using data from previous sampling campaigns, under the assumption that flow conditions were the same. The estimated degradation rate for the first 350 m of the plume compares well between 2006 (0.17 yr^{-1}), 2014 (0.14 yr^{-1}) and 2017 (0.12 yr^{-1}), though the degradation rate appears to become slower over time. There is a more remarkable change from 350 m to 750 m, as the estimated rate is approximately 3 times larger in 2017 (0.35 yr^{-1}) compared to 2014 (0.11 yr^{-1}), though similar to the rate from 2006 (0.41 yr^{-1}). The difference is caused by a weaker enrichment of PCE in B28-1 (750 m downgradient) in 2014, contrary to what would have been expected from the development in redox conditions. The data reveal that degradation quantification estimations are sensitive to redox conditions not only in the longitudinal direction but also in the vertical direction; as an example another screen measured in 2014, B23-2, would have provided a degradation rate of 0.53 yr^{-1} between the source and 350 m downgradient (compared to the 0.14 yr^{-1} above). It is therefore important to combine this assessment with other lines of evidence to understand at which spatial orientation it is most reasonable to assume similar conditions and thus which estimated degradation rates are most representative for a given stretch of the plume. Regardless, neither estimated rate is large enough to completely degrade PCE within the first 750 m. Although there is some variation in the estimated degradation rates, they are in general at the low end of the literature reported range of $0.3\text{--}7.3 \text{ yr}^{-1}$ (Ottosen et al., 2019). Thus, PCE degradation likely continues between 750 m and 1050 m downgradient from the source, as the plume crosses the pyrite oxidation front and enters the sulfate-reducing zone. Indeed, the PCE concentration drops so low between these locations (Figure 4) that isotope analysis was not possible at 1050 m downgradient from the source.

Table 2: Estimated degradation rates for PCE and cDCE as a function of distance and time, where L = distance for calculation, t = time frame for calculation, V_p = pore water velocity at calculation location (more information in SI), k = degradation rate, and $t_{1/2}$ = contaminant half-life.

	Part of plume	ϵ_c (‰)	$\delta^{13}C_0$ (‰)	$\delta^{13}C$ (‰)	L (m)	t (yr)	V_p (m yr ⁻¹)	k (yr ⁻¹)	$t_{1/2}$ (yr)
PCE 2017	0-350m		-25	-23.7	350	-	306	0.12	5.8
	350-750m	-8.4	-23.7	-18.8	400	-	281	0.35	2.0
	0-750m		-25	-18.8	750	-	294	0.25	2.8
PCE 2014	0-350m		-25	-23.1	350	-	306	0.14	5.0
	350-750m	-10.3	-23.1	-21.3	400	-	281	0.11	6.3
	0-750m		-25	-21.3	750	-	294	0.12	5.8
PCE 2006	0-350m		-25	-22.6	350	-	306	0.17	4.1
	350-750m	-10.3	-22.6	-15.5	400	-	281	0.41	1.7
	0-750m		-25	-15.5	750	-	294	0.31	2.2
cDCE 2014-2017	1050m (B34-3)	-6.9 &	-21.3	-20.7	-	3	-	0.03-0.01	23-69
	1050m (B34-4)	-31.1	-22	-20.6	-	3	-	0.07-0.02	10-35
PCE 2014-2017	750m (B28-1)	-8.4 & -10.3	-21.2	-18.8	-	3	-	0.10-0.08	6.9-8.7

619

The degradation observed for cDCE was so localized that degradation rates over distance could not be estimated from the 2017 data. However, because degradation occurred in the same area in 2014 and 2017, a degradation rate can be calculated through time rather than space. The rate was estimated for two depths at 1050 m downgradient from the source where there was enrichment over time, which revealed maximum degradation rates of 0.03 yr⁻¹ and 0.07 yr⁻¹. These degradation rates are low compared to the literature reported range of 0.3-3.3 yr⁻¹ (Ottosen et al., 2019). The results highlight the importance of determining site-specific enrichment factors, as the literature reported ϵ_c range resulted in at least a three-fold difference in the estimated degradation rates.

