Abstract

Shale gas, as a potential substitute for energy source, requires important processing steps before utilization. The most common separation technology applied is distillation, which is energy-intensive. With good stability, non-volatility and tailored properties, ionic liquids (ILs) are regarded as novel potential solvents and alternative media for gas absorption. Therefore, a new strategy for hybrid shale gas separation processing, where IL-based absorption together with distillation is employed for energy-efficient and cost economic gas processing, is developed. In this work, a

three-stage methodology for shale gas separation process is proposed: IL screening, where a systematic screening method with two options (database screening and computer-aided design based on UNIFAC model) is established; suitable ILs are selected as promising candidates; process design and simulation, where separation schemes and important design issues in the IL-based processes are determined; and, process evaluation, where the performance of the final separation process is evaluated and verified.

1. Introduction

Coal has been a primary energy source since the industrial revolution. With increasing environmental pollution and decreasing energy sources, finding alternative energy sources is very important. With a large potential amount available for utilization, shale gas, as a kind of natural gas trapped within shale formations, has been receiving much attention. In addition to its important role as a fuel, shale gas is also a source of hydrocarbons for petrochemical feedstocks to produce value-added chemicals. Due to the presence of large amounts of CH_4 and reasonable amounts of C_2H_6 , many studies have been undertaken on natural gas and shale gas related to the production of potential products such as syngas, methanol and ethylene^{1,2}. Although it is usually regarded as a “clean” fuel compared to other fossil fuels, the shale gas found in reservoir deposits is not strictly “clean” and free from impurities. It is primarily composed of CH_4 , considerable amounts of light and heavier hydrocarbons as well as contaminating compounds such as CO_2 , H_2 , H_2S , etc.³. Thus, the impurities must be removed before their utilization to meet strict pipe-line quality standards

specifications for a consumer fuel to avoid pipeline and equipment corrosion as well as to enhance its calorific value. Therefore, different technologies need to be employed for the separation of unwanted gases. The most common separation technology applied is distillation, which consumes large amounts of energy to give the desired high purity products ⁴. These distillation columns operate at low temperatures and high pressures and have high energy demands. Therefore, an alternative scheme, a hybrid shale gas separation scheme, which combines distillation with absorption to achieve the desired separation at lower energy consumption, is proposed.

With the unique properties of good stability and non-volatility, ionic liquids (ILs) are regarded as attractive mass separating agents for gas absorption ⁵. In this work, a hybrid gas separation process synthesis to separate a model shale gas mixture is proposed with a workflow. The designed flowsheet consists of distillation and IL-based absorption for a model five-component shale gas. As large amounts of solubility of CO₂ in ILs data are available ⁶, most of the developments related to the use of ILs for gas absorption have focused on the CO₂ absorption in different ILs ^{7,8}, including introducing new structures in common ILs ⁹⁻¹¹. Zhang et al.^{12, 13} reviewed the CO₂ absorption with different types of IL, ranking them in terms of CO₂ solubility for different anions with the same cation. Encouraged by good absorption of CO₂ with ILs, new studies have concentrated on the solubility of other gases in ILs. Lei et al ¹⁴ have summarized solubility data of different gases in ILs over a wide range of temperatures and pressures, indicating a high-potential for IL application. However, as many ILs that may be potentially applicable are identified, selection of the most

appropriate IL for specific gas absorption for different gases also needs to consider. In addition to the solubility of the selected gas in ILs, the selectivity of the gases to be separated is also very important, together with other pure component properties of ILs, such as viscosity, melting point and density. Therefore, before a selection-screening method for ILs for use in absorption based gas separation can be developed, the needed properties must be available in the form of data or property models from which they can be reliably estimated.

Some researchers have developed different thermodynamic models for gas solubility estimation, such as the equation of state models ^{15, 16}, COSMO-RS ¹⁷ and UNIFAC ¹⁸, while, GC-based models ^{19, 20} have been used for estimation of pure component properties. With the binary interaction parameters regressed from experimental data, the UNIFAC model has been found to give good quantitative prediction accuracy for specific gas-IL systems. Moreover, as a group contribution-based model, it is very useful for a quick and reliable solvent screening ^{21, 22}. Having the UNIFAC model available, the optimal IL for gas separation can be designed through a computer-aided molecular design approach ²³. Zhen et al. ²⁴ have developed a UNIFAC-IL model and found the optimal solvent for extractive desulfurization of fuel oils through computer-aided IL design.

Current studies published regarding different IL-based separation processes either emphasize on IL design ²⁴ or on process simulation with an improvement of energy-reducing and cost-saving ^{5, 25-31}. However, in our study, we have followed a multi-scale research strategy which includes an extended database and models from

the view molecular to the macroscopic engineering aspect. These models have been applied to IL-based gas separation in this work. This method includes ILs screening and design, process design and simulation, as well as process assessment. In our previous work, experimental data for the solubility of gases in different ILs were collected and a UNIFAC-IL model was developed for different gas-IL systems by regressing binary parameters with available experimental data ³². To lay a solid foundation for IL screening and design, an extended database and pure component property prediction models are firstly established in this work. In addition to applying only one technology (IL-based absorption), a hybrid scheme including IL-based absorption and distillation to separate a model shale gas mixture is developed and evaluated.

