Abstract
Background: Food processing, including heat-treatment, can affect protein structure and stability, and consequently affect protein immunogenicity and allergenicity. A few studies have shown that structural changes induced by heat-treatment impact the intestinal protein uptake and suggest this as a contributing factor for altered allergenicity.
Objective: To investigate the impact of heat-treatment of a whey-based protein product on allergenicity and tolerogenicity as well as on intestinal uptake in various animal models.
Methods: Immunogenicity and sensitizing capacity of the heat-treated whey product were compared to that of the unmodified product by intraperitoneal and oral exposure studies, while tolerogenic properties were assessed by oral primary prevention and desensitization studies in high-IgE responder Brown Norway rats.
Results: Heat-treatment of whey induced partial protein denaturation and aggregation, which reduced the intraperitoneal sensitizing capacity but not immunogenicity. In contrast, heat-treatment did not influence the oral sensitizing capacity, but the heat-treated whey showed a significantly reduced eliciting capacity compared to unmodified whey upon oral challenge. Heat-treatment did not reduce the tolerogenic properties of whey, as both products were equally good at preventing sensitization in naïve rats as well as desensitizing already sensitized rats. Results from inhibitory ELISA and immunoblots with sera from sensitized rats demonstrated that heat-treatment caused an altered protein and epitope reactivity. Protein uptake studies showed that heat-treatment changed the route of uptake with less whey being absorbed through the epithelium but more into the Peyer’s patches.
Conclusion and Clinical Relevance: These results support the notion that the physicochemical features of proteins affect their route of uptake and that the route of uptake may affect the protein allergenicity. Furthermore, the study highlights the potential for heat-treatment in the production of efficient and safe cow’s milk protein-based products for prevention and treatment of cow’s milk allergy.

KEYWORDS
allergens and epitopes, animal models, food allergy, food processing, IgE, intestinal uptake, paediatrics
Cow’s milk allergy (CMA) is the most common food allergy among small children, with a prevalence of approximately 0.5%-3%, varying from country to country. The optimal way to prevent sensitization to cow’s milk is to exclusively breastfeed infants in their first months of life until introduction of solid foods. However, in many cases, breast milk must be supplemented with or replaced by infant formulas. Infants suffering from CMA or at high risk of developing an allergy are recommended to use hypoallergenic infant formulas, which are most often based on hydrolysed cow’s milk proteins. The risk of eliciting an allergic reaction is reduced because epitopes are degraded by hydrolysis, but this may also compromise the tolerogenic effects of these products. Currently, there is no accepted treatment for CMA or any other food allergy, yet immunotherapeutic strategies for desensitizing food-allergic patients have shown promising results. The only accepted strategy to manage CMA is strict avoidance of foods containing cow’s milk allergens. Different types of processing, including heat-treatment of cow’s milk proteins, are being investigated with the aim of reducing allergenicity but retaining immunogenicity, with the ultimate goal of producing safe and efficient products for prevention and treatment of CMA.

It is the general perception that heat-treatment reduces cow’s milk allergenicity since many milk allergic children can tolerate baked milk, yet tolerogenic properties of heat-treated milk are not well characterized. It has been reported that the introduction of baked milk into the diet of cow’s milk allergic patients can accelerate the development of tolerance to fresh milk, and baked milk has been used for oral immunotherapy in human clinical trials. However, it has been questioned whether heat-treated milk in fact has a true tolerogenic effect, or whether tolerance to baked milk is just a biomarker for spontaneous resolution of CMA since adverse reactions to baked milk are associated with severe CMA.

A direct comparison of allergenic and tolerogenic properties of unmodified and heat-treated milk can be addressed in controlled animal studies. A few animal studies have been performed to assess the sensitizing and eliciting capacity of heat-treated milk, but results from these studies are conflicting. These studies showed that effects on allergenicity are not only related to masking or exposure of antibody binding epitopes as have previously been described for cow’s milk allergic patients, but that heat-treatment also impacts on allergenicity by influencing the route of intestinal protein uptake. Evidence of the tolerogenic properties of heat-treated milk proteins from controlled animal studies is very limited, but development of oral tolerance will likely also be affected by intestinal uptake.

