Abstract

Iron nitrogen heterocyclic carbenes (NHC) have received a great deal of attention recently, due to their growing potential as e.g light sensitizers and photocatalysts. We present a sub-ps x-ray spectroscopy study of a Fe^{II}NHC complex allowing us to identify and quantify the states involved in the deactivation cascade after light absorption. We find that excited molecules relax back to the ground state along two pathways: after population of a hot ³MLCT state, from the initially excited ¹MLCT state, ~30 % of the molecules undergo ultrafast (150 fs) relaxation to the ³MC state, in competition with vibrational relaxation and cooling to the relaxed ³MLCT state. The relaxed ³MLCT state then decays much more slowly (7.6 ps) to the ³MC state. The ³MC state is rapidly (2.2 ps) deactivated to the ground state. The ⁵MC state is not involved in the deactivation pathway. The ultrafast partial deactivation of the ³MLCT state constitutes a loss channel from the point of view of photochemical efficiency and highlights the necessity to screen other FeNHC complexes (and perhaps other transition metal complexes) for this ultrafast decay of ³MLCT population, in order to optimize photochemical performance.

1 Introduction

Light harvesting systems based on first-row transition metals like iron are attractive for large-scale application due to their abundance and non-toxic properties. In a light harvesting complex, the absorption of light creates a charge separated state and the study of ultrafast photo-induced dynamics has recently received considerable attention.[1, 2, 3, 4, 5, 6, 7] The ultrafast progression of excited states after the initial light absorption is determined by the shapes and crossings of the excited state potential energy surfaces, which determine the photophysical and photochemical properties of the complexes and how they can be used. A challenge is to manipulate the positions and shapes of these potential energy surfaces, such that the charge separated state becomes sufficiently long lived for reducing or oxidizing catalysts/semiconductor acceptor systems. Traditional low spin Fe^{II} – polypyridyl complexes generally show ultrafast <100 fs decay of metal to ligand charge transfer states (MLCT) into metal centered (MC) states.[8] For instance, in the extensively studied prototype Fe^{II} molecule $\text{Fe}^{\text{II}}(\text{bpy})_3$ ($\text{bpy} = 2,2'$ – bipyridine), the charge separated MLCT state deactivates on an ultrafast timescale into high spin MC states.[9, 10] Similar ultrafast transitions into ^3MC states have been observed and described for ruthenium sensitizer complexes.[11, 12, 13] By de-stabilizing the MC scavenger states we, and other groups, have recently developed iron complexes with significantly slower deactivation of the MLCT states.[14, 15, 16, 17, 18, 19, 20, 21] This makes the iron carbene complexes interesting as a promising new class of photosensitizers [22], with recently demonstrated capability to inject electrons efficiently into a TiO_2 substrate, and carry out bimolecular oxidation and reduction processes.[17, 15] Ultrafast optical measurements in combination with quantum chemical calculations have provided significant insight into the excited state structure underlying this remarkable improvement of photochemical properties.[23, 24]

As an element-specific technique x-ray spectroscopy is a powerful tool to probe the electronic structure of the metal site and surrounding ligands. With the recent advent of x-ray free electron laser (XFEL) facilities with high flux and a temporal resolution better than 30 fs[25] it has become possible to identify the nature of the excited states directly.[10, 26, 27, 28, 29, 30, 31, 32] In these studies the oxidation state, spin and charge transfer charac-

ter of the molecular state was identified by modeling the measured time resolved spectra with a linear combination of measured or calculated static reference spectra. Here, we use ultrafast K_α and K_β x-ray emission spectroscopy (XES) to investigate the excited state dynamics of one of the recently introduced Fe^{II} carbene complexes, $\text{Fe}^{\text{II}}(\text{bpy})(\text{btz})_2(\text{PF}_6)_2$ where btz is 4,4'-bis(1,2,3-tri-azol-5-ylidene) with significantly altered photophysics compared to prototype polypyridyl Fe^{II} complexes like $\text{Fe}^{\text{II}}(\text{bpy})_3$. [33]

Figure 1: Bidentate Fe^{II} complex measured in this paper, the hydrogen atoms are hidden.

