The mark of 18% power conversion efficiency (PCE) was recently overcome by laboratory-scale organic solar cells (OSCs) thanks to the development of nonfullerene acceptors (NFAs). NFA-based solar cells show improved performance and stability compared with those of their fullerene-acceptor-based counterparts. However, only a few studies focus on scalable deposition techniques or roll-to-roll compatible processing, which is of paramount importance for the commercialization of the technology. Here, we report a simple and fast fabrication of slot-die-coated poly(3-hexylthiophene-2,5-diyl):(5*Z*,5'*Z*)-5,5'-{[7,7'-(4,4,9,9-tetraoctyl-4,9-dihydro-*s*-indaceno[1,2-*b*:5,6-*b'*]dithiophene-2,7-diyl)bis(benzo[*c*][1,2,5]thiadiazole-7,4-diyl)]bis(methanylylidene))bis(3-ethyl-2-thioxothiazolidin-4-one) (P3HT:O-IDTBR) OSCs using a roll platform on flexible ITO-free substrates under ambient conditions. We show that the optical band gap of the active layer increases when an isopropanol-diluted poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) hole-transport layer is coated on top of it, changing the device properties. Optimization of the coating conditions leads to the achievement of up to 3.6% PCE for single cells of 1 cm² fabricated under ambient conditions with flexographic printed Ag back electrodes, compared with solar cells with evaporated Ag (3.8% PCE), Au (2.1% PCE), or Cu (3.0% PCE) back contacts. OSCs with larger areas of 4 cm² with 2.3% PCE are also fabricated, where the fast increase of the series resistance with the area is the main PCE-limiting factor. The efficiencies herein reported for NFAs obtained by roll processing show the excellent potential of the P3HT:O-IDTBR blend for large-scale fabrication.

I. INTRODUCTION

Organic solar cells (OSCs) have been under the spotlight thanks to their short energy payback times and the possibility of being solution-processed at high speeds and under ambient conditions, using roll-to-roll manufacturing [1,2].

Usually, donor-acceptor (D-A) materials are the starting point to improve the efficiency and stability of OSCs. A proper D-A blend combination can lead to an optimized morphology, resulting in improved photovoltaic parameters [3–8].

Fullerene derivatives are some of the most researched electron-acceptor materials of recent decades. However, the efficiency achieved for single-junction fullerene-based devices has leveled out at around 10% [9]. Moreover, there is no improvement expected from employing acceptor materials based on conventional fullerene derivatives, mainly because of their limited contribution to light

absorption, the difficulty of tuning their energy levels, and their fast degradation under ambient conditions [10].

Nowadays, nonfullerene acceptors (NFAs) have attracted interest of the OSCs community mostly due to the possibility of altering their properties through molecular design, which allows for a precise tuning of their absorption spectrum, energy levels and stability [11–13]. During the last few years, the research on NFAs has skyrocketed the efficiency of OSCs, overcoming the 18% mark [14]. The small molecule (5*Z*,5'*Z*)-5,5'-{[7,7'-(4,4,9,9-tetraoctyl-4,9-dihydro-*s*-indaceno[1,2-*b*:5,6-*b'*]dithiophene-2,7-diyl)bis(benzo[*c*][1,2,5]thiadiazole-7,4-diyl)]bis(methanylylidene))bis(3-ethyl-2-thioxothiazolidin-4-one) (O-IDTBR) is one of these recently developed NFAs [15–18]. Its molecular structure is shown in Fig. 1. In blends together with poly(3-hexylthiophene-2,5-diyl) (P3HT), small-scale spin-coated devices on ITO-coated glass have shown efficiencies close to 7% [19]. P3HT is one of the most well-known electron-donor materials and has been widely used in combination with phenyl-C61(or 70)-butyric acid methyl ester (PCBM) in the last decades. Although the reported efficiencies for P3HT:PCBM are

*mesro@dtu.dk

[†]These authors contributed equally to this work.

FIG. 1. Chemical structures of O-IDTBR and P3HT.

not impressive, P3HT is still one of the best-suited polymers for the large-scale fabrication of OSCs, due to its inexpensive and simple synthesis and its superior operation in thick active layers obtained when using scalable deposition techniques [20]. Recently, large-scale devices (59.52 cm^2) were fabricated with this exact blend on ITO-coated glass substrates, achieving an impressive 5% power conversion efficiency (PCE) [21]. Using ITO-free substrates, a 5.5% PCE was recently reported using a different material system, slot-die-coated on a sheet-to-sheet platform [22].

There have been no reports previously on P3HT:O-IDTBR OSCs slot-die-coated on ITO-free flexible substrates fabricated on a roll-processing platform, which mimics large-scale full roll-to-roll processing. We strongly believe there is a need to enhance the performance of nonfullerene OSCs fabricated using scalable deposition techniques [22,23].

The so-called temperature-controlled slot-die coating (or hot slot-die coating), which consists of coating with a hot slot-die head, has demonstrated to be effective in increasing the photovoltaic (PV) performance of organic solar cells. It has been proven that matching the substrate and head temperatures yields the best performance possible, when it comes to active-layer coating of fullerene-acceptor devices [24]. Additionally, it is suggested that matching temperatures in nonfullerene acceptor devices can have the same effect if the experimental conditions permit it [25].

