Abstract—The growing installations of variable renewable energy (VRE) sources, which are driven by weather patterns, can cause challenges to the operation and planning of power systems. This paper minimizes the variance of aggregate VRE generation based on the amount of different VRE technology types installed in different countries over a large geographical area. A mixture of offshore and onshore wind, and solar photovoltaic generation is considered. In the presented case study in Northern Europe, the optimized scenario provides a doubling of the expected annual VRE energy with a much lower increase in the aggregate VRE generation variability compared to other scenarios. The optimized scenario shows clearly the benefit of having a mixture of different VRE technologies with geographically highly spread installations.

Keywords—Optimization, renewable energy, solar, variance, wind.

I. INTRODUCTION

The installed capacities of variable renewable energy (VRE) sources have been growing rapidly and are expected to grow more in the future. VRE generation, which consists mostly of wind and solar power, is dependent on weather patterns and thus variable. This can cause challenges to the operation and planning of power systems compared to only having traditional generation (e.g., thermal and hydro) in the system.

Wind power variability modelling has been a topic of interest for several years [1]–[3]. The geographical distribution of wind installations has a significant effect on the aggregate wind generation. Increasing the geographical spread can decrease the variability of the aggregate generation significantly over a large geographical area [3]. Compared to wind, the geographical distribution has a lesser effect on the variability of solar photovoltaic (PV) generation [4]. However, a mixture of wind and solar PV can be very interesting when considering variability of aggregate VRE generation, as they are often negatively correlated [5]. The effect of this is discussed more in Section II.

As the geographical distribution of different VRE sources has an effect on the variability of the aggregate VRE generation, one can ask if the variability could be minimized. It has been shown that this can be done for the variance of the aggregate generation [3], [6]–[10]. In [6], [7], mean-variance portfolio optimization was used for optimizing wind farm locations in a single country. In [8], [9], similar optimization was carried out for several European countries. In [10], portfolio optimization

was used to optimize the management of both wind and solar energy resources in Spain.

This paper models the effects of different VRE technology types and their geographical distribution on the aggregate VRE generation variance in Northern Europe. The approach is similar to [10], but applied on a larger geographical area covering multiple countries. The VRE technologies are split to onshore wind, offshore wind and solar PV. The inclusion of solar PV into the generation mix is an extension of modelling only wind in [3], [6]–[9]. Compared to [10], the separation of wind to onshore and offshore is an addition. 34 years of simulated hourly wind and solar PV generation data are used to estimate the mean vector and covariance matrix required in the variance minimization. In addition to minimizing the aggregate VRE generation variance, the full probability distribution of the resulting aggregate generation is studied.

The studied countries are Denmark (DK), Finland (FI), Norway (NO), Sweden (SE), Estonia (EE), Lithuania (LT), Latvia (LV), Germany (DE), Netherlands (NL) and Poland (PL). The starting point is the VRE installation situation in 2016. The expected annual VRE energy from these installations is estimated, and a doubling of the annual energy is implemented while minimizing the aggregate variance. Ambitious but feasible investments limits (assuming highly interconnected future) for the different countries are implemented in the optimization constraints. It is shown that optimizing both the mix of the different VRE technology types and their geographical distribution lowers the aggregate variance significantly compared to other scenarios.

In [9], the variance of hourly aggregate VRE generation ramp rates, rather than the overall variance, was minimized. Motivated by the analysis of residual load behavior in future scenarios in [11], where the additional ramping from VRE generation compared to load was considered modest in Nordic and Baltic countries, a decision to minimize the overall variance was taken in this paper. However, it will be shown that the optimized scenario shows also a reduced ramp rate variance.

This paper is structured as follows. Section II takes a theoretical look at the variance of aggregate VRE generation, and describes its minimization. Section III presents the VRE data used, and Section IV presents the resulting optimized scenario. Section V provides discussion on the assumptions

taken and discusses possible future work. Section VI concludes the paper.

II. MINIMIZING VARIANCE OF AGGREGATE VRE GENERATION

This section provides a theoretical look at the variance of aggregate VRE generation, and how it depends on the statistical properties of the different VRE sources. The minimization of the aggregate variance, and related assumptions, are then described.

A. Variance of Aggregate VRE Generation

Considering k different sources of VRE generation, their aggregate generation at time t is

$$p_t = \sum_{i=1}^k w_i y_{i,t}, \quad (1)$$

where w_i is the installed capacity (or weight) of source i , and $y_{i,t}$ is its standardized generation. A VRE source means, e.g., solar PV generation in DE or offshore wind generation in DK. Standardized generation means that $y_{i,t}$ get values between 0 and 1, where 1 means that the source is generating at full installed capacity.