A time-based degradation rate was also estimated for PCE in B28-1, where the change of degradation extent was greatest between 2014 and 2017. Interestingly, the degradation rate found at this one location, at 750 m, (0.08 yr⁻¹ or 0.10 yr⁻¹, depending on the applied enrichment factor) is equivalent to the one found between immediately downgradient from the source and 750 m (0.12 yr⁻¹). The travel time from the source to 750 m downgradient is approximately three years, the same

633 period as is evaluated in the time-based degradation rate; the estimated rate in one location over
 634 time corresponds to what occurred over the upgradient distance in the same time frame.

635 4.5 Specific degrader quantification and bacterial community composition

636 In order to further understand the extent to which chlorinated ethene biodegradation processes occur
 637 in the plume, 16S rRNA gene amplicon sequencing and specific gene/degrader qPCR analyses were
 638 conducted for the genera *Dehalococcoides* and *Dehalogenimonas*. Activity transcription analysis
 639 based on RNA was also conducted for *Dehalococcoides*, *bvcA* and *vcrA*. It is not uncommon for
 640 RNA extraction to be unsuccessful for subsurface samples (Richards et al., 2019), and RNA was
 641 only quantifiable in three samples. However, in these three screens where RNA was quantifiable,
 642 the qPCR signal was indistinguishable from the acceptable negative control, which indicates either
 643 no activity or that insufficient biomass was collected in the sample.

644 Table 3: Quantitative organohalide respiration relevant genera and functional gene data, as analyzed
 645 by Microbial Insights; bd = below detection, where the detection limit is 1.00e2 cell L⁻¹ or copies L⁻¹
 646 ¹ for all analyses except *cerA*, where detection limits are indicated in the table.

	Well-Screen	F3-3	F4-3	B23-1	B34-3	B58-6	B61-1	B75-1

651 detection limit of 6.90×10^1 copies L^{-1} .

652 Both *Dehalococcoides* and *Dehalogenimonas* were detected throughout the plume, with the highest
653 concentrations of 1.4×10^5 cells L^{-1} and 3.7×10^6 cells L^{-1} , respectively, found just down gradient of
654 the source zone (Table 3). These abundances are comparable to those found in similar naturally
655 degrading plumes (Damgaard et al., 2013). It is prudent to note, however, that microbial abundance
656 measurements from groundwater samples have limitations. Groundwater samples allow collection
657 of only those microorganisms that are not sorbed to the porous media (Griebler et al., 2009) and
658 may not accurately represent what is present in the subsurface. Additionally, microbial community
659 composition and the abundance of specific degraders in the subsurface varies greatly at the
660 centimeter scale, as was determined with high resolution sampling in Damgaard et al., 2013 and
661 Richards et al., 2019. Discrete sediment sampling in a deep, saturated sandy aquifer, as is found at
662 Røddekro, is not feasible. The abundances presented in Table 3 represent a large sample collection
663 area, and relatively few samples were collected along a plume length of 2 km. While there are
664 limitations that may prevent, for example, rate quantification based on microbial populations,
665 microbial abundance measurements from groundwater samples do reflect OHRB distribution
666 throughout the plume, and knowledge of which OHRB are present along the contaminant plume is
667 requisite for process understanding.

668 In well B34-3, in the sulfate reducing zone where conditions are favorable for biotic degradation of
669 cDCE and VC, both *Dehalococcoides* and *Dehalogenimonas* were present, however
670 *Dehalococcoides* was not at all detected in B58-6, the first well after the sulfate reducing zone.
671 *Dehalogenimonas* was present in higher amounts than *Dehalococcoides* in all measured locations
672 except in B75-1, 1680 m from the source zone, where both concentrations were lowest; both
673 concentrations here were three and four orders of magnitude lower than the highest concentrations

674 nearest the source zone. Auxiliary analyses conducted at Aarhus University show that both specific
675 degrader genera were also detected at B16-1 and B17-1, approximately 100 m from the source zone
676 (Table S4). Prior to recognition of the *Dehalogenimonas* capability to use cDCE and VC as electron
677 acceptors (Yang et al., 2017), those wells with no measured *Dehalococcoides* population would not
678 be identified as exhibiting the potential for complete dechlorination. In other studies,
679 *Dehalogenimonas* may be present in locations where *Dehalococcoides* was not detected but lower
680 chlorinated ethenes were detected (Badin et al., 2016; Nijenhuis et al., 2007). The presence of these
681 known degraders, especially at higher concentrations immediately downgradient from the source
682 zone, indicates the possibility that the microbial community is capable of complete biotic reduction
683 of PCE to ethene.