Several of these complexes have been characterized by transient optical spectroscopy to have a ~ 10 ps or longer excited state lifetime that manifests itself both in excited state absorption features originating from persistent population of a MLCT excited state, as well as ground state recovery on the same timescale.[33, 34] These timescales are quite similar with recent results from time resolved x-ray measurements for $\text{Fe}^{\text{II}}(\text{bpy})(\text{CN})_4$ [35] ascribed to a ~ 20 ps long-lived population of a $^3\text{MLCT}$ state. This state decayed to the ground state without undergoing noticeable spin transition to a metal centered state. These times are however noticeably different from the ~ 260 ps lifetime obtained in a recent x-ray scattering study and assigned to a prolonged population of a high-spin MC state.[36]

One aspect of particular current interest concerns the experimental distinction between triplet states of MLCT and spectroscopically elusive MC character in the decay cascade on ultrafast to intermediate timescales in the range of 1 ps to 100 ps. This includes systems with intermediately destabilized MC states as the emerging iron carbene photosensitizers.[37, 38] The new results obtained here in particular show that the conventional picture of a consecutive or parallel progression through a number of excited states has to be revised to a branched decay involving hot (vibra-

tionally unrelaxed) and cold (vibrationally relaxed) de-excitation pathways through CT and MC states as has also been recognized by other groups.[39] This significantly enriches our understanding of the factors limiting the photochemical efficiency of this type of complexes.

2 Description of the experiment

We dissolved the molecule into anhydrous acetonitrile to 21 mMol/l and measured the dynamics in a round 30 μm jet with the recycled solution in an inert gas atmosphere. The interaction region was pumped with 400 nm 70 fs pulses at a fluence of 0.85 mJ/mm² predominantly within the linear absorption regime and probed near co-linearly in a 10 μm region with the 8.5 keV beam of the LCLS XFEL. The induced non-resonant K_β emission of the central iron atom with a maximum at 7058.2 eV was detected after different time intervals from the photo-excitation on a 140k Cornell-SLAC PIXEL Array Detector (CSPAD) after dispersion on four cylindrical bent Ge $\langle 620 \rangle$ crystals.[40, 41, 42]

The K_α x-ray fluorescence was collected at 6404 eV, corresponding to the maximum intensity, with a single spherically bent Ge $\langle 440 \rangle$ crystal in Johann geometry on a second 140k CSPAD. Each pump-probe exposure was recorded separately and binned into a relative arrival time using the timing tool and selected pump-probe delay. The presented short timescale data originates from one run in which we selected a fixed pump-probe delay and used the arrival time jitter of the x-rays to probe a variety of time delays until 1.5 ps after the pump event. During a second run a series of longer time delays were selected to probe the evolving dynamics on a longer timescale up to 300 ps. In both cases the time resolution of ~ 130 fs originates from the convolution of the 70 fs FWHM excitation pulse, with the 20 fs - 50 fs duration of the coherent SASE pulse and the ability of the timing tool to determine the relative arrival time of the two pulses.[42]

During the data reduction the recorded images of the K_β spectra were compensated for the varying gain mode of the CS-pad, the background rejected by a threshold and the AD values converted into single photon counts. The images were then integrated into energy spectra along the von-Hamos focal axis and crystal misalignment corrected by a previously described procedure.[43]

3 Results

Figure 2 shows a series of K_β spectra measured at selected time-delays after excitation A) together with a series of reference spectra for different spin states B). We use two independent approaches to model the temporally evolving excited state K_β spectra shown in Figure 2 A). First we followed the previously established approach to deconvolute the spectrum at each time point with a linear combination of the reference spectra shown in Figure 2 B).[44, 31]

Figure 2: Measured K_β XES spectra of $[\text{Fe}^{\text{II}}(\text{bpy})(\text{btz})_2](\text{PF}_6)_2$ at a different time scale A, reference K_β XES spectra for different spin state B.

