A time-dependent equation-of-motion coupled-cluster singles and doubles (TD-EOM-CCSD) method is implemented, which uses a reduced basis calculated with the asymmetric band Lanczos algorithm. The approach is used to study weak-field processes in small molecules induced by ultrashort valence pump and core probe pulses. We assess the reliability of the procedure by comparing TD-EOM-CCSD absorption spectra to spectra obtained from the time-dependent coupled-cluster singles and doubles method, and observe that spectral features can be reproduced for several molecules, at much lower computational times. We discuss how multiphoton absorption and symmetry can be handled in the method, and general features of the core-valence separation projection technique. We also model the transient absorption of an attosecond x-ray probe pulse by the glycine molecule.

I. INTRODUCTION

Stimulated by the recent experimental realization of various laser pulses with durations on the attosecond (1×10^{-18} s) time scale [1–5], capable of monitoring electronic motion, the theoretical simulation of coherent electron dynamics is currently an active field of research [6].

Real-time electronic structure theory considers the explicit time dependence of the electronic system by evolving the time-dependent Schrödinger equation in the time domain [6]. Explicitly time-dependent methods can directly provide the time-domain evolution of electronic wave functions together with nuclear motion, representing a versatile way of tracking ultrafast phenomena in both perturbative and nonperturbative regimes [7,8].

The development of real-time methods commenced in the late 1970s and early 1980s in the field of nuclear physics [9–11]. Despite these early endeavors, real-time methods did not become practical at that time due to the lack of electron correlation effects at the Hartree-Fock level and the high computational cost associated with propagation of correlated wave functions. However, decades of steady advancements in computing power and numerical algorithms have led to a renewed interest in explicit time propagation in correlated methods like density-functional theory [12,13], multiconfigurational self-consistent-field [14–16], configuration-interaction [17–20], algebraic diagrammatic construction [21,22], and coupled-cluster [23–33] methods.

In this paper, we present an implementation and representative case studies of the time-dependent equation-of-motion coupled-cluster (TD-EOM-CC) model for simulating weak-field attosecond valence pump–core probe processes. In conjunction with a reduced-space band Lanczos algorithm for obtaining the valence and core excited states, this model offers results similar to its time-dependent coupled-cluster (TDCC) counterpart in weak fields, at significantly lower computational costs. The reduction in cost enables the study of larger systems.

The paper is organized as follows. In Sec. II we detail the theory behind TD-EOM-CC and the asymmetric band Lanczos algorithm. Here, we also discuss a strategy used in order to guide the reduced space solver to directly obtain the transitions between excited states. The computational procedure used is detailed in Sec. III. In Sec. IV, simulations for various molecular systems are presented. First a benchmark study is presented for LiF, validating our proposed method. Second, the applicability of the core-valence separation (CVS) scheme is tested for LiH. Then, a two-photon absorption phenomenon has been captured using a stepwise procedure emulating the actual physical process for C_2H_4 . Finally, we put forward a theoretical assessment of pump-probe absorption for the glycine molecule, which is deemed suitable for further experimental investigations. The findings are summarized in Sec. V.

II. THEORY

A. System

We model the system, composed of a molecule and its interaction with laser pulses, with the Hamiltonian

$$H(t) = H^{(0)} + V(t), \quad (1)$$

*These authors contributed equally to this work.

[†]soco@kemi.dtu.dk

[‡]henrik.koch@sns.it

where the field-free Hamiltonian $H^{(0)}$ describes the molecule with fixed nuclei and without interactions with the external electromagnetic field. The semiclassical time-dependent interaction term, written in the dipole approximation and length gauge, is

$$V(t) = -\mathbf{d} \cdot \mathcal{E}(t) \quad (2)$$

and describes the interaction between the molecular electrons and the external electromagnetic field. The latter is represented by the electric field $\mathcal{E}(t) = [\mathcal{E}_x(t) \ \mathcal{E}_y(t) \ \mathcal{E}_z(t)]^T$ and electronic dipole operator vectors, $\mathbf{d} = [d_x \ d_y \ d_z]^T$. We assume that the molecule is initially in the ground state of the field-free Hamiltonian, and take the electric field to be a linear combination of the electric fields of any number of laser pulses:

$$\mathcal{E}(t) = \sum_n \mathcal{E}_{0n} \cos[\omega_{0n}(t - t_{0n}) + \phi_n] f_n(t). \quad (3)$$

The field of laser pulse n has an associated carrier frequency ω_{0n} , peak strength $|\mathcal{E}_{0n}|$, polarization $\mathcal{E}_{0n}/|\mathcal{E}_{0n}|$, and an $8\sigma_n$ -truncated Gaussian envelope function

$$f_n(t) = \begin{cases} e^{-(t-t_{0n})^2/(2\sigma_n^2)} & \text{if } |t - t_{0n}| \leq 8\sigma_n \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

with duration specified by σ_n , the temporal rms width. It is also specified by the central time t_{0n} and the carrier-envelope phase ϕ_n . We assume the carrier-envelope phase to be zero for all pulses, meaning that the maximum values of the envelope and cosine carrier functions belonging to pulse n coincide at t_{0n} .

The energy absorbed during the interaction can be given by [28,34]

$$\Delta E = \int_0^\infty \omega S(\omega) d\omega, \quad (5)$$

where $S(\omega)$ is the response function

$$S(\omega) = -2\text{Im}[(\tilde{\mathbf{d}}(\omega) \cdot \tilde{\mathcal{E}}^*(\omega))] \quad \omega > 0. \quad (6)$$

The vectors $\tilde{\mathbf{d}}(\omega)$ and $\tilde{\mathcal{E}}(\omega)$ are the Fourier transforms of the time-dependent dipole moment expectation value and electric-field vectors, respectively, and the asterisk denotes complex conjugation. A positive or negative value of the function $S(\omega)$ describes the probability of absorption or emission of light with frequency ω , respectively [34].

B. TD-EOM-CC states

The time-dependent ket and bra of a TD-EOM-CC state can be expressed as

$$|\Psi(t)\rangle = \sum_j |\psi_j\rangle s_j(t), \quad \langle\tilde{\Psi}(t)| = \sum_i k_i(t) \langle\tilde{\psi}_i|, \quad (7)$$

where the italic indices i and j are used to denote general equation-of-motion coupled-cluster (EOM-CC) states, including the ground state with index zero. The time-independent EOM-CC kets and bras are given by

$$|\psi_j\rangle = e^T R_j |\text{HF}\rangle, \quad \langle\tilde{\psi}_i| = \langle\text{HF}| L_i e^{-T}. \quad (8)$$

We assume that the EOM-CC states are biorthonormal:

$$\langle\tilde{\psi}_i|\psi_j\rangle = \delta_{ij}. \quad (9)$$

In the following, we let the indices κ and λ denote general determinants in the projection space, including the reference Hartree-Fock determinant with index zero. We use the indices μ and ν , on the other hand, to denote excited determinants.

The cluster operator T and the right and left operators R_j and L_i of Eq. (8) can be expressed as linear expansions in a finite set of operators τ_λ and τ_κ^\dagger ,

$$T = \sum_\nu \tau_\nu t_\nu, \quad R_j = \sum_\lambda \tau_\lambda r_{\lambda j}, \quad L_i = \sum_\kappa l_{i\kappa} \tau_\kappa^\dagger, \quad (10)$$

where the operator with index zero is the unit operator,

$$\tau_0 = \tau_0^\dagger = 1, \quad (11)$$

and the τ_ν and τ_μ^\dagger operators generate excited determinants from the ket and bra reference Hartree-Fock determinants, respectively:

$$\tau_\nu |\text{HF}\rangle = |\nu\rangle, \quad \langle\text{HF}| \tau_\mu^\dagger = \langle\mu|, \quad (12)$$

$$\tau_\mu^\dagger |\text{HF}\rangle = 0, \quad \langle\text{HF}| \tau_\nu = 0. \quad (13)$$

We assume that the determinants are biorthogonal:

$$\langle\kappa|\lambda\rangle = \delta_{\kappa\lambda}. \quad (14)$$

If all possible electronic excitations are included in the summations in Eq. (10), the method is equivalent to full configuration interaction. The sum can also be restricted to given excitation levels, giving approximate methods that scale polynomially with the system size. This includes the coupled-cluster singles and doubles method, where summation is only done over single and double excitations. We do not explicitly state the excitation levels included in the following expressions, since they hold for both restricted and unrestricted summation.

The cluster amplitudes t_ν in Eq. (10) can be found from solving equations involving the similarity-transformed field-free Hamiltonian operator $\bar{H}^{(0)}$ projected onto the right reference and left excited determinants

$$\langle\mu|\bar{H}^{(0)}|\text{HF}\rangle = 0, \quad (15)$$

where the similarity transformation of an operator X is denoted by an overbar:

$$\bar{X} = e^{-T} X e^T. \quad (16)$$

After the optimal cluster amplitudes t_ν have been determined, the right and left vectors of EOM-CC state i , with components $r_{\lambda j}$ and $l_{i\kappa}$, can be found as right and left eigenvectors of the field-free Hamiltonian matrix, with elements

$$H_{\kappa\lambda}^{(0)} = \langle\kappa|\bar{H}^{(0)}|\lambda\rangle. \quad (17)$$

The right and left eigenvectors of the matrix in Eq. (17) with the lowest eigenvalue, specifying the ground EOM-CC state with index zero, have the following structure:

$$r_{00} = 1, \quad r_{\nu 0} = 0, \quad (18)$$

$$l_{00} = 1, \quad l_{0\mu} = \bar{l}_\mu. \quad (19)$$

The multipliers \bar{l}_μ are solutions to the equations

$$\langle\text{HF}|\bar{H}^{(0)}|\nu\rangle + \sum_\mu \bar{l}_\mu A_{\mu\nu}^{(0)} = 0, \quad (20)$$

where elements of the field-free coupled-cluster Jacobian matrix $\mathbf{A}^{(0)}$ are given by

$$A_{\mu\nu}^{(0)} = \langle \mu | [\bar{H}^{(0)}, \tau_\nu] | \text{HF} \rangle. \quad (21)$$

The other right and left eigenvectors of the matrix in Eq. (17) correspond to excited EOM-CC states, denoted by the italic indices m and n . The eigenvectors have the following reference determinant components:

$$r_{0n} = - \sum_v \bar{t}_v r_{vn}, \quad (22)$$

$$l_{m0} = 0. \quad (23)$$

These components enforce the biorthogonality between the ground and excited states, in accordance with Eq. (9). The vectors \mathbf{R}_m and \mathbf{L}_m , containing the components r_{vm} and l_{mv} of excited EOM-CC state m , are right and left eigenvectors of $\mathbf{A}^{(0)}$ with eigenvalue ω_m .