684 The genera *Dehalobacter*, *Desulfitobacterium*, and *Desulfuromonas*, which contain species that are
685 capable of partial PCE dechlorination, were detected at relatively high concentrations throughout
686 the plume. *Dehalobacter* was detected in the pyrotag sequencing analysis in 2014, but the Microbial
687 Insights QuantArray analysis is the first documentation of presence of *Desulfitobacterium* and
688 *Desulfuromonas* in the Røddekro plume.

689 *Dehalococcoides* VC reductase genes *vcrA* and *bvcA* were detected within 1050 m from the source
690 zone (Table 3), where $\delta^{13}\text{C}$ indicate cDCE degradation. Auxiliary analyses at Aarhus University
691 detected *vcrA* at wells within 100 m from the source (Table S4). The *cerA* gene from
692 *Dehalogenimonas*, which codes for the enzyme responsible for reductive dechlorination of vinyl
693 chloride to ethene (Yang et al., 2017), was only detected in F3-3 and F4-3, directly downgradient
694 from the source zone. Expression of the genes to respire VC is a positive indication of the
695 occurrence of this process in this portion of the plume (Liang et al., 2017); non-detection of the
696 genes does not indicate the reverse, as other currently unidentified genes or bacteria may be capable
697 of carrying out this respiration process.

698

699 Figure 6: 16S rRNA gene amplicon sequencing results, where the bar plot shows the distribution of
 700 the relative abundance of selected reads and the italicized percentage below each column denotes
 701 the proportion of the selection to the total number reads in each sample. Distance indicates distance
 702 from the source zone.

703 16S rRNA gene amplicon sequencing yielded information as to the relative abundance of the entire
 704 microbial community in each sampled screen. Operational taxonomic units (OTUs) known to
 705 represent anoxic redox and degradation functional guilds were included in the analyses, including
 706 Organohalide Respiring-Respiring Bacteria (OHRB), Organohalide Cometabolic / Oxidizing
 707 Bacteria (OHCB), Sulfate Reducing Bacteria (SRB), Iron Reducing Bacteria (FeRB), and Iron
 708 Oxidizing Bacteria (FeOB) (Table S5). OHRB were further divided into the categories partial and
 709 total, where OHRB-partial denotes those OTUs with known capability to dechlorinate PCE and
 710 TCE to cDCE and OHRB-total denotes those OTUs with known capability to dechlorinate cDCE
 711 and VC to ethene. Guilds that were not selected for in depth analysis accounted for approximately
 712 three quarters of the reads in each sample and include, for example, fermenting and aerobic
 713 bacteria.

714 Figure 6 shows that the OHRB total and partial guilds combined account for up to 14% of the total
715 reads in some samples. This portion is consistently greater than that of other guilds, such as SRB,
716 and indicates that organohalide respiration is a significant enough process to support a substantial
717 portion of the total microbial community. Most OHRB OTUs are those with partial degradation
718 capability; the exception to this is screen B17-1, 100 m from the source zone, where 44% of the
719 selected OTUs represent bacteria with the capacity to degrade cDCE and VC, with the primary
720 contribution from the genus *Dehalogenimonas*. However, B17-1 was not analyzed for *cerA*, so it is
721 not possible to ascertain whether these *Dehalogenimonas* express this VC *rdhA* gene. The largest
722 OTUs identified to partially respire chlorinated ethenes are those in the Dehalococcoidales order
723 and Dehalococcoidaceae family that could not be further classified to a family or genus. It is
724 therefore possible that some of these reads could belong to the *Dehalococcoides* or
725 *Dehalogenimonas* genera, which were coded as OHRB-total, but were unable to be identified as
726 such.

