                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | -0.15<br>-<br>-0.15<br>-<br>-<br>-<br>-<br>-<br>-<br>-<br>-<br>-<br>-<br>-<br>-<br>-                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          | 1.00<br>•<br>1.00<br>•<br>1.00<br>•<br>1.00<br>•<br>1.00<br>•<br>1.00<br>•<br>1.00<br>•<br>1.00<br>•<br>1.00<br>•<br>1.00<br>•<br>1.00<br>•<br>1.00<br>•<br>•<br>1.00<br>•<br>•<br>•<br>•<br>•<br>•<br>•<br>•<br>•<br>•<br>•<br>•<br>•                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

(a)  $MN_4C_{10}$ :  $\Delta G_R(pH = 7, -0.80 V_{SHE}) / eV$ 

**Figure 4.6:**  $\Delta G_R$  of the most stable adsorbate on  $MN_4$  site in 0.1 M electrolytes at pH = 7, U = -0.80 V\_{SHE}: (a)  $MN_4C_{10}$ , (b)  $MN_4C_A$ . The inserted text indicates the most stable adsorbate on the metal site and its corresponding  $\Delta G_R$  in eV. The background color corresponds to the  $\Delta G_R$  value. The brighter the background color, the more stable it is against the dissolution.

Furthermore, a series of M/N/C catalysts (M =  $Mn^{3+}$ ,  $Fe^{3+}$ ,  $Co^{2+}$ ,  $Ni^{2+}$ ,  $Cu^{2+}$ ,  $Zn^{2+}$ , and  $Sn^{2+}$ ) has been synthesized and evaluated for the CO<sub>2</sub> reduction in 0.5 M KHCO<sub>3</sub> + 0.5 M K<sub>2</sub>SO<sub>4</sub> [141]. The Cu/N/C catalyst has been found to produce hydrocarbon products with significant amounts, which correlates with a partial reduction of Cu<sup>2+</sup> to Cu<sup>0</sup> and a partial demetallation of the CuN<sub>4</sub> site. According to our calculation at CO<sub>2</sub>RR condition in 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO, both the CuN<sub>4</sub> and the MnN<sub>4</sub> sites on both bulk graphene and the graphene edge have a relatively higher thermodynamic driving force toward the dissolution than other metal elements considered in the experiment. Our calculation results for the CuN<sub>4</sub> site agree with the experiment [141].

#### 4.8 $CO_2$ **RR** Activity

Similar to the ORR mechanism with the electrolyte anion ligand on the back side of the metal atom, the following mechanism for CO<sub>2</sub> to CO formation is considered.

$$^{*}A/^{*}A + ne^{-} \rightarrow^{*}/^{*}A + A^{n-}$$

$$CO_{2} + H^{+} + e^{-} + ^{*}/^{*}A \rightarrow^{*} COOH/^{*}A$$

$$^{*}COOH/^{*}A + H^{+} + e^{-} \rightarrow^{*} CO/^{*}A + H_{2}O$$

$$^{*}CO/^{*}A \rightarrow^{*}/^{*}A + CO$$

At any considered pH and  $U_{SHE}$ , the reaction free energy of the consecutive step along the CO<sub>2</sub> to CO can be expressed as

$$\Delta G_0(U_{\text{SHE}}, \text{pH}) = \Delta G(^* \text{A}^{n-} / ^* \text{A})$$
(4.21)

$$\Delta G_1(U_{SHE}, pH) = G(*COOH/*A) - G(*/*A) - G(CO_2)$$
(4.22)

$$-\frac{1}{2}G(H_2) - \Delta G_e - \Delta G_H \tag{4.22}$$

$$\Delta G_{2}(U_{SHE}, pH) = G(^{*}CO/^{*}A) + G(H_{2}O) - G(^{*}COOH/^{*}A) - \frac{1}{2}G(H_{2}) - \Delta G_{e} - \Delta G_{H}$$
(4.23)

$$\Delta G_3(U_{SHE}, pH) = G(*/*A) + G(CO) - G(*CO/*A)$$
(4.24)

It should be noted that G(CO) and G(CO<sub>2</sub>), which are the free energy of CO and CO<sub>2</sub> gas molecule, are corrected by 0.15 eV and 0.30 eV, respectively, considering for the systematic DFT errors originated from an inaccurate description of C=O double bond [115]. The possible electrolyte anion participating in the CO<sub>2</sub>RR is the most stable adsorbate at pH = 7 and U = -0.8 V<sub>SHE</sub>. The catalytic activity is also considered at this condition by calculating the thermodynamic barrier of the limiting step.

