Resonant inelastic x-ray scattering (RIXS) provides remarkable opportunities to interrogate ultrafast dynamics in liquids. Here we use RIXS to study the fundamentally and practically important hydroxyl radical in liquid water, OH(aq). Impulsive ionization of pure liquid water produced a short-lived population of OH(aq), which was probed using femtosecond x-rays from an x-ray free-electron laser. We find that RIXS reveals localized electronic transitions that are masked in the ultraviolet absorption spectrum by strong charge-transfer transitions—thus providing a means to investigate the evolving electronic structure and reactivity of the hydroxyl radical in aqueous and heterogeneous environments. First-principles calculations provide interpretation of the main spectral features.

DOI: 10.1103/PhysRevLett.124.236001

The hydroxyl radical (OH) is of major importance for atmospheric, astrochemical, biological, industrial, and environmental research. In the gas phase, OH is the primary oxidizing agent that rids the atmosphere of volatile organic compounds and other pollutants [1]. It is a key tracer describing the evolution and thermodynamics of interstellar clouds [2]. Despite its reactive nature stemming from an open electronic shell, the gas-phase absorption spectrum of OH has been fully characterized in the microwave [3], infrared, optical or ultraviolet (UV) [4], and, more recently, the x-ray [5] spectral ranges. Beyond purely gas-phase processes, these OH fingerprints also characterize heterogeneous processes such as the generation of reactive oxygen species from photocatalysis [6].

Spectroscopic characterization of the hydroxyl radical in the condensed phase is more challenging, owing to its extreme reactivity and short lifetime. Of particular interest is the characterization of OH in aqueous environments, which impacts radiation biology [7] and chemistry [8]. Given its unpaired spin, electron spin resonance techniques are a natural choice to detect the presence of OH, either directly or through spin traps, but only microsecond timescales are accessible [6]. For faster timescales, desired for tracking reaction dynamics, one may consider UV spectroscopy. The UV spectrum of solvated OH obtained via pulsed radiolysis of water [9] is reproduced in Fig. 1. It is dominated by a strong feature at 230 nm (5.4 eV), whereas the dominant gas-phase absorption at 309 nm (4 eV), due to valence excitation from the ground (X) to the lowest excited electronic state (A), is barely visible. On the basis of electronic structure calculations [10–13], this dominant spectral feature of OH(aq) was attributed to charge-transfer (CT) transitions from the lone pair of nearby waters, filling the hole in the OH 1π orbital (Fig. 1, bottom left).

Resonant inelastic x-ray scattering (RIXS) delivers atomic-site specific information about the local electronic structure and dynamics in condensed phase. The application of soft x-ray RIXS to liquids [14] has generated considerable attention; improvements in sensitivity [15] and energy resolution [16] continue to open new perspectives on...
suppressed because the compact shape of the core hydroxyl radicals in various complex and heterogeneous of the solute and can, therefore, be used to track reactive and its local structure, local transitions (LT) are fingerprints to CT transitions, which are characteristic of the solvent is obscured in the UV region by CT transitions. In contrast in intrinsic local electronic structure of solvated OH, which

2

between the
electronic structure of transient species in solutions\[20,21\]. Recently, the combination of RIXS, liquid microjets, and x-ray free-electron lasers enabled time-resolved measurements of electronic structure of transient species in solutions [20,21].

Here we report the RIXS spectrum for the short-lived OH radical in water (Fig. 1). In sharp contrast to the UV spectrum, the RIXS spectrum of OH\((aq)\) features two peaks corresponding to transitions between the OH orbitals (Fig. 1, bottom right). The energy difference between the elastic and inelastic peaks corresponds to the \(X \rightarrow A\) transition, which, in turn, roughly equals the energy gap between the \(2\sigma\) and \(1\pi\) orbitals. Thus, RIXS reveals intrinsic local electronic structure of solvated OH, which is obscured in the UV region by CT transitions. In contrast to CT transitions, which are characteristic of the solvent and its local structure, local transitions (LT) are fingerprints of the solute and can, therefore, be used to track reactive hydroxyl radicals in various complex and heterogeneous environments. The CT transitions in the RIXS spectrum are suppressed because the compact shape of the core \(1s_O\) orbital results in poor overlap with the lone pairs of neighboring waters. We confirm this by \(ab initio\) RIXS calculations using a new electronic structure method [22,23] based on the equation-of-motion coupled-cluster (EOM-CC) theory. These calculations also reproduce the relative RIXS line intensities, positions, and widths for the elastic and inelastic peaks of OH\((aq)\) and OH\(^-\)(\(aq)\).