727 The OHRB guilds are present throughout the plume, and their relative abundances generally
728 decrease with increased distance from the source, which corroborates the trend seen in the specific
729 degrader DNA analyses. These results match well with pyrotag sequencing data from 2014, where
730 *Dehalococcoides* and *Dehalogenimonas* were found throughout the plume, and also with specific
731 degrader analyses conducted by GEUS in 2014, where *Dehalococcoides* was detected, but were
732 below the quantification limit throughout the portion of the plume that is 1050 m and further from
733 the source (i.e. the sulfate reducing zone and the plume front). It could be that these bacteria were
734 present and active in this area in 2014, but were first definitely quantifiable in 2017 due to the time
735 it may take for the bacteria to establish themselves. *Dehalobacter*, *Desulfitobacterium*, and
736 *Desulfuromonas*, detected in the Microbial Insights analysis in 2017, were not found in the 2017
737 community sequencing analysis. Imfeld et al., 2010 also found that more OHRB genera were

738 detectable using taxon specific rather than clone library analysis. In the 2017 sequencing analysis,
 739 the only reads assigned to the Peptococcaceae family, which includes both *Dehalobacter* and
 740 *Desulfitobacterium*, belonged to the SRB *Desulfosporosinus meridiei* (Robertson et al., 2001),
 741 though *Dehalobacter* was detected in the pyrotag sequencing in 2014 using the same sequence
 742 library, Greengenes.

743 OHCB were detected consistently throughout the plume, though at low relative abundance as
 744 compared to the OHRB. Aerobic oxidation of chlorinated ethenes has been documented to occur in
 745 what are typically labelled anaerobic conditions that contain as little as 0.1 mg L⁻¹ of dissolved
 746 oxygen (Gossett, 2010; Richards et al., 2019). However, all measured concentrations of oxygen
 747 below the pyrite oxidation front were an order of magnitude lower than this limit (see
 748 Supplementary Information). Additionally, the genes *etnE* and *etnC* were not detected by the
 749 Microbial Insights QuantArray analysis at any point in the plume, which suggests etheneotrophs
 750 implicated in cometabolic aerobic degradation of VC are not active (Liang et al., 2017).

751 Possible SRB, FeRB, and FeOB containing OTUs are observed in all measured wells. The relative
 752 proportion of FeRB in each well has increased to 2%-48% in 2017, as compared to 0%-4% in 2014,
 753 which is consistent with the redox chemical parameters that show less reduced conditions in 2017
 754 as compared to 2014. B64-1 in particular, at 1900 m from the source zone, exhibits a large relative
 755 abundance of FeRB and low relative abundance of OHRB. The low abundance of OHRB is
 756 consistent with the lower concentrations of chlorinated ethenes at the plume front, and the higher
 757 relative abundance of FeRB is consistent with indications from the redox chemical analyses.

758 Multiple factor analyses at chlorinated ethene contaminated sites have shown that VC reduction and
 759 iron reduction are competing processes (Shani et al., 2013), and thus the capability for the microbial
 760 community to reduce iron at this section of the plume may inhibit VC reduction. However, it should
 761 be noted that FeRB and FeOB are phylogenetically diverse, which renders their identification in the

762 Illumina sequencing results more uncertain than for the specialists OHRB and OHCB (Weber et al.,
763 2006). Pyrite oxidation is in general carried out by FeOB (Schippers and Jorgensen, 2002;
764 Silverman, 1967). While F4-3, which is closest to the surface, and B61-1, which is located at 28.5
765 mbgs, both have larger selected proportions of FeOB, these bacteria also appear to be more or less
766 well distributed throughout the length and depth of the plume. OTUs purportedly capable of sulfate
767 reduction were identified in all wells; there was no distinct trend at B34-4, in the sulfate reducing
768 zone. Some SRB are facultative and can use electron acceptors other than sulfate, which could
769 explain their ubiquitous distribution in the plume (Castro et al., 2000). Sulfate reduction has been
770 shown to inhibit organohalide respiration (Berggren et al., 2013; Murray et al., 2019), but has also
771 in some cases stimulated dechlorination (Harkness et al., 2012; Murray, 2019). The two processes,
772 sulfate reduction and DCE dechlorination, have been documented to occur concurrently by
773 geochemical and microbial community analysis in a constructed wetland, which is similar to the
774 Røddekro plume in that it is an anoxic, sandy environment (Imfeld et al., 2010). Microbial
775 community interactions are complex; metabolic complementarity in the microbial community and
776 the functional capabilities of the organisms that support OHRB may play an important role in
777 stimulation or inhibition of dechlorination (Hug et al., 2012; Murray, 2019; Pérez-De-Mora et al.,
778 2014; Wang et al., 2019).

