Abstract—Super-resolution imaging (SRI) can achieve sub-wavelength resolution by detecting and tracking intravenously injected microbubbles (MBs) over time. However, current SRI is limited by long data acquisition times since the MB detection still relies on diffraction-limited conventional ultrasound images. This limits the number of detectable MBs in a fixed time duration. In this work, we propose a deep learning-based method for detecting and localizing high-density multiple point targets from radio frequency (RF) channel data. A Convolutional Neural Network (CNN) was trained to return confidence maps given RF channel data. The pixel values of the confidence maps correspond to the confidence of point targets existing in the pixels. The point target positions were extracted from the confidence maps by identifying local maxima. The CNN was trained and evaluated using simulated RF channel data. To further investigate the method on measured data, a phantom experiment was performed using a 3-D printed PEGDA 700 g/mol hydrogel phantom [7].

II. Method

A. Simulated Dataset

1) RF channel data: The Field II ultrasound simulation program [8], [9] was used to simulate RF channel data for generating a training and a test datasets. The datasets were composed of a certain number of frames. One frame was created by transmitting three steered plane waves after placing 100 point targets randomly within a region of $6.4 \times 6.4 \text{mm}^2$ (an average target density of $2.44 \text{mm}^{-2}$) where the center was $18 \text{mm}$ away from a transducer. The transducer was modeled after a commercial 192-element linear array, and the measured impulse response [10], [11] was applied to make the RF data as close to real measured data as possible. The parameters used in simulation are listed in Table I. The simulated raw RF data were not beamformed but delayed, based on the time-of-flight calculated by

\[
\tau_i(x, z) = \left(\sqrt{(x - x_i)^2 + z^2 + z} \right)/c
\]

where $\tau_i$ is the time-of-flight of the $i$-th transmission, $(x, z)$ is the point, $x_i$ is the center of the $i$-th transmission aperture, and $c$ is the speed of sound. The delayed RF data were then sampled to have the same number of samples as that of confidence maps along the axial direction. The size of resulting RF data for one frame was $256 \times 64 \times 3$. 

\[
\tau_i(x, z) = \left(\sqrt{(x - x_i)^2 + z^2 + z} \right)/c
\]
2) Confidence Map: Non-overlapping Gaussian confidence maps were used as labels for training CNNs. Initially, binary confidence maps were created, where pixel values of one indicated a point target and the remaining pixel values were zero. A $21 \times 21$ Gaussian filter with a standard deviation of six was then applied at each point target position in the binary confidence maps. The filter values from the targets will be overlapped when some targets are closer than a half of the filter size in the confidence maps. In that case, the maximum value at each pixel location was taken. This maintained local maxima at target positions as opposed to the overlapping PSFs of DAS beamforming, and enabled the CNN to resolve targets closer than the diffraction limit.

The pixel size of the confidence maps was set to $25\, \mu m$, and the image size of them became $256 \times 256$, given the pixel size and the region of interest.

B. Convolutional Neural Network

1) Network Architecture: The proposed CNN is adapted from U-Net [12] which has an encoder-decoder structure. The feature maps are downsampled while the number of feature maps increases in the encoding path. Then, the feature maps are upsampled to their original size while the number of feature maps decreases in the decoding path. U-Net has a large receptive field, an effective input size that is covered by a convolution operation in an unit, for the sake of this structure. This is beneficial because a partial view of RF data is not enough to determine point target existence.

A detailed CNN architecture is illustrated in Fig. 1. Convolution and rectified linear unit (ReLU) layers in U-Net were replaced with pre-activation residual units (Fig. 1a) [13]. The pre-activation residual units ease optimization problem by introducing shortcuts, thereby improving performance. The proposed CNN (Fig. 1e) mainly consisted of four down-blocks (Fig. 1b), one conv-block (Fig. 1c), and four up-blocks (Fig. 1d). The skip-connections in U-Net was removed since it hindered the training. Instead, CoordConv [14] was added to transfer spatial information over convolution layers. Dropout [15] was attached after the shortcut in residual blocks for regularization. For pooling and unpooling, strided convolution and pixel shuffle [16] were chosen, respectively. Leaky rectified linear units (Leaky ReLU) [17] were applied as non-linear activation to avoid dying ReLU problem causing non-activated units.

2) Training Details: The CNN was trained by minimizing the mean squared error (MSE) between true confidence maps and CNN outputs. The training dataset consisted of a total of 10,240 frames. The kernel weights were initialized with orthogonal initialization [18] and optimized with ADAM [19] by setting $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 10^{-7}$. The initial learning rate was $10^{-4}$ and it was halved at every 100 epoch while limiting the minimum learning rate to $10^{-6}$. The number of epochs was 600 and the mini-batch size was 32.