As an example, the free energy diagrams of the CO<sub>2</sub>RR to CO for some  $MN_4C_{10}$  structures (M = Mn, Fe, Co, Ni, Cu, Zn and Sn) in 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO solution are given in Figure 4.7 (a). At pH = 7, U = -0.80 V<sub>SHE</sub>, the \*CO is more stable than water on the MnN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>10</sub>, CoN<sub>4</sub>C<sub>10</sub> structure. At the same time, the \*HCO<sub>3</sub> is the most stable adsorbate on the ZnN<sub>4</sub>C<sub>10</sub> structure but there is no adsorbate on the

NiN<sub>4</sub>C<sub>10</sub>, CuN<sub>4</sub>C<sub>10</sub> and SnN<sub>4</sub>C<sub>10</sub> structures. It is found that the ligands are not thermodynamically favorable on both sides of the metal atom. Thus the other side of the metal atom is available for the reaction intermediate. The CO<sub>2</sub>RR on the considered MN<sub>4</sub>C<sub>10</sub> structure in 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO solution at pH = 7 and U = -0.8 V<sub>SHE</sub> is limited by the reduction of CO<sub>2</sub> to \*COOH which is the change from the reaction state 1 to 2 in Figure 4.7 (a). Thus, the thermodynamic barrier of the limiting step is the energy barrier for reducing CO<sub>2</sub> to \*COOH. Under the same condition, the ligand atom on the considered MN<sub>4</sub>C<sub>A</sub> structures is slightly different. However, the thermodynamic barrier of the limiting step is still the energy barrier for the reduction of CO<sub>2</sub> to \*COOH, as shown in Figure 4.7 (b).

**Figure 4.7:** Free energy diagram of the CO<sub>2</sub>RR to CO at pH = 7, U = -0.80 V<sub>SHE</sub> on: (a)  $MN_4C_{10}$ , (b)  $MN_4C_A$  in 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO solution, where M = Mn, Fe, Co, Ni, Zn, Cu and Sn. The ligand on the back side of the metal atom is the most adsorbate at pH = 7, U = -0.80 V<sub>SHE</sub>. The insets show the side view of the \*COOH/\*CO and \*CO/\*CO on the FeN<sub>4</sub> site. (C = gray, N = blue, H = white, O = red, Fe = orange).

Further comparison between the calculation results and the experiments [139, 141] is shown in Figure 4.8 (a). An experimental study by Ju *et al.* [139] has evaluated the electrochemical performance of the M/N/C catalyst (M = Mn, Fe, Co, Ni, and Cu) for CO<sub>2</sub> to CO formation and reported the order of the onset potential in 0.1 M KHCO<sub>3</sub> as follows: Co (-0.36 V<sub>RHE</sub>) > Fe (-0.37 V<sub>RHE</sub>) > Mn (-0.41 V<sub>RHE</sub>) > Cu (-0.52

 $V_{RHE}$  ) > Ni (-0.36  $V_{RHE}$  ). Their theoretical results have suggested that the potentialdetermining step on these M/N/C catalysts is the first proton-coupled electron transfer reduction of CO<sub>2</sub> to \*COOH [139]. The experimental onset potentials reported by Ju *et al.* [139] are marked with red stars in Figure 4.8 and use the y-axis on the right.

Based on the  $MN_4C_{10}$  structure in 0.1 M H<sub>2</sub>CO<sub>3</sub> with CO, we find the thermodynamic barrier of the limiting step at U = -0.80 V<sub>SHE</sub> and pH = 7 in the following order: Co (0.46 eV) < Fe (0.59 eV) < Mn (0.70 eV) < Cu (0.79 eV) < Ni (1.16 eV), agreeing with the onset potential order reported by Ju *et al.* [139]. For the  $MN_4C_A$  structure in 0.1 M H<sub>2</sub>CO<sub>3</sub> with CO, the thermodynamic barrier of the limiting step at the same condition is in the following order: Fe (0.67 eV) < Mn (0.70 eV) < Cu (0.94 eV) < Co (0.95 eV) < Ni (1.21 eV), deviating from the experimental trend.