The present study investigated the impact of heat-treatment on the immunogenicity, sensitizing capacity, eliciting capacity and on the ability to induce tolerance as well as on intestinal uptake of a whey product. This was done with the ultimate goal to guide the future design of modified cow’s milk proteins with low allergenicity but retained tolerogenicity. The immunogenicity and sensitizing capacity of unmodified and heat-treated whey were assessed by intraperitoneal (ip) and oral exposure studies, while the tolerogenic properties were assessed by oral primary prevention and desensitization studies with recently established models. The intestinal uptake was evaluated in naive rats by quantifying protein levels in different intestinal tissues at different time points after oral administration of the whey products by gavage. In addition, protein uptake was evaluated by two different in vitro assays. In all animal studies, high-IgE responder Brown Norway (BN) rats, resembling atopic individuals, were used.

2 | METHODS

2.1 | Product characterization

Whey protein isolate (WPI) with approx. 60% β-lactoglobulin (BLG) and a heat-treated (HT) (90°C for 10 minutes) version of the same WPI were kindly provided by Arla Foods Ingredients (Videbæk, Denmark).

2.1.1 | Quantification of whey proteins

To examine native protein composition, TSK gel permeation chromatography (GPC) and high-performance liquid chromatography (HPLC) were performed. Whey products were dissolved in solvent (20 mmol/L NaH₂PO₄, Merck KGaG, pH 7.5) to a protein concentration of 0.1% (w/v), left overnight at 4°C and subsequently filtered with a 0.22 µm filter. A total of 25 µL was loaded on two connected TSKgel3000PWx1 (7.8 mm, 30 mm; TOSOH Bioscience GmbH) columns equipped with a PWx1 precolumn (6 mm, 4 cm; TOSOH Bioscience GmbH) at 25°C. Whey products were separated at a flow rate of 0.4 mL/min with 47% (v:v) acetonitrile (CHEM-LAB NV) in Milli Q water, and proteins were detected at a wavelength of 210 nm. Peak areas were normalized with the peak area of the casein macropieceptide (CMP).

2.1.2 | Analysis of protein aggregation

To examine protein aggregation status, ethylene-bridged hybrid (BEH) GPC and ultra-performance liquid chromatography (UPLC) was performed. Whey products were dissolved in solvent (50 mmol/L NaH₂PO₄, 0.15 mol/L NaCl, Merck KGaG, pH 7.0) to a protein concentration of 0.25% (w/v), left overnight at 4°C and subsequently filtered with a 0.22 µm filter. The 5 µL was loaded on an ACQUITY UPLC Protein BEH SEC column (200 Å, 1.7 µm, 4.6 x 150 mm; Waters Corporation) with an ACQUITY UPLC protein BEH SEC Guard column (200 Å, 1.7 µm, 4.6 x 30 mm, 10-500 K; Waters Corporation) at 25°C. The columns were connected on a Waters ACQUITY UPLC equipped with a Waters 2487 Dual λ Absorbance Detector. The whey products were separated at a
flow rate of 0.2 mL/min in solvent and detected at a wavelength of 214 nm.

2.1.3 | Native and SDS-PAGE

For analysis of proteins under non-reducing conditions by native polyacrylamide gel electrophoresis (PAGE), 40 µg of whey product was dissolved in native sample buffer (62.5 mM Tris-HCL pH 6.8, 25% glycerol, 0.01% bromophenol blue; BioRad) and loaded onto a 4%-20% TGX polyacrylamide gel (BioRad). Gel electrophoresis was conducted in Tris/glycin running buffer (25 mM Tris, 192 mM Glycine; BioRad) with 200 V constant current.

For analysis of proteins under reducing conditions, sodium dodecyl sulphate (SDS)-PAGE was conducted with 20 µg of whey product as previously described. Native and SDS-PAGE gels were washed three times in deionized water, and proteins were stained by Bio-Safe Coomassie stain (BioRad) for 1 hour at RT and washed three times, at day 0, 14 and 28, without any use of adjuvant. They were euthanised one week after the last dosing, blood samples were collected from the sublingual vein, converted to serum and stored at −20°C until analysis (overview of animal experimental design in Figure 3A).

2.4 | Oral sensitization experiment

To investigate the oral sensitizing capacity of the two whey products, BN rats (4-8 weeks of age, only females) were given either either WPI or HT-WPI together with 20 µg cholera toxin (CT, List Biological Laboratories Inc) in 0.5 mL PBS (n = 12/group). Rats were dosed three times per week (Monday, Wednesday and Friday) for five weeks. Ten days after the last dosing, blood samples were collected from the sublingual vein, converted to serum and stored at −20°C until analysis (overview of animal experimental design in Figure 3A).