An ideal electrode for solar cells should be ohmic, charge-carrier selective, and surface passivating [26–28]. Historically, the simplest way of inducing carrier selectivity for an electrode has been through the use of metals with different work functions. However, a metal electrode for OSCs with optimal properties might still need an interfacial layer of a different material [29], which can be metals, metal oxides (e.g., MoO_x), or conductive polymers (e.g., PEDOT:PSS), to improve the carrier selectivity through modulation of the metal work function [30,31]. Here, we experiment with different thicknesses of the PEDOT:PSS layer prior to the deposition of Ag, Cu, and Au metal contacts. Several coating parameters are varied, with the

aim of finding the deposition conditions that lead to an optimal device performance. In the first section, the drum temperature (DT), the slot-die head temperature (HT), and thickness of the active layer are optimized. In the second part, we present the effect of diluting PEDOT:PSS with isopropanol (IPA). In the third part, we compare vacuum-deposited and open-air-printed electrodes. In the final experimental section, solar cells with different areas ($0.08\text{--}4 \text{ cm}^2$) are fabricated as a proof of concept of the scalability of our approach, with printed and evaporated Ag electrodes. We conclude that our devices printed in open air are suitable for large-scale production.

II. EXPERIMENTAL SECTION

A. Materials

All materials involved in this study are purchased and used without any further purification, unless mentioned otherwise. P3HT is purchased from Ossila Materials (batch M1011, $\sim 60 \text{ kDa}$). O-IDTBR is purchased from 1-Material Inc. Dichlorobenzene (DCB), bromoanisole (BrA), IPA, and butanol are purchased from Sigma Aldrich Inc. PEDOT:PSS, for the hole-transport-layer study, is purchased from Heraeus (Heraeus CLEVIOS FET). The flexible substrate (flextrode) is produced at the Technical University of Denmark (DTU) [32]. It is composed of a polyethylene terephthalate (PET) substrate; a Ag grid (flexographic printing) as the top electrode; a layer of PEDOT:PSS (screen-printing); and, finally, a layer of ZnO nanoparticles as the electron-transport layer (slot-die coating) [33].

B. Solar-cell fabrication

The main piece of equipment used for the fabrication of fully roll-coated devices is an in-house-made roll coater, which is composed of a rotating drum and a slot-die coating head. This machine is compatible with roll-to-roll machines (Fig. 2). The full setup allows for the control of both temperature and speed of the drum, temperature of the head, drum-to-head distance, and ink flow rate. By simply attaching a rotating flexographic roll instead of a

FIG. 2. In-house-made roll coater used to fabricate OSCs at DTU. Coating of the different layers, starting with the ITO-free flextrode substrate (a), the active layer of P3HT:PCBM (b), the PEDOT:PSS layer (c), and flexoprinted Ag fingers as the back contact (d).

coating head, flexographic printing is also possible with this equipment. The active-layer and hole-transport-layer coatings, as well as the flexographically printed silver back electrode, are fully done under ambient conditions (Fig. 2). Unless stated otherwise, a solution of P3HT:O-IDTBR with a concentration of 40 mg/mL in a 1:1 donor-to-acceptor ratio is prepared in dichlorobenzene with 5% (v/v) BrA as an additive and magnetically stirred on a hot plate at 45 °C for 15 min. All devices in this work have an inverted architecture, namely, flextrode/P3HT:O-IDTBR/PEDOT:PSS/back electrode (Ag-printed, Ag, Cu, or Au).

Flextrode (1 m) is fixed on the roll-coater drum; six different drum temperatures are tested for the drying of the active layer: room temperature (25), 40, 60, 70, 80, and 90 °C. To study the impact of slot-die coating P3HT:O-IDTBR at different temperatures, the slot-die head is heated to different temperatures (25, 40, 60, and 80 °C),

while keeping the drum at 60 °C. The temperature of the drum and slot-die head are independently controlled (± 0.5 °C).

The active layer is then slot-die-coated on the flextrode using a drum speed of 0.6 m/min with a flow rate of 0.08 mL/min, resulting in a film with a dry thickness of 480 nm, calculated by

$$d = \frac{cf}{\rho vw} \quad (1)$$

where f corresponds to the ink flow rate; w is the width of the film, in this case equal to 1 cm; v is the coating velocity; c stands for the concentration of active layer materials (P3HT:O-IDTBR) per mL of solvent, in mg/mL; and ρ is the density of the materials in bulk, set to 1.1 g/cm³. The distance from the meniscus guide to the flextrode is set to approximately 2 mm, always ensuring $w = 1$ cm.

The flow rate is also modified to study the impact of the thickness on the performance and fixed to 0.06, 0.10, and 0.12 mL/min. These flow rates correspond to 360, 600, and 720 nm, respectively, when introduced in (1). The procedures for subsequent layers remains the same. The active layer is surface treated using slot-die-coated butanol (drum: 1.2 m/min, 70 °C, head: 25 °C, 0.25 mL/min) to allow PEDOT:PSS to stick to the surface of the bulk heterojunction. After sonication in a Hielscher UIP1000hdT homogenizer and filtering (1 μ m filter) of PEDOT:PSS, it is slot-die-coated on top of the active layer (drum: 1.25 m/min, 70 °C, head: 25 °C, 0.8 mL/min), resulting in a dry thickness on the micrometer order of magnitude. PEDOT:PSS is left to dry for 45 min on the drum at 70 °C.