In this approach no prior assumption is made which dynamic model the molecule is following except for the selection of what states to include in the de-convolution. In this language the MLCT excited states would correspond to a doublet, or quartet after an intersystem crossing and the MC states corresponds to a triplet or quintet reference state (please see SI for further information). As references for this deconvolution we used for a doublet: $[\text{Fe}^{\text{III}}(\text{bpy})_3]^{3+}$, a triplet: $(\text{Fe}^{\text{II}}\text{phtcy}, \text{phtcy}=\text{phthalocyanine})$, a quartet: $(\text{Fe}^{\text{III}}\text{phtcy})$ and a quintet: $(\text{Fe}^{\text{IV}}(\text{Phen})_2(\text{NCS})_2, \text{Phen} = \text{phenanthroline}, \text{NCS} = \text{isothiocyanate})$. The ground state of these ligands is strongly influenced by the σ -donation and π -backbonding character of the ligand field. To achieve a good agreement with the measured ground-state we used as model the linear combination of the singlet Fe^{II} complexes $[\text{Fe}^{\text{II}}(\text{bpy})_3](\text{PF}_6)_2$ (75 %) and $[\text{Fe}^{\text{II}}(\text{CN})_6]$ (25 %). Creating similar mixes of reference spectra for the excited states is not feasible due to the lack of isolated states at other time points and the thus limited statistical certainty. The challenge of this approach is thus the use of reference spectra that are potentially slightly different from the actual

spectra of a given state, introducing sources of error.

Modelling of the excitation fraction allows the conclusion that in this experiment $\approx 8\%$ of the excited fraction of molecules have absorbed a second photon in the excited state, leading to a very long lived state that manifests as an oxidized/ionized state at the iron center. This long lived state was then taken into account in the kinetic and spectral modeling.

Figure 3: Comparison of population parameters as a function of time gained by the linear combination of reference spectra for each time point and the model formed by global analysis. The fractional population can be understood as the fraction of excited molecules that are in this state.

The result of forming a linear combination of model spectra for each time point is a set of parameters representing the population in each spin/excitation state. For a good description of the temporal evolution of the measured Fe – K_{β} XES spectrum in Figure 2 the model spectra of the ground state (GS), $^3\text{MLCT}$ and ^3MC states are required. Figure 3 shows the temporal evolution of population of these states, with an assigned standard confidence interval. Linear combinations of model spectra without the ionized state, or with the involvement of the quintet MC state were tested, but led to a worse description of the measured data, as judged from an increased local (larger uncertainty) and total error (χ^2 of the fit). The $^1\text{MLCT}$ state was omitted from this plot as its typical lifetime is shorter than the instrument response function and the $^1\text{MLCT}$ and $^3\text{MLCT}$ K_{β} spectra are very similar. The state population dynamics resulting from the model spectra based analysis does not itself provide a characterization of the temporal evolution in terms of exponential

time constants. The discussion below of the population dynamics is therefore quantified with the help of the time constants generated by the global analysis method discussed below; as can be seen from Figure 3 there is a very good agreement between the temporal evolution generated by the two methods.