The OH\((aq)\) spectra are also compared to the x-ray emission spectra (XES) of liquid water, where the role of hydrogen bonding and ultrafast dynamics has long been debated [15,18,24–28]. If core-ionized water dissociates prior to core-hole decay, a core-excited OH\((aq)\) is formed in the \(1s_O\) \(\sigma^2\sigma^2\pi^1\pi^1\) intermediate RIXS state (Fig. 1). The lower-energy component of the water XES doublet has been attributed to this ultrafast dissociation [15] and our measurement of the position of the OH\((aq)\) RIXS resonance directly provides relevant information that previously was indirectly deduced [27].

Here, as in our companion study using x-ray transient absorption (XTAS) [29], strong-field ionization is used to create the hydroxyl radical in pure liquid water. After initial formation of a water cation (H\(^+\)) ultrast short proton transfer to a neighboring water molecule on a sub-100 fs timescale [30] creates the hydroxyl radical, OH\((aq)\), and the hydronium ion (H\(_3O^+\)). In the time window between proton transfer (\(\sim\)100 fs) and geminate recombination (\(\sim\)20 ps), the ionized liquid water sample contains OH\((aq)\). Previously [29], we used XTAS to probe the kinetics of OH\((aq)\), a study facilitated by the fact that the resonant \(1s_O \rightarrow 1\pi\) transition of OH\((aq)\) occurs cleanly in the “water window,” i.e., below the liquid water absorption edge. Here we report on our simultaneous use of RIXS to probe OH\((aq)\), thus allowing spectroscopic investigation of local valence transitions that are chemically most relevant.

Briefly, optical-pump x-ray-probe RIXS was performed using the soft x-ray research (SXR) instrument [30] at the Linac coherent light source (LCLS) at SLAC National Accelerator Laboratory. Monochromatized x-ray pulses were scanned from 518 to 542 eV (\(\sim\)10 \(\mu\)J, \(\sim\)40 fs, 200 meV bandwidth). Three photon detection channels were simultaneously recorded: transmission, total fluorescence, and dispersed emission. A detailed description of the performance of the optical laser, water jet, and x-ray monochromator calibration, shot-by-shot normalization procedures can be found in [29]. Here we describe additionally the x-ray emission spectrometer and experimental geometries for RIXS measurements of OH\((aq)\).

X-ray emission was collected perpendicular to the incoming x-ray beam and along the x-ray polarization axis to suppress elastic scattering using a variable-line-spacing grating-based spectrometer with an efficiency of \(\sim 10^{-5}\) [31]. The low collection efficiency for the RIXS spectrum combined with a limited collection time precluded binning of these RIXS spectra with the 40-fs, 200-meV time and energy resolutions associated with the XFEL pulse. A CCD camera located at the exit plane of the spectrometer recorded images on a shot-by-shot basis. The energy dispersion and absolute energy of the incoming monochromatized radiation

---

FIG. 1. UV absorption and RIXS energy-loss spectra of OH\((aq)\) (top) and molecular orbital diagrams (bottom). The electronic configuration of OH is \(1\pi^2\) \(\sigma^2\sigma^2\) \(1\pi^1\). The lowest valence transition (\(2\sigma \rightarrow 1\pi\), marked as LT\(_{\text{val}}\) for local transition) has low oscillator strength due to its \(p_z \rightarrow p_z\) character; the UV spectrum is dominated by charge-transfer transition (CT\(_{\text{val}}\)) from nearby waters. In resonantly excited OH (\(1s_O\) \(\sigma^2\sigma^2\pi^3\)), both \(1\pi \rightarrow 1s\) and \(2\sigma \rightarrow 1\pi\) transitions are bright, giving rise to the elastic peak (zero energy loss) and a feature at \(\sim 4\) eV. The gap between the two RIXS peaks corresponds to the \(2\pi \rightarrow 1\pi\) energy.