C. Derivation of TD-EOM-CC equations

The time derivative of the coefficients of the TD-EOM-CC ket can be found from projecting the ket time-dependent Schrödinger equation (TDSE)

$$\iota \frac{\partial}{\partial t} |\Psi(t)\rangle = H(t) |\Psi(t)\rangle, \quad (24)$$

where ι denotes the imaginary unit, onto the bra of EOM-CC state i , giving

$$\iota \frac{\partial s_i(t)}{\partial t} = \sum_j H_{ij}(t) s_j(t), \quad (25)$$

where the matrix elements of an operator $X(t)$ are given by

$$X_{ij}(t) = \langle \tilde{\psi}_i | X(t) | \psi_j \rangle. \quad (26)$$

Likewise, the time derivative of the coefficients of the TD-EOM-CC bra can be found from projecting the bra TDSE,

$$-\iota \frac{\partial}{\partial t} \langle \tilde{\Psi}(t) | = \langle \tilde{\Psi}(t) | H(t), \quad (27)$$

onto the ket of EOM-CC state j , giving

$$-\iota \frac{\partial k_j(t)}{\partial t} = \sum_i k_i(t) H_{ij}(t). \quad (28)$$

The TD-EOM-CC equations (25) and (28) were to our knowledge first presented in Ref. [18], and have also been used in Ref. [19]. In those works, the matrix elements d_{ij} of the dipole moment operator, entering in the time-dependent Hamiltonian, are approximated by discarding non-Hermitian components. This was achieved by using the Hermitian $(d_{ij} + d_{ji}^*)/2$ instead of the d_{ij} given by Eq. (26). In the present paper, however, the full non-Hermitian d_{ij} are used in the solution of Eqs. (25) and (28). After the time-dependent coefficients $k_i(t)$ and $s_i(t)$ have been obtained, the time-dependent expectation value of a time-independent operator X can be calculated according to

$$\langle X \rangle(t) = \sum_{ij} k_i(t) X_{ij} s_j(t). \quad (29)$$

D. Asymmetric band Lanczos algorithm

We use the asymmetric band Lanczos algorithm to generate approximate eigenvalues $\tilde{\omega}_n$ and right $\tilde{\mathbf{R}}_n$ and left $\tilde{\mathbf{L}}_n$ eigenvectors of the field-free Jacobian matrix $\mathbf{A}^{(0)}$. As outlined in Sec. II F, the approximate eigenvectors are used as a reduced basis for solving Eqs. (25) and (28).

The algorithm is a generalization of the simple asymmetric Lanczos algorithm, employing m right $(\mathbf{b}_1, \dots, \mathbf{b}_m)$ and p left $(\mathbf{c}_1, \dots, \mathbf{c}_p)$ starting vectors instead of single ones [35–37]. A sequence of right vectors is constructed by transforming the right starting vectors by increasing powers of a given square asymmetric matrix \mathbf{M} . For our purpose, $\mathbf{M} = \mathbf{A}^{(0)}$. The i first vectors in the sequence, which can be linearly dependent, span the n -dimensional right band Krylov subspace,

$$\begin{aligned} \mathcal{K}_i(\mathbf{M}, \mathbf{b}_1, \dots, \mathbf{b}_m) \\ = \text{span}\{\underbrace{\mathbf{b}_1, \dots, \mathbf{b}_m, \mathbf{M}\mathbf{b}_1, \dots, \mathbf{M}\mathbf{b}_m, \mathbf{M}^2\mathbf{b}_1, \dots}_{i}\}, \end{aligned} \quad (30)$$

where $i - n$ is the number of redundant vectors in the sequence. Likewise, a sequence of left vectors is constructed by transforming the left starting vectors by increasing powers of the transpose matrix \mathbf{M}^T . The j first vectors in the sequence, which can be linearly dependent, span the n -dimensional left band Krylov subspace,

$$\begin{aligned} \mathcal{K}_j(\mathbf{M}^T, \mathbf{c}_1, \dots, \mathbf{c}_p) \\ = \text{span}\{\underbrace{\mathbf{c}_1, \dots, \mathbf{c}_p, \mathbf{M}^T\mathbf{c}_1, \dots, \mathbf{M}^T\mathbf{c}_p, (\mathbf{M}^T)^2\mathbf{c}_1, \dots}_{j}\}, \end{aligned} \quad (31)$$

where $j - n$ is the number of redundant vectors in the sequence. Note that the subspaces can be regarded as block Krylov subspaces [37] whenever i and j are multiples of the number of starting vectors. The n right $(\mathbf{v}_1, \dots, \mathbf{v}_n)$ and left $(\mathbf{w}_1, \dots, \mathbf{w}_n)$ Lanczos vectors, which form respective bases for $\mathcal{K}_i(\mathbf{M}, \mathbf{b}_1, \dots, \mathbf{b}_m)$ and $\mathcal{K}_j(\mathbf{M}^T, \mathbf{c}_1, \dots, \mathbf{c}_p)$, are obtained by discarding redundant vectors of the sequences in Eqs. (30) and (31). A $n \times n$ -dimensional band Krylov subspace approximation of \mathbf{M} can then be obtained by expressing the matrix in the Lanczos vector bases.

The right and left Lanczos vectors can be generated iteratively with the recurrence relations [35]

$$\mathbf{M}\mathbf{V}_n = \mathbf{V}_n \mathbf{T}_n + \hat{\mathbf{V}}_n^C + \hat{\mathbf{V}}_n^D, \quad (32)$$

$$\mathbf{M}^T \mathbf{W}_n = \mathbf{W}_n \tilde{\mathbf{T}}_n + \hat{\mathbf{W}}_n^C + \hat{\mathbf{W}}_n^D, \quad (33)$$

where the right and left Lanczos vectors form the matrices $\mathbf{V}_n = [\mathbf{v}_1 \ \dots \ \mathbf{v}_n]$ and $\mathbf{W}_n = [\mathbf{w}_1 \ \dots \ \mathbf{w}_n]$, respectively. The un-normalized vectors that form the nonzero columns of $\hat{\mathbf{V}}_n^C = [\mathbf{0} \ \dots \ \mathbf{0} \ \hat{\mathbf{v}}_{n+1} \ \dots \ \hat{\mathbf{v}}_{n+m_c}]$ and $\hat{\mathbf{W}}_n^C = [\mathbf{0} \ \dots \ \mathbf{0} \ \hat{\mathbf{w}}_{n+1} \ \dots \ \hat{\mathbf{w}}_{n+p_c}]$ serve as candidates for the next right and left Lanczos vectors, respectively. The sparse matrices $\hat{\mathbf{V}}_n^D$ and $\hat{\mathbf{W}}_n^D$ contain un-normalized candidates from previous iterations that have been deflated (i.e., discarded) due to linear dependence on already accepted right and left Lanczos vectors, respectively. Finally, the nonzero elements of \mathbf{T}_n and $\tilde{\mathbf{T}}_n$ are used to enforce the biorthogonality

between the $m + p + 1$ vectors that can overlap in exact arithmetic at each iteration [35].

In numerical implementations, vectors are usually deflated when linear independence is below a given threshold, since inexact arithmetic prevents the description of exact linear dependence. The numbers m_c and p_c , initially equal to the number of right and left starting vectors m and p , give the current number of vectors available for deflation. We say that the sequence in Eqs. (30) and (31) is fully exhausted when m or p deflations have occurred, respectively. The iterative procedure is then terminated, giving equal numbers of right and left Lanczos vectors.

The iterative solution of Eqs. (32) and (33) is done in accordance with Algorithm 5.1 of Ref. [37], with two exceptions. The following biorthogonalization step is added at the beginning of step 1:

```

if  $n > 1$  then
  for  $k = 1$  to  $\max\{1, n - p_c - 1\}$  do
     $\hat{\mathbf{v}}_n \leftarrow \hat{\mathbf{v}}_n - \mathbf{v}_k (\mathbf{w}_k^T \hat{\mathbf{v}}_n)$ 
  end for
end if

```

and the following at the beginning of step 2:

```

if  $n > 1$  then
  for  $k = 1$  to  $\max\{1, n - m_c - 1\}$  do
     $\hat{\mathbf{w}}_n \leftarrow \hat{\mathbf{w}}_n - (\hat{\mathbf{w}}_n^T \mathbf{v}_k) \mathbf{w}_k$ 
  end for
end if

```

These additions lead to an algorithm that enforces the biorthogonality between all Lanczos vectors in inexact arithmetic,

$$\mathbf{W}_n^T \mathbf{V}_n = \mathbf{\Delta}_n = \text{diag}(\delta_1, \delta_2, \dots, \delta_m), \quad (34)$$

and not just between the vectors that can overlap in exact arithmetic. We observe that this modification of the algorithm is important for numerical stability when the number of iterations becomes large, but the modification also makes the number of vector operations substantially higher. The number of operations can potentially be reduced in future implementations, e.g., by formulating a restarted asymmetric band Lanczos algorithm, based on existing approaches [38].

The iterative procedure continues until a given maximum chain length (i.e., number of iterations) $n = n^{\max}$ is reached, unless the procedure is terminated at a lower n because of full exhaustion of the sequence in Eq. (30) or (31). The algorithm generates the $n \times n$ matrices

$$\begin{aligned} \mathbf{T}_n^P &= \mathbf{\Delta}_n^{-1} \mathbf{W}_n^T \mathbf{M} \mathbf{V}_n \\ &= \mathbf{T}_n + \mathbf{\Delta}_n^{-1} \mathbf{W}_n^T \mathbf{V}_n^D, \end{aligned} \quad (35)$$

$$\begin{aligned} \tilde{\mathbf{T}}_n^P &= (\mathbf{W}_n^T \mathbf{M} \mathbf{V}_n \mathbf{\Delta}_n^{-1})^T \\ &= \tilde{\mathbf{T}}_n + [(\mathbf{W}_n^D)^T \mathbf{V}_n \mathbf{\Delta}_n^{-1}]^T, \end{aligned} \quad (36)$$

in accordance with Algorithm 5.1 of Ref. [37]. The matrices \mathbf{T}_n^P and $\tilde{\mathbf{T}}_n^P$ are related by

$$\mathbf{\Delta}_n \mathbf{T}_n^P = (\tilde{\mathbf{T}}_n^P)^T \mathbf{\Delta}_n, \quad (37)$$

and are banded when no deflations have occurred [35].