779 The microbial analyses in general show that there is the possibility for anaerobic reductive, aerobic
780 metabolic, or co-metabolic degradation of chlorinated ethenes throughout the plume, including at
781 1050 m from the source in the sulfate reducing zone. The capability for complete reduction is
782 strongest directly downgradient of the source zone, where the genes *vcrA*, *bvcA*, and *cerA* are
783 detected, and weakest at the plume front, where FeRB are present in the highest relative abundance.

5. Degradation mechanisms / Summary

The information provided by the physical, chemical, isotopic, and microbial lines of evidence can be combined to create one comprehensive, holistic picture of the fate and transport of chlorinated ethenes (Badin et al., 2016; Courbet et al., 2011; Hunkeler et al., 2011; Nijenhuis et al., 2018, 2007), as was done in the Rødekro plume. The overview of the degradation mechanisms cannot only be elucidated spatially, but also temporally when the results from all three sampling campaigns are analyzed collectively, as depicted in Figure 7. Figure 7-2017 includes all new information from the current study. Figure 7-2006 and Figure 7-2014 are re-depictions of data presented in Hunkeler et al., 2011 and Badin et al., 2016, respectively. The colored boxes in Figure 7 coarsely delineate various areas of the plume with common characteristics.

794

795 Figure 7: Summary of conditions and degradation mechanisms present in the plume during each
 796 major sampling campaign. The colored boxes coarsely delineate zones in the plume where different
 797 conditions/processes occur and the relevant parameters found in these zones. Parameters not
 798 discussed in the boxes indicate both not measured and not detected. CE = chlorinated ethene, *Dhc* =
 799 *Dehalococcoides* spp., *Dhg* = *Dehalogenimonas* spp.

800 The effect of the source zone thermal remediation on the plume is the most marked change between
 801 2006 and 2014. In 2006, chlorinated ethene concentrations were very high immediately

802 downgradient from the source zone depicted in Figure 7 as the black box. After the remediation,
803 this area became reduced due to the released DOC, biotic degradation began to take place, and the
804 chlorinated ethene concentrations decreased by 85%. Biotic degradation was also enhanced in the
805 red and orange boxes, and *Dehalococcoides* was present and active here in 2014, unlike before the
806 remediation event. The DOC release also reduced conditions further from the source, and a sulfate
807 reducing zone, depicted in blue, was identified in 2014. Isotopic signatures provided evidence that
808 decreases in TCE and cDCE concentrations were indeed due to degradation. Conditions in this
809 reduced zone were favorable for biotic degradation, though *Dehalococcoides* was only present, and
810 at low abundance and activity, at one point between well B34 and the plume front in 2014. This is
811 similar to results from 2006, where a *Dehalococcoides* signal, below the quantification limit, was
812 observed in two screens between well B34 and the plume front.

813 The enhanced degradation continued to be apparent in 2017, and the evolution of the plume can be
814 determined using the multiple lines of evidence. Despite that active *Dehalococcoides* populations
815 were not detected in 2017, the microbial line of evidence overall more firmly indicates biotic
816 degradation than in previous sampling campaigns as the specific degraders *Dehalococcoides* and
817 *Dehalogenimonas* and VC *rdhA* genes were detected throughout the plume in 2017, with the
818 exception that no VC *rdhA* genes were detected near the plume front. This is a marked change from
819 2014, where *Dehalococcoides* was principally located within the first 350 m from the source, and
820 no VC *rdhA* genes were detected. Another overall change is that the $\delta^{13}\text{C}$ values for cDCE have
821 become more enriched in some key locations, though isotopic evidence of degradation is found in
822 the same locations in 2017 as in 2014.