The variance of the aggregate VRE generation p_t is

$$\text{Var}(p_t) = \sum_{i=1}^k w_i^2 \sigma_i^2 + 2 \sum_{i \leq j \leq k} w_i w_j \sigma_i \sigma_j \rho_{i,j}, \quad (2)$$

where $\sigma_i^2 = \text{Var}(y_{i,t})$ and $\rho_{i,j} = \text{Cor}(y_{i,t}, y_{j,t})$ [3]. As can be seen from (2), the variance of the aggregate VRE generation depends on the variances of the individual sources σ_i^2 , and on the correlations between the sources $\rho_{i,j}$.

B. Minimizing the Aggregate Variance

In (2), the variables σ_i and $\rho_{i,j}$ are mostly defined by meteorological behavior. In this paper, it is considered that those parameters do not change (this is discussed more in Section V). However, the weights w_i can be optimized so that (2) is minimized. This means that the variance of the aggregate generation is minimized in relation to the installed capacities of the different VRE generation sources.

As can be seen in (2), increasing the share w_i of a VRE source with high variance σ_i^2 makes the aggregate variance higher. Avoiding sources with high variance is, however, not the only concern in the minimization, as changing w_i also affects the correlation part of (2). The minimization of (2) was carried out using Matlab function `fmincon` (Matlab R2016b, Optimization Toolbox [12]).

C. Constraints

1) Expected Annual VRE Energy Generated

It was chosen that each studied scenario (i.e., a set $w_1, \dots, w_k$) should give the same expected annual VRE energy (assuming 8760 hours per year). This is given as a constraint in the $\mathbf{Ax} = \mathbf{b}$ form as

$$\begin{bmatrix} E(y_{1,t}) & \dots & E(y_{k,t}) \end{bmatrix} \begin{bmatrix} w_1 \\ \vdots \\ w_k \end{bmatrix} = \frac{E_a}{8760}, \quad (3)$$

where E_a is the expected annual VRE energy generated with installed capacities w_i for the different VRE sources with expected values $E(y_{i,t})$. As $y_{i,t}$ are given as standardized

generation, the expected values are the capacity factors of the different sources.

2) Lower and Upper Bounds for the Weights

It was considered that current VRE installations will not be decreased. Thus, the lower bounds of w_i are the installed capacities of 2016; they are taken from the ENTSO-E Statistical Factsheet for 2016 [13].

Upper bounds of w_i for wind installations are taken mostly from the WindEurope 2030 high scenario [14], which was considered to represent ambitious but still feasible installations for the different countries. However, for Baltic countries the onshore wind installation limits were increased to 2 GW. For offshore wind, a maximum limit of 5 GW was set for NO, 2 GW for FI and SE, and 1.2 GW for the Baltic countries.

For solar PV, the SolarPower Europe's medium scenario for 2021 was considered as the starting point [15]. However, to extend the horizon further into the future, a 50 % increase was implemented. The results were used as the upper bounds for DE and NL. To allow for some solar investments also in the north, a 5 GW limit for the Nordic countries and PL, and a 2 GW limit for the Baltic countries were set for solar PV installations. The resulting lower and upper bounds for w_i can be seen in Appendix C.

III. VRE GENERATION DATA USED

This section describes the VRE generation time series from which the statistical parameters required for (2) and (3) are estimated from. The most important aspects of these statistical characteristics are then described.

A. 34 Years of Meteorological Reanalysis Data

The VRE generation time series are simulated using the CorRES tool developed at DTU Wind Energy, which is based on meteorological data obtained from the mesoscale Weather Research and Forecasting (WRF) model [16]. The downscaling method presented in [17], [18] has been used to generate time series of, e.g., wind speed and irradiance. The simulations are a reanalysis of past weather, currently covering 34 years with hourly resolution. The analyzed countries are shown on a map in Fig. 1.

From the WRF model, hourly meteorological time series are obtained on a 10 km x 10 km grid that covers the area of interest. This grid of data was used to create wind and solar PV generation time series for the different countries (installations were aggregated to closest grid points). For countries with wind generation installations, the existing locations were used. For countries without installations, e.g., offshore wind for NO, planned locations were used [19]. For solar PV, installations were assumed to be scattered throughout the countries, with more weight to the south for FI, NO and SE. The application of WRF reanalysis data in large-scale wind and solar PV generation simulation has been validated, e.g., in [20], [21].