2. Methodology

In this work, a three-stage methodology is proposed (Figure.1) in order to synthesize and design IL-based shale gas separation processes. The first stage involves IL screening where the separation problem is defined and the gas mixture is analyzed. Then appropriate IL is selected based on available and predicted solubility and selectivity for specific gas separation problems. This stage includes a systematical method of screening the appropriate solvent for a multi-component gas mixture separation. The screening method has two options: a) selects the IL-based on its availability and already known properties; b) generates and selects IL candidates through computer-aided molecular design techniques that best match the desired

target properties. In option b, appropriate thermodynamic models for the prediction of properties need to be employed. The UNIFAC model is used to predict solubility of gas in ILs, while COSMO-RS model is employed as a backup model when parameters of UNIFAC model are unavailable. Also, group contribution models for prediction of pure properties prediction are needed. These models constitute a model library through which not only potentially better ILs could be designed but also existing ILs not selected in option-a could now be considered based on available data as well as estimated missing properties, thereby, extending the application range of the IL screening method. The second stage involves process design and simulation for the gas separation problem for both selected ILs. The gas separation sequence is decided for each IL and the corresponding separation schemes are generated. The required thermodynamic models for the simulation of the selected gas-IL systems are established through fitting of needed model parameters from experimental data or predicted data. After verification of the model (to make sure the simulation results are correct), the whole process is simulated. The important design parameters such as the amount of solvent needed, operating conditions (temperature and pressure), are determined through sensitivity analysis on the separation performance. The third stage involves process evaluation, where the total energy consumption and selected economic performance indicators are calculated. Then the process is verified with an acceptable design decision. The results obtained for different IL-based processes with selected ILs from the first stage are compared. As a case study, in this work, two ILs are selected as candidates, one is selected from option-a employing database search to

identify the most appropriate IL (for immediate application as the IL already exists), while, a second IL is generated and selected through option-b, having better selectivity and other missing properties. Note that this second IL could be an existing IL that could not be selected previously because of missing properties, or, a potentially attractive candidate for possible future synthesis as it is not currently available. The comparison indicates whether the potential improvements are sufficient to invest in the development of the new IL, providing a foundation of a comprehensive objective-oriented design from molecule to the whole process.

3. ILs Screening

3.1 Problem Definition and Gas Mixture Analysis

For a given gas mixture separation problem, the absorbed gas and products are first defined. In this work, based on the reported raw shale gas ³, a model with 5 gases is considered, as given in Table 1. We assume that 2000 kmol/h of raw shale gas is available at 30 bar and 20°C ². In order to have low solvent consumption, the gas present in the largest amount (methane, CH₄, whose concentration is 80%) is not absorbed and the other gases are removed, if necessary. For example, if the processed shale gas is to be used as fuel, it is necessary to remove CO₂, which is present in the raw shale gas, giving a gas mixture of H₂ and CH₄, which can be utilized as a high-quality fuel. Note that economically feasible separation of high purity C₂H₄ and C₂H₆, which are regarded as common building blocks for the production of thousands of chemical products ³³, could also be considered.

The solubility of each gas in ILs is checked based on the solubility database

established in previous work³². Together with an extended experimental pure property database and models (given in Tables S1-S2 of the Supporting Information), the feasibility and the potential for industrialization of the selected IL are also analyzed. If the IL does not absorb CH_4 , then all other gases could be potentially removed and the method needs to identify which gas to remove first. In this case, the solubility of the gas and the selectivity of the gas compared to CH_4 in the IL needs to be checked. Also, the boiling points of the gases compared to CH_4 needs to be checked. The first gas to be removed should have the highest solubility and selectivity compared to CH_4 in IL. For the other gases that could not be absorbed by IL, they can be separated through a series of distillation steps, whose sequence is based on a ranking beginning from the gas with lowest boiling point and going to the highest.

3.2 IL Screening Method

The gas solubility and selectivity are quantified through Henry's law constant. However, as the reported Henry's law constant is usually mole-based and the solvent is usually measured on a mass basis, therefore, in this work, the mass-based Henry's law constant, which is the mole-based Henry's law constant multiplied by the molecular mass of IL (kg/mol), is considered. The most suitable IL is the one, which has the minimum mass-based Henry's law constant of gas and high selectivity of gas/ CH_4 . In addition, judging a solvent's potential for industrial application, the following pure component properties are also considered: viscosity, which affects the absorption capacity of solvent as well as the fluidity in process, normal melting point,

making sure that the solvent is liquid at the operation condition³⁴. It should be noted, however, these pure component properties may not be available for the selected IL based on solubility and selectivity alone. Therefore, it is useful to also have an option for model-based IL screening.