823 In the area immediately downgradient from the source, indicated by the red boxes, all chlorinated
824 ethenes were detected in both 2014 and 2017. The $\delta^{13}\text{C}$ were enriched for all chlorinated ethenes in

2017 and indicate that TCE and cDCE are degradation products, rather than impurities, as was the case in 2006. The local anoxic areas suitable for anaerobic cDCE reduction in the mixed redox zone were still present in 2017. Unlike in 2014, however, all three analyzed VC *rdhA* genes were detected. The isotopic evidence combined with expression of these genes by *Dehalococcoides* and *Dehalogenimonas* is a strong indication that VC is biotically degraded in this area.

The mixed zone extends past the red boxes in both 2014 and 2017, though it has decreased in size, and dual C-Cl isotope slopes indicate that when PCE and TCE are degraded in the red, orange, and green boxes, the mechanism is anaerobic reductive dechlorination. Thus, biotic degradation still occurs here as in 2014; however, the $\delta^{13}\text{C}$ values for TCE show that TCE is no longer degraded in the deeper part of the plume at 350 m downgradient from the source, represented by the change in shape of the green box. The rate at which PCE is degraded between the orange and the green box is three times higher than in 2014, yet in both years, PCE is fully converted to daughter compounds before reaching the blue box. VC was detected in neither the orange nor the green boxes in both years. In 2017, *vcrA* was detected, which indicates that VC is used as an electron acceptor and degradation past cDCE may occur in this area. Community sequencing data in 2017 also show that bacteria that may be capable of complete dechlorination comprise 44% of the community in B17-1, in the orange box.

The sulfate reducing zone, depicted as the blue box, is still present in 2017, though it is less reduced than in 2014 and has decreased in size. The redox conditions appear to slowly be returning to the conditions prior to the remediation event, though the impact after one decade is still strong and apparent; the presence of *Dehalococcoides*, *Dehalogenimonas*, and *bvcA* indicate that biotic degradation occurs in this area. The enriched $\delta^{13}\text{C}$ values for cDCE document that it is degraded here, however because Cl isotopic ratios for cDCE could not be obtained in 2017, dual isotope plots

are not available to assess the degradation pathway. Dual isotope slopes for cDCE from the previous sampling campaigns suggest the mechanism could be anaerobic reductive dechlorination and/or abiotic degradation by iron minerals. The shortest estimated half-lives for cDCE in this area of the plume are 23 and 10 years for 2014 and 2017, respectively, and the conditions favorable for anaerobic reductive dechlorination would need to be present for at least a kilometer to reduce the concentration of cDCE to half of its 2014 level. The slow rate is insufficient to completely reduce cDCE within the blue box, which is disappearing, though this may be compensated for by increased degradation prior to the chlorinated ethenes entering this reduced zone. The evolution of this dynamic can be investigated in future sampling campaigns.

The plume front is more or less stationary; from 2014 to 2017, it has moved downgradient significantly less than would be expected from groundwater transport. While it may be that the clay lens that begins 1500 m from the source influences the contaminant transport, the stationary nature of the plume is most likely evidence that the cDCE that enters the purple box undergoes a destructive process. VC concentrations in the purple box in 2017 are low, such that measurement of the isotopic signature was not possible. However, in 2006 both cDCE and VC $\delta^{13}\text{C}$ values were enriched in this part of the plume, documenting that transformation of both compounds occurred. The low concentrations of VC measured in 2017 may be due to abiotic degradation of cDCE, where VC is not produced or is produced in small amounts (Lee and Batchelor, 2002a), or may be because biotic cDCE degradation is the rate limiting step. Though well B76 was deemed to be on the plume fringe rather than on the flowline (see SI), the VC $\delta^{13}\text{C}$ ratio in well B76 shows significant enrichment, which is evidence that VC degradation occurs at this location. This point may only provide insight to the local conditions at well B76, or may be representative of this area of the plume, where VC concentrations are too low to measure isotopic signals. cDCE isotopic analyses along the plume centerline do not document that degradation of cDCE occurs in this area of the