**Figure 4.8:** Comparison the onset potentials from the experiments [139, 141] and calculated  $\Delta G_{max}$  for the CO<sub>2</sub>RR to CO on MN<sub>4</sub>C<sub>10</sub> (circle) and MN<sub>4</sub>C<sub>A</sub> (square) with M = Mn, Fe, Co, Ni, Cu, Zn, and Sn at pH = 7: (a) U = -0.8 V<sub>SHE</sub> and (b) U = -1.0 V<sub>SHE</sub>. The ligand on the back side of the metal atom is the most stable adsorbate at pH = 7: (a) U = -0.8 V<sub>SHE</sub> and (b) U = -1.0 V<sub>SHE</sub>.

Recently, Li *et al.* [140] have synthesized and evaluated the activity toward CO formation in 0.1 M KHCO<sub>3</sub> for the M/N/C catalysts with M = Mn, Fe, Co, Ni, and Cu. They have reported the following order of CO partial current density at U =  $-0.6 V_{RHE}$ : Co > Fe > Ni > Cu > Mn. The thermodynamic barrier order obtained from the MN<sub>4</sub>C<sub>10</sub> structure agrees with this experimental results only for the relative order between Co, Fe, and Mn.

In another experimental study by Paul *et al.* [141], the M/N/C catalyst with M = Mn, Fe, Co, Ni, Cu, Zn, and Sn was synthesized and evaluated the performance of the CO<sub>2</sub>RR in gas diffusion electrodes. The experimental onset potential for the CO formation in 0.5 M KHCO<sub>3</sub> + 0.5 M K<sub>2</sub>SO<sub>4</sub> at pH = 7.5 has been reported in the following order: Fe (-0.27 V<sub>RHE</sub>) > Co (-0.35 V<sub>RHE</sub>) > Mn (-0.36 V<sub>RHE</sub>) > Cu (-0.46 V<sub>RHE</sub>) > Ni (-0.56 V<sub>RHE</sub>) > Zn (-0.83 V<sub>RHE</sub>) > Sn (-0.92 V<sub>RHE</sub>). The onset potentials reported by Paul *et al.* [141] are marked with blue stars in Figure 4.8. Our thermodynamic barriers calculated from the MN<sub>4</sub>C<sub>10</sub> and MN<sub>4</sub>C<sub>A</sub> structures in 0.1 M H<sub>2</sub>CO<sub>3</sub> with CO do not give the same order as this experiment.

It should be noted that other possible sites with different coordination environments [160–162] could be involved in the catalytic process and that the distribution of active sites could be different in each experiment, depending on the synthesis process. Also, the onset potential in each experiment is defined differently. Furthermore, it is assumed that the CO<sub>2</sub>RR to CO in the experiments is limited by the reduction of CO<sub>2</sub> to \*COOH step, same as in our calculation results.

On top of that, the ligand is defined as the most stable adsorbate at U = -0.8 V<sub>SHE</sub> and pH = 7. The most stable ligand could be different when the potential slightly deviates from U = -0.8 V<sub>SHE</sub> on some metal sites, i.e., the CoN<sub>4</sub>C<sub>10</sub> site. The thermodynamic barrier of the limiting step on the metal site in 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO at U = -1.0 V<sub>SHE</sub> and pH = 7 is shown in Figure 4.8 (b). The most stable adsorbate at U = -1.0 V<sub>SHE</sub> and pH = 7 is considered to be a ligand on the back side of the metal site. At this condition, most of the considered MN<sub>4</sub>C<sub>10</sub> sites still have the same ligand, except on the CoN<sub>4</sub>C<sub>10</sub> site where the ligand is now \*H. For the MN<sub>4</sub>C<sub>10</sub> structure, the limiting step is still the reduction of CO<sub>2</sub> to \*COOH as shown in Figure B.8 (a) of Appendix B. The thermodynamic barrier is in the following order: Fe < Mn < Co < Cu < Ni < Sn < Zn. The most active site is shifted from the CoN<sub>4</sub>C<sub>10</sub> to FeN<sub>4</sub>C<sub>10</sub> site. Still, this order is slightly different from the experimental trend reported by Paul *et al.* [141]. For the MN<sub>4</sub>C<sub>A</sub> structures at U = -1.0 V<sub>SHE</sub>, pH = 7, we find the same order of thermodynamic barrier as the MN<sub>4</sub>C<sub>10</sub> structures.