C. Back-electrode modifications

As our reference case, a heat-curing silver paste (DuPont 5025) is used to flexographically print the fingerlike back electrode [Fig. 2(d)] on top of the PEDOT:PSS layer (drum: 0.8 m/min, 70 °C), giving a total area of 1 cm². It is left to cure for 10 min at 70 °C on the drum. Alternatively, 250 nm of Ag (99.99%), Au (99.99%), or Cu

TABLE I. Maximum and average key parameters. PCE, (FF), V_{OC} , and J_{SC} of encapsulated slot-die-coated solar cells on flexible ITO-free substrates with varying HT and DT.

HT (°C)	DT (°C)	PCE (%)	FF (%)	J_{SC} (mA/cm ²)	V_{OC} (V)
25	25	1.71 (1.66 $\pm$ 0.04)	51.88 (51.75 $\pm$ 0.13)	4.81 (4.72 $\pm$ 0.09)	0.68 (0.68 $\pm$ 0.01)

80	60	3.08 (3.01 $\pm$ 0.07)	64.35 (64.44 $\pm$ 0.10)	6.87 (6.70 $\pm$ 0.17)	0.70 (0.70 $\pm$ 0.01)

(99.9%) from Sigma-Aldrich are thermally evaporated on top of the PEDOT:PSS layer through a shadow mask, giving an active area of 1 cm^2 . An INFICON XTM/2 system is used to monitor the deposition rate (5 Å/s) of the metals from tungsten boats with a base pressure of $1 \times 10^{-5} \text{ mbar}$. During the evaporation process, heating of the solar cells is negligible and these remain at ambient temperature.

D. Hole-transport-layer study

After slot-die coating a 480-nm-thick active layer (drum: 0.6 m/min , 60°C , head: 60°C , 0.08 mL/min), a solution made of diluted PEDOT:PSS in IPA in a ratio of 3:1 (v/v) is coated using the following parameters, to achieve good covering films: head: 25°C , 0.30 mL/min ; drum: 0.8 m/min , 70°C . Deposition of the thin film of PEDOT:PSS is followed by 250 nm evaporated Ag or flexoprinted Ag back electrodes.

E. Activation and encapsulation

A final step before encapsulation is necessary for working solar cells. After fabrication, the testing of the obtained layer stack results in a nonoperating device, showing a J - V curve similar to that of a simple resistor. Activation of the final devices is done by applying a quick negative bias ($I=0.5 \text{ A}$ and $V=20 \text{ V}$) through the cell [34]. Encapsulation of the solar cells is achieved using a custom-made epoxy-based glue, EPXR, based on bisphenol A diglycidyl ether and Chissox 221 monomers. The procedure consists of sandwiching the cell between two glass slides and applying the EPXR glue on both sides. Subsequently, the encapsulated solar cells are cured under UV light for 5 min. A temperature of $(66 \pm 0.5)^\circ\text{C}$ under the light is measured on the glass slides using a thermocouple.

F. Characterization

All current density-voltage (J - V) curves are measured using a solar simulator with a xenon lamp as the light source, which is calibrated by a certified reference cell (monocrystalline silicon certified by Fraunhofer) under AM1.5G illumination, 1000 W/m^2 intensity, and acquired by a Keithley 2400 source meter (25 mV step reverse to forward). No current is obtained outside the solar-cell area, as the flextrode is cut to ensure 1 cm^2 devices. The areas below 1 cm^2 are obtained using shadow masks. The external quantum efficiency (QE) and absorbance are measured using a QEX10 system (PV Measurements Inc.) from 300 to 900 nm (5 nm step size) calibrated with a Si photodiode. The sheet resistance is measured with a four-point probe (Kulicke & Soffa) acquired by a Keithley 2401 source meter. The morphology of the active layers is characterized with an AFM DS95-50 instrument from DME Danish Micro Engineering. The scans are

carried out on $5 \times 5 \text{ μm}^2$ surface areas using noncontact mode.

III. RESULTS AND DISCUSSION

The morphology and crystalline-packing parameters of the active layer in OSCs have an important impact on the PV performance, because they affect exciton dissociation and charge transport inside the solar cells [35,36]. Morphology and crystallinity can be optimized by changing the drying kinetics of the organic films, through manipulation of the solvents or the temperature during deposition [37]. Our efforts towards optimizing the deposition of the P3HT:O-IDTBR active layer and the hole-transport layer using flexoprinted and evaporated electrodes are exposed in the following sections.

A. Active-layer optimization

Here, DCB-BrA (5%) is used as the solvent combination. Other solvents are tested by choosing a wide range of boiling points (chloroform, chlorobenzene, and trichlorobenzene); none of them show a better performance than that of DCB (not shown here). BrA is chosen because of the promising results in our first tests, and in other publications, which suggest that this additive might be beneficial for the morphology of the blend [21]. The D-A ratio is also fixed at 1:1 after tests with representative ratios of 1.5:1 and 1:1.5, showing that the optimal PV parameters are achieved with a 1:1 blend (see supporting information Figure S1, Table S1); this is the ratio used in all subsequent experiments.