The matrix \mathbf{T}_n^P can be viewed as the oblique projection of \mathbf{M} onto the n -dimensional $\mathcal{K}_i(\mathbf{M}, \mathbf{b}_1, \dots, \mathbf{b}_m)$ and orthogonally to the n -dimensional $\mathcal{K}_j(\mathbf{M}^T, \mathbf{c}_1, \dots, \mathbf{c}_p)$ [37]. Diagonalization of the matrix yields n eigenvalues, which approximate the eigenvalues of \mathbf{M} , and associated right and left eigenvectors. The right eigenvectors can be transformed to approximate eigenvectors of \mathbf{M} by premultiplication by \mathbf{V}_n , and the left eigenvectors to approximate eigenvectors of \mathbf{M}^T by premultiplication by $\mathbf{W}_n^T \mathbf{\Delta}_n^{-1}$ [35]. Approximate eigenvectors with dominant (low- and high-lying) eigenvalues are typically better converged than the ones in the middle [39–41].

E. Choice of starting vectors

In Appendix A, we demonstrate that operator matrix elements involving excited state n are linear in the right and left vector components r_{vn} and $l_{n\mu}$. We assume that n is one of the states targeted by the band Lanczos algorithm, and state i is a previously calculated ground or excited state. Matrix elements between n and i can thus be written as the product of two vectors. The first vector is the right or left vector of state n . The second vector, which we take to be the starting vector of the algorithm, is based on state i and operator X . This choice of starting vectors simplifies the calculation of operator matrix elements, as will be shown in the following. Analogous arguments have been used in previous work [42–45] to guide the choice of start vectors for the simple Lanczos algorithm for coupled-cluster response [42,43] and EOM-CC theories [44,45].

The starting vectors based on the ground state $i = 0$, which are similar to the starting vectors used in coupled-cluster linear response theory [42,43], are given by

$$b_{\mu 0}^X = \xi_{\mu}^X, \quad (38)$$

$$c_{0v}^X = \text{EOM} \eta_v^X - X_{00} \bar{t}_v, \quad (39)$$

and the starting vectors based on excited EOM-CC state $i = m$ are given by [44]

$$b_{\mu m}^X = \sum_v (\text{EOM} A_{\mu v}^X + \delta_{\mu v} X_{00} - \xi_{\mu}^X \bar{t}_v) r_{vm}, \quad (40)$$

$$c_{mv}^X = \sum_{\mu} l_{m\mu} (\text{EOM} A_{\mu v}^X + \delta_{\mu v} X_{00} - \xi_{\mu}^X \bar{t}_v). \quad (41)$$

The specification of ξ_{μ}^X , $\text{EOM} \eta_v^X$, X_{00} , and $\text{EOM} A_{\mu v}^X$ is given in Appendix A.

The starting vectors can be expressed in the Lanczos basis by inserting the resolution of identity in terms of the biorthonormal Lanczos vectors:

$$\begin{aligned} b_i^X &= \sum_j \mathbf{v}_j (\mathbf{w}_j^T b_i^X) \\ &= \sum_{j=1}^m \mathbf{v}_j b_{ji}^X, \end{aligned} \quad (42)$$

$$\begin{aligned} (c_i^X)^T &= \sum_j [(c_i^X)^T \mathbf{v}_j] \mathbf{w}_j^T \\ &= \sum_{j=1}^p c_{ij}^X \mathbf{w}_j^T. \end{aligned} \quad (43)$$

The sum in Eq. (42) is restricted since $\mathbf{b}_i^X \in \text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_m\}$ while each $(\mathbf{w}_{m+1}, \dots)$ is biorthogonal to all $(\mathbf{v}_1, \dots, \mathbf{v}_m)$. Likewise, the sum in Eq. (43) is restricted since $\mathbf{c}_i^X \in \text{span}\{\mathbf{w}_1, \dots, \mathbf{w}_p\}$ while each $(\mathbf{v}_{p+1}, \dots)$ is biorthogonal to all $(\mathbf{w}_1, \dots, \mathbf{w}_p)$.

Thus, the transition moments involving excited states can be obtained by contracting the starting vectors with the vectors of excited state n :

$$\begin{aligned} X_{in} &= (\mathbf{c}_i^X)^T \mathbf{R}_n \\ &= \sum_{j=1}^p c_{ij}^X (\mathbf{w}_j^T \mathbf{R}_n) \\ &= \sum_{j=1}^p c_{ij}^X R_{jn}, \end{aligned} \quad (44)$$

$$\begin{aligned} X_{ni} &= \mathbf{L}_n^T \mathbf{b}_i^X \\ &= \sum_{j=1}^m (\mathbf{L}_n^T \mathbf{v}_j) b_{ji}^X \\ &= \sum_{j=1}^m L_{nj} b_{ji}^X. \end{aligned} \quad (45)$$

R_{jn} and L_{nj} are simply the components of the right and left eigenvectors of \mathbf{T}_n^P , respectively, and $b_{ji}^X = \mathbf{w}_j^T \mathbf{b}_i^X$ and $c_{ij}^X = (\mathbf{c}_i^X)^T \mathbf{v}_j$ are products of starting vectors and biorthonormal Lanczos vectors.

F. Generation of a reduced basis

The iterative process that is used to calculate sets of excited EOM-CC states is given below. The set J_c contains the indices of already calculated EOM-CC states. At the beginning of the procedure, where $c = 0$, only the ground state has been calculated, and $J_0 = \{0\}$. The iterative procedure for the c th EOM-CC state calculation is as follows.

(1) Choose a subset of the state indices from previous calculations, $I_c \subseteq J_{c-1}$, and a set of operators X_c based on the final states that can be accessed by the operators (see Sec. IV). Also choose a maximum chain length n_c^{\max} , and maximum eigenvalue ω_c^{\max} and minimum transition strength S_c^{\min} values.

(2) Sequences of right and left starting vectors, $(\mathbf{b}_i^X)_{i \in I_c, X \in X_c}$ and $(\mathbf{c}_i^X)_{i \in I_c, X \in X_c}$, are constructed in accordance with Eqs. (38)–(41).

(3) The band Lanczos algorithm described in Sec. IID is run with the maximum chain length n_c^{\max} , the field-free Jacobian matrix $\mathbf{A}^{(0)}$, and the sequences of starting vectors. The algorithm terminates at $n_c \leq n_c^{\max}$, constructing the matrix $\mathbf{T}_{n_c}^P$.

(4) The eigenvalues and corresponding right and left eigenvectors of $\mathbf{T}_{n_c}^P$ are calculated. Together, these determine a set of n_c approximate EOM-CC states indexed by N_c .

(5) States $n \in N_c$ with approximate eigenvalues $\tilde{\omega}_n$ of $\mathbf{A}^{(0)}$ that are greater than ω_c^{\max} are discarded.

(6) Matrix elements for all operators $X \in X_c$ and combinations of final $n \in N_c$ and initial $i \in I_c$ states are calculated in accordance with Eqs. (44) and (45). States $n \in N_c$ with

FIG. 1. Illustration of the structures of lithium fluoride (top left), lithium hydride (top right), ethylene (bottom left), and glycine (bottom right), together with the polarization of the valence-exciting pump (orange arrow) and core-exciting probe (purple arrow) pulses.

transition strengths $S_{in}^X = X_{in} X_{ni}$ that are smaller than S_c^{\min} for all operators and initial states are discarded.

(7) For each nondiscarded state $n \in N_c$, the right and left eigenvectors of $\mathbf{T}_{n_c}^P$ are transformed to approximate right and left eigenvectors $\tilde{\mathbf{R}}_n$ and $\tilde{\mathbf{L}}_n$ of $\mathbf{A}^{(0)}$ by premultiplication by \mathbf{V}_n and $\mathbf{W}_n^T \mathbf{\Delta}_n^{-1}$, respectively.

(8) If an assessment of the convergence of the vectors is requested, residual norms of all approximate right and left vectors are calculated. All states with a left or right residual norm exceeding a given threshold are discarded.

(9) Finally, nondiscarded states with vectors linearly independent of previously calculated vectors are stored, and indexed by $N'_c \subseteq N_c$. The indices are added to the previous index set $J_c = J_{c-1} \cup N'_c$.

The iterative procedure is repeated if states of higher excitation levels are desired. Afterwards, the excited-state Jacobian and overlap matrices, with elements $\tilde{A}_{mn}^{(0)} = \tilde{\mathbf{L}}_m^T \mathbf{A}^{(0)} \tilde{\mathbf{R}}_n$ and $\tilde{S}_{mn} = \tilde{\mathbf{L}}_m^T \tilde{\mathbf{R}}_n$, are constructed in the reduced basis of the approximate eigenvectors. The right and left generalized eigenvalue problems are solved, giving new sets of right and left eigenvectors of $\tilde{\mathbf{A}}^{(0)}$. The dipole and field-free Hamiltonian matrices are then calculated in the basis of both the ground and the newly generated excited states, in accordance with Eq. (26), and used in solving the time-dependent problems defined by Eqs. (25) and (28).

III. COMPUTATIONAL DETAILS

Experimental geometries from the NIST database [46] are used for LiH, LiF, and C₂H₄. An optimized geometry from the same database is used for glycine, obtained with the MP2 method with all electrons correlated and the cc-pVTZ basis set. The linear molecules LiH and LiF are aligned along the z axis, as done in Ref. [28]. The ethylene molecule is placed in the xy plane, with the C-C bond along the x axis. The glycine molecule is of C_s symmetry for the chosen geometry, with the xy plane as the mirror plane. An illustration of the structures of the molecules, together with the polarizations of the valence-exciting pump and core-exciting probe pulses, is shown in Fig. 1.