The IL screening method has two options; a) practical IL screening based on the experimental database to identify any IL for which the needed gas solubility data and experimental pure property of the IL are available; b) computer-aided additional IL design option using a predictive thermodynamic model (UNIFAC-IL), which have been developed in our previous work³² together with a suite of verified GC-based pure component property models. The collected set of pure component property prediction models are listed in Table S2 of Supporting Information as part of the pure property model library. These models are required such that unavailable pure properties of ILs with good separation potential could be further considered in the next stages. The objective of the model-based option-b is to systematically design a potentially superior IL that may provide the incentive for further studies on its future synthesis, development and application. In this work, both options are developed and the two best ILs from each option are further investigated below.

3.2.1 Option-a

For the model shale gas components. H₂ is almost not soluble in ILs³⁵. Henry's law constant of CO₂ and three gases (CH₄, C₂H₄, C₂H₆) in ILs are retrieved from the database. Experimental data of mass-based Henry's law constant of gas and selectivity of gas to CH₄ in different ILs are retrieved and the comparison of their values is

shown in Figure.2. Measured pure component properties (such as viscosity, density) of the ILs are collected and added as an extension to the database (given in Table S1 in Supporting Information), which not only helps to check if all necessary data for a potentially promising IL is available, but also helps to identify a solvent with relative low viscosity.

From Figure 2, it is observed that with increasing temperature, both the gas solubility and the selectivity decreases. All the data in Figure 2 are divided into 4 regions: bottom-left, bottom-right, top-left, top-right. The ILs located at the top-left region under room temperature are considered to be potentially attractive because they have acceptable solubility (note that in Figure 2, the solubility is the inverse of the plotted value on the x-axis) and selectivity. Therefore, the ILs from the top-left region have the necessary solubility and selectivity properties to be Next, we check if the experimental pure component properties are available in Table S1 for these selected ILs. The ILs with available data that matches the requirements of low viscosity, etc., could be regarded as potential candidates suitable for investigation in stages 2 & 3. The ILs that have acceptable solubility data, such as [amim][dca], but for which the necessary measured pure component properties are not available, they are selected for consideration in option-b, where the missing properties would be estimated through available models. However, since none of these ILs are found to have significantly better solubility of CO₂ and selectivity of CO₂/CH₄ than the selected IL, they are discarded. IL-a, [thtdp][phos], (see Figure 3 for the IL structure details), with the minimum Henry's law constant, relatively high selectivity and

available measured pure component properties in the database, is selected as the most appropriate IL for absorption of CO₂ from CH₄. This result is consistent with that reported by Ramdin et al.³⁶. In addition, C₂H₄ and C₂H₆ are also contained in remaining shale gas, therefore, the solubilities of C₂H₄ and C₂H₆ in the selected IL-a are checked respectively through the estimated properties from the corrected COSMO-RS (since measured data are not available) and found to be much lower than that of CO₂ in option-b (seen in Figure 2b and 2c). Then, [thtdp][phos] is regarded as the best-known IL selected from available data for CO₂ removal from the model shale gas considered in this work. Then the rest gases are separated further through traditional distillation.

3.2.2 Option-b

In addition to the UNIFAC-IL model and corrected COSMO-RS model established in previous work³², some pure component property models for IL are collected (listed in Table S2 of Supporting Information). As stated in section 2, this option should be used to design a significantly better IL than what can be found from option-a as well as complete the missing properties for an IL that looks promising in option-a. In this work, in order to find a better IL for the specific gas absorption, we specify stricter constraints on the pure component properties (Eq.1-2) than that in IL-a to find an IL that is placed higher than IL-a in the top-left region of Figure 2.

$$T_m < 298.5 \text{ (K)} \quad (1)$$

$$\eta < 0.1 \text{ (Pa} \cdot \text{S)} \quad (2)$$

The Henry's law constant of CO₂ and other 3 light hydrocarbon gases in ILs

comprised of different groups are calculated based on the UNIFAC-IL model established in our previous work for the activity coefficient of shale gas components in common ILs. The groups having parameter with both CO₂ and CH₄ are used. It contains 2 substituents, 2 kinds of cations and 7 anions as molecular building blocks, as given in Table S3 of Supporting Information. In the computer-aided IL design, various functional cations, anions and substituents are combined systematically based on certain structural constraints to generate feasible ILs with desired properties. Detailed information for IL design in GAMS is given in Table S4 of the Supporting Information. Similar to option-a, no solvent could be found with acceptable solubility and selectivity for absorbing C₂H₄ and C₂H₆. Then minimization of mass-based H_{CO_2} (Eq. 3) with a higher selectivity (Eq. 4) than IL-a is considered as the optimal target in this computer-aided IL design problem. The IL having better properties than IL-a, that is, pyridinium based IL ([MMpy][eFAP] (IL-b): 1,3-dimethylpyridinium tris(pentafluoroethyl) trifluorophosphate), has been found (see Figure 4). This IL-b has almost three times higher selectivity than IL-a. As seen in Figure 2a, the point of IL-b falls right in the top corner of the top-left region and also has low solubility for C₂H₄ and C₂H₆ gases as shown in Figures 2b and 2c, indicating a much better separation property.

$$H_i = M_{IL} P_i^{sat} \gamma_i^{\infty} \quad (3)$$

$$H_{CH_4}/H_{CO_2} \geq 15 \quad (4)$$

Where, M_{IL} is the molar mass of ionic liquid, γ_i^∞ is the infinite dilution activity coefficient of component i , obtained from UNIFAC-IL model, P_i^{sat} is the saturated pressure of component i . T_m is the melting point of IL and η is the viscosity of IL.