Fig. 1. Map of the analyzed countries. © EuroGeographics for the administrative boundaries.

B. Statistical Characteristics of the Individual VRE Sources

Descriptive statistics of the different VRE sources are given in Appendix A. A low relative standard deviation (RSD), which is standard deviation (SD) divided by the mean, shows which VRE sources are favorable for the minimization of (2) when looking only at the first part of the equation $\sum_{i=1}^k w_i^2 \sigma_i^2$. It can be seen that offshore wind generation at the best locations, e.g., DK and NO are the most favorable sources. Solar PV are the least favorable sources when looking at only the RSD values.

C. Correlations Between the VRE Sources

Average correlations between the different VRE types are shown in Table I, and more detailed numbers are given in Appendix A. Wind generations in the different countries are on average quite correlated, but correlation decreases as distance between the countries increases. Solar PV generations in the different countries are always highly correlated.

The most interesting case considering the correlations are the slightly negative correlations between solar PV and wind generation. It can be seen in Appendix A that the correlations between all solar and wind generation sources are negative. This allows a combination of solar and wind to decrease the variance of the aggregate VRE generation (2), as the second part $2 \sum_{i \leq j \leq k} w_i w_j \sigma_i \sigma_j \rho_{i,j}$ can be even negative.

TABLE I. AVERAGE CORRELATIONS BETWEEN THE VRE TYPES

	Onshore wind	Offshore wind	Solar PV
Onshore wind	0.414	0.406	-0.163
Offshore wind	0.406	0.337	-0.137
Solar PV	-0.163	-0.137	0.903

IV. RESULTS FOR THE CASE STUDY

This section shows the resulting optimized scenario and compares it to other scenarios.

A. The Scenarios

The weights for “Today” are taken from the ENTSO-E Statistical Factsheet for 2016 [13]. The scenario called “Today

doubled” is created by doubling all the installations in the today’s scenario, which leads to a doubling of the expected annual VRE energy.

The “Optimized” scenario is created by minimizing the variance of the aggregate VRE generation (2), while respecting the constraints specified in Section II C, with the target of getting double the annual VRE energy. To study the effects of having both wind and solar in the generation mix, an “Only wind” scenario is also created; it is like the “Optimized” scenario, but with zero weights for solar PV sources.

B. General comparisons

The optimized frontier in Fig. 2 shows that a small increase of the expected annual VRE energy from “Today” can be achieved with only a small increase in the SD of the aggregate VRE generation. However, as the upper bounds for w_i start to affect more, the aggregate SD starts to increase more rapidly when annual VRE energy increases.

As can be seen Table II, in the “Today doubled” scenario the SD of the aggregate VRE generation is double compared to “Today” (because it is simply a scaled-up version of “Today”). In the “Optimized” scenario, the doubling of the annual VRE energy is achieved by having a 21 % lower SD of the aggregate VRE generation than in “Today doubled”.

In the “Only wind” scenario, the aggregate VRE generation SD is notably (20 %) higher than in the “Optimized” scenario, which shows the significance of having both solar and wind in the future VRE generation mix.

Fig. 2. The optimized frontier from today’s annual VRE energy to its doubling, and how the different scenarios compare to it.

TABLE II. OVERALL RESULTS OF THE SCENARIOS

Scenario	SD of aggregate (GWh/h)	Annual VRE energy (TWh)	Onshore wind share	Offshore wind share	Solar PV share
Today	12.8	187	67 %	11 %	22 %
Today doubled	25.7	375	67 %	11 %	22 %
Optimized	20.4	375	51 %	30 %	19 %
Only wind	24.5	375	56 %	44 %	0 %

C. The Optimized Weights

As can be seen in Table II, in the “Optimized” scenario the share of offshore wind is greater than in “Today doubled”. However, the optimization does not simply maximize the amount of offshore wind everywhere, as can be seen Appendices B and C; both the onshore wind and solar PV installations are also increased.

Fig. 3 shows a country-wise aggregated view of the optimized VRE installations in the “Today” and “Optimized” scenarios. For DE, which already has a lot of VRE generation installed, the optimization puts no more installations. The optimization chooses to put much of the additional VRE installations into countries further away from the areas with high VRE installations today, such as FI, NO and EE.

Fig. 3. The sums of installed VRE generation capacities in the different countries.