In all following calculations, the aug-cc-pCVDZ basis set [47,48] is used for atoms targeted by the core-exciting pulses; the aug-cc-pVDZ [47] basis set is adopted for the remaining

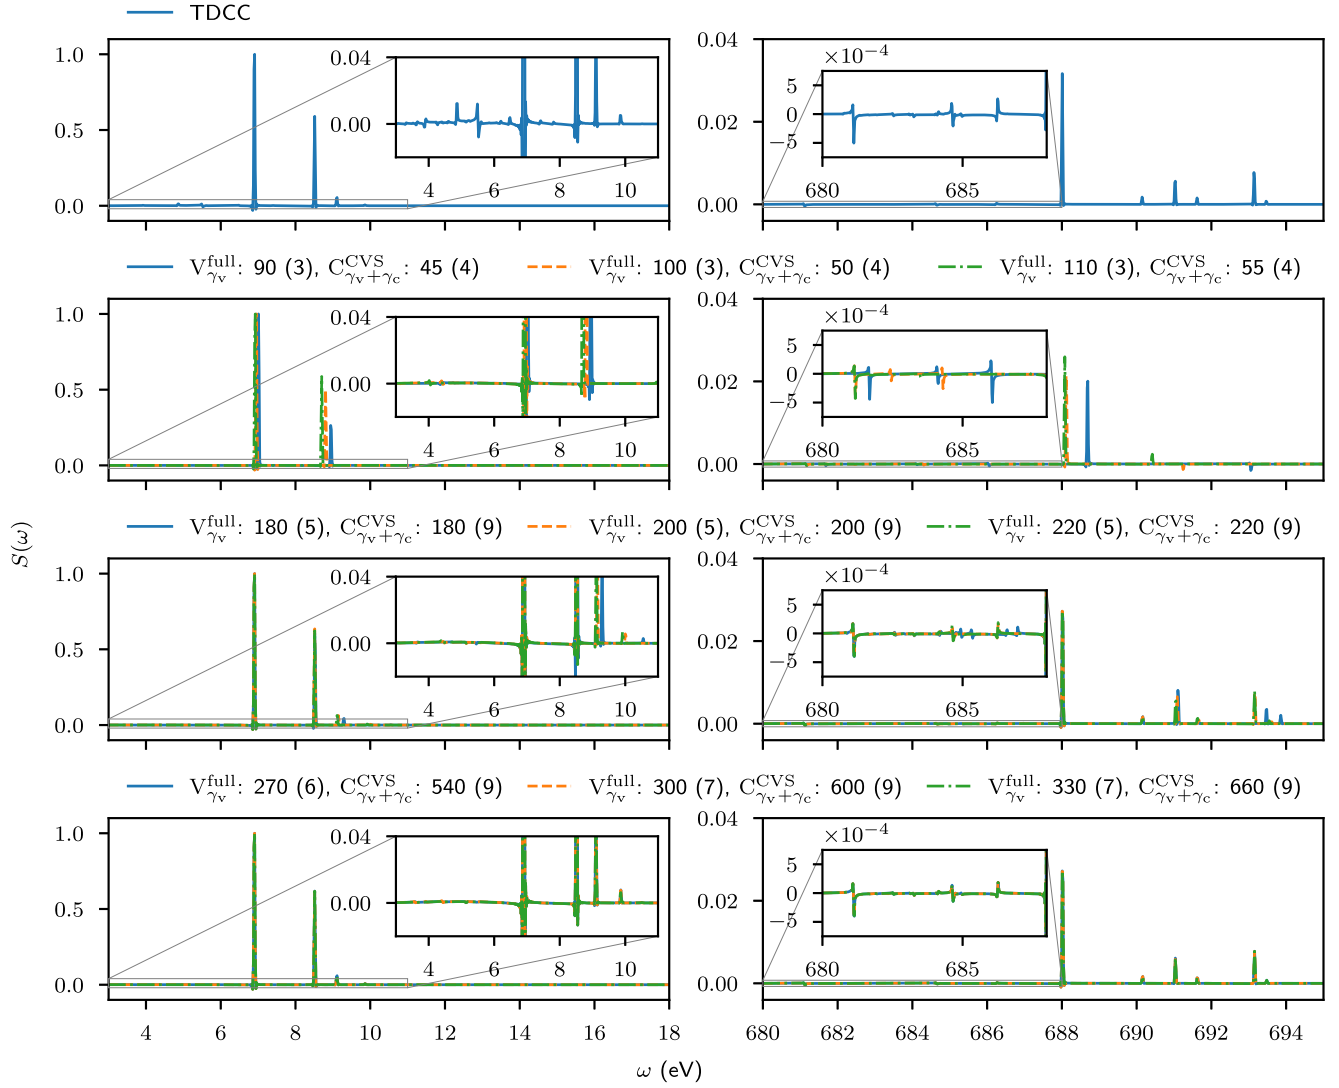

FIG. 2. LiF pump-probe absorption $S(\omega)$ as a function of frequency ω in the valence and core regions, normalized by the tallest peaks in the spectra. The TDCC results are shown in the top left and right panels. TD-EOM-CC results, calculated at different band Lanczos chain lengths, are shown in the lower panels. EOM-CC valence (V) states are calculated in the full projection space, while the core (C) states are calculated within the CVS approximation. Valence states energetically inaccessible by a single pump photon γ_v are discarded, and so are core states energetically inaccessible by subsequent absorption of a probe photon $\gamma_v + \gamma_c$. The chain lengths of the calculations are given, together with the number of converged states (in brackets).

atoms in the molecules. Valence and core states are obtained with the asymmetric band Lanczos algorithm with varying chain lengths as specified in Sec. IV.

Lanczos vectors with Euclidian norms of less than 1×10^{-9} are deflated, but this did not occur in any of the calculations. Final excited states that do not have a minimum transition strength of at least 1×10^{-7} to any initial state, for any of the operators used to construct the starting vectors, are discarded. This is done to only keep states that give a non-negligible contribution to the dynamics. Also, states with excitation energies above $\omega^{\max} = \sum_i^{n_\gamma} E_{\gamma_i}^{\max}$ are discarded, where $E_{\gamma_i}^{\max} = \omega_i + 8\sigma_i^\omega$ is an estimate of the maximum energy of photon i involved in the n_γ -photon transition to the desired excited states. The carrier frequency ω_i and the frequency rms width $\sigma_i^\omega = 1/(2\sigma_i^t)$ are parameters of the pulse providing photon i (see Sec. II A).

CVS [49–51] projectors were used to calculate core states. A “core-only” CVS projector is applied to remove excitations that originate exclusively from valence orbitals. This is done by zeroing out all right and left vector elements that only involve molecular orbitals with energies greater than the energy of the lowest core molecular orbital of a given atom. This yields a Lanczos spectrum starting at the lowest core excitation energy of the chosen edge. A complementary “valence-only” CVS projector is used to obtain valence excited states that are orthogonal to the core excited states.

Except for the spectra presented in Fig. 2, only sufficiently converged valence and core band Lanczos vectors are used for calculating stationary states and corresponding Hamiltonian and transition moment matrices. This is done by discarding states with either right or left residual norms greater than 1×10^{-2} for valence states and 1×10^{-1} for core states.

In all calculations, valence states are calculated first, with starting vectors based on the ground state. All accepted valence states are, together with the ground state, used to construct starting vectors for the core state calculations (see Sec. II F). The energies and maximum transition strengths for all accepted valence and core states are given in the Supplemental Material [52].

A fixed pump-probe delay of 40 a.u. (about 0.968 fs) is used for lithium fluoride, lithium hydride, and ethylene. The delay is varied for glycine, in order to calculate the transient absorption of the molecule. In all calculations the central time of the probe pulse is set to zero and the negative central times of the pump pulses are set accordingly.

Unless otherwise stated, integration of the TD-EOM-CC and TDCC equations is done using a Dormand-Prince 5(4) integration scheme [53] with a maximum time step of 0.1 a.u., and maximum and minimum local errors of 1×10^{-7} and 1×10^{-9} , respectively (see Appendix B). Each component of the time-dependent dipole moment expectation value and electric-field vectors is multiplied with the Hann window before Fourier transformation.

All calculations are performed using a development version of the e^T program [54].

IV. RESULTS AND DISCUSSION

A. Lithium fluoride: Convergence and nonlinear pump interaction

When discussing the applicability of the band Lanczos algorithm for modeling attosecond pump-probe processes, a key question is how spectra are affected by the chain length used. With this in mind, a single TDCC LiF pump-probe absorption spectrum, calculated with the RK4 integrator and fixed time steps of 5×10^{-3} a.u., is in Fig. 2 compared to TD-EOM-CC spectra calculated with the Dormand-Prince 5(4) integration scheme and various band Lanczos chain lengths. In all calculations, the pulses have the parameters used for the LiF spectra in Sec. III B of Ref. [28], where the F K edge is targeted by the probe pulse. Figure 1 illustrates the polarization of the pulses relative to the orientation of the molecule. All states with energies inaccessible by the absorption of one photon from each pulse are discarded from the TD-EOM-CC calculations.

For lower chain lengths, the peaks of the band Lanczos spectra shown in Fig. 2 both shift and scale significantly with variations in the chain length, indicating that excitation energies and dipole matrix elements are badly converged. The convergence generally improves with the chain length, and low-energy high-amplitude peaks seem to converge first. Higher chain lengths are needed for good convergence of high-energy low-amplitude peaks, as expected from the convergence behavior of Lanczos algorithms.

As demonstrated, the inclusion of badly converged states can give spectral peaks with incorrect positions and amplitudes. In addition, these states can also increase the cost of matrix element calculation and propagation, decrease the convergence rate of consecutive band Lanczos calculations, and cause serious numerical instabilities during propagation. In order to avoid these adverse effects, states with badly con-

verged right or left vector residual norms will be discarded in the following band Lanczos calculations.

In Fig. 3, the aforementioned TDCC LiF pump-probe absorption spectrum is compared to TD-EOM-CC spectra from converged states only. Note that the three most dominant peaks in the TDCC spectrum are present in the green spectrum, which is calculated with a valence chain length of 300, but a chain length of 400 is needed in order to converge the short peak at around 9.9 eV. The low amplitude peaks below and around the tall peak at around 6.9 eV are missing.

In an earlier work [28], we speculated that the smaller peaks below 6.9 eV in the pump-only LiF spectrum could originate from two-photon absorption. This claim was later discussed by Pedersen *et al.* [32], where the TDCC state of LiF interacting with the pump pulse was analyzed in terms of stationary state populations. Their analysis supports the interpretation that two photons are absorbed from the pump pulse.

In order to take two-photon absorption into account, spectra are recalculated with the inclusion of valence states energetically accessible by two pump photons and core states accessible by an additional probe photon. The corresponding results obtained with chain lengths of 300 and 400 are shown in purple and red in Fig. 3, respectively. Note that the 300 valence chain length spectrum still lacks the smaller features of the TDCC spectrum, but the 400 valence chain length spectrum is practically indistinguishable from the TDCC one. This similarity corroborates the claim that two photons are absorbed from the pump pulse. Furthermore, the results demonstrate that reduced-basis TD-EOM-CC can faithfully reproduce TDCC results in particular systems, even when nonlinear interactions are involved. The embedded Dormand-Prince 5(4) integrator is seen to perform well for TD-EOM-CC.

The bottom panel of Fig. 3 demonstrates the use of the valence-only CVS projector to calculate the valence states. The approximation seems to improve the rate of convergence with respect to chain length, as a length of 300 is enough to retrieve all the features of the TDCC spectrum while a higher number is necessary in the nonprojected case. This improved convergence can be explained by the reduction in dimension from projecting out transitions from core orbitals. Moreover, since the approximation does not seem to lead to significant scaling or shifting of the valence peaks, it is adopted in the following calculations.