2.5 | Primary prevention experiment

To investigate de novo tolerance inducing capacity, also designated primary preventive capacity, of the two whey products, naïve BN rats (4-6 weeks of age, both sex) were given either WPI or HT-WPI ad libitum in their drinking bottles (12.5 g protein per litre water) for 21 consecutive days (n = 8/group). After one week of rest, rats were post-immunized ip with 100 µg WPI in 0.5 mL PBS once a week for eight weeks. Blood samples from the sublingual vein were collected after tolerance induction and after the fourth post-immunization. Rats were euthanised one week after the last post-immunization by exsanguination using carbon dioxide inhalation as anaesthesia, and blood was collected, converted to serum and stored at −20°C until analysis (overview of animal experimental design in Figure 4A).

2.6 | Desensitization experiment

To investigate the desensitizing capacity of the two whey products, three groups of BN rats (4-8 weeks of age, only females, n = 12) were
orally sensitized to WPI with CT (as described above) and subsequently given either water, WPI or HT-WPI *ad libitum* in their drinking bottles (12.5 g protein per litre water) for 21 consecutive days. After one week of rest, desensitized rats together with naïve control rats were post-immunized ip with 50 µg WPI in 0.5 mL PBS once per week for three weeks. The day after the last post-immunization, rats were subjected to an ear swelling test with WPI, as described above. Blood samples were collected from the sublingual vein the day after *ad libitum* administration and on the day of second and third post-immunization. Rats were euthanised by exsanguination using carbon dioxide inhalation as anaesthesia, and blood was collected, converted to serum and stored at −20°C until analysis (overview of animal experimental design in Figure 5A).

### 2.7 In vivo uptake experiment

To investigate the intestinal uptake of the two whey products, naïve BN rats (9-16 weeks of age, only females) were gavaged with 100 mg of either WPI or HT-WPI in 1 mL water and euthanised at different time points (n = 4/group/time point). Rats were euthanised 15, 30, 60 or 90 minutes after gavage by exsanguination using carbon dioxide inhalation as anaesthesia. The small intestine was excised and a 20 cm section (7 cm distal from the stomach) was rinsed with 0.9% (w:v) NaCl and divided into three fractions; Peyer’s patches, lamina propria and epithelium, which were individually snap frozen in liquid nitrogen and stored at −80°C until analysis. Total proteins from Peyer’s patches and epithelium samples were extracted by homogenization by rotor-stator in 10 µL/mg tissue lysis buffer (150 mmol/L NaCl, 20 mmol/L Tris, 1 mmol/L EGTA, 1% Triton X-100, 1 mmol/L EDTA) with 2% (v:v) Halt protease inhibitor cocktail (Thermo Fisher) on ice. Lamina propria samples were homogenized in lysis buffer, and 2% (v:v) Halt protease inhibitor cocktail (Thermo Fisher) was immediately added to 1 mL of the homogenized tissue. Samples were incubated on ice for 20 minutes and mixed by vortexing every 5 minutes and cleared by centrifugation at 15 000 g for 20 minutes at 4°C. The supernatants were stored at −80°C until analysis. BLG concentrations of supernatants were quantified by a commercial bovine BLG ELISA kit (Bethyl Laboratories) in 96-well MaxiSorp plates (Nunc) according to the manufactures protocol. Tight junction integrity was confirmed by TEER (EVOM2, World Precision Instruments) before and after the uptake assay. In vivo intestinal transepithelial transport of the whey products through a Caco-2 cell layer was examined as previously described. Total proteins from Peyer’s patches and epithelium samples were extracted by homogenization by rotor-stator in 10 µL/mg tissue lysis buffer (150 mmol/L NaCl, 20 mmol/L Tris, 1 mmol/L EGTA, 1% Triton X-100, 1 mmol/L EDTA) with 2% (v:v) Halt protease inhibitor cocktail (Thermo Fisher) on ice. Lamina propria samples were homogenized in lysis buffer, and 2% (v:v) Halt protease inhibitor cocktail (Thermo Fisher) was immediately added to 1 mL of the homogenized tissue. Samples were incubated on ice for 20 minutes and mixed by vortexing every 5 minutes and cleared by centrifugation at 15 000 g for 20 minutes at 4°C. The supernatants were stored at −80°C until analysis. BLG concentrations of supernatants were quantified by a commercial bovine BLG ELISA kit (Bethyl Laboratories) in 96-well MaxiSorp plates (Nunc) according to the manufactures protocol. Tight junction integrity was confirmed by TEER (EVOM2, World Precision Instruments) before and after the uptake assay. Each condition was performed in triplicate and repeated three times.