C. 3-D Printed Scatterer Phantom

A PEGDA 700 g/mol hydrogel scatterer phantom [7] was 3-D printed to investigate the proposed method on measured data. The phantom contained water-filled cavities which acted as scatterers. A total of 100 scatterers were placed on a $10 \times 10$ grid with a spacing of $518\, \mu m$ in the lateral direction and $342\, \mu m$ in the axial direction, as illustrated in Fig. 2.

The 3-D printed phantom was scanned by the Synthetic Aperture Real-time Ultrasound System (SARUS) [20] to acquire RF channel data. The same imaging scheme and transducer described in Table I were used. The phantom was placed on a motion stage and scanned at different positions by moving the motion stage at a step of $50\, \mu m$ in the lateral direction. A total of 33 frames were obtained.

III. RESULTS

A. Simulation Experiment

The trained CNN was initially evaluated on a simulated test dataset. It was simulated in the same way as the training dataset in Field II, and consisted of 3,840 frames. In Fig. 3 the result of applying the CNN method to a test frame is compared with simply using the conventional DAS beamforming on the same frame. The CNN method was able to identify highly concentrated point targets while the DAS beamforming failed due to the overlapping PSFs. Full width at half maximum (FWHM) of the DAS beamforming at a depth of $18\, mm$ was $387\, \mu m$ (1.36 $\lambda$) in the lateral direction and $140\, \mu m$ (0.49 $\lambda$) in the axial direction.

The CNN’s capability to detect and localize point targets were quantitatively evaluated. Detection was measured by precision and recall that are defined by

\[
\text{Precision} = \frac{TP}{TP + FP} \quad (2)
\]

\[
\text{Recall} = \frac{TP}{TP + FN} \quad (3)
\]

where $TP$ is the number of true positives, $FP$ is the number of false positives, and $FN$ is the number of false negatives. The positive and negative detections were determined by comparing estimated target positions with true target positions based on their pair-wise distances. The CNN method achieved
Fig. 1. The proposed CNN architecture and its components. (a) residual unit, (b) down-block, (c) conv-block, (d) up-block, and (e) the network overview. n and s in the parenthesis are the number of kernels and stride. The asterisk in (e) indicates that its first convolution in the block is CoordConv. The three numbers between blocks in (e) represent feature map size in the order of height, width, and the number of feature maps.

a precision and recall of 0.999 and 0.960, while DAS beamforming achieved a precision and recall of 0.986 and 0.756.

Localization uncertainties in the lateral and axial position were calculated using the positive detections, and is illustrated using a box-and-whisker plot in Fig. 4a. The bottom and top edges of the blue box indicate the 25th ($q_1$) and 75th percentiles ($q_3$) and the center red edge indicates the median. The vertically extended line from the box (whisker) indicates the range of inliers which are smaller than $q_3 - 1.5 \times (q_3 - q_1)$ and greater than $q_1 + 1.5 \times (q_3 - q_1)$. The inliers were within $\pm 46 \mu m$ (0.16$\lambda$) in the lateral direction and $\pm 27 \mu m$ (0.09$\lambda$) in the axial direction.

B. Phantom Experiment

The CNN trained for the simulation experiment was not effective on the measured data because the scatterers in the phantom are not infinitesimally small point targets. The ultrasound beam is actually scattered twice at each scatterer in the phantom. Therefore, the RF data in the training dataset were simulated a second time by modeling a target using two points. In addition, the first scattering was phase reversed since the acoustic impedance is higher in the phantom than in the water inside the targets.

A new CNN was trained using the modified training dataset, and it successfully identified scatterers from the measured data as shown in Fig. 5. The achieved precision and recall were 0.976 and 0.998. The inliers were within $\pm 101 \mu m$ (0.33$\lambda$) in the lateral direction and $\pm 75 \mu m$ (0.25$\lambda$) in the axial direction, as illustrated in Fig. 4b.

IV. CONCLUSION

A CNN-based ultrasound multiple point target detection and localization method was demonstrated. The CNN was trained...
to learn a mapping from RF channel data to non-overlapping Gaussian confidence maps, and point target positions were estimated from the confidence maps by identifying local maxima. The non-overlapping Gaussian confidence maps were introduced to relax the sparsity of binary confidence maps while maintaining local maxima as target positions. The CNN method resolved point targets closer than the diffraction limit, whereas DAS beamforming failed as shown in Fig. 4.

It is also shown that the CNN method is applicable to real-world data, as well as simulated data, through the phantom experiment. It is notable that the training was performed solely using simulated data because it is nearly impossible to obtain a large number of measurements with ground truth for these kinds of work. It was also imperative to employ the measured impulse response and model targets following realistic physical modeling in the simulation.

We expect that this method can be extended to MB detection and potentially shorten the data acquisition time of SRI by detecting a greater number of MBs in a shorter amount of time.