4. Process Design and Simulation

4.1 Process Design

As stated in section 3.1, the gas separation process consists of an absorption step followed by two distillation (or hybrid distillation-membrane) steps. Thus, the total gas separation process consists of two main parts; CO₂ removal and light hydrocarbon gas separation. As illustrated in Figure 5, the CO₂ removal section consists of an absorption column followed by a series of depressurized flash vessels. To ensure a high CO₂ recovery rate, a vacuum pressure (around 0.5 bar) is fixed for the last flash vessel, from which, the recovered IL solvent is recycled to the top of the absorber.

4.2 Preparation of Thermodynamic Models

Process simulation and assessment are essential for any process design before it is implemented in the industry. Due to the shortage of rigorous thermodynamic models for complex IL-containing systems in process simulators, ILs are created as pseudo components and added to their databases. Therefore, before simulations could be made, the thermodynamic models for the selected ILs ([thtdp][phos] and [MMpy][eFAP]) need to be established. The models include three parts: single value pure component properties (critical properties, normal melting points, viscosities, densities, etc.), temperature-dependent functional pure component properties, composition and temperature-dependent mixture functional properties.

4.2.1 Single Value Pure Component Properties

Critical properties together with the normal melting point are needed as they are used in many corresponding state correlations for volumetric and thermodynamic properties of ILs. The normal melting point is estimated based on a group contribution model developed by Lazzús et al.³⁷, the group parameters for ILs are regressed in our previous work¹⁹ (given in Table S2 of the Supporting Information). There are several studies on how critical properties for ILs can be estimated. Valderamma and Robles³⁸ used a method to estimate the critical properties of 200 ionic liquids using 26 groups. The results show good consistency in determining the density of the ILs. Considering the selected two ILs ([thtdp][phos], [MMpy][eFAP]) (structure seen in Figures 3 and 4), which we will use for the CO₂ removal step, they can be divided into, respectively, 6 groups (-CH₃, -CH₂-, >CH-, -O-, -P) and 7 groups (-CH₃, =CH-, >CH=, >C<, [>N=]+, -F, -P) according to Valderamma's work. The same method is applied for estimating the critical property of [thtdp][phos] and [MMpy][eFAP]. The relevant equations, estimated critical property values and the verification results can be found in Eqs.S1-S6, Table S2 and Figure S1, respectively, of the Supporting Information.

4.2.2 Temperature-Dependent Functional Pure Component Properties

Several temperature-dependent pure component properties are required in the process simulation. In the simulator chosen (Aspen Plus), these properties are estimated using Eqs. 5-9 listed in Table 2. The equation coefficients used for the two ILs are given in Table S5 of the Supporting Information. They are obtained from experimental data and group contribution models developed in our previous work¹⁹

using the objective function of Eq. 10. Detailed verification results are shown in Figure S2 of the Supporting Information.

$$Obj = \sum_{i=1}^{NP} \left(\frac{X_{i,\text{exp}} - X_{i,\text{cal}}}{X_{i,\text{exp}}} \right)^2 \quad (10)$$

4.2.3 Composition and Temperature Dependent Mixture Functional Properties

In Aspen Plus, the phase equilibrium relationship for the dissolved gases is:

$$\phi_i^V y_i p = x_i \gamma_i^* H_{iA} \quad (11)$$

$$\gamma_i^* = \gamma_i / \gamma_i^\infty \quad (12)$$

Where p , y_i , and x_i are the total pressure, the mole fraction of component i in vapor phase and liquid phase, respectively, ϕ_i^V is the fugacity coefficient in the vapor phase, which can be obtained by the Soave-Redlich-Kwong (S-R-K) equation of state, related parameters can be found in Table S6 and S7 of Supporting Information. H_{iA} is Henry's law constant of component i in solvent A.

Henry's law constant is calculated using the following temperature-dependent equation:

$$\ln H_{iA}(\text{bar}) = a_{iA} + b_{iA}/T + c_{iA} \ln T + d_{iA} T \quad (13)$$

where a_{iA} , b_{iA} , c_{iA} , d_{iA} are the equation parameters. For the gas-IL systems in this work, the values are listed in Tables S8 of Supporting Information.

The activity coefficient of gas in IL is modeled by the NRTL just for the simulation part.

$$\ln \gamma_i = \frac{\sum_{j=1}^n x_j \tau_{ji} G_{ji}}{\sum_{k=1}^n x_k G_{ki}} + \sum_{j=1}^n \left(\frac{x_j G_{ij}}{\sum_{k=1}^n x_k G_{kj}} \left(\tau_{ij} - \frac{\sum_{m=1}^n x_m \tau_{mj} G_{mj}}{\sum_{k=1}^n x_k G_{kj}} \right) \right) \quad (14)$$

where $G_{ji} = \exp(-\alpha_{ji} \tau_{ji})$, $\tau_{ji} = a_{ij} + b_{ij}/T$, $\alpha_{ji} = \alpha_{ij}$, n is the number of components; x is the mole fraction; R is gas constant; T is the absolute temperature; and G_{ij} is a dimensionless interaction parameter; a_{ij} and b_{ij} are the binary parameters which are regressed in this work and the values are listed in Tables S9 of Supporting Information; α_{ij} is the nonrandomness factor which can be fixed at 0.3 used for most polar systems.