It should be noted that the oxidation state on the single metal atom in the pristine  $MN_4$  structure is considered to be 2+. Our calculations give a relatively high thermodynamic barrier for the NiN<sub>4</sub> site on both bulk graphene and graphene edge, compared to the FeN<sub>4</sub> site. While the Fe/N/C and particularly Ni/N/C catalyst have been suggested as a highly promising catalyst for selective CO production [139–141]. One possible explanation is that the Ni<sup>2+</sup>N<sub>4</sub> site is not active for the CO<sub>2</sub>RR. According to a previous study by Li *et al.* [140], the Ni<sup>1+</sup>N<sub>4</sub>C<sub>10</sub> site binds CO<sub>2</sub> more strongly than the Ni<sup>2+</sup>N<sub>4</sub>C<sub>10</sub> site, resulting in a higher activity toward CO formation for Ni<sup>1+</sup>N<sub>4</sub>C<sub>10</sub> than

the Ni<sup>2+</sup>N<sub>4</sub>C<sub>10</sub> site. In fact, by the DFT calculations, they have found that the Ni<sup>1+</sup>N<sub>4</sub> site has the highest activity among considered MN<sub>4</sub> sites in their study where M =  $Mn^{2+}(*O)$ , Fe<sup>2+</sup> (\*H<sub>2</sub>O), Co<sup>2+</sup> (\*H<sub>2</sub>O), Ni<sup>1+</sup>, and Cu<sup>2+</sup>. The letter in parentheses is the ligand considered in their study [140].

The local environment could also influence the catalytic activity. According to a previous study by Yang *et al.*, the NiN<sub>3</sub> site has been found to be more active for the  $CO_2RR$  than the NiN<sub>4</sub> site [161]. Furthermore, it has been suggested that the NiN<sub>4</sub> site has a weaker binding to \*H than the CoN<sub>4</sub> site, making the hydrogen evolution reaction (HER) unfavorable for the Ni/N/C catalyst compared to the Co/N/C catalyst. Also, the CO selectivity is higher for the Ni/N/C catalyst than the Co/N/C catalyst [139]. According to Figure B.8 in Appendix B, the binding energy of \*H on the NiN<sub>4</sub> site is weaker than that on the CoN<sub>4</sub> site. Thus the NiN<sub>4</sub> sites in this study are also expected to have higher selectivity toward CO formation than the CoN<sub>4</sub> sites.

The  $\Delta G_{max}$  along the CO<sub>2</sub>RR to CO path at pH = 7, U = -0.80 V<sub>SHE</sub> is shown in Figure B.9. It is seen that the two NO gas molecules can be adsorbed on both sides of IrN<sub>4</sub>C<sub>x=10,A</sub> and ReN<sub>4</sub>C<sub>A</sub> structure. In 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO + NO solution at pH = 7 and U = -0.8 V<sub>SHE</sub>, the thermodynamic barrier of the limiting step is the energy to remove one \*NO plus the energy to form \*COOH on theses metal site. Similarly, the two CO gas molecules can be adsorbed on both sites of ReN<sub>4</sub>C<sub>x=10,A</sub>, OsN<sub>4</sub>C<sub>x=10,A</sub>, RuN<sub>4</sub>C<sub>A</sub>, and WN<sub>4</sub>C<sub>A</sub> structure. In 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO solution at pH = 7 and U = -0.8 V<sub>SHE</sub>, the thermodynamic barrier of the limiting step is the energy to remove one \*NO plus the energy to form \*COOH on these metal site. Similarly, the two CO gas molecules can be adsorbed on both sites of ReN<sub>4</sub>C<sub>x=10,A</sub>, OsN<sub>4</sub>C<sub>x=10,A</sub>, RuN<sub>4</sub>C<sub>A</sub>, and WN<sub>4</sub>C<sub>A</sub> structure. In 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO solution at pH = 7 and U = -0.8 V<sub>SHE</sub>, the thermodynamic barrier of the limiting step on these metal sites is also the energy to remove one \*CO plus the energy to form \*COOH.