As expected from previously reported studies [24], we find that matching the slot-die head and drum temperatures at 60°C leads to an optimal performance. The temperature used on the drum during active-layer coating is varied between 25°C and 90°C . Figure 3(a), inset, shows the PCE evolution with the drum temperature for solar cells before (boxes) and after (dots) encapsulation for 30 and 15 devices, respectively. Each box encloses the first to the third quartile, where the median (horizontal line) and the mean (square) values are indicated. The epoxy-UV-curing process is similar to annealing. Annealing of the active layer is known to improve the crystallinity of the P3HT:O-IDTBR active layer, enhancing charge transport, electron diffusion, and charge separation [15]. During this process, the temperature of the solar cell under the UV lamp reaches $(66 \pm 0.5)^\circ\text{C}$, as measured with a K-type thermocouple touching the surface of the encapsulation glass directly exposed to the UV light. The PCE steadily improves when increasing the head temperature from room temperature (around 25°C) to 60°C , reaching an average maximum value of $(2.99 \pm 0.13)\%$, which is higher than that of solar cells coated at 70°C (Table I). This value is the result of improved photocurrent from $(4.72 \pm 0.09) \text{ mA/cm}^2$ at 25°C to $(6.64 \pm 0.32) \text{ mA/cm}^2$ at 60°C and fill factor

FIG. 3. Representative J - V curves of encapsulated solar cells with (a) DT variations (with HT = 25 °C), (b) HT variations (with DT = 60 °C), and (c) thickness variations (DT = HT = 60 °C). Insets in (a)–(c) show summary statistics of J - V characteristics of solar cells before (boxes) and after (dots) encapsulation. External QE at 0 V bias of representative encapsulated solar cells from (d) DT variations, (e) HT variations, and (f) thickness variations. Insets in (d),(e) show the QE ratio at –1 and 0 V bias.

from $(51.75 \pm 0.13)\%$ at 25 °C to $(64.63 \pm 0.33)\%$ at 60 °C (Appendix A, Drum temperature variations figure) for encapsulated devices. The QE curves [Fig. 3(d)] also follow this photocurrent gain trend. However, for these solar cells made with HT = room temperature (25 °C), the QE curves are clearly composed of two parts in the short- and long-wavelength regions. The combined photocurrent generation of the donor and acceptor is visible in the short-wavelength region, whereas the contribution of the acceptor has a maximum in the long-wavelength region. The QE bias ratio [Fig. 3(d), inset] shows that, from the spectral carrier collection viewpoint, DT = 60 °C is the optimum temperature, whereas DT = 90 °C is the one that drifts the most from optimum. The DT/HT = 25 °C/25 °C solar cell [Fig. 3(a)] has both a low short-circuit current density (J_{SC}) and low fill factor (FF), as well as the lowest open-circuit voltage (V_{OC}). These differences automatically lead to a lower PCE ($1.66 \pm 0.04\%$), even after encapsulation (Figure S2).

The temperatures tested in the coating slot-die head are 40, 60, and 80 °C. These are chosen to have a range of temperatures centered on the optimal DT, both higher and lower. The limit is set to 80 °C to avoid known problems in the head, such as an unstable meniscus during coating, i.e., due to the formation of bubbles in the solution. The solar cells obtained with HT = 60 °C (Table I) show a high average PCE ($3.26 \pm 0.14\%$). Going to lower or higher head

temperatures reduces J_{SC} , and hence, PCE (Figure S3). The spectral photocurrent collection improves when using a hot coating head, as shown in Fig. 3(e). In this case, the integrated QE photocurrents for HT = 40, 60, and 80 °C [Fig. 3(e)] are 7.87, 8.00, and 6.91 mA/cm², respectively, in agreement with their 1 sun J - V curves from Table I. The optimal head temperature is then set to 60 °C.

As shown in Figs. 3(a)–3(c) and Table I, the coating parameter that affects the PV performance most is the DT (if HT = 25 °C). The optimal combination of head and drum temperatures, in terms of PV parameters, corresponds to both being set at 60 °C, which is in accordance with the previously mentioned studies in different D-A systems [24]. This combination of temperatures is an easy way to improve charge extraction from slot-die-coated OSCs via film morphology control and crystallinity. Ultimately, the combination of DT and HT improved the encapsulated devices by around 48% PCE and 18% FF compared with the 25 °C and 25 °C ones.

Subsequently, three additional thicknesses of P3HT:O-IDTBR are tested with the optimal temperature combination, with values 360, 600, and 720 nm versus the previously deposited 480 nm. This is done by keeping the speed of the drum constant, while increasing or reducing the ink flow rate accordingly. The results from this test are summarized in Figs. 3(c) and 3(f), which report the PCE, J - V , and QE curves obtained for each of the four thicknesses.

Table S2 (Supporting Information) reports the average PV parameters obtained in this thickness study, where all PCEs are around 3%. The best-performing cells correspond to those fabricated with a dry thickness of 480 nm (Figure S4) using a rate of only 0.08 mL/min, which allows 7.5 m of active layer to be coated per milliliter of active material.