4.3 Phase Equilibrium Calculation Results

Among the components of the model shale gas, H_2 is almost not soluble in IL, associated binary parameters are set to be very small to obtain a zero value of the solubility. As a result, the binary interactions in this work include four systems: CO_2 -IL, CH_4 -IL, C_2H_4 -IL and C_2H_6 -IL. For CO_2 and CH_4 , the measured Henry's law constant and solubility data in [thtdp][phos] are retrieved from the database referred in literature ^{7, 36}. For C_2H_4 and C_2H_6 in [thtdp][phos] and the gases in the other IL ([MMpy][eFAP]), as stated in section 3.2, the corrected COSMO-RS model together with the UNIFAC-IL model, proposed from our previous work ³², have been applied to obtain the virtual-measured Henry's law constant and solubility data, which are used further in the simulations. Henry's law constant can be obtained from the calculated activity coefficients and the saturated vapor pressure (see Eq. 3).

Figure.6 shows the comparison of measured data with the calculated values for IL-a. It shows that the model results agree well with the measured data having an AARD (average absolute relative deviation) of 3% and 9%, respectively, for CO_2 and CH_4 .

This good agreement indicates the reliability of the thermodynamic model in process simulation used for IL-a.

The calculated solubility results of all gases in both ILs using Aspen are shown in Figure.7. It can be seen that the solubility of CO₂ in the two ILs is similar but the solubility of CH₄ in [MMpy][eFAP] is much smaller than that in [thtdp][phos]. This means that a higher selectivity of CO₂/CH₄ is found in [MMpy][eFAP], almost three times higher than that of [thtdp][phos]. This result is consistent with the values obtained at the IL screening stage, demonstrating the reliability of the thermodynamic model used for IL-b.

4.4 Process Simulation

4.4.1 Gas Separation Measurement

The process simulation for the shale gas separation is divided into two main parts: CO₂ removal and light hydrocarbon gas separation. In order to evaluate the process separation performance, the CO₂ removal rate in absorber, gas purification (Vol%) of each gas stream and the gas recovery rate are considered using the following equations.

$$Removal_{gas} = 1 - \frac{\text{mole/mass flow of } X \text{ in gasout stream top in absorber}}{\text{mole/mass flow of } X \text{ in feedgas stream}} \times 100\% \quad (15)$$

$$Recovery_{gas} = \frac{\text{mole/mass flow of } X \text{ out of related } X \text{ stream}}{\text{mole/mass flow of } X \text{ in feedgas stream}} \times 100\% \quad (16)$$

4.4.2 Sensitivity analysis of key operation parameters

Consumption of IL and stage numbers in absorber: The influence of solvent consumption on the absorbed rate of CO₂ is shown in Figure.8. In order to evaluate

the separation capacity under different stages of the absorber, the CO₂ absorbed rate at each different stage number in the absorber is calculated based on Eq. 15. As seen from Figure.8, with increasing IL amount and stage number, more CO₂ can be absorbed, but the IL amount plays a more important role by removing most of CO₂. As a result, the stage number of absorber is set to 10. The remaining shale gas can fulfill requirement (<Vol3%) of CO₂ content in commercial gas. The comparison of the two IL-based absorption processes shows that the IL amount required for a 100% removal is different. Less amount of IL-a ([thtdp][phos]) is needed under the same CO₂ removal rate because of a 0.25-times-higher solubility than that in IL-b. However, in addition to the selectivity, IL-b shows better performance on other pure component properties for the application, such as a much lower value in viscosity and heat capacity. Considering that more than 95% CO₂ has been absorbed, the solvent amount is determined to be 630 ton/h for [thtdp][phos] and 750 ton/h for [MMpy][eFAP]. According to another research for IL-based CO₂ removal work³¹ (72 ton/h IL used to purify the biogas containing 390kg/h CO₂ in the feed gas), the amount of IL used in this work is reasonable.

Desorption pressure of flash: Being a physical solvent-based process, the CO₂ is usually desorbed through a series of 3 flashes with decreasing pressures. The pressure is determined based on the mass flow of CO₂ coming out of the last flash. Figure.9 shows the influence of the pressure of first flash (flash-1) on the mass flow of CO₂ out of the system for the two different IL-based processes. The stream coming out of the absorber has a high pressure which is 30 bar. It is found that the CO₂ recovery out of

the last flash decreases rapidly when the pressure decreases to around 8 bar. This implies that a large decrease of the pressure in the first flash would lead to a lower CO₂ recovery rate with a large amount of gas going back to the absorber. Then, the pressure of flash-1 for [thtdp][phos] and [MMPy][eFAP] is set to 20 bar and 14 bar, respectively. Similarly, for flash-2, to keep a high recovery rate of CO₂, the pressure is determined to be 8 bar, 12 bar, respectively for the [thtdp][phos] and [MMPy][eFAP] based processes.