B. Lithium hydride: Applicability of the CVS projectors

To further assess the performance of the proposed procedure, as well as the applicability of the CVS projectors, we use the TD-EOM-CC procedure to model the interaction of the lithium hydride molecule with the pump-probe pair described in Sec. III A of Ref. [28]. Figure 1 illustrates the polarization of the pulses relative to the orientation of the molecule. Li K -edge spectra are notoriously difficult to describe accurately due to the small energy separation between the valence and core excitation regions. This can be considered a challenging test case for the applicability of the core-valence separation scheme.

A comparison between TD-EOM-CC and TDCC spectra is given in Fig. 4, where the latter is taken from Ref. [28]. In all core state calculations a fixed band Lanczos chain length of

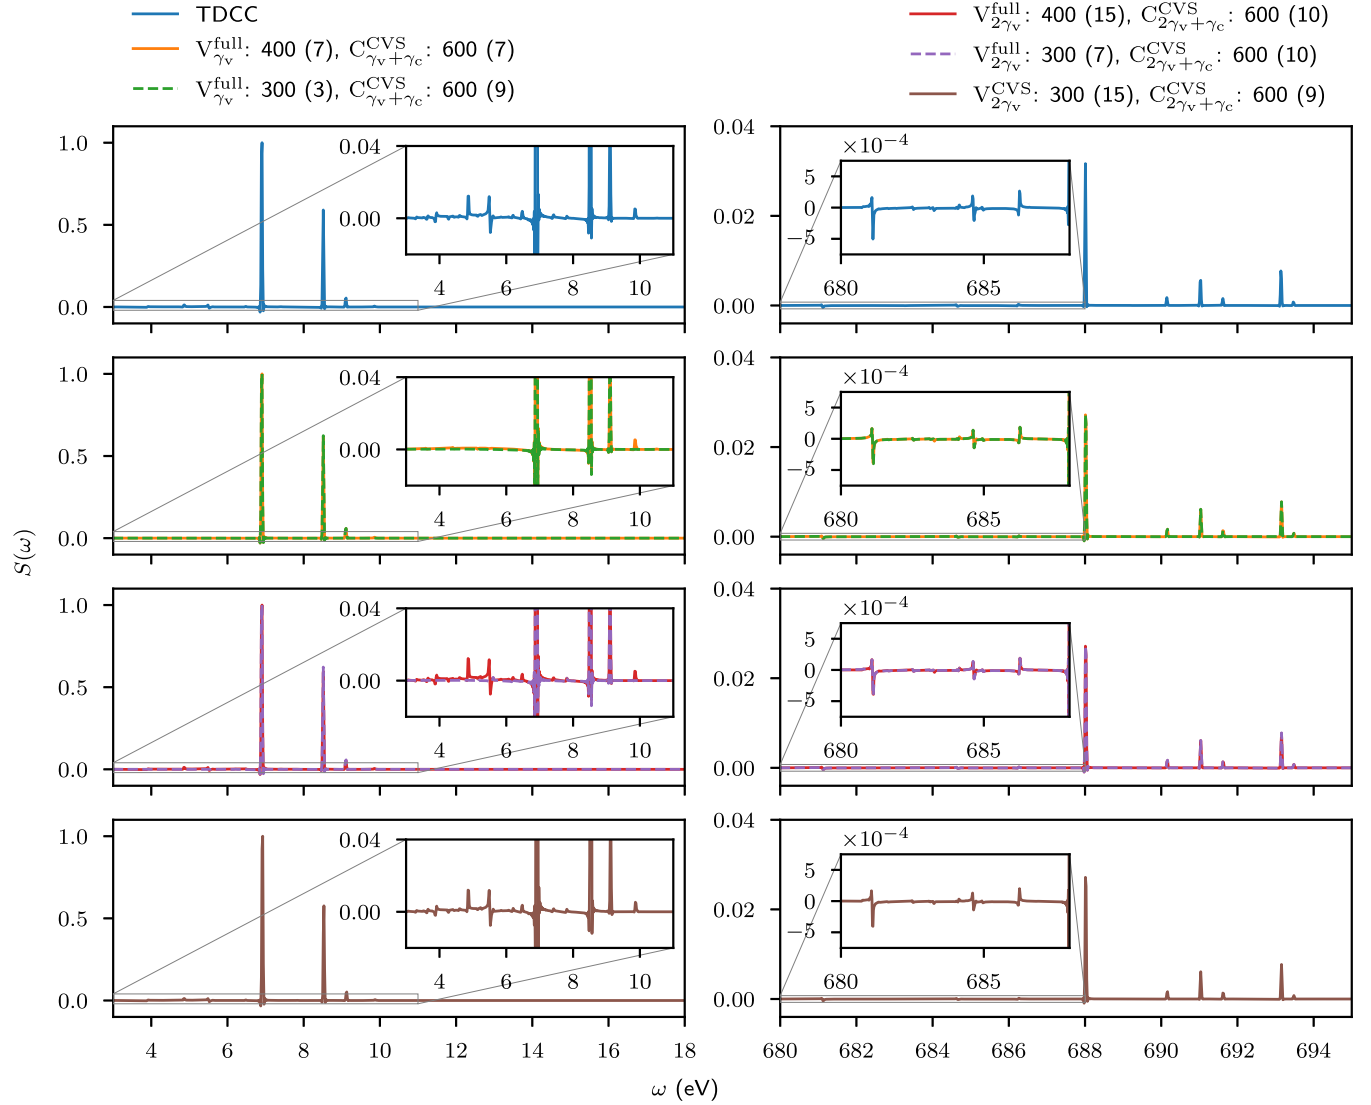

FIG. 3. LiF pump-probe absorption $S(\omega)$ as a function of frequency ω in the valence and core regions, normalized by the tallest peaks in the spectra. The TDCC results are shown in the top left and right panels. TD-EOM-CC results, calculated at different band Lanczos chain lengths, are shown in the lower panels. EOM-CC valence (V) states are calculated in the full projection space (middle panels) or within the CVS approximation (bottom panels), while the core (C) states are calculated within the CVS approximation only. Valence states energetically inaccessible by a single or two pump photons, γ_v or $2\gamma_v$, are discarded, and so are core states energetically inaccessible by subsequent absorption of a probe photon, $\gamma_v + \gamma_c$ or $2\gamma_v + \gamma_c$. The chain lengths of the calculations are given, together with the number of converged states (in brackets).

400 is used. However, the number of converged core states, given in brackets, differs due to the different starting vectors employed.

Since TD-EOM-CC with energy-limited valence and core states successfully reproduced the TDCC spectrum of LiF in Sec. IV A, a similar procedure is attempted for calculating the TD-EOM-CC LiH spectrum. That is, valence states inaccessible by two pump photons and core states inaccessible by an additional probe photon are discarded. The results are shown in orange in the second topmost panels of Fig. 4. The spectrum lacks some of the weaker features in the valence excitation energy region, and, more notably, many of the dominant features in the core excitation region. In other words, a characteristic of the LiH molecule seemingly prevents us from reproducing the TDCC spectrum using the procedure in

the previous section. In the following, we argue that the Li K edge in LiH involves states that cannot be obtained with the core-only CVS projector alone, since they do not correspond to core excitations.

TD-EOM-CC spectra calculated with states obtained with the valence-only CVS projector, energetically accessible by two pump and one probe photons, are shown in the three middle rows of panels in Fig. 4. The valence chain lengths used are 100 (green), 150 (red), and 200 (purple). The number of converged states in the valence region increases with the chain length. Remarkably, increasing the valence chain length also leads to additional peaks in the core region, illustrated in the right panels. This demonstrates that, apart from the two intense peaks obtained at about 54.1 eV and 57.7 eV, the other peaks are of pure valence excitation character.