The population dynamics resulting from model spectra fitting (Figure 3) exhibits an ultrafast “bleach” of the ground state and a delayed ps-scale exponential recovery. We observe an immediate formation of the $^3\text{MLCT}$ state, which has a single-exponential decay rate identical to the rate of the GS recovery. A fraction ($\sim 30\%$) of the ^3MC population forms within the time resolution of the experiment. The ~ 0.7 fractional population of the $^3\text{MLCT}$ state and only 0.3 of the ultrafast ^3MC formation suggests another relaxation pathway from the $^3\text{MLCT}$ state. The nature of this path becomes clear when we consider the decay of the ^3MC population – it decays with the same delayed single exponential kinetics as the $^3\text{MLCT}$ decay and GS recovery. Since the ^3MC state is expected to be populated from the $^3\text{MLCT}$ state (due to its significantly lower energy[33]) and both states decay with the same time constant (7.6 ps), this strongly suggests a relaxation pattern where the $^3\text{MLCT} \rightarrow ^3\text{MC}$ process is the rate limiting step in the sequence $^3\text{MLCT} \rightarrow ^3\text{MC} \rightarrow \text{GS}$. For ^3MC and $^3\text{MLCT}$ decays (and GS recovery) to be the same, the $^3\text{MC} \rightarrow \text{GS}$ decay must be much faster than the $^3\text{MLCT} \rightarrow ^3\text{MC}$ process. This so called “inverted kinetics” shows up as a delayed rise in the ^3MC and GS kinetics, with a fitted time constant of 2.2 ps for the $^3\text{MC} \rightarrow \text{GS}$ step. The faster depopulation then population (2.2 vs 7.6 ps) of the ^3MC state implies that no visible population builds up through this channel, explaining the “missing” fractional population. This behavior was already observed in optical TA measurements on the first FeNHC synthesized.[21] The partial ultrafast formation of the ^3MC state implies that there will be a 2.2 ps decay of the state with the same amplitude, as well as the same partial recovery of the ground state. This decay will to a certain extent cancel the 2.2 ps rise in the inverted kinetics of the ^3MC majority population, but because this is the dominating part the rise is nevertheless clearly observable.

The global analysis fitting returns the ^3MC formation time constant as 150 fs, on the limit of the time resolution of the experiment, and the $^1\text{MLCT}$ to $^3\text{MLCT}$ transition cannot be resolved with any certainty because of very high rate and similar spectra.

Therefore, it is difficult to judge whether the ultrafast population of the ^3MC state occurs directly from the $^1\text{MLCT}$ state or from the $^3\text{MLCT}$ state following $^1\text{MLCT}$ to $^3\text{MLCT}$ ISC. In the latter case, the ISC from the $^1\text{MLCT}$ state would have to occur to a hot $^3\text{MLCT}$ state, followed by a branched decay to the ^3MC and cold $^3\text{MLCT}$ states, in order to be compatible with the observed branching ratio.

This is consistent with the generally fast cooling of charge transfer states. Optical TA measurements on similar FeNHC complexes suggesting $\ll 100$ fs $^1\text{MLCT} \rightarrow ^3\text{MLCT}$ ISC [3, 32, 39, 43, 45, 46] would support this scenario. Time constants and associated amplitudes of the processes are summarized in the conclusions.

As to our knowledge novel approach in the field of time resolved XES is a reference free global analysis scheme which is often used in the field of transient optical absorption spectroscopy. [47, 48] In the global analysis approach used here, a parametric model based upon a set of differential equations is created for all time points. In a separate step the optimal spectral representation is calculated by solving the equation system with the observed intensity as a goal (see SI for further details). This approach avoids the use of rigid reference spectra, which may be difficult to obtain for these complexes with strong metal-ligand interaction. The optimal spectral representation is calculated anew for each step of the optimization. In the progress of the analysis a number of potential models are generated, refined with a matrix of starting parameters, and evaluated against measured spectra.