For the last flash-3, vacuum pressure is employed to obtain a high recovery rate of CO₂. As seen in Figure 10, when the pressure is set to 0.5 bar, for the [thtdp][phos] based process, 90% recovery rate of CO₂ could be achieved, but for the [MMPy][eFAP] based process, a lower pressure is needed (0.25 bar).

Key parameters of the distillation columns: Due to the close boiling points of C₂H₄ and C₂H₆ (see data given in Table 1), more stages and also higher reflux ratio are needed in D2. Detailed key parameters of the two columns after separation optimization can be found in Table S10 of the Supporting Information. Besides, as other hybrid process schemes for these gas separation have been reported^{43,44}, they are not investigated in detail here. The important issue here is how much C₂H₄ and C₂H₆ are available and whether an economically feasible scheme for their separation is necessary. Also, it could be that C₂H₄, C₂H₆ with a small amount of CO₂ could be directly used in synthesis of other higher-value chemicals⁴⁵. Note that the main fuel product is obtained from the first distillation column quite easily.

5. Process Evaluation

The following two processes are simulated: (a) IL-based process with IL-a ([thtdp][phos]) obtained from option-a. (b) IL-based process with IL-b ([MMpy][eFAP]) designed through option-b.

A selection of the simulation results that helps to assess the four gas streams corresponding to gas separation processes for the two ILs are summarized in the Supporting Information Tables S11. Several performance criteria are compared under same gas recovery rate or same purity rate in this section.

5.1 Energy and Cost Estimation Methodology

5.1.1 Energy Consumption Evaluation

Energy consumption is regarded as a key indicator of any process evaluation, especially for CO₂ separation processes. Usually, the total energy consumption (TEC) for a process includes thermal energy and electricity. Then, the total energy is expressed by an equivalent energy penalty ⁵, but in the IL-based processes of this work, only electricity is consumed in the three-stage flash vessels without any other heat requirements (not considering the two distillation steps). As a result, the total energy consumption is, in our case, equal to the electricity consumption. To compare with other processes with different raw gas and with other technologies, the specific energy consumption (SEC) is a useful indicator:

$$SEC = \frac{TEC}{m_{out}} \quad (17)$$

where the units of TEC and SEC are MJ/h, MJ/kg gas, respectively, m_{out} is the mass flow of the gas out of the system.

5.1.2 Economic Evaluation

The purpose of the economic analysis of the process is to calculate the total removal cost (TRC) which is used to evaluate and compare the two processes. TRC is calculated from the sum of the annualized capital cost (ACC) and total operating expense (OPEX) both of which are computed based on other types of costs, as shown in Table 3^{26, 46, 47}. Detailed calculation information can be found in Tables S10-S11 of the Supporting Information.

The annualized capital cost (ACC) can be calculated from translating the total capital expense (CAPEX) into annualized capital investment of the whole project, as in Eq.18. CAPEX is then computed on the basis of Table S12 in the Supporting Information, following Abu-Zahra et al.⁴⁶ and Schach et al.⁴⁸. The purchased equipment cost (PEC) is obtained according to Walas⁴⁹. The size of the equipment is obtained from the simulation in Aspen Plus. All the equipment costs are updated to the year 2018 with the Chemical Engineering Cost Index⁵⁰.

The ACC equation is:

$$ACC = \frac{TCI}{((1 + ir)^n - 1)/ir(1 + ir)^n} \quad (1)$$

8)

Where *ir* denotes the annual interest rate, assuming 8% in this work, *n* denotes project lifetime, assuming 25 years²⁶.

The total operating expense (OPEX) includes two parts: one is the variable operating cost (VOC) which contains the solvent make-up and the public utilities such as heat steam, cooling water and electricity. The other part is the fixed operating cost (FOC), including the operating labor, maintenance, R & D cost, etc. Detailed

calculation methods can be found in Table S13 of Supporting Information. The price of utilities is obtained from literature ⁵¹⁻⁵⁴. The price of both ILs is estimated to be 100k\$/ton under the assumption of industrial production in the future based on the estimation by Linzhou Keneng Materials Technology Co., Ltd. China ²⁶. Due to the non-volatility of IL, most of IL is recycled during the process and a little fresh IL is needed. We have assumed 0.35g/ton CO₂ in this work ³⁰. As a result, the two processes could be compared under the condition of same unit price in solvent.

5.2 Process Evaluation Results

5.2.1 Energy Consumption

For the IL-based CO₂ removal process in this work, the total energy consumption (TEC) is only consumed through electricity. It is generated from the pump, vacuum pump and compressor for solvent recycle and gas recovery. To make a better comparison, we simulate the two processes under same CO₂ recovery rate (90%), as seen in Table 4. The TEC for CO₂ removal in the two processes are shown in Figure.11. It is found that the IL-b process could achieve a 54% reduction in TEC compared with the IL-a process. As a result, we can conclude that even though the designed IL-b has somewhat lower solubility than IL-a (leading a high solvent consumption, given in Table 4), the high CO₂/CH₄ selectivity results in less gas to be recycled and thus the electricity consumed in compressor (given in Table 4) can be much reduced. The specific energy consumption (SEC) in these two processes are 0.71 MJ/kg CO₂, 0.33 MJ/kg CO₂, respectively for processes using IL-a and IL-b as given in Table 4, indicating a better improvement of using the designed ILb. In

addition, compared with the SEC in the MDEA process (1.56MJ/kgCO₂) and also in another IL ([bmim][NTf₂]) based process (0.86MJ/kgCO₂) reported in our previous work⁵, the IL-based process gives an improved energy-based technology.