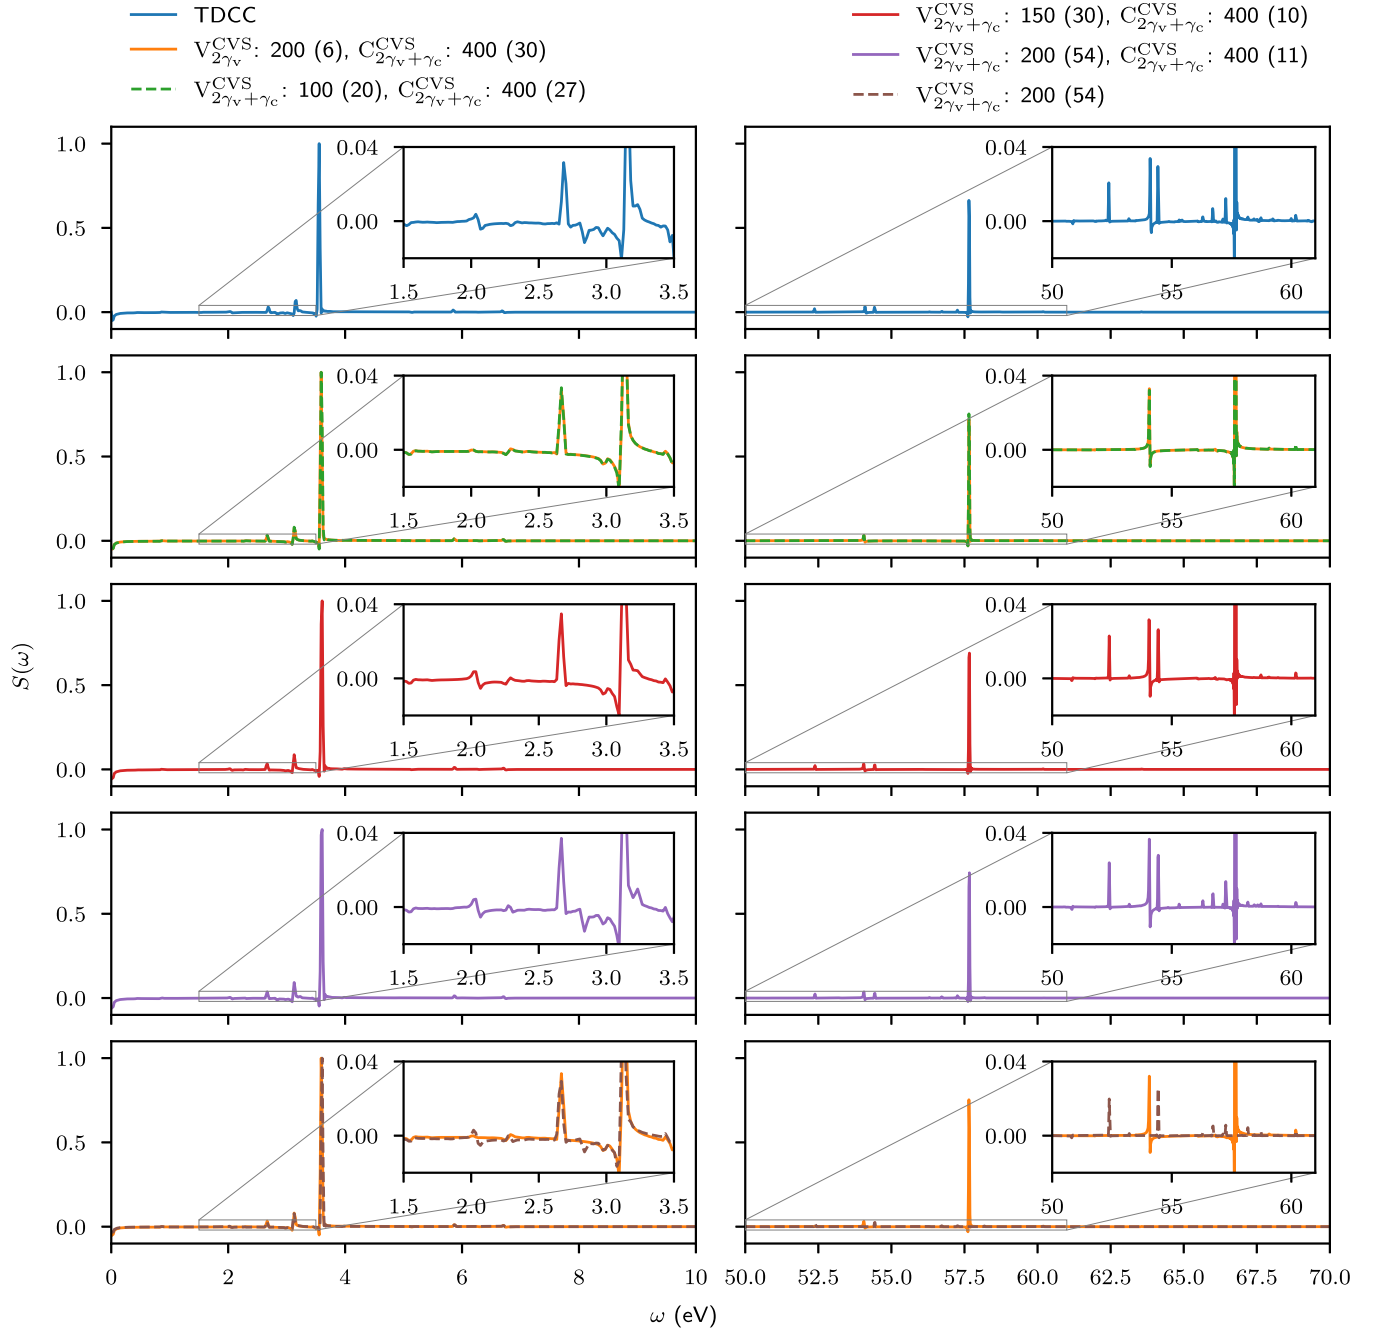

FIG. 4. LiH pump-probe absorption $S(\omega)$ as a function of frequency ω in the valence and core regions, normalized by the tallest peaks in the spectra. The TDCC results are shown in the top left and right panels. TD-EOM-CC results, calculated at different band Lanczos chain lengths, are shown in the lower panels. All EOM-CC valence (V) and core (C) states are calculated within the CVS approximation. For the CVS valence calculation for the results shown in orange, states energetically inaccessible by two pump photons, $2\gamma_v$ are discarded. For all other band Lanczos calculations, only the states inaccessible by two pump photons and one probe photon $2\gamma_v + \gamma_c$ are discarded. The results shown in brown are calculated from CVS valence states only. The chain lengths of the calculations are given, together with the number of converged states (in brackets).

The necessity to include high-energy states calculated with the valence-only CVS projector is further validated by superimposing a spectrum exclusively from valence-only CVS states (brown) with the spectrum calculated from energy-limited valence and core states (orange), shown in the bottom panels of Fig. 4. The peaks of the composite spectrum are in good agreement with the TDCC ones. Therefore, we assert that use of both the core-only and the complementary

valence-only CVS projectors is necessary in order to accurately capture the spectral features around the Li K edge in LiH. Note that this should not be taken as a failure of the CVS projectors, but as a consequence of the peculiar electronic structure of LiH. In fact, the high-energy states of pure valence character can be more easily calculated in the dimension reduced by the valence-only CVS projector. One may still question whether the corresponding peaks will be as

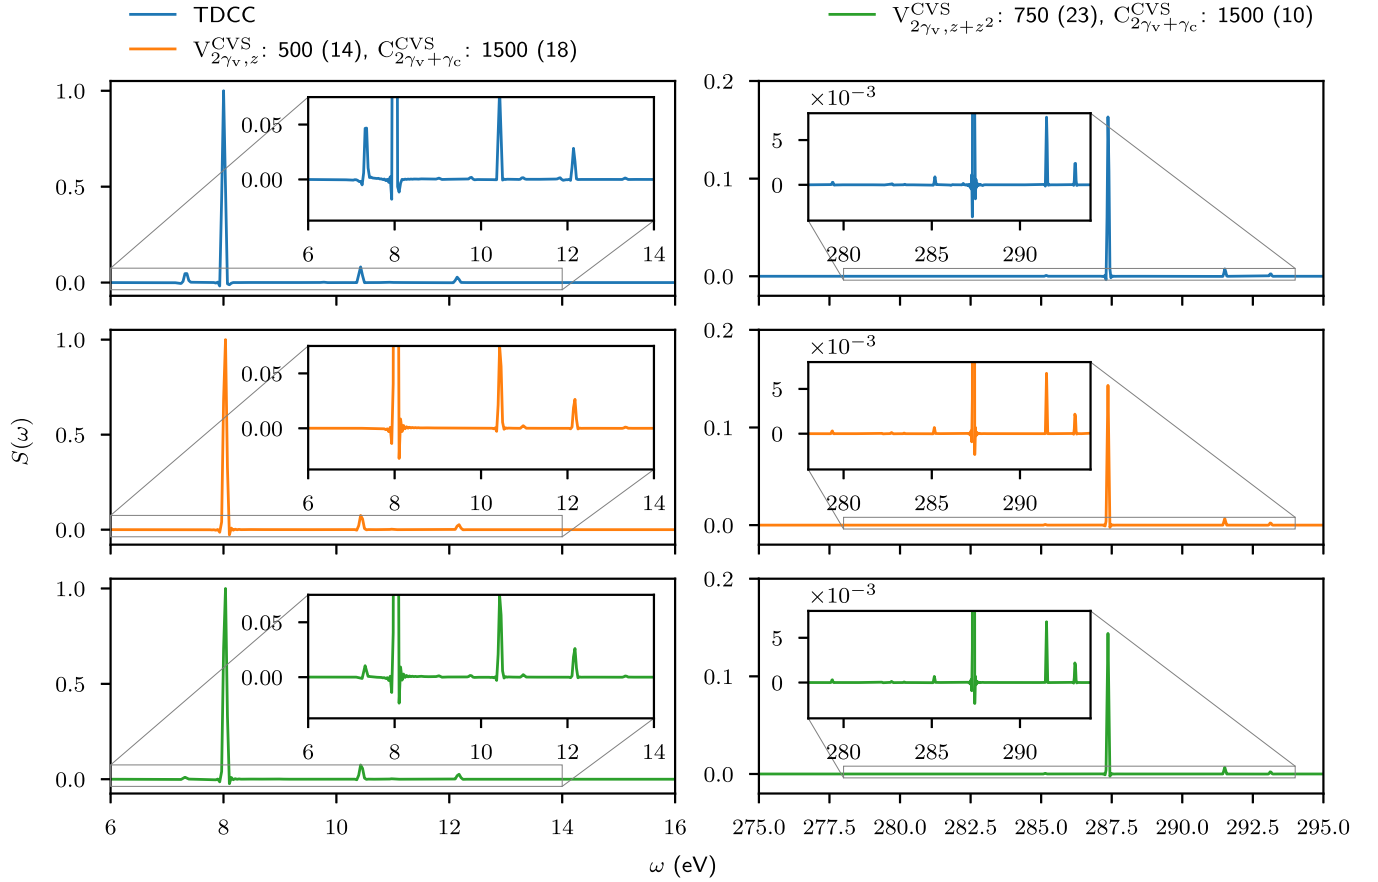

FIG. 5. Ethylene pump-probe absorption $S(\omega)$ as a function of frequency ω in the valence and core regions, normalized by the tallest peaks in the spectra. The TDCC results are shown in the top left and right panels, and TD-EOM-CC results are shown in the lower panels. In the middle panels, a ground-state z dipole operator starting vector is used for calculating the valence (V) states. In the bottom panels, both ground-state z dipole operator and z^2 quadrupole operator starting vectors are used. All valence and core (C) states are calculated within the CVS approximation. The chain lengths of the calculations are given, together with the number of converged states (in brackets).

prominent in experimental spectra, since continuum electrons are very crudely represented in the chosen basis set.

C. Ethylene: Nonlinear pump interaction for a different symmetry group

For ethylene, rms widths of the z -polarized pump and x -polarized probe pulses are set to 10 a.u. and 5 a.u., corresponding to intensity full width at half maximum (FWHM) durations of about 403 as and 201 as, respectively. Figure 1 illustrates the polarization of the pulses relative to the orientation of the molecule. The carrier frequency of the pump pulse is set to 0.294 114 89 a.u. (about 8.0 eV), and the probe pulse is set to 10.495 830 66 a.u. (about 285.6 eV, C K edge). The field strengths of the pump and probe pulses are set to 0.01 a.u. and 0.1 a.u., respectively. The time-dependent state is propagated with the Dormand Prince 5(4) integration scheme, from -2500 a.u. to 2500 a.u. of time. The TDCC spectrum, shown in the top panel Fig. 5, is characterized by four dominant peaks in the valence excitation region. A low amplitude peak at around 7.3 eV is present in the TDCC spectrum, but missing in the TD-EOM-CC spectrum calculated with a z dipole operator starting vector, shown in the middle panels. In accordance with the interpretation of the spectrum of LiF in Sec. IV B, we attribute the missing peak to a two-photon excitation process,

even though valence states energetically accessible by two photons are included. Note that quadratic functions of the z dipole operator belong to the A_g representation of D_{2h} , the point group of ethylene for the chosen geometry. Hence, we should not expect the single starting vector, belonging to the B_{1u} representation, to facilitate the convergence of the two-photon peaks.