### 2.8 Analysis of product-specific IgG1 by various ELISAs

For detection of product-specific IgG1 antibodies, indirect ELISA was performed as previously described. For evaluation of the antigen-antibody binding strength, avidity IgG1 ELISA was performed as described. For evaluation of the specificity of the antigen-antibody binding, inhibitory IgG1 ELISA was performed as previously described with the exception that sera were pre-incubated with WPI and HT-WPI inhibitor solutions.

### 2.9 Antibody-capture ELISA for detection of product-specific IgE

For detection of product-specific IgE antibodies, antibody-capture ELISA was performed as previously described with two exceptions: that plates were blocked with 3% (v:v) horse serum (BioWest-bw) in PBS with 0.01% (w:v) Tween 20, and product-specific IgE was detected by 50 µL/well of 0.1 µg/mL of 10:1 digoxigenin (DIG)-coupled WPI or HT-WPI in blocking solution.

### 2.10 Immunoblot

To investigate reactivity of IgG1 antibodies raised against WPI and HT-WPI after ip or oral administration, immunoblots were performed with serum pools as previously described with SDS-PAGE loaded with 5 µg whey product. Serum pools were diluted 1:500 (ip study both groups), 1:800 (oral study, WPI group) or 1:1000 (oral study, HT-WPI group) for optimal visualization.

### 2.11 In vitro epithelial transcytosis

To evaluate the in vitro epithelium permeability, transport of the whey products through a Caco-2 cell layer was examined as previously described. In short, culture media were replaced with fetal bovine serum (FBS)-free media on day 20 after seeding. The day after, whey products dissolved in FBS-free culture media were added to make a final concentration of 500 µg/mL in the apical compartment. After 1, 3, 6 and 24 hours, 250 µL was sampled from the basolateral compartment and stored at −20°C. Only data from 24 hours are shown. Supernatant BLG concentrations were quantified by a commercial bovine BLG ELISA kit (Bethyl Laboratories) in 96-well MaxiSorp plates (Nunc) according to the manufacture’s protocol. Tight junction integrity was confirmed by TEER (EVOM2, World Precision Instruments) before and after the uptake assay. Each condition was performed in triplicate and repeated three times.

### 2.12 In vitro dendritic cell uptake

To evaluate the in vitro product uptake by dendritic cells, murine bone marrow-derived dendritic cells (BMDC) were generated as described elsewhere and co-incubated with fluorescein isothiocyanate (FITC)-labelled whey products as previously described. In short, bone marrow cells from femur bones of BALB/c mice were isolated and cultured six days in RPMI medium with 10% (v:v) FBS and 10 ng/mL GM-CSF (R&D). To access protein uptake and
endocytosis, 10 μg/mL of FITC-labelled products was incubated with 1 × 10⁶ BMDC/mL in 2.4 mL of cell culture medium in a 37°C water bath. After 0, 5, 15, 30, 45, 60 and 120 minutes, 300 µL of this cell culture was harvested and immediately washed twice in 1 mL cold PBS and twice in cold FACS buffer (PBS with 2% [v:v] FBS and 0.05% [w:v] NaN₃) and centrifuged for 5 minutes at 250 g at 4°C. The percentage of FITC-positive cells and mean fluorescence intensity (MFI) was measured using FACS BD Accuri C6 flow cytometer (BD Biosciences). Flow cytometry data were analysed in Cylogic software (CyFlo Ltd). Each condition was performed twice in duplicates.

2.13 Statistical analysis

Curve and statistical analyses were made using GraphPad Prism (version 8.1.1 for Windows, GraphPad Software). For inhibitory ELISA curves, best-fit slope estimates (HillSlope) with standard errors were compared by one-way ANOVA. IC50 values were only compared for graphs with slope estimates that were not significantly different.

ELISA results were expressed as log2 antibody titres. Normal distribution of data was tested by D’Agostino-Pearson normality test. For data that passed the normality test, group means are indicated on graphs and differences between groups were analysed by t test (two groups) or one-way ANOVA followed by Tukey’s post-test for multiple comparison (>2 groups). For data that did not pass the normality test, group medians are indicated on graphs, and group differences were analysed by non-parametric Mann-Whitney test (two groups) or Kruskal-Wallis test followed by Dunn’s post-test for multiple comparison (>2 groups). MFI of BMDC was compared between the two groups at each time point by a two-way ANOVA of square root transformed data with Sidak’s post-test. Asterisks indicate statistically significant difference between two given groups: *P ≤ .05, **P ≤ .01 and ***P ≤ .001, ns: no statistically significant difference.