Phy Rev Lett 124, 236001 (2020)
were previously calibrated [29,32]. The dispersion of the emission spectrometer was determined by fitting a first degree polynomial to the elastic line visible in Fig. 2(b).

To gain insight into the nature of main spectral features, we carried out electronic structure calculations using EOM-CC [33] with single and double excitations (EOM-CCSD) augmented by core-valence separation (CVS) [34] to enable access to core-level states [22,35]. As a multistate method, EOM-CC treats different valence and core-level states on an equal footing and is particularly well suited for modeling molecular properties, including nonlinear properties [33,36–38]. To account for solvent effects, the spectral calculations of OH(aq)/OH\(^{+}\)(aq) were carried out within the QM/MM (quantum mechanics-molecular mechanics) scheme with water molecules described by classical force field and OH/OH\(^{−}\) described by EOM-CCSD by using snapshots from equilibrium \textit{ab initio} molecular dynamics simulations.

The electronic factors entering RIXS cross sections are the RIXS transition moments given by the following simulation: snapshots from equilibrium enable access to core-level states [22,35]. As a multistate method, EOM-CC treats different valence and core-level states on an equal footing and is particularly well suited for modeling molecular properties, including nonlinear properties [33,36–38]. To account for solvent effects, the spectral calculations of OH(aq)/OH\(^{+}\)(aq) were carried out within the QM/MM (quantum mechanics-molecular mechanics) scheme with water molecules described by classical force field and OH/OH\(^{−}\) described by EOM-CCSD by using snapshots from equilibrium \textit{ab initio} molecular dynamics simulations.

The resulting method combines rigorous treatment of RIXS cross sections and high-level description of electron correlation. To describe vibrational structure in the RIXS spectrum, we computed Franck-Condon factors (FCFs) using three-state model (as was done in Ref. [17]) and harmonic approximation. To quantify the relative strengths of LT and CT transitions, we also carried out calculations of LT and CT transitions, we also carried out calculations on model water-OH structures. All calculations were performed using the Q-Chem electronic structure package [41]. Full details of computational protocols are given in the Supplemental Material [42].

Theoretical estimates of key structural parameters of the isolated OH given in Table I agree well with experimental values [4,5]. Theory overestimates the energy of the valence transition by 0.08 eV and underestimates the energy of the core-excited state by 0.7 eV; these differences are within the error bars of the method [22]. The variations in bond lengths and frequencies among different states are consistent with the molecular orbital picture of the electronic states. The structural differences between the states give rise to a vibrational progression in the x-ray absorption spectrum; the computed FCFs are in excellent agreement with the experimental ones (see the Supplemental Material [42]).

FIG. 2. RIXS maps of ionized liquid water (a) before valence ionization and (b) after valence ionization, integrated for time delays between 200–1400 fs. The intensity of the maps is the number of counts on the emission spectrometer (15 054) normalized by the number of XFEL pulses (365 846). Before ionization, a threshold for emission is seen near 534 eV incident photon energy. After ionization, a resonant feature appears at 526 eV due to the transient OH(aq) radical. The two energy windows used to create the spectra shown in Fig. 3 are marked: 536–542 eV for bulk water and 525.70–526.12 eV for OH(aq).
Figure 2 shows the RIXS maps before and after the ionization pulse. The RIXS map prior to ionization, Fig. 2(a), is in agreement with earlier measurements \[15,24,26\]. There is a threshold for emission at \( \sim 534 \) eV excitation energy and a pre-edge peak at 535 eV. After ionization, Fig. 2(b), a new resonant feature appears at 526 eV excitation energy that is identified as \( 1s_O \rightarrow 1\pi \) transition of \( \text{OH}^{(aq)} \): its position is near that of gas-phase OH [5] and its kinetics are consistent with proton transfer [29]. The position of the quasielastic RIXS line of \( \text{OH}^{(aq)} \) coincides with the lower-energy component of the water XES doublet (see dashed line in Fig. 3), providing a check on the absolute energy and consistent with the interpretation [15] of this peak as due to ultrafast dissociation.