AFM images are obtained from fresh slot-die-coated films to study the surface topography of the active-layer films. They are coated with different drum and head temperatures, as shown in Figs. 4(a)–4(c). The films show a surface topography composed of micron-sized grainlike structures with varying root-mean-square (rms) roughness. A flat bulk heterojunction topography induces a better interface with the PEDOT:PSS hole-transport layer (HTL), improving charge collection (Table I) [38,39]. The blend/HTL interface presented in Fig. 4 (showing the blend surface) exhibits significant differences between the surfaces of organic films coated at different head and drum temperatures. Figure 4(a) shows that the 25 °C/25 °C-coated film results in the highest surface roughness (rms = 77 nm). When the active layer is coated at DT = 60 °C, the bulk morphology of the active layer during roll coating might improve [40]; as a side effect, the film surface is smoother in terms of its rms (28 nm). A further surface roughness reduction is found when 60 °C is used in both drum and coating head temperatures showing rms = 25 nm. Similar rms values are found in different areas of the films as shown in the supporting information Figure S5. In general, the changes observed in surface roughness may be a consequence of bulk morphology changes induced by the coating-temperature variations that influence the drying kinetics [41]. The hot drum and hot slot-die head induce highly ordered molecular packing [24], which improves carrier transport inside the bulk heterojunction [24,25,42], improving J_{SC} and FF (Table I).

Modifications in the drum and head temperatures during coating also affect the optical properties of the films. Figure 4(d) shows the normalized absorbance of only donor, only acceptor, and P3HT:O-IDTBR blend films. The films

are slot-die-coated on bare PET substrates, the effects of which are removed from the spectra. The measurement spots of the QE and absorbance are of the same size. The thicknesses of neat donor, neat acceptor, and blend films in Fig. 4(d) are 237, 242, and 240 nm, respectively, which are thinner than the films used in the solar cells in this work, in order not to saturate the detector and be able to measure the possible absorbance variations in the ultraviolet-to-visible (UV-vis) spectral range. The long-wavelength inflection point of the P3HT absorbance curve is at 1.99 eV, with strong absorbance in the visible region. The O-IDTBR absorbance curve has a long-wavelength inflection point at 1.71 eV, which is the same as that for the 1:1 blend, as expected. The inflection-point value indicates the point at which the absorbance is weak, i.e., radiation with longer wavelength can be harvested by other materials or technologies. The shaded area in Fig. 4(d) shows the absorbance enhancement of the blend when coated with the optimum parameters. A beneficial orientation effect of the acceptor might be induced when coating the active layer with a hot slot-die head (in this case at 60 °C), as the absorbance increases where the acceptor has absorption peaks. It might lead to efficient carrier transport [25], resulting in solar cells with better performance (Table I).

B. Hole-transport-layer study

To investigate the influence of diluting the PEDOT:PSS hole-transport layer with IPA, a dilution of PEDOT:PSS in IPA was prepared, in a ratio of IPA-to-PEDOT:PSS of 3:1. The possible advantages of diluting PEDOT:PSS with IPA are skipping the butanol surface-treatment step after active-layer coating (as IPA improves the wettability of the active layer), reducing the energy used to dry the HTL (because of a shorter drying time, as explained in the Sec. II), fabricating semitransparent solar cells, and reducing PEDOT:PSS consumption.

FIG. 4. AFM images (scan sizes $5 \times 5 \mu\text{m}$) of P3HT:O-IDTBR blends (1:1) slot-die-coated in PET, with DT/HT = (a) 25 °C/25 °C, (b) 60 °C/25 °C, and (c) 60 °C/60 °C. (d) Normalized absorbance of as-deposited P3HT, O-IDTBR, and P3HT:O-IDTBR in 1:1 ratio with DT/HT = 25 °C/25 °C, 60 °C. Vertical lines indicate the inflection point of the curves corresponding to their optical band gaps.

FIG. 5. Effect of diluting PEDOT:PSS HTL with IPA in OSCs with flexographically printed (a),(c) or thermally evaporated (b),(d) Ag back electrodes directly on top of the PEDOT:PSS layers. (a),(b) J - V curves of P3HT:O-IDTBR solar cells with IPA-diluted PEDOT:PSS layers; inset tables show the key photovoltaic parameters of the best-performing devices. (c),(d) Left axes show the external quantum efficiency of solar cells with printed or evaporated electrodes, respectively; vertical lines show the position of the photovoltaic band gap [49] of the devices. (c) Right axis shows absorbance of only PEDOT:PSS slot-die-coated films.

PEDOT:PSS layers are coated on top of the optimized 480 nm active layer, with both coating head and drum temperatures set at 60 °C. It is important to mention that IPA in the 3:1 solution is enough to make the PEDOT:PSS stick without butanol surface treatment of the active layer. A smaller amount of IPA leads to a lower chance of adhesion between PEDOT:PSS and the active layer due to the poor wettability of the active layer by PEDOT:PSS.