3 RESULTS

3.1 Characterization of products

WPI and HT-WPI were analysed for native versus denatured protein composition and aggregation status, which showed that heat-treatment caused changes in the physicochemical features of the WPI. Results from TSK GPC showed that some but not all of the proteins in the HT-WPI were denatured; about 35% of the BLG, 50% of the α-lactalbumin and 100% of glycomacropeptides remained in native form after the heat-treatment (Figure 1A). Results from BEH GPC showed that heat-treatment of WPI resulted in partial protein aggregation (Figure 1B). SDS-PAGE confirmed that the protein distribution was the same in the two products (Figure 1C). However, results from native PAGE revealed that protein conformation differed between the two products; while some distinctive protein bands were detectable for WPI, proteins in HT-WPI were retained in the top of the gel and formed a smear under non-reducing conditions (Figure 1D).

3.2 Intraperitoneal sensitization

To compare the inherent sensitizing capacity of the two whey products, serum from rats immunized ip with either WPI or HT-WPI (Figure 2A) was analysed for specific antibody responses. A statistically significant reduction in the serum level
of product-specific IgE was observed in the group of rats ip immunized with HT-WPI compared with those immunized with WPI (Figure 2B). The reduction in sensitizing capacity was not caused by a reduction in immunogenicity, as the serum level of product-specific IgG1 was similar in the two groups (Figure 2C). The binding strength of the raised IgG1 antibodies was similar in the two groups (Figure 2D). Results from inhibitory ELISAs demonstrated that the two products differed in competitive capacity; while HT-WPI fully inhibited the binding between WPI and IgG1 antibodies raised against WPI, WPI was not able to fully inhibit the binding between HT-WPI and antibodies raised against HT-WPI, indicating that new epitopes had developed as a result of heat-treatment.
In fact, for antibodies raised against HT-WPI, the IC50 values for HT-WPI were 70 times less than that of WPI, indicating that 70 times more WPI was needed to inhibit 50% of the binding between HT-WPI and antibodies raised against HT-WPI. Immunoblots of SDS-PAGE showed that serum from HT-WPI sensitized rats recognized more protein bands compared with that of WPI-sensitized rats (Figure 2F). Those bands were detectable in both products.

**FIGURE 3** Oral sensitization study. A, Animal experimental design: groups of 12 Brown Norway rats were gavaged with whey protein isolate (WPI) or heat-treated WPI (HT-WPI) three times per week for five weeks. At day 35, an oral challenge (OC) and, on day 38, an ear swelling test (EST) were performed. B, Product-specific IgE titres. C, product-specific IgG1 titres, D, binding strength between IgG1 and products, E, competitive capacity of products by inhibitory IgG1 ELISA, F, changes in core body temperature after OC, G, acute allergic response from an EST and H, immunoblotting based on sodium dodecyl sulphate polyacrylamide gel electrophoresis with pooled sera for detection of protein reactivity. Differences between the two blots are indicated by <. Analyses were performed on sera from day 42. Each symbol represents a single rat, with the exception of inhibitory ELISA where a symbol represents a group of rats and vertical lines indicate standard derivation of three independent technical replicates. Horizontal lines indicate median (B,C) or mean (D,F,G) value. Statistically significant differences between indicated groups (B-D,F,G) or relative to naïve controls (G) are shown as *P ≤ .05, **P ≤ .01, ***P ≤ .001 and ns, no statistically significant differences.
3.3 | Oral sensitization

To compare the oral sensitizing capacity of the two whey products, serum from rats orally gavaged with either WPI or HT-WPI together with the adjuvant CT (Figure 3A) was analysed for specific antibody responses.

In contrast to the ip sensitization study, oral dosing with WPI or HT-WPI resulted in similar serum levels of product-specific IgE (Figure 3B) and IgG1 antibodies (Figure 3C). However, the antigen-IgG1 binding strength was significantly increased in the group of rats that were dosed with the HT-WPI compared with WPI (Figure 3D). This difference between the binding strength of IgG1 antibodies raised against the two products was observed consistently in both animal experiments in which the products were administered by the oral route (data not shown). Results from inhibitory ELISA confirmed results from the ip sensitization study; while HT-WPI was able to fully inhibit the binding between WPI and IgG1 antibodies raised against WPI, WPI was not able to fully inhibit the binding between HT-WPI and antibodies raised against HT-WPI (Figure 3E). However, for antibodies raised orally against HT-WPI, the IC50 values for HT-WPI were only approximately 30 times less than that of WPI; hence, the difference between competitive capacities of the two products was much less for antibodies raised by oral administration compared with antibodies raised by ip immunizations.