In transient optical spectroscopy an initial approach often used to get a first qualitative picture of the processes and time scales involved, is to perform single color kinetic measurements, i.e. to measure the excitation pulse induced dynamics at a few different probe wavelengths, rather than measuring the broad-band full spectral response. The analysis of single kinetic traces is also less demanding than that of the full spectral temporal evolution. The kinetic traces in Figure 4 are the single color kinetics taken at two different energies in the Fe – K_β XES spectrum in Figure 2, 7057.6 eV and 7060.5 eV, on the low- and high-energy side of the spectrum, respectively. Kinetics measured at 7057.6 eV exhibits a decreasing signal as time progresses, while kinetics at 7060.5 eV shows an increasing signal. The reference spectra now show that the decrease/increase of signal at 7057.6/7060.5 eV is a result of increas-

ing spin density on the iron atom with a rise time of ~ 150 fs, indicating the presence of an ultrafast intersystem crossing, in agreement with many previous studies on iron complexes. [3, 32, 39, 43, 45, 46] At later times we observe a recovery of the excitation-induced spin momentum, but it does not fully recover to the ground state level within the 1 ns experimental window, due to the long lived oxidized/ionized state formed through excited state absorption.

Figure 4: Kinetic spectrum of two single energetic slices extracted from the measured Fe – K_β spectra. Left: Focusing on fast kinetics. Dots represent the observed intensity in a single temporal bin as defined by the timing tool. Right: Focusing on temporal development over multiple picoseconds. Error bars represent the variance of measurements within a temporal bin.

The model of the involved states for the analysis of single color kinetic data (Figure 4) as well as the full spectral evolution (Figure 5) is the same as emerging from the model spectra based analysis (Figure 5) of the measured Fe – K_β XES spectrum: An ultrafast, unresolved $^1\text{MLCT}$ to a hot (not relaxed) $^3\text{MLCT}$ ISC, followed by a branched decay of the hot $^3\text{MLCT}$ state into the ^3MC state and relaxed (cold) $^3\text{MLCT}$ state, which decays into the ^3MC state; the ^3MC state finally decays back to ground state. The formation of the permanently (on this time scale) oxidized state through excited state absorption from the $^1\text{MLCT}$ state was also included in this modeling. As already mentioned above, the two ultrafast processes $^1\text{MLCT}$ to $^3\text{MLCT}$ and partial decay to the ^3MC state cannot clearly be distinguished as two separate processes, because they both are similar or faster than the measurement response function. In principle, the ultrafast formation of part of the ^3MC population could occur from the $^1\text{MLCT}$ state, but we choose the relaxation scheme summarized in the conclusions, based on results from optical TA on similar molecules. [3, 32, 39, 43, 45, 46] A comprehensive discussion of the other, less successful, tested models

Figure 5: Comparison of Measured Matrix of spectral intensity vs time (left) with model (middle) and difference between model and data (right)

as well as the used rate equations are given in the supplementary information.

Figure 6: (solid lines) Spectra extracted from Global modelling of full kinetic dataset, often called Decay associated spectra, compared to reference spectra for identification

Free parameters in the global analysis fitting of single color kinetics and XES spectral evolution are the lifetimes and the branching ratio from the hot ³MLCT state to the ³MC and relaxed ³MLCT states. The result of this modelling is a full 2D map of spectral intensity vs. time that was formed without imposing a particular spectrum and that used the statistical information of the whole dataset. Figure 5 shows the measured Fe – K_β XES spectrum as a function of time, the time dependent spectrum obtained from the global analysis fitting and residuals of the analysis with a feature-free error matrix. The solid lines in Figure 4 labeled "GA", and in Figure 3 are a narrow band spectral integration of the full 2D map. It is encouraging to see that the global analysis approach generates kinetics that almost perfectly traces

the temporal evolution of the population of states obtained from the model spectra based analysis (Figure 3).

It should be noted that all analysis and model optimization was performed on the absolute recorded K_β spectra. This reduces noise and avoids the introduction of spectral errors due to changes of the ground state over time, e.g. due to sample degradation. The calculated spectra can be understood as species associated spectra and be compared to reference spectra and identified with spin/charge transfer states as has been done in Figure 6. The small deviations between the global analysis spectra and reference spectra can originate from the different bonding environments in the studied molecule as compared to the molecules used for reference spectra, experimental conditions like the spectral deconvolution, or statistical limitations of minority species. During the analysis we do not enforce the use of a specific spectrum and are thus robust against influences that are present for all spectra (like misalignment of the spectrometer), or insufficient reference spectra quality. It thus appears as a useful strategy to use both analysis methods in parallel and ensure that one receives good agreement between the two methods like in Figure 3.