With the intention of comparing the performance of these devices produced by diluting PEDOT:PSS with IPA, a new batch of solar cells with pure PEDOT:PSS is also made. We encounter difficulties when printing the silver top electrode on the diluted PEDOT:PSS layers, as they are too thin to resist the flexoprinting procedure. Indeed, many of the resulting printed silver cells perform poorly. Before encapsulation, the printed silver cells with a 3:1 ratio exhibit an S-shaped J - V curve (Figure 6) under illumination. It is reported to be caused by mechanisms affecting

the extraction of electrons near the device cathode [28,43], in some cases, because of changes in the device architecture [28]. In our case, one possible reason could be the lack of a butanol surface-treatment step. Nevertheless, the J - V curves of the solar cells with an evaporated silver back electrode do not show S-shaped J - V curves before encapsulation. One hypothesis is that it could be due to the desorption of molecular oxygen [44]. Adsorbed oxygen could act as a trap state; in our case, oxygen desorption is induced by the vacuum step. The readsorption process is kinetically slow [45,46], allowing for switching and encapsulation of the devices in a few minutes. An additional possibility is light activation of the ZnO layer, which fills electron traps in the ZnO layer upon UV exposure [47], increasing its conductivity. This is in agreement with our results, as UV light is reported to improve the organic photovoltaic performance, correct the S shape, and promote favorable redistribution of oxygen in encapsulated OSCs [48].

After process optimization, encapsulated solar cells with nondiluted PEDOT:PSS show a PCE of 3.59% [Fig. 5(a)], obtained in a full open-air process, whereas a slightly higher PCE of 3.8% is measured in a device with evaporated Ag back electrode [Fig. 5(b)]. The average PCEs of this set of samples are $(3.44 \pm 0.14)\%$ and $(3.64 \pm 0.12)\%$, respectively (see Table S3). The higher FF and J_{SC} values of the solar cells with Ag evaporated back electrodes are, in part, responsible for the higher PCE.

The J - V characteristics of solar cells with diluted PEDOT:PSS show a decline in performance for both printed [Fig. 5(a)] and evaporated [Fig. 5(b)] Ag electrodes, mainly because of a decrease in the collected photocurrent. In the solar cells used to obtain the results reported in Fig. 5, PEDOT:PSS diluted with IPA and pure PEDOT:PSS cover the desired area of the active layer, resulting in solar cells with the same active area. On average, an encapsulated solar cell with printed Ag electrodes with nondiluted PEDOT:PSS produces (3.38 ± 0.24) mA/cm² more than a solar cell with diluted PEDOT:PSS 3:1. The J - V curve of a solar cell without PEDOT:PSS is shown in Fig. 5(b), where a very poor performance is obtained due to the absence of a HTL layer that could impede recombination of the generated carriers in forward bias.

The absorbance of the PEDOT:PSS HTL slot-die-coated on bare PET foil is shown in Fig. 5(c), with the contribution of the PET substrate removed. It shows a broad absorption over the full spectral range for both films, where the reduction in thickness resulting from diluting PEDOT:PSS with IPA is evidenced by an optically thinner film with lower absorption. The QE curves [Figs. 5(c) and 5(d)] of the devices with diluted PEDOT:PSS show an overall decrease, with respect to the QE curves of the solar cells with nondiluted PEDOT:PSS. For the case of Ag printed electrodes [Fig. 5(c)], the integrated QE currents are 8.03 and 4.49 mA/cm² (Table S4) for pure and diluted PEDOT:PSS, respectively, which are in agreement with their 1 sun J - V curves. For the solar cells with evaporated electrodes on top of IPA-to-PEDOT:PSS layers in

ratios 0:1, 3:1, and 1:0, the QE integrated currents are 8.24, 6.33, and 5.28 mA/cm² (Table S4), respectively, in agreement with their 1 sun J - V curves.

The PV parameter that is affected most when using a HTL diluted with IPA is the J_{SC} . There are many possible reasons that may explain the lower current density of the devices with diluted PEDOT:PSS. Given that the V_{OC} and FF values remain almost the same, this effect could be due to alterations of the blend morphology produced by penetration of IPA into the active layer during the drying step at 70 °C. Another hypothesis is that IPA dissolves some of the acceptor at the interface (with subsequent mixing with PEDOT:PSS), causing a different interface composition compared with that of devices where IPA is not used. An alternative scenario could be the diffusion of some component of the IPA:PEDOT dilution into the active layer, doping it, and creating charge traps, thereby reducing the current and modifying the band gap of the active layer. A thorough explanation of the changes in the optoelectronic characteristic of devices with diluted PEDOT:PSS is beyond the scope of this publication. The hypotheses proposed here may not be exhaustive.

C. Back-electrode modifications

In the inverted configuration of OSCs, the back electrode is the last part of the device to be prepared. In this section, we present a direct comparison of different back electrodes viewed only as a channel for the generated carriers to an external circuit. As described in Sec. II, we compare two deposition techniques for the back electrode: flexographic printing (Fig. 2) and thermal evaporation. Different materials are employed as electrodes, both printed silver fingers and evaporated silver, evaporated copper, and evaporated gold, which are tested in two to four batches of solar cells with a total area of 1 cm².

By employing different back electrodes, we experimentally examine if a less-expensive metal, such as copper, could improve the solar-cell performance, as well as if, conversely, it would be worthwhile to use a more

FIG. 6. Summary of key PV parameters of P3HT:O-IDTBR solar cells with different back electrodes, before (boxes) and after (dots) encapsulation for (a) power conversion efficiency, (b) fill factor, (c) current density, and (c) open-circuit voltage.

TABLE II. Photovoltaic characteristics [50] of organic solar cells with printed back electrodes. Areas below 1 cm^2 are obtained using shadow masks; the shadow area of the silver fingers from the flextrode is not subtracted (aperture area) [54].