To further evaluate the allergenicity, rats were subjected to two elicitation tests: an oral challenge and an ear swelling test. For the oral challenge, the body temperature of the rats was monitored before and 30 minutes after rats were administered with the same product as they were sensitized to, where a reduction of core body temperature is a sign of anaphylaxis. Despite a similar serum level of specific IgE in the two groups, the relative reduction in body temperature was significantly smaller in the group of rats dosed and challenged with HT-WPI compared with the group dosed and challenged with WPI (Figure 3F). No statistically significant difference between acute allergic skin responses in the two groups of rats could be observed in the ear swelling test (Figure 3G). Immunoblots of SDS-PAGE showed that serum from orally WPI-sensitized rats recognized more protein bands (Figure 3H) compared with that of the ip WPI-sensitized rats (Figure 2F). The immunoblots with serum from WPI and HT-WPI orally sensitized rats were overall very similar, but did show different binding pattern in the region between 25 and 37 kDa, which are likely due to binding of different caseins present in small amounts (Figure 3H). This showed that intestinal digestion diminished the difference between the products, but that some of the unique epitopes were still present on HT-WPI after ingestion.

3.4 | Primary prevention

To compare the de novo tolerance inducing properties of the two different products, the primary preventive capacity was evaluated by administering naïve rats with either water, WPI or HT-WPI ad libitum in their drinking bottles for 21 consecutive days before the rats were post-immunized ip by WPI (Figure 4A). Only one rat in each prevention group had a detectable level of WPI-specific IgE after eight post-immunizations while all rats in the control group were sensitized (Figure 4B). Analysis of WPI-specific IgG1 revealed that less rats had detectable levels of IgG1 after four post-immunizations in the group administered with HT-WPI compared with WPI (Figure 4C).

3.5 | Desensitization

To further investigate the tolerogenic properties of the two different whey products, the desensitizing capacity was evaluated by administering rats that were pre-sensitized to WPI with either water, WPI or HT-WPI ad libitum in their drinking bottles for 21 consecutive days.
Desensitization study. A, Animal experimental design: groups of 12 Brown Norway rats were orally gavaged with whey protein isolate (WPI) three times per week for five weeks. WPI-sensitized rats were given water, WPI or heat-treated WPI (HT-WPI) ad libitum in their drinking bottles for 21 d. After one week of rest, the three groups of desensitized and one group of naïve rats were post-immunized by intraperitoneal injections with WPI once per week for three weeks. The day after the last post-immunization, rats were subjected to an ear swelling test (EST). Blood samples were taken after sensitization (day 42) after desensitization (day 70) and after each post-immunization (day 77, 84 and 91). B, WPI-specific IgE titres, C, WPI-specific IgG1 titres, and D, acute allergic response from an EST. Each symbol represents a single rat and horizontal lines indicate mean values. Statistically significant differences relative to the water desensitization control group (unframed) and relative to WPI desensitization group (framed) are shown as *P ≤ .05, **P ≤ .01, ***P ≤ .001 and ns, no statistically significant differences.
Subsequently, the desensitized rats as well as naïve controls were post-immunized three times ip with WPI (Figure 5A). It was confirmed that serum levels of WPI-specific IgE and IgG1 were not significantly different in the three groups before desensitization was initiated.

While the natural decrease in WPI-specific IgE in the water control group was minimal, the IgE levels were dramatically decreased in both WPI and HT-WPI groups (Figure 5B). WPI-specific IgE levels increased slightly with increasing number of ip post-immunizations in both WPI and HT-WPI groups, but remained significantly reduced compared with the water control group at all time points after desensitization.

In the water control group, WPI-specific IgG1 levels decreased slightly after the desensitization period and then increased with increasing numbers of immunizations (Figure 5C). In both WPI and HT-WPI groups, levels remained constant throughout the study. Hence, there was a statistically significant difference in the levels compared with the water control group at all time points after desensitization. Neither WPI-specific IgE nor IgG1 levels differed significantly between the WPI and HT-WPI groups at any time point. After the third post-immunization, antibody levels in the WPI and HT-WPI groups did not differ significantly from naïve controls that were just ip immunized (not pre-sensitized and desensitized). Acute allergic skin response, measured by an ear swelling test, was significantly reduced in both WPI and HT-WPI groups compared with the water control group, and the response in the WPI and HT-WPI groups was not different from each other nor from that of naïve rats (Figure 5D).