#### 4.9 Stability vs Activity

In order to identify the promising catalysts which are both electrochemically stable and active from our calculation results, the  $\Delta G_R$  of the most stable surface of the MN<sub>4</sub> site is plotted against its corresponding thermodynamic barrier of the limiting step under the same condition.

For the ORR catalyst, it is considered at  $U = 0.80 V_{SHE}$  and pH = 1 as shown in Figure 4.9 (a-b). It is seen that the FeN<sub>4</sub>, CoN<sub>4</sub>, MnN<sub>4</sub>, and RuN<sub>4</sub> sites on both bulk graphene and graphene in many electrolytes emerge as promising candidates, as many previous experimental studies have reported [9, 12, 19, 91, 92, 136, 146]. In the previous chapter, where the electrolyte adsorption was not included, the MnN<sub>4</sub>C<sub>10</sub> and MnN<sub>4</sub>C<sub>A</sub> structures were not promising candidates for the ORR in the acid condition. However, the MnN<sub>4</sub> site becomes more stable against the dissolution through electrolyte adsorption in this study. Other promising combinations between metal elements and acid electrolytes are shown in Table 4.1. It is seen that p-block metals, mainly on the graphene edge, have comparable stability and activity to the transition metal site. The Sn/N/C catalysts have been synthesized and exhibited similar activity, and selectivity toward the four-electron ORR to the Fe/N/C catalyst in 0.1 M HClO<sub>4</sub> [163]. The Sb/N/C catalyst has also been synthesized and exhibited promising activity toward the ORR, although in 0.1 M KOH [144].

In the case of the catalyst for  $CO_2RR$  to CO, it is considered at U = -0.80 V<sub>SHE</sub> and pH = 7 as shown in Figure 4.9 (b-c). Besides the FeN<sub>4</sub>, CoN<sub>4</sub>, NiN<sub>4</sub> and MnN<sub>4</sub> sites which have been experimentally suggested for CO production [139–141, 164], other promising combinations between metal elements and electrolytes or gas molecules are identified as shown in Table 4.2.

**Figure 4.9:**  $\Delta G_R$  vs  $\Delta G_{max}$  for the ORR: (a) MN<sub>4</sub>C<sub>10</sub> (b) MN<sub>4</sub>C<sub>A</sub>.  $\Delta G_R$  vs  $\Delta G_{max}$  for the CO<sub>2</sub>RR to CO: (c) MN<sub>4</sub>C<sub>10</sub> (d) MN<sub>4</sub>C<sub>A</sub>. Classification plot for possible CO<sub>2</sub>RR products of promising candidates based upon the binding energies of H and CO criterion by Bagger *et al.* [165, 166]: (e) MN<sub>4</sub>C<sub>10</sub> and (f) MN<sub>4</sub>C<sub>A</sub>

Additionally, the competing HER is crucial in determining the catalytic efficiency. It has been shown that the binding strengths of \*CO and \*H play the role of a descriptor for CO<sub>2</sub>RR selectivity on transition metal surfaces [166] and single site porphyrin-like structures [165]. Figure 4.9 (e) and (f) show the classification of possible products from CO<sub>2</sub>RR on the single metal sites. It is seen that the promising candidates are selective toward CO over H<sub>2</sub> production. As shown in Figure B.10 in Appendix B, the effect of the ligand is clearly observed on the MoN<sub>4</sub>, RuN<sub>4</sub>, WN<sub>4</sub>, ReN<sub>4</sub>, and OsN<sub>4</sub> sites where the bare metal sites strongly bond with \*H. Thus these sites are highly selective for the HER. However, the binding of \*H becomes weaker with the presence of the ligand. As a result, the competing HER can be suppressed. In addition to the CO formation, it is found that IrN<sub>4</sub>C<sub>x=10,A</sub> in H<sub>2</sub>CO<sub>3</sub>+CO; OsN<sub>4</sub>C<sub>A</sub> in H<sub>2</sub>CO<sub>3</sub>+CO solution potentially reduce CO<sub>2</sub> to the products beyond CO. Other promising candidates that can produce the products beyond CO are RuN<sub>4</sub>C<sub>x=10,A</sub>, RhN<sub>4</sub>C<sub>10</sub>, OsN<sub>4</sub>C<sub>10</sub> in H<sub>2</sub>CO<sub>3</sub>+CO solution; ReN<sub>4</sub>C<sub>A</sub>, WN<sub>4</sub>C<sub>A</sub> in H<sub>2</sub>CO<sub>3</sub>+CO or H<sub>2</sub>CO<sub>3</sub>+CO+NO solution; and CrN<sub>4</sub>C<sub>A</sub>, MoN<sub>4</sub>C<sub>10</sub> in H<sub>2</sub>O + CO solution.