In order to mimic the two pump photon absorption process, we include a starting vector constructed from the z^2 quadrupole operator in the valence-state calculation. The results, shown in the bottom panels of Fig. 5, now capture the two-photon peak at around 7.3 eV. The amplitude yielded by TD-EOM-CC is, however, underestimated compared to the TDCC one, which might indicate that more secondary valence excited states should be included in the computation. It might also hint at differences in two-photon absorption as described by TD-EOM-CC and TDCC.

D. Glycine: Transient absorption

As a final example, we use the computational procedure to model attosecond transient absorption by the glycine molecule. The polarization of the pump pulse is set to the polarization of the EOM-CC transition dipole moment between the ground and first dipole allowed valence excited

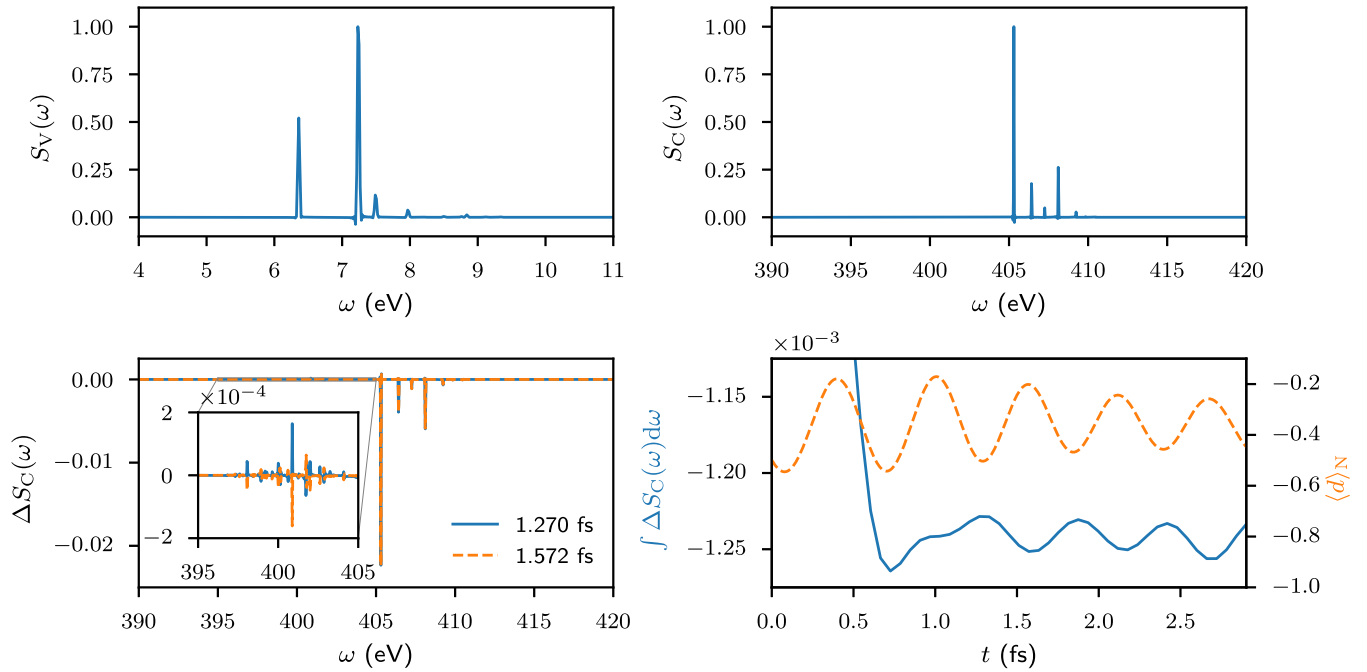

FIG. 6. Glycine. Top left: Pump pulse absorption from the ground state $S_V(\omega)$, normalized by the tallest peak in the spectrum. Top right: Probe pulse absorption from the ground state $S_C(\omega)$, normalized by the tallest peak in the spectrum. Bottom left: Pump-probe absorption minus the probe absorption from the ground state $\Delta S_C(\omega) = S(\omega) - S_C(\omega)$, normalized by the tallest peak in the $S_C(\omega)$ spectrum. The results for two different pump-probe delays are shown. Bottom right: In blue, the numerically integrated probe absorption difference $\int \Delta S_C(\omega) d\omega$ is shown as a function of pump-probe delay. In orange, the dipole induced by the pump pulse in the direction from the center of mass to the N atom, $\langle d \rangle_N$, is shown as a function of time after the center of the pump pulse.

state, $(0.490\,072x + 0.871\,682y)$, which is in the mirror plane of the molecule (xy plane). The probe is z polarized. Figure 1 illustrates the polarization of the pulses relative to the orientation of the molecule. The rms widths of the pump and probe pulses are set to 20 a.u. and 10 a.u., corresponding to intensity FWHM durations of about 806 as and 403 as, respectively. The carrier frequency of the pump pulse is set to $0.233\,683\,25$ a.u. (about 6.4 eV), and the probe pulse is set to $14.894\,573\,19$ a.u. (about 405.3 eV, N K edge). The field strengths of the pump and probe pulses are set to 0.01 a.u. and 0.1 a.u., respectively. The time-dependent state is propagated with the Dormand Prince 5(4) integration scheme, from -5000 a.u. to 5000 a.u. of time.

A single band Lanczos calculation is used for constructing the valence states, where states energetically inaccessible by two-photon transitions are discarded. Note that we do not need to use quadrupole operators in order to get two-photon valence states of glycine in the reduced basis, as otherwise done for the ethylene valence states, since both linear and quadratic functions of x and y dipole operators belong to the A' representation of C_s . A valence-state calculation, with ground-state starting vectors and a chain length of 1500, gives 17 converged states. A subsequent core state calculation, with ground- and valence-state starting vectors and a chain length of 3000, gives 20 converged states.

As a note of caution, all the converged valence states have energies below 10.5 eV, which is below the double frequency of the carrier photons. This indicates that two-photon absorption is not properly accounted for by the reduced basis, and

nonlinear features involving higher-energy valence states may be missing in the spectra.

In the top left panel of Fig. 6, the absorption of the pump pulse is shown as a function of frequency. Even though the glycine molecule is substantially larger than the other molecules considered, the spectrum is still dominated by a small number of peaks. The number of dominant peaks is also smaller than the number of converged states in the basis ($=17$). The spectrum of the absorption of the probe pulse by the ground state, shown in the top right panel, also has fewer dominant peaks than the number of converged states ($=20$).

In order to calculate the transient absorption of the probe pulse by the glycine molecule, absorption spectra are calculated with the pump-probe setup used for the other molecules, with pump-probe delays varying from 0 a.u. to 120 a.u. (about 2.903 fs) in intervals of 2.5 a.u. The reduced basis energies and dipole matrix elements do not have to be recalculated between the different TD-EOM-CC calculations, since these are independent of the pump-probe delay. Difference spectra are then calculated by subtracting the ground-state probe absorption spectrum from the pump-probe absorption spectra, before normalizing by the tallest peak in the ground-state probe spectrum. In the bottom left panel, the difference spectra at 52.5 a.u. and 65 a.u. (about 1.270 fs and 1.572 fs) are shown in blue and orange, respectively. Both spectra are dominated by negative peaks, indicative of ground-state bleaching. In addition, the spectra vary slightly with pump-probe delay, which is particularly visible for the peaks that are not energetically accessible from the ground state, e.g., in the energy range from 395 eV to 405 eV shown in the inset.

In order to quantify the delay-dependent difference in the absorption of the full probe pulse, each of the 49 pump-probe difference spectra are numerically integrated from 390 eV to 420 eV using the trapezoidal rule. The results are shown as function of pump-probe delay in the bottom right panel of Fig. 6, in blue. Note that the absorption difference is smaller for short pump-probe delays, which can be explained by the fact that ground-state bleaching happens gradually during the pump pulse interaction. A shorter pump-probe delay implies that the molecule is probed while bleaching still occurs, which can lead to a smaller difference between the pump-probe absorption and the ground-state probe absorption.

We have also calculated the pump-induced time-dependent dipole moment in the direction from the center of mass to the center of the N atom, as a way of quantifying the migration of charge between the end containing the N atom and the opposite end of the molecule. The dipole moment is shown in the bottom right panel of Fig. 6, in orange.

Note that the dominant periods of both the time-dependent dipole moment and the integrated absorption (after 1 fs), shown in the bottom right panel of Fig. 6, fall within 0.57(4) fs. This indicates that the pump-induced TD-EOM-CC state is a coherent superposition dominated by states with energy differences of 7.3(6) eV, which is in agreement with the ground-state pump absorption spectrum (top left). It also indicates that the dominant features of the time-dependent charge migration and the delay-dependent *K*-edge absorption are correlated and can be measured with phase-controlled pulses with finite duration, as has previously been demonstrated for instantaneous pulses [55,56].

V. CONCLUSION

We have demonstrated the use of the asymmetric band Lanczos algorithm to generate reduced TD-EOM-CC bases for various molecules, taking the characteristics of pulses suitable for probing attosecond phenomena into account. The specific starting vectors used in the calculations direct the band Lanczos algorithm towards states that are useful for representing the interactions. The starting vectors also allow for the affordable calculation of transition strengths, which are used, together with excitation energies, to automatically select the reduced basis. The basis is further reduced by removing unconverged states.

In Sec. IV A, we demonstrated how lithium fluoride spectral peaks can converge towards peaks calculated with TDCC by increasing the band Lanczos chain length and taking a sufficient number of relevant states into account. In particular, we showed that two-photon absorption has to be taken into account in order to reproduce the smaller features of the TDCC spectrum, as speculated in Ref. [28].

In Sec. IV B, we demonstrated that the core-only CVS projector eliminates several of the peaks around the *K* edge of lithium in lithium hydride. The missing peaks can be captured with the complementary valence-only CVS projector, which enabled us to target high-energy states of pure valence character. This observation indicates that care should be taken when the CVS scheme is used for light elements such as lithium, where the energy separation of the core and valence orbitals is small, so that pure valence excitations can fall within the region of core excitations.

In Sec. IV C, we used starting vectors constructed from both dipole and quadrupole operators, in order to converge ethylene valence states that are dark with respect to one-photon transitions from the ground state.