872 plume, as the $\delta^{13}\text{C}$ values for cDCE were nearly the same as the $\delta^{13}\text{C}_0$. It is possible that cDCE here
873 is degraded via a mechanism/bacterial strain that does not influence the $\delta^{13}\text{C}$ ratios, though it is
874 expected that during future sampling campaigns, the enriched cDCE detected at well B34 in 2014
875 would be detected in well B58 the purple box. *Dehalococcoides* and *Dehalogenimonas* were
876 detected in the purple box, though no VC reductase genes were detected. Non-detection of the VC
877 reductase genes does not necessarily indicate that VC reduction does not occur, as lower chlorinated
878 ethene concentrations in total would provide fewer electron acceptors for this bacterial guild, and
879 thus these bacteria would be present in smaller quantities and are possibly below detection. It is also
880 possible that VC respiration in this part of the plume is facilitated by currently unidentified species
881 or genes or by microaerophilic or anaerobic oxidation (Bradley et al., 1998; Liang et al., 2017;
882 Smits et al., 2011).

883 Chlorinated ethenes can be degraded abiotically by pyrite to become acetylene (Lee and Batchelor,
884 2002a). Although abiotic reduction by iron sulfide minerals is well documented in laboratory
885 experiments, the degradation products are easily converted to readily biodegradable compounds, so
886 it is difficult to document *in situ* (Liang et al., 2009). Additionally, it is not well investigated,
887 especially in comparison to biotic degradation (He et al., 2015). The stable iron sulfide mineral
888 pyrite is commonly found in sandy Danish aquifers, but it is also likely that other iron sulfide
889 minerals are present, such as mackinawite or amorphous FeS precipitate as a result of sulfate
890 reduction. Both cDCE and VC have been shown to be reactive with a number of iron minerals, such
891 as pyrite and green rust (Lee and Batchelor, 2002a, 2002b), however there are conflicting results on
892 whether cDCE degradation can be mediated by mackinawite (Hyun and Hayes, 2015; Jeong et al.,
893 2011). While it is possible that abiotic reduction of chlorinated ethenes does occur in the aquifer
894 based on the presence of iron-sulfide minerals and dual C-Cl isotope slopes, it is not possible to
895 establish that any particular mechanism is responsible. Information provided by the different lines

896 of evidence are not necessarily mutually exclusive – the detection of specific degraders does not
897 exclude the possibility that abiotic degradation also occurs. From 1450 m downgradient from the
898 source to the plume front, chlorinated ethenes do undergo a destructive process, and it is likely that
899 some combination of abiotic and biotic degradation of cDCE and VC occurs here.

900 **6. Perspectives on Rødekro plume evolution**

901 The removal of the majority of the source in 2006 has still not resulted in detachment of the plume
902 in Rødekro, as was also documented in 2014. While the plume is growing in the longitudinal
903 direction, it is at a very slow rate; natural destructive processes are currently able to compensate for
904 chlorinated ethene transport in the aquifer and the plume has remained at more or less steady state
905 after the remediation event. However, the aquifer redox conditions, which were altered by the DOC
906 release, are returning to their natural state prior to the source remediation.

907 The microbial response to the DOC release from the thermal remediation indicates that if
908 remediation were to be applied to the plume, it would be a good candidate for biostimulation.
909 Furthermore, the relatively high pore water velocity would ensure quick, widespread donor
910 distribution. Nevertheless, the DOC concentrations in the wells immediately downgradient from the
911 source still match the levels recorded in 2014 and there is more evidence of biotic degradation than
912 in previous sampling campaigns. The degree to which the destructive processes occur is sufficient
913 to contain the contamination and remediation is not necessary at present. This is fortunate, as
914 despite the positive microbial response to the DOC release, a plume of such depth and extent is still
915 difficult to remediate, and monitored natural attenuation is a more efficient use of resources.