3.6 | In vivo intestinal uptake

Naïve rats were orally gavaged with WPI or HT-WPI, and euthanised at different time points to examine intestinal protein uptake. BLG was quantified in total protein extracts of three different tissue fractions (Peyer’s patches, lamina propria and epithelium) from a piece of the proximal small intestine (Figure 6A). The distribution of protein between the different tissue fractions differed between the two treatment groups with a larger proportion of BLG being present in epithelium of WPI-dosed rats, while a larger proportion of BLG was present in Peyer’s patches and lamina propria of HT-WPI dosed rats (Figure 6B).

3.7 | In vitro epithelial transcytosis and uptake by DC

In vitro epithelial transcytosis was assessed by measuring BLG transport across polarized Caco-2 cells grown on semi-permeable membranes. BLG concentrations were quantified in the basolateral compartments 24 hours after apical application of the products. This experiment showed a tendency of the basolateral BLG concentration being higher in wells applied with WPI compared with HT-WPI (Figure 7A). In vitro product uptake in DC was assessed by co-incubating murine BMDC with FITC-labelled product preparations. The cells were harvested and washed at different time points, and protein uptake was measured as the level of fluorescence. The experiment showed that BMDC uptake of HT-WPI was more pronounced than the uptake of WPI (Figure 7B,C).

4 | DISCUSSION

There is a great interest in producing new and improved hypoallergenic infant formulas for prevention, management and treatment of CMA. Such infant formulas should have a reduced allergenicity without compromising tolerogenicity. To accomplish this, we need a solid understanding of how structural changes induced by food processing, such as heat-treatment, affect immunological properties of food proteins. This study investigated how heat-treatment affects intestinal uptake, allergenicity and tolerogenicity of a whey protein product.

The whey product was subjected to mild heat-treatment at 90°C for 10 minutes, which induced partial protein denaturation and aggregation. Heat-treatment disrupts the secondary and tertiary protein structure by breaking hydrogen bonds and hence causes an unfolding of proteins. In BLG, unfolding has been shown to result in exposure of hydrophobic sulphhydryl groups previously buried inside the folded protein. Interactions of the sulphhydryl
Conformational changes induced by heat-treatment may influence allergenicity directly by affecting IgE-binding epitopes, or indirectly by affecting biophysical properties of proteins such as digestibility and solubility, or the route of intestinal uptake. The heat-treatment may influence protein epitopes in various ways that either promote or prevent antibody binding: unfolding may expose epitopes that were previously inaccessible inside the folded protein and/or dissociate conformational epitopes, while aggregation may cause formation of neo-epitopes and/or masking of others. Previous studies have indicated that the effect of heat-treatment on epitope accessibility is temperature dependent, as they observed that heat-treatment below 90°C increased BLG antibody reactivity, while heating above 90°C reduced reactivity.

In the present study, heat-treatment reduced the inherent ip sensitizing capacity, while the oral sensitizing capacity was unaffected when the products were administered together with the mucosal adjuvant CT. However, HT-WPI induced significantly milder oral symptoms in sensitized rats compared with WPI upon oral challenge without adjuvant. Despite reduced allergenicity, heat-treatment did not reduce the tolerogenic properties as WPI and HT-WPI were equally good at preventing sensitization of naïve rats and desensitizing pre-sensitized rats. In line with our results, it was previously observed that heat-treatment reduced the ip sensitizing capacity of BLG and egg ovalbumin. However, in contrast to our results, other studies found that heat-treatment increased the oral sensitizing capacity of BLG, which might be a matter of the exact heat-treatment applied to the products or related to the use of adjuvants.

Tolerogenic properties of heat-treated milk are not well characterized. It has been reported that the introduction of baked milk in the diet of cow’s milk allergic patients can accelerate the development of tolerance to fresh milk, but it has been questioned whether tolerance to baked milk is just a biomarker for spontaneous resolution of milk allergy, or whether heat-treated milk has a true tolerogenic effect. Evidence from controlled animal studies is scarce, but one study reported, in line with our results, that feeding of unmodified and heat-treated WPI protected mice against subsequent immunization with unmodified WPI equally well. To our knowledge, no published animal studies have until now investigated the desensitizing effect of heat-treated milk proteins, but results with egg ovomucoid showed, in line with our results, that heated ovomucoid was as efficacious as unmodified ovomucoid for oral desensitization of mice.