An independent verification of this modelling can be achieved by using the simultaneously collected K_α line. It has been shown by us and others previously that the intensity and width of the Fe/Co K_α emission spectrum is a good marker of the total spin momentum at the metal center.[29, 49, 50] We measured the K_α emission at 6404 eV and can use this correlation to monitor the evolution of the total spin momentum in the molecule. Figure 7 shows the measured intensity changes and we analyze the signal independently of the previous analysis in the left-hand panel and then overlay the results we gained from the K_β analysis with the data in the middle and right-hand panel.

Figure 7: Single wavelength K_{α} emission spectrum measured in parallel with K_{β} spectrum. Left: Measured data independently modeled with single and double component exponential decay. Middle and right: Measured data with overlayed model.

In the left-hand panel the data was modeled with one and two consecutive exponential decay functions, respectively, given arbitrary intensity variation. In order to superimpose the previously obtained population factors we convert the population of the excited states into a change of the total spin momentum at the iron. The state $^1/3\text{MLCT}$ thus corresponds to a change of $\Delta S = \frac{1}{2}$ vs. the GS, the ^3MC with $\Delta S = 1$ and the ^5MC state with $\Delta S = 2$ at the iron center.

In the independent fit two exponential functions are required to explain the measured kinetics, reproducing in general the same time constants. The model created by optimizing the measured dynamics with the K_{β} spectra also shows a good agreement with the here measured spectrum. This approach is particularly valuable to test for the involvement of high spin states. If e.g. only a small fraction of the complex would decay over a quintet state, the subtle changes to the total K_{β} spectrum might be difficult to identify. As the difference of the total spin momentum change is x2 for the ^5MC compared to the ^3MC the signal is significantly clearer in the K_{α} spectrum, allowing exclusion of models involving high spin states.

4 Discussion

Both optically bright and dark states are important players in the photochemical behavior of transition metal complexes, and optical spectroscopy only provides part of the complete picture. Here we have used ultrafast x-ray emission spectroscopy to monitor the relaxation pathways and identify the nature (spin state) of involved excited states following photoexcitation. Through the K_{β} emission spectrum we observed an ultrafast and strong rise of the spin momentum on the iron atom (Figure 4). This spin increase is

analyzed with two different methods, reference spectra based analysis of the temporal evolution of the K_{β} spectrum, and a global analysis approach “inspired” by optical TA spectroscopy. In very good mutual agreement, both methods show that $\text{Fe}^{\text{II}}(\text{bpy})(\text{btz})_2$, following photoexcitation and ultrafast ISC to a hot $^3\text{MLCT}$ state, relaxes along a branched pathway back to the ground state (Figure 8). This relaxation pattern is in addition supported by the temporal evolution of the K_{α} spectrum. In accordance with recent results from optical TA spectroscopy and quantum chemistry calculations a majority ($\sim 70\%$) of the population of excited molecules return to the ground state via inverted kinetics through a relaxed $^3\text{MLCT}$ state and the ^3MC state, where the transition $^3\text{MLCT} \rightarrow ^3\text{MC}$ is rate limiting (7.6 ps) and the transition $^3\text{MC} \rightarrow \text{GS}$ is much faster (2.2 ps). Along a previously unknown pathway $\sim 30\%$ of the $^3\text{MLCT}$ state population is “short circuited” by an ultrafast (~ 150 fs) decay to the ^3MC state. From a photochemical and application point of view this implies that $\sim 30\%$ of the excited molecules are dumped through an ultrafast process into a photochemically inactive state, which in addition is very short lived (2.2 ps).