916 While the future of the plume is impossible to foretell, based on the response to the remediation
917 event over the past decade, it is likely that the natural attenuation processes in the plume will be
918 sustained for some time in the future. The reduced conditions in the plume required substantial

919 input to change, but appear to be sustained longer than was originally predicted. This may be due to
920 further production of electron donor, hydrogen, from fermentation of endogenous biomass decay
921 products as the activity of the microbial community decreases (Adamson and Newell, 2009; Sleep
922 et al., 2005). Monitored natural attenuation in the plume will likely remain a sufficient approach
923 considering that some biotic degradation was documented to occur prior to the remediation event
924 and that, post remediation, there is much less contaminant mass entering the plume. The long-term
925 evaluation of the plume response to the source remediation event gives a broader perspective to
926 management of the risk posed by contaminated sites.

927 **7. Conclusion**

928 Continued, in-depth study of the Røddekro plume has produced an extensive dataset from multiple
929 lines of evidence that encompasses more than a decade of plume evolution. This dataset allows for a
930 unique, deep dive into the processes and degradation mechanisms that impact the fate and transport
931 of the chlorinated ethenes. The various scales and scopes of the site investigation allow for us to not
932 only make conclusions about the plume as a whole, but also to investigate processes on a smaller
933 scale and over time. For example, the delayed response to the 2014 redox changes can be identified
934 by the appearance of quantifiable amounts of bacteria and *rdhA* genes in 2017. The estimation of
935 local degradation rates yields information about the fate of the contaminants and also adds to the
936 library of degradation rates available in the literature for risk assessment (Ottosen et al., 2019).
937 Furthermore, the dataset provides the opportunity to reassess old data with new knowledge, such as
938 estimation of degradation rates, dual C-Cl isotope slopes, and discovery of new *rdhA* genes.

939 However, there are still limitations to what can be achieved with the extensive dataset. The lines of
940 evidence approach is successful for definite identification that the chlorinated ethenes undergo a
941 destructive process, but when two lines of evidence indicate different mechanisms, it is still
942 problematic to ascertain the distinct mechanism(s) responsible for the contaminant degradation. As

943 was discussed in Badin et al., 2016, sites with complex iron geochemistry are not well explored.
944 More research on these systems could further our understanding of the interplay between biotic and
945 abiotic degradation. Additionally, the field of dual C-Cl isotope analysis is relatively new and is still
946 evolving, as Cl isotope analysis has only become more reliable in recent years (Elsner et al., 2012).
947 While dual C-Cl isotope slopes can provide valuable information in the assessment of which
948 degradation mechanism(s) occur, further research is required to combine slope trends and
949 degradation by specific bacteria strains, and to evaluate how simultaneously occurring degradation
950 pathways influence these trends.

951 The extensive temporal and spatial analysis of the Rødekro plume allows for tracking the evolution
952 of the plume and the lasting impact of the source remediation. The plume itself is complex
953 throughout its length, and the multiple lines of evidence approach is essential to elucidate the
954 primary degradation mechanisms in its various areas. Each line of evidence can be used to
955 strengthen the others, and the information they give in combination is greater than the sum of their
956 parts.

957 **Acknowledgements**

958 We gratefully acknowledge the Region of Southern Denmark, Denmark for the opportunity to
959 sample at the site and for partial financing of the sampling campaign. Arwos, Denmark is
960 acknowledged for the remainder of the funding for the sampling campaign. DTU is acknowledged
961 for PhD student funding. We further acknowledge Lone Dissing (Region of Southern Denmark) for
962 feedback on the manuscript and Lone Dissing and Niels Just (Region of Southern Denmark) for
963 their contributions to planning and executing the campaign. Jesper L. Gregersen and Bjarke Foss
964 (Region of Southern Denmark) are acknowledged for their hard work in the field. Aikaterini
965 Tsitonaki (Orbicon) is acknowledged for her feedback on the manuscript, and Aikaterini Tsitonaki
966 and Kresten Andersen (Orbicon) are acknowledged for their involvement in preparing and

967 executing the sampling campaign. Aline Adler and Emmanuelle Rohrbach (EPFL) are
968 acknowledged for their work with sequencing and bioinformatics. Britta Drude (DTU) is
969 acknowledged for her hard work in the field and laboratory and for her contributions to the data
970 treatment and analysis in her MSc project. Lastly, we acknowledge two anonymous reviewers for
971 their constructive comments and help improving the quality of the manuscript.