Currently, most hypoallergenic infant formulas are based on hydrolysed milk proteins. Animal studies have shown that hydrolysed products have some capacity to prevent subsequent sensitization. Evidence on the desensitizing capacity of hydrolysed milk products is scarce, but two studies found no desensitizing capacity of hydrolysed whey products. The present study suggests that heat-treatment could be used as an alternative or supplement to hydrolysis for production of hypoallergenic infant formulas. Future studies should aim for a direct comparison of the allergenic versus tolerogenic properties of milk proteins modified by heat-treatment and hydrolysis to investigate which type of modification is superior.

The present study showed that heat-treated products elicited milder oral symptoms in sensitized animals compared with the unmodified product, which is in agreement with results from previous studies with BLG and egg white proteins. This divergence between IgE levels and oral symptoms is hardly related to functionality of the raised IgE antibodies, since no difference in acute allergic skin response was observed, but could be explained by differences in intestinal degradation or intestinal uptake upon oral challenge. BLG is a relatively stable protein resistant to pepsin and acid proteolysis. Previous studies showed that heating increased BLG
digestibility$^{23,50,51}$ due to the exposure of peptic cleavage sites by unfolding.$^{52}$ In the small intestine, food proteins can be taken up through the layer of epithelial cells covering lamina propria by different transport mechanisms, or through M cells into Peyer’s patches. The physicochemical features of proteins have been suggested to impact the route of uptake, and the uptake route has been suggested to impact the type of immune response that will be mounted.$^{53,54}$

The present study showed that heat-treatment altered the route of uptake, with less being absorbed through the epithelium but more into the Peyer’s patches in vivo and into BMDC in vitro after heat-treatment. This is in line with previous in vivo and in vitro uptake results for aggregated whey induced by heat-treatment$^{19}$ or by cross-linking through laccase treatment.$^{32}$ Despite that results from the in vivo and in vitro intestinal uptake in the present studies were in line with previous studies, this did not increase oral sensitization as was previously observed.$^{39,32}$ This inconsistency could be due to differences in sensitization study design, in particular, dose and potency of CT. The adjuvant function of CT includes induction of the tight junction complex protein claudin-2 on intestinal epithelial cells, which promote antigen transport across the epithelia barrier$^{45}$ and could possibly mask differences in intestinal uptake of the products during the sensitization phase. Alternatively, the inconsistency between the studies might indicate that differences in intestinal uptake are most important in the elicitation phase, for which the results are consistent, while other factors, such as differences in protein epitopes, which depend on the exact heat-treatment,$^{37-39}$ are critical for sensitization.

In the present study, results from inhibitory ELISA indicated that antibodies from rats dosed with HT-WPI react to epitopes that were not present or accessible in WPI under physiological conditions. However, considering the results from immunoblotting, performed under reducing conditions, the antibodies from HT-WPI-sensitized rats reacted to the same protein bands in the two products, which indicated that the new epitopes were at least partly due to exposure of epitopes previously buried inside the folded proteins. Results from avidity ELISA suggested that the reactivity towards new epitopes increased the binding strength between HT-WPI and antibodies raised against HT-WPI.

In conclusion, this study showed that heat-treatment overall reduced the allergenicity without compromising immunogenicity and tolerogenic capacity of a whey protein product. This result could be related to differences in intestinal uptake since it was observed that WPI was transported more efficiently through the epithelia cell layer and that heat-treatment increased uptake into Payer’s patches. These results highlight the potential for heat-treatment in the production of efficient and safe whey-based products as an alternative or supplement to whey-based hydrolysates for prevention and treatment of CMA in an attempt to accelerate the outgrowth of allergy and for tolerance development. However, clinical studies are needed to validate the safety and efficacy of heat-treated whey.

ACKNOWLEDGEMENTS

The authors thank Elise Navntoft, Kenneth Rene Worm, Maja Danielsen, Olav Dahlgaa and Anne Ørngreen for their great assistance with the animal experiments. Furthermore, the authors wish to thank the laboratory technicians Juliane Margrethe Gregersen and Sarah Grundt Simonsen, and the BSc. students Chantida Asukovit and Julie Wolpers for their excellent assistance and support in the laboratory. Finally, the authors thank Jeffrey Edward Skiby for thorough revision of the manuscript. This work was supported by the Danish Dairy Research Foundation.

CONFLICT OF INTEREST

LNJ, HFC and LVS are employees at Arla Foods Ingredients. KLB and KGB have ongoing collaboration with the company Arla Foods Ingredients, which supplied the whey protein products for the current study. Other authors declare no conflict of interest.

DATA AVAILABILITY STATEMENT

The data that support the findings of this study are available from the corresponding author upon reasonable request.