	Area (cm^2)	PCE (%)	FF (%)	J_{SC} (mA/cm^2)	V_{OC} (V)	R_s ($\Omega \text{ cm}^2$)	R_{sh} ($\text{k}\Omega \text{ cm}^2$)	Max. power (mW)
Ag printed	4.00	2.31	54.04	5.84	0.733	21.80	1.00	9.26
	0.70	3.50	64.83	7.69	0.703	4.91	1.59	2.45
	0.25	3.58	67.25	7.90	0.674	1.86	1.27	0.90
	0.20	3.38	67.36	7.55	0.665	1.50	1.25	0.68
	0.08	2.98	62.59	7.55	0.632	0.59	0.75	0.24

expensive non-air-sensitive metal, such as gold. After evaporation of the back contacts, all solar cells are exposed to air for a few minutes for switching before encapsulation. As a first step, the sheet resistance of all four materials is measured on bare PET foil (Figure S7). The Ag front electron-collecting electrode on the flextrode is also measured. The lowest values are measured for evaporated silver on PET $0.277 \pm 0.007 \text{ }\Omega/\text{sq}$, closely followed by silver on the flextrode $0.329 \pm 0.005 \text{ }\Omega/\text{sq}$. Copper and gold have sheet resistance values of 0.587 ± 0.007 and $0.589 \pm 0.007 \text{ }\Omega/\text{sq}$, respectively. The highest sheet resistance is measured for printed silver, $2.26 \pm 0.08 \text{ }\Omega/\text{sq}$, which turns out to be practically as good as that of evaporated silver, in terms of PCE. It should be noted that these sheet-resistance values might differ from those of the electrodes on the actual solar cells after encapsulation and the epoxy-UV-curing process.

The J - V and Q_e curves of representative solar cells with the different electrodes from this section are shown in Figure S8. The solar cells with Cu electrodes show a very high tolerance to the switching current needed to activate the cells before characterization under the solar simulator. The electrode does not show any trace of damage, even when enduring repeated high currents (600 mA, 2 s). However, more effort is needed to obtain working devices compared with the evaporated or printed silver cells. The solar cells with Cu electrodes show an average (see Table S5) PCE and FF of $2.98 \pm 0.08\%$ and $64.27 \pm 0.66\%$, respectively; these values are both lower than those in the devices with evaporated or printed Ag. The low J_{SC} of the solar cells with the Cu electrode ($1.5 \text{ mA}/\text{cm}^2$ lower than that of the evaporated Ag counterpart) is the main reason for the low PCE. The QE of a solar cell with a Cu back electrode, shows low values over the entire spectral range, implying a smaller integrated J_{SC} ($6.53 \text{ mA}/\text{cm}^2$, see Table S5), in agreement with its 1 sun J_{SC} value.

The cells with Au electrodes are especially difficult to switch, as the electrode cannot tolerate a small reverse bias current as easily as that of Cu or Ag. The solar cells with Au electrodes perform very poorly compared with the rest, as can be seen from their PCE, FF, and J_{SC} values in Fig. 6. The J_{SC} of the solar cells with Au electrodes is especially low, with an average value (see Table S5)

of $4.61 \pm 0.32 \text{ mA}/\text{cm}^2$, which suggests that Au alone on top of PEDOT:PSS is a less-efficient electrode than that of Ag. The series resistance (R_s), shunt resistance (R_{sh}), and recombination current density (J_0) for the solar cells with different back electrodes are reported in supporting information Table S6, where the solar cell with the Au electrode has the highest R_s of $12.7 \text{ }\Omega \text{ cm}^2$ and the solar cell with the evaporated Ag back electrode has a lower J_0 value of $0.2 \text{ }\mu\text{A}/\text{cm}^2$ in the dark.

Some of the optical losses are illustrated in Figure S8(b), where the transmittance of glass and glass/epoxy is presented. The front glass used for encapsulation transmits only 95% of the incoming light for $\lambda > 350 \text{ nm}$. After encapsulation, the optical window glass/epoxy transmits light only for $\lambda > 363 \text{ nm}$, reaching 94% transmittance only for $\lambda > 550 \text{ nm}$. This opens up the possibility for future optical improvements.

Figure 6 shows the key PV parameters of 1 cm^2 solar cells with the electrode materials used in this section, for 24 solar cells before (boxes) and after (dots) encapsulation. The wide spread of values before encapsulation reveals the difficulties in switching, and after encapsulation some of the solar cells with Cu or Au electrodes even stop working. Despite Cu and Au being good electrical conductors, with low sheet resistance, these results show that these are necessary, but not sufficient, conditions to form a good electrode. One possibility for the enhanced photocurrent of the solar cells with Ag evaporated electrodes could be that Ag reflects more light than that of Cu or Au. However, the front total reflectance of the OSCs (the reflectance measured on the PET side of the solar cells) with Ag and Cu electrodes is very similar in both devices, around 6% over the entire spectral range (see Figure S9). Reflected light is possibly absorbed by the PEDOT:PSS and active layer before it leaves the solar cell, which makes both devices reflect almost the same amount of light. Despite some obvious differences in photocurrent for each contact, the reason behind them is unclear and a trend cannot be found, meaning that further investigation is needed. Possible reasons for their low photocurrent could be that switching does not activate the full area, leaving inactive areas in the solar cell. An additional reason could be that evaporated Cu and Au metals penetrate into the