Table II summarizes the main RIXS features of \( \text{OH}^{(aq)} \) and \( \text{OH}^{-}^{(aq)} \), comparing experimental and theoretical values. The RIXS spectrum has a peak with 0.7 eV FWHM that is assigned to quasielastic \( \text{GS} \rightarrow 1s \rightarrow 1\pi + 1 \rightarrow \text{GS} \) scattering to the electronic ground state. We also observe a 1.5 eV wide structure beginning at 3.6 eV energy loss that corresponds to scattering to the first electronically excited state: \( \text{GS} \rightarrow 1s \rightarrow 1\pi + 1 \rightarrow 2\sigma - 1\pi + 1 \). The calculations reproduce the gap (\( \Delta E \)) between the quasielastic and energy-loss peak well; however, the absolute position of the \( 1s_O \rightarrow 1\pi \) transition is 1 eV off. EOM-EE-CCSD excitation spectra for core-level transitions often exhibit systematic shifts of 0.5–1.5 eV, attributed to insufficient treatment of electron correlation [22], whereas the relative positions of the peaks are reproduced with higher accuracy. The intensity ratio of the two peaks stems from their \( \pi \) and \( \sigma \) character and is reproduced qualitatively by our calculations.

Both quasielastic and energy-loss peaks are broadened due to the interaction with polar solvent and to vibrational structure. As shown in Table I, the dipole moment in electronically excited OH is 14% larger than in the ground state, suggesting larger inhomogeneous broadening for the energy-loss peak; this is confirmed by our QM/MM calculations, where the effect of the solvent is treated explicitly. The analysis of structural differences between the ground \( X^{(2\Pi_1)} \), valence excited \( A^{(2\Sigma^+)} \), and core-excited states suggests longer vibrational progression for the energy-loss peak, which is confirmed by the computed FCFs (see the Supplemental Material [42]). This trend can be rationalized by the shapes of molecular orbitals: the
bonding character of $2\sigma$ orbital involved in the $GS \rightarrow 1s_{O}^{-1}\pi^{+} \rightarrow 2\sigma^{-1}\pi^{+1}$ transition renders it more sensitive to vibrational excitations.

The middle and bottom panels of Fig. 3 compare the RIXS of OH(aq) to that of OH$^-$(aq) [15]. The two species show very similar emission spectra, as expected from the similarity of the intermediate RIXS state. There is a similarity of the intermediate state and, therefore, would be very sensitive to the excitation frequency; thus, the discrepancy between the computed values and Ref. [15] could be due to different excitation regimes.

To rationalize the apparent absence of the CT$_{core}$ transitions in RIXS, we computed valence and core-level transitions for model OH-H$_2$O structures. The oscillator strength for the CT$_{val}$ valence transition is five times smaller than that of the CT$_{val}$ transition. In contrast, the oscillator strength for the CT$_{core}$ transition is $\sim$50 times smaller than that of the LT$_{core}$ due to the poor overlap of the lone pair of water with the compact $1s_{O}$ orbital of OH.

In summary, we have measured RIXS of the short-lived hydroxyl radical in pure liquid water. At the OH resonance of 526 eV, an energy-loss feature at 3.8 eV, corresponding to the localized $X \rightarrow A$ transition of OH(aq), was observed. The position of the OH resonance relative to bulk water XES provides information relevant to the long-standing debate on the structural versus dynamical interpretation of water XES. Ab initio calculations reproduce the positions, relative intensity, and broadening of the quasielastic and energy-loss peaks of OH(aq) and OH$^-$(aq) and provide insight into the relative intensities of the local and CT RIXS transitions. Time-resolved RIXS on femtosecond time-scales, enabled by the availability of intense tunable ultrafast x-ray pulses from XFELs, highlights the localized transition in this transient species, which is otherwise hidden in direct UV absorption spectra. This ability to report on intrinsic electronic structure of OH, rather than on the properties of the solvent and its structure (as revealed by the CT transitions dominating the UV spectrum), represents the key advantage of RIXS, demonstrating that it may be used to track ultrafast reactions of the chemically aggressive hydroxyl radical in aqueous and potentially more complex environments.