5.2.2 Economic Analysis

For the CO₂ removal process, the distribution of total removal cost (TRC) per ton CO₂ is shown in Figure 12. Detailed equipment cost results are given in Table S14 of the Supporting Information. It can be observed that the total operating expense (OPEX) occupies more than 90% of the annualized total removal cost. Even though the high price of IL, the solvent make-up per year is around 1560\$/year which occupies little of the OPEX. The main utility cost is electricity consumed by the compressor and pump due to gas and solvent recovery. Besides the fixed operating cost (FOC), the variable operating cost (VOC) is the second dominating contributor to the OPEX. This illustrates the importance of reducing total energy consumption. Compared with the IL-a process, the higher selectivity of CO₂/CH₄ in IL-b process gives a reduction of 54% and 30%, respectively for electricity cost and TRC of per ton CO₂ removal. Additionally, compared with the conventional amine-based processes reported by other researchers in total cost (for instance, 55\$/ton CO₂ by Hassan et al.⁵⁵, 74€/ton CO₂ by Raynal et al.⁵⁶, 112\$/ton CO₂ by Mores et al.⁵² and 70\$/ton CO₂ by Huang et al.²⁶), the designed IL-b process cost (38\$/ton CO₂) is lower, demonstrating the important effect of the selectivity property of a solvent on the whole process. The cost for IL-a process (54\$/ton CO₂) is similar to the above-reported costs for traditional technology. Both these two processes indicate a

promising cost-efficient technology for IL-based CO₂ removal.

For the light hydrocarbon gas separation, as given in Table 4, two high-purity streams (CH₄ and C₂H₆ gas streams with more than Vol 96%) could be obtained as two commercial products in both the IL-based processes. Some performance criteria are compared under the same gas purity rate. Detailed equipment cost can be found in Table S14 of the Supporting Information.

The utility applied in the distillation columns to produce each gas and the total cost of the whole separation process to produce per ton gas are calculated and shown in Table 4. It is found that the utility cost to produce light hydrocarbon gases in the two distillation columns in IL-b process is slightly lower than that in IL-a process. This is because the higher selectivity of CO₂ to other gases in IL-b, leading much more light hydrocarbon gases that come out from top of the absorber in the IL-b process than that in IL-a process. Similarly, combined with the lower cost in CO₂ removal process, the total cost for these two gas production processes could be reduced much more in IL-b process than in IL-a process, especially for C₂H₆. However, considering the higher recovery rate of CH₄, C₂H₆ and lower total cost for CO₂ removal, the designed IL-b process points to a better choice than the IL-a process. According to the price of commercial CH₄ (~2400\$/tonCH₄⁵⁷), this further light hydrocarbon gas separation has the potential to achieve a good profit. Note also that additional energy could be reduced through the use of other hybrid technologies for the light hydrocarbon gases separation such as combined with membrane⁴³ or adsorption processes, which is a topic for future consideration.

6. Conclusion

This work proposes a hybrid IL-based technology for the gas separation process where the IL is used to remove the gas in small amount to obtain the desired final products. A three-stage methodology, in which systematic IL screening, process design and simulation, and process evaluation, is established. Extended database and property prediction model library are made available for the 3 stages of the methodology. The screening stage (first stage) offers two options for IL screening: screening based on database (option-a) and model library (option-b), in which option-b could be used as a backup if no suitable IL could be found through option-a. However, if neither option gives an acceptable IL, then there is need for models of wider application range and more research. The use of different property models for the overall goal of development of reliable CO₂ removal technologies from shale gases is highlighted. That is, the COSMO-RS model is used to generate pseudo-experimental data needed for developing the GC based models (UNIFAC-IL). Then the UNIFAC-IL model is applied for process synthesis-design, where a larger search space is necessary. For a greater search space, use of predictive models such as UNIFAC-IL has an advantage. However, for the verification by simulation, a third model, the NRTL model, which is good for a specific chemical system, has been used. Clearly, for a successful and wider application of the methodology, further extension of database and IL design models are needed.