PEDOT:PSS layer [52,53], causing a performance drop. A thin layer of transition-metal oxide (i.e., MoO_x) can help slow the diffusion of metals, passivate the back interface, and improve the hole selectivity of the electrode. If diffusion of metals takes place, it does not reach the active layer, as the V_{OC} [50,51] and E_g^{PV} of the solar cells is similar for all, with $\Delta V_{\text{OC}}^{\text{PV}}$, in all cases, in the order of 0.8 V (see Table S4 and Table S5). It is important to mention that other phenomena could be responsible for such discrepancies in performance when using Cu and Au contacts. In fact, the small difference in sheet resistance between Cu and Ag is unlikely to explain such a large drop in J_{SC} . Likewise, the small work-function difference between Au and Ag is unlikely to justify such a loss of performance.

Figure 7(a) clearly shows that the optimal electrode materials are those used in the previous section: printed and thermally evaporated silver, with maximum PCEs of 3.59% and 3.80%, respectively. These results are especially important for considering a manufacturing trade-off. In fact, flexographic printing does not require any added vacuum steps in the process, yet still yields efficiencies that are comparable to those of evaporated silver.

D. Different area devices

As a proof of the scalability of our approach, larger area devices are also fabricated to study the evolution of photovoltaic performance when upscaling. The exact same experimental procedure is followed. The printed cells are cut into larger areas by simply not separating individual cells, creating solar cells with total areas of up to 4 cm^2 [Fig. 7(a)]. The maximum PCE measured in this case is 2.31%, with a FF of 54%, and a maximum short-circuit current of 23.39 mA, achieving a maximum power point of 9.26 mW [Fig. 7(c), Table II]. The 4 cm^2 solar cell with printed electrodes shows a decrease in PCE of around 35% when compared with the maximum PCE demonstrated by the 1 cm^2 cells. A component of the loss can be associated with the decrease in FF, which correlates with the extremely high $R_s = 21.8 \Omega \text{ cm}^2$, which increases by one order of magnitude with respect to the 1 cm^2 device. The evolution of R_s with the area of the solar cells is presented in Fig. 7(b). R_s is one of the challenges of upscaling, as it includes the influence of the electrodes and different layers in the solar cell; optimization of the process and materials should provide a value of R_s that is as low as possible. One way to reduce it is to use full-area electrodes, as in the case of the evaporated Ag electrodes (See Figure 7(b) and Table S7), where R_s is systematically low. Full-area electrodes help to compensate for the small diffusion length of some photoactive materials [55]. However, they can increase the probability of carrier recombination for nonpassivated electrodes [56]. The significantly lower J_{SC} value of the $>1 \text{ cm}^2$ solar cell cannot be explained

FIG. 7. (a) J - V curves of solar cells with different active areas using printed Ag back electrodes. Areas below 1 cm^2 are obtained using shadow masks on the 1 cm^2 cell. (b) Series resistance (R_s) of solar cells with flexoprinted (squares) and evaporated (circles) Ag back electrodes. (c) Electrical power delivered by solar cells with flexoprinted Ag back electrodes and different aperture areas.

solely by the increase in R_s (see Table 7 supporting information [57]), which means that alternative mechanisms are playing a role in decreasing the performance of that device. A feasible explanation for this could be the presence of inhomogeneities in the active layer, disconnected areas, nonswitched areas, or shadowing from the Ag fingers in the flexrode that cause an effectively smaller active area of the device, resulting in a lower short-circuit current. At this point, the introduction of vacuum steps into the process does not show a clear advantage, and consequently, open-air-produced OSCs are more suitable for upscaling. Additional experimental results can be found in the Supplementary information [58].

IV. CONCLUSIONS

An optimization approach for the scalable fabrication of fullerene-free OSCs based on P3HT:O-IDTBR is developed using roll processing on flexible and ITO-free substrates. The optimization method is based on independently modifying several coating parameters, which are known to affect the photovoltaic performance of organic solar cells. The substrate temperature, the slot-die head temperature, the thickness of the active layer, the hole-transport layer, and the back electrode are studied and optimized.

By optimizing the processing conditions, power conversion efficiencies as high as 3.59% are achieved for 1 cm² solar cells, which are fabricated fully under ambient conditions. This is the state-of-the-art efficiency for this active-layer system using ITO-free flexible substrates on an open-air roll-processing platform. The efficiency is improved up to 3.8% PCE when evaporated silver is used as a back electrode. Improving the current density is the main challenge of the solar cells presented herein.

We strongly believe that our results can be used as a general approach for the optimization of nonfullerene organic solar cells fabricated by slot-die coating. Our findings also show that further attention to intermediate steps in the fabrication of devices is necessary, as crucial steps are not usually described and can severely affect the overall performance of the final devices.

In addition, this work clearly confirms P3HT:O-IDTBR as a suitable candidate for the large-scale fabrication of organic solar cells and, therefore, for the possible commercialization of the technology.

ACKNOWLEDGMENTS

We gratefully acknowledge funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (SEE-WHI Solar Energy Enabled for the World by High Resolution Imaging, Grant No. 681881).