D. A Look at the Full Probability Distributions

In addition to looking only at the first and second statistical moments, which fully specify (2) and (3), Fig. 4 shows the full probability distribution functions (PDFs) of aggregate VRE generation in the scenarios “Today doubled” and “Optimized”. In addition to lower SD, the optimized scenario has also significantly reduced aggregate VRE generation 5th and 95th percentiles, as can be seen in Table III.

Ramp rates were not considered in the minimization of (2) at all. However, Fig. 5 shows that the “Optimized” scenario has also lower aggregate hourly ramping (i.e., variability of the 1st difference of aggregate hourly generation) than the “Today doubled” scenario. Table III shows that both ramp rate SD and the 5th and 95th percentiles are lower.

Fig. 4. Estimated PDFs of the aggregate VRE generation for the “Today doubled” and “Optimized” scenarios

Fig. 5. Estimated PDFs of the hourly ramp rates of aggregate VRE generation for the “Today doubled” and “Optimized” scenarios.

TABLE III. STATISTICS FOR THE SCENARIOS

Scenario	5 th and 95 th percentiles (GWh/h)	SD of 1 st difference (GWh/h)	5 th and 95 th percentiles of 1 st difference (GWh/h)
Today doubled	10.9, 95.6	4.31	-7.65, 7.51
Optimized	15.0, 82.0	3.53	-6.23, 6.15

V. DISCUSSION

It was assumed that only the weights w_i can be used in the minimization of (2), and that the statistical VRE parameters σ_i^2 and ρ_{ij} , and $E(y_{i,t})$ in (3), remain the same in the future. This assumes, e.g., that the future wind installations have similar capacity factors to today and that additional installations in the countries do not change the SDs shown in Appendix A.

Assuming that countries experience relatively similar capacity factor development in the future, the optimal shares of wind in the different countries should remain relatively similar to the ones showed in Appendix B. However, the optimal shares between wind and solar PV can be quite different when capacity factors change. The changing capacity factors will be considered in future research.

In the numbers shown in Appendix A, no clear difference in SD was noticed between countries with currently high or low shares of onshore wind generation (the geographical sizes of the countries seem to explain most of the differences). For offshore wind, for countries with currently no installations, a few planned projects were modelled to make them comparable to countries with offshore wind installed today. For solar PV, installations were assumed to be geographical scattered for all countries (this represents mostly residential solar PV installations). These notions give some justification that the statistical parameters estimated from today’s data are also representative of the future.

Grid constraints were not considered in the analysis. While the per-country installation limits were considered feasible, grid constraints should be considered in future work. Also, dynamic studies of the optimized scenario need to be carried out before its feasibility can be verified.

An important consideration in future work is to include load in the analysis, and to model the variability of the residual load [11]. This is important as the residual load is what the non-VRE

generation needs to fulfill (or it needs to be handled by demand-side management or transmission to other countries).

VI. CONCLUSION

This paper has shown a method to minimize the variance of aggregate VRE generation based on the amount of different VRE technology types installed in different countries. A case study in Northern Europe was presented with the aim to double the expected annual VRE energy. It was shown that the optimized scenario can provide this with a 21 % lower increase in the aggregate VRE generation SD compared to if the doubling would be achieved by simply scaling up the current installations.

It was shown that the optimized scenario uses a mixture of offshore wind, onshore wind and solar PV. Although offshore wind has the lowest RSD in the individual countries, the negative correlations between solar PV and wind generation make the case for having both solar and wind in the future VRE generation mix. This was emphasized by showing that without solar generation, the SD in the optimized scenario would be 20 % higher. A look at the VRE installations in the different countries showed the benefit of having VRE installations more geographically spread compared to today.

The presented optimized scenario is based on a minimization of a single statistical parameter, namely variance of the aggregate VRE generation. However, it was shown that the resulting optimized scenario shows also significantly reduced probabilities of very high and low aggregate VRE generation and reduced ramp rates compared to simply scaling up the today's installations.

The results highlight the importance of considering larger geographical regions than single countries when planning future power and energy systems. Also, a mixture of VRE technologies should be considered. Although the locations or types of future VRE installations cannot be forced, e.g., market structures and policies may be planned in a way that they incentivize future VRE installations that lower the variability of the aggregate generation.

As VRE generation is moving away from subsidies, market prices will affect generators more directly. In addition to maximizing annual energy generation, the correlations to other VRE generations can become an important consideration as spot market prices vary according to the overall generation available to the market. To quantify this, the presented simulations will be further analyzed using energy system models. Such modelling will also consider required transmission investments.

Some important statistics for the aggregate variance minimization are colored: green means generally favorable when looking at the variability of the aggregate VRE generation.