The here observed lifetime of the relaxed $^3\text{MLCT}$ state is shorter than previously measured with optical transient absorption spectroscopy (~ 13 ps). Part of the reason is the different excitation wavelength (705 nm vs. 400 nm used here) and analysis method used in the two experiments. Another reason may be difficulties in state assignment. We performed new optical TA measurements using 400 nm excitation and the branched relaxation model of Figure 8 to analyze the response. This gives a 9.2 ps lifetime of the rate limiting $^3\text{MLCT} - ^3\text{MC}$ step, close to the 7.6 ps determined with the x-ray probe. The ^3MC to

GS process is now characterized by a 2.3 ps lifetime, identical within experimental error to the 2.2 ps obtained in the x-ray measurements. A small fraction of the MC state, not visible in the x-ray experiment decays with 13.6 ps. (See also the supplementary information)

As mentioned above, since the development of this complex, other FeNHC molecules with CT state lifetimes up to ~ 2 ns have been developed.[15] Although these molecules are highly interesting for photochemical applications, their photophysics and photochemistry have so far only been characterized with optical spectroscopy. This implies that the involvement of quantum yield and efficiency reducing processes like the ultrafast $^3\text{MLCT} \rightarrow ^3\text{MC}$ process identified here is unknown and might reduce their overall efficiency. Our work shows that a combination of optical and x-ray methods, providing sufficient temporal resolution and state/spin selectivity is required for a complete characterization of the excited state relaxation pattern, involving both relaxation rates and yields of optical bright and dark states. With this knowledge we are well armed to modify the ligand sphere and binding patterns to optimize photochemical and electrochemical properties of these promising molecules.

Figure 8: Jablonski diagram with suggested dynamics as determined in this study.

5 Conclusion

We have used x-ray spectroscopic techniques to investigate a Fe^{II} transition metal complex of the recently developed nitrogen heterocyclic carbene type, which have drastically extended CT state lifetimes as compared to traditional polypyridyl complexes. Measurement and analysis of the temporal evolution of the K_β and K_α spectra following photoexcitation helped us to identify and quantify the population dynamics of the different excited states involved in the relaxation cascade. The analysis involved two meth-

ods for extracting excited state dynamics and spectra, a model spectra based and global analysis of the time dependent K_β spectrum. This analysis was further supported by recording the temporal evolution of the K_α spectrum, whose peak intensity is a sensitive marker of the total spin momentum of the molecule. The results of this analysis can be summarized as three major findings: 1) Substantiating previous conclusions from optical TA measurements and quantum chemical calculations we conclude that the ^5MC state is never populated in the relaxation from the $^3\text{MLCT}$ state back to ground state. Thus, a major effect of the increased electron density on the Fe-center accomplished by the NHC ligands is to move the ^5MC state out of the relaxation pathway; 2) A previously unknown relaxation channel is identified: an ultrafast sub-ps decay from a hot $^3\text{MLCT}$ state to the ^3MC state, in competition with vibrational cooling of the $^3\text{MLCT}$ state. This process constitutes a partial “short circuit” of the $^3\text{MLCT}$ state and reduces the yield of molecules available for photochemical functions. 3) The ultrafast deactivation of the $^3\text{MLCT}$ state of Fe-polypyridyl complexes, and $\text{Fe}^{\text{II}}(\text{bpy})_3$ in particular, has been explained as a sequential process involving the ^5MC and ^3MC states[43, 51, 52, 26, 53, 54], or a direct one-step process[3]. The present results, highlighting a branched decay of a hot $^3\text{MLCT}$ state, may perhaps offer a possibility to reconcile these apparently disagreeing results: also in the Fe-polypyridyl complexes there is perhaps a branched decay of the $^3\text{MLCT}$ state, but various time resolved methods (e.g. optical and x-ray) used to monitor the relaxation processes have different sensitivity to the two pathways and states.