For the model shale gas considered, two ILs are selected through the two options: IL-a ([thtdp][phos]) is identified through an experimental database while IL-b,

([MMpy][eFAP]) is obtained using a model-based option (UNIFAC-IL) to find additional IL based on Computer-Aided design. Before process simulation could be performed, NRTL and Henry's law constant models for the related IL-gas systems and IL pure property predicted models are established in ASPEN-Plus, the selected process simulator. In this work, for the IL-design stage, the predictive UNIFAC-IL model is used, while for verification by simulation, the fitted NRTL model is used. The calculated solubility data of CO₂ and CH₄ in IL-a from the established model are in good agreement with the available experimental data. The two IL-based CO₂ removal processes followed by distillation for hydrocarbon gas separation are simulated and evaluated in terms of energy consumption and economics. Even though larger amount of IL-b is needed, the higher selectivity of CO₂/CH₄ helps to not only obtain a higher purity CO₂ gas under the same gas recovery rate, but also achieve a 54% lower total energy demand, compared with IL-a process, resulting in a lower total removal cost per ton CO₂ to around 30%. Economic analysis shows that the operation expense (OPEX) is one of the main contributors to the total removal cost of per ton CO₂ separation, showing the importance of reducing the total energy demand. High purity (>96%) of CH₄ and C₂H₆ gas streams could be obtained as products with a good profit in both IL-based separation processes, with much better results for IL-b process. As a result, IL-b with its good separation results, designed through option-b, provides a promising recommendation for future solvent development of gas separation process. Future work would focus on further removing the hydrogen for syngas production combining with the removed CO₂ as well as separation and use of

C_2H_4 and C_2H_6 .

Appendix Supporting information

Supporting information associated with this article can be found in the online version.

Notation

Symbols

p_i^s = vapor pressure of pure component i

P = pressure, Pa

T = temperature, K

x_i = composition of component i in liquid

y_i = composition of component i in vapor

γ_i = activity coefficient

γ_i^∞ = the infinite dilution activity coefficient of component i

H_{iA} = Henry's law constant of component i in solvent A, $bar \cdot kg/mol$

M_i = is the molar mass of component i .

η = viscosity, Pa.S.

V = molar volume, m^3/mol .

C_{pi} = heat capacity of component i , J.K⁻¹.mol⁻¹.

λ = thermal conductivity, W/mK.

σ_f = surface tension in mN/m.

ϕ_i^V = fugacity coefficient in the vapor phase.

Abbreviations

IL	Ionic liquid
MEA	monoethanolamine
MDEA	methyldiethanolamine
DEA	diethanolamine
[thtdp][phos]	trihexyltetradecylphosphonium bis(2,4,4-trimethylpentyl)phosphinate)
[MMpy][eFAP]	1,3-dimethylpyridinium tris(pentafluoroethyl) trifluorophosphate
EoS	equation of state
COSMO-RS	conductor-like screening model for real solvents
UNIFAC	universal quasichemical functional-group activity coefficient
NRTL	non-random two liquid
AARD	average absolute relative deviation
TEC	total energy consumption
SEC	specific energy consumption
TRC	total removal cost
ACC	annual capital cost
OPEX	total operating expense
CAPEX	total capital expense
PEC	purchased equipment cost
VOC	variable operating cost
FOC	fixed operating cost

	IL-a process	IL-b process
CO ₂ recovered from last flash (CO ₂ stream), kg/h	5541.6	5548.5
CO ₂ recovery rate, %	90.0	90.1
CO ₂ purity in CO ₂ stream, %	50.0	61.0
Solvent needed, kg/kg CO ₂	81.5	131.3
Total equivalent energy penalty, GJ/ton CO ₂	0.7	0.3
Electricity cost for CO ₂ removal process, \$/ton CO ₂	19.8	9.1
Total cost for CO ₂ removal process, \$/ton CO ₂	54.0	37.8
CH ₄ purity in CH ₄ stream, Vol%	96.1	96.1
CH ₄ recovery rate, %	95.5	97.2

Utility cost to produce CH ₄ in D1, \$/ton CH ₄	12.0	12.0
Total cost to produce CH ₄ in whole shale gas separation process, \$/ton CH ₄	29.8	26.3
C ₂ H ₆ purity in C ₂ H ₆ stream, Vol%	96.0	97.5
C ₂ H ₆ recovery rate, %	65.8	74.7
Utility cost to produce C ₂ H ₆ in D2, \$/ton C ₂ H ₆	30.2	29.1
Total cost to produce C ₂ H ₆ in whole shale gas separation process, \$/ton C ₂ H ₆	263.8	208.5

Note: D1, D2 denote the two distillation columns.

Figures:

Figure 1 the whole workflow for hybrid IL-based gas separation process

Figure 2 Henry's law constant of different gases versus selectivity to CH₄ in ILs; a) CO₂, b) C₂H₄, c) C₂H₆ (Note: Pred. means predicted values)

Figure 3 Structure of [thtdp][phos]
(C₄₈H₁₀₀O₂P₂); (a) cation, (b) anion

Figure 4 Structure of [MMpy][eFAP]
(C₁₃H₁₀F₁₈NP); cation (a), anion (b)

Figure 8 CO₂ removal rate versus IL amount in two IL-based processes. N means stage number.

Figure 9 Pressure of flash-1 versus mass flow of CO₂ out of last flash for the two ILs considered in this work

Figure 10 Temperature of flash-3 versus recovery rate of CO₂ for the two ILs considered in this work

Figure 11 The total energy consumption (TEC) for the CO₂ removal process in the two IL-based processes

Figure 12 Comparison of total cost for CO₂ removal in the two IL-based processes