In Sec. IV D, pump and probe pulses with varying time delays were used to assess the transient absorption of a *K*-edge probe pulse as a function of pump-probe delay. We showed how the transient absorption seems to correlate with the migration of charge induced by the pump, and how both quantities seem to reveal the dominant timescale in the coherent superposition.

ACKNOWLEDGMENTS

We acknowledge Sarai D. Folkestad for her role in implementing the simple Lanczos algorithm and density-based excited-state transition moments, available in the *e^T* program, which served as precursors to the implementations here. We acknowledge financial support from The Research Council of Norway through FRINATEK Projects No. 263110 and No. 275506; from the Marie Skłodowska-Curie European Training Network Computational Spectroscopy in Natural Sciences and Engineering, Grant No. 765739; and from the Independent Research Fund Denmark, DFF-FNU Research Project 2, Grant No. 7014-00258B. Computing resources through UNINETT Sigma2 at the National Infrastructure for High Performance Computing and Data Storage in Norway (Project No. NN2962k) and through the Center for High Performance Computing at SNS are also acknowledged. Finally, COST Action Grant No. CA18222, AttoChem, is acknowledged.

S.C. and H.K. conceptualized and supervised the project. T.M., S.C., and A.S.S. implemented and optimized the band Lanczos solver. A.B. and A.S.S. did the initial TDCC implementation, and A.S.S. did the TD-EOM-CC extension. A.C.P. implemented procedures for calculating eigenstates and matrix elements of combined sets of EOM-CC states. A.S.S. and T.M. carried out the calculations. All authors contributed to the interpretation of the results and the writing of the paper.

APPENDIX A: REWRITING EOM-CC MATRIX ELEMENT EXPRESSIONS

The matrix element X_{ij} of the operator X and the left and right vectors of EOM-CC states i and j , respectively, can be written as

$$\begin{aligned}
 X_{ij} &= \langle \tilde{\psi}_i | X | \psi_j \rangle \\
 &= \sum_{\kappa\lambda} l_{i\kappa} \langle \kappa | \tilde{X} | \lambda \rangle r_{\lambda j} \\
 &= \sum_v l_{i0} \langle \text{HF} | \tilde{X} | v \rangle r_{vj} + \sum_{\mu v} l_{i\mu} \langle \mu | \tilde{X} | v \rangle r_{vj} \\
 &\quad + \left(l_{i0} X_{00} + \sum_{\mu} l_{i\mu} \tilde{\epsilon}_{\mu}^X \right) r_{0j} \\
 &= \sum_v l_{i0} \langle \text{HF} | [\tilde{X}, \tau_v] | \text{HF} \rangle r_{vj}
 \end{aligned}$$

$$\begin{aligned}
& + \sum_{\mu\nu} l_{i\mu} \left({}^{\text{LR}}A_{\mu\nu}^X + \langle \mu | \tau_\nu \bar{X} | \text{HF} \rangle \right) r_{\nu j} \\
& + \left(l_{i0} X_{00} + \sum_{\mu} l_{i\mu} \xi_{\mu}^X \right) r_{0j}, \tag{A1}
\end{aligned}$$

where

$$A_{\mu\nu}^{\text{LR}X} = \langle \mu | [\bar{X}, \tau_\nu] | \text{HF} \rangle, \quad (\text{A2})$$

$$X_{00} = \langle \text{HF} | \bar{X} | \text{HF} \rangle, \quad (\text{A3})$$

$$\xi_{\mu}^X = \langle \mu | \bar{X} | \text{HF} \rangle. \quad (\text{A4})$$

1. Excited-state left and ground-state right vectors

The left vector of excited state m has the reference component $l_{m0} = 0$ [see Eq. (23)], while the right vector of the ground state has components $r_{00} = 1$ and $r_{v0} = 0$ [see Eq. (18)]. Inserting this into Eq. (A1), we obtain

$$X_{m0} = \sum_{\mu} l_{m\mu} \xi_{\mu}^X, \quad (\text{A5})$$

which is also the expression appearing in CC response theory [42]. Note that this expression is linear in the excited determinant components $l_{m\mu}$.

2. Ground-state left and excited-state right vectors

The left vector of the ground state has the components $l_{00} = 1$ and $l_{0\mu} = \bar{t}_\mu$ [see Eq. (19)], while the right vector of excited state n has the reference component $r_{0n} = -\sum_\nu \bar{t}_\nu r_{\nu n}$ [see Eq. (22)]. Inserting this into Eq. (A1), we obtain

$$X_{0n} = \sum_v \left(\text{LR} \eta_v + \sum_\mu \bar{t}_\mu \langle \mu | \tau_v \bar{X} | \text{HF} \rangle \right) r_{vn} - \left(X_{00} + \sum_\mu \bar{t}_\mu \xi_\mu^X \right) \sum_v \bar{t}_v r_{vn}, \quad (\text{A6})$$

where

$${}^{\text{LR}}\eta_v = \langle \text{HF}[\tilde{X}, \tau_v] \text{HF} \rangle + \sum_{\mu} \bar{t}_{\mu} {}^{\text{LR}}A_{\mu v}^X. \quad (\text{A7})$$

The term $\sum_v \text{LR} \eta_v r_{vn}$ appears in CC response theory [42], and the other terms are specific to EOM-CC. Equation (A6) is equivalent to Eq. (65) in Ref. [57] and can also be written as

$$X_{0n} = \sum_v (\text{EOM} \eta_v^X - X_{00} \bar{t}_v) r_{vn}, \quad (\text{A8})$$

where

$$\text{EOM}_{\eta_v}^X = \text{LR}_{\eta_v}^X + \sum_{\mu} \bar{t}_{\mu} \langle \mu | \tau_v \bar{X} | \text{HF} \rangle - \left(\sum_{\mu} \bar{t}_{\mu} \xi_{\mu}^X \right) \bar{t}_v \quad (\text{A9})$$

[see Eq. (18) of Ref. [58]]. Note that Eq. (A8) is linear in the excited determinant components $r_{\nu n}$.

3. Excited-state left and right vectors

The left vector of excited state m has the reference component $l_{m0} = 0$, while the right vector of excited state n has $r_{0n} = -\sum_v \tilde{t}_v r_{vn}$ [see Eqs. (22) and (23)]. Inserting this into Eq. (A1), we obtain

$$\begin{aligned}
X_{mn} &= \sum_{\mu\nu} l_{m\mu} (\text{LR}A_{\mu\nu}^X + \langle \mu | \tau_\nu \bar{X} | \text{HF} \rangle) r_{\nu n} \\
&\quad - \sum_{\mu} l_{m\mu} \xi_{\mu}^X \sum_{\nu} \bar{t}_{\nu} r_{\nu n} \\
&= \sum_{\mu\nu} l_{m\mu} (\text{LR}A_{\mu\nu}^X + \langle \mu | \tau_\nu \bar{X} | \text{HF} \rangle - \xi_{\mu}^X \bar{t}_{\nu}) r_{\nu n} \\
&= \sum_{\mu\nu} l_{m\mu} (\text{EOM}A_{\mu\nu}^X + \delta_{\mu\nu} X_{00} - \xi_{\mu}^X \bar{t}_{\nu}) r_{\nu n}, \quad (\text{A10})
\end{aligned}$$

where

$$\begin{aligned} \text{EOM}A_{\mu\nu}^X &= \langle \mu | \bar{X} | \nu \rangle - \delta_{\mu\nu} X_{00} \\ &= \text{LRA}_{\mu\nu}^X + \langle \mu | \tau_\nu \bar{X} | \text{HF} \rangle - \delta_{\mu\nu} X_{00} \end{aligned} \quad (\text{A11})$$

[see Eq. (20) in Ref. [58]].

The term $\sum_{\mu\nu} l_{\mu\nu} \text{LR}^X_{\mu\nu} r_{\nu n}$ appears in CC response theory, and the other terms are specific to EOM-CC [44,58]. Note that all matrix elements in Eq. (A10) are linear in both $l_{\mu\nu}$ and $r_{\nu n}$.

APPENDIX B: INTEGRATION SCHEME

In order to limit the error of the time-dependent results, the integration of the TDCC and TD-EOM-CC equations is done with the embedded Dormand-Prince method of order 5(4) [53]. This method yields both fourth- and fifth-order accurate solutions at each time step, and is specified by the Butcher tableau [53,59]

0						
$\frac{1}{5}$	$\frac{1}{5}$					
$\frac{3}{10}$	$\frac{3}{40}$	$\frac{9}{40}$				
$\frac{4}{5}$	$\frac{44}{45}$	$-\frac{56}{15}$	$\frac{32}{9}$			
$\frac{8}{9}$	$\frac{19372}{6561}$	$-\frac{25360}{2187}$	$\frac{64448}{6561}$	$-\frac{212}{729}$		(B1)
1	$\frac{9017}{3168}$	$-\frac{355}{33}$	$\frac{46732}{5247}$	$\frac{49}{176}$	$-\frac{5103}{18656}$	
1	$\frac{35}{384}$	0	$\frac{500}{1113}$	$\frac{125}{192}$	$-\frac{2187}{6784}$	$\frac{11}{84}$
	$\frac{35}{384}$	0	$\frac{500}{1113}$	$\frac{125}{192}$	$-\frac{2187}{6784}$	$\frac{11}{84}$
	$\frac{5179}{57600}$	0	$\frac{7571}{16695}$	$\frac{393}{640}$	$-\frac{92097}{339200}$	$\frac{187}{2100} \quad \frac{1}{40}$

where the next-to-last and last rows give the coefficients of the fifth- and fourth-order solutions, respectively. Although the method has seven stages, its *first same as last* property assures that only six function evaluations are needed per time step.

The Euclidean distance between the solutions gives a fourth-order estimate of the local integration error:

$$\epsilon_{O(4)} = ||\mathbf{y}_{O(5)} - \mathbf{y}_{O(4)}||_2. \quad (\text{B2})$$

This local error estimate is kept below a given maximum value by adapting the time step during the integration. The fifth-order solution is accepted as the solution at the beginning of the next step whenever the error estimate satisfies this condition.

The following adaptive time-stepping scheme was designed, implemented, and used together with the Dormand-Prince 5(4) method for the relevant calculations in Sec. IV. At the start of the integration, the step size is set to a given maximum value. During the integration, the variable step size is halved, and the integration step redone, whenever the error estimate exceeds the given maximum error. After a successful integration step, the step size is doubled whenever the error

estimate is below a given minimum value, provided that the doubled step size is smaller than the maximum step size and also a submultiple of the elapsed time. This is in order to increase the efficiency of the integration while ensuring that the solution is evaluated at times corresponding to integer increments of the maximum time-step size. Evaluation of time-dependent observables is done using the solutions at these integer increments.