For the transition metal single atom considered in this study, it is found that the reaction intermediate binding on the MN<sub>4</sub> site on the graphene edge is generally weaker than that on the MN<sub>4</sub> site on the bulk graphene. Figure 4.10 illustrates the projected density of states (PDOS) for the CoN<sub>4</sub>C<sub>10</sub> and CoN<sub>4</sub>C<sub>A</sub> sites without and with adsorbate (either one \*OH or \*COOH adsorbate). In the pristine structure of the CoN<sub>4</sub>C<sub>10</sub> site, we find the 3d<sub>xy</sub> hybridization with the 2p orbitals of the surrounding N atoms forms the Co-N bonds. While the other 3d orbitals are non-binding orbitals. For the pristine structure of the CoN<sub>4</sub>C<sub>A</sub> site, both 3d<sub>xy</sub> and 3d<sub>x<sup>2</sup>-y<sup>2</sup></sub> orbitals overlap with the 2p orbitals for the surrounding N atoms. When either \*OH or \*COOH adsorbs on the Co center atom, the 2p orbitals of \*OH or \*COOH overlap with 3d<sub>z<sup>2</sup></sub> and 3d<sub>yz</sub> orbitals of the Co atom on both the CoN<sub>4</sub>C<sub>10</sub> and CoN<sub>4</sub>C<sub>A</sub> sites. However, it is found that in the CoN<sub>4</sub>C<sub>10</sub> site, the Co 3d<sub>x<sup>2</sup>-y<sup>2</sup></sub> orbital locates below, while the Co 3d<sub>xy</sub> orbital locates above the Fermi energy. The opposite trend is found for the CoN<sub>4</sub>C<sub>A</sub> site. It appears that the difference in d-orbitals located near the Fermi level, possibly caused by different local carbon structures, could affect the binding strength of the adsorbates [30].

Furthermore, with the ligand on the other side of the single metal atom, the adsorption of the reaction intermediate is likely to become weaker. The change in adsorption behavior of the ORR intermediate with the ligand on the back side in the  $CrN_4C_{12}$  and the  $CoN_4C_{12}$  structure has been previously explained by Svane *et al.* [93, 121] using the crystal field theory. Figure 4.11 shows the possible electronic configuration in the d-orbitals of the metal center in the  $MN_4C_{10}$  (M = Cr, Mn, Fe, and Co) structure with one and two adsorbates, based on the converged magnetization projected on the metal atom and the crystal field theory. The  $MN_4$  site with two adsorbates adopts an octahedral structure. According to the crystal field theory, the d-orbitals of the metal center are split into two different energy levels,  $t_{2g}$  and  $e_g$ . For  $Co^{2+}$  with a low spin configuration in the octahedral geometry, transferring more than one electron to the adsorbates may not be thermodynamically favorable. Since after the first unpaired electron is transferred from the  $e_g$  d-orbitals, the remaining electrons are paired and placed in

the lower  $t_{2g}$  d-orbitals. Similarly, for Fe<sup>2+</sup> in the octahedral geometry with a low spin configuration, all d-electrons are placed in the lower  $t_{2g}$  d-orbitals. Removing electrons from these fully occupied orbitals may not be thermodynamically favorable. After all, this could destabilize \*COOH and \*OH when they bind as the second adsorbate. A similar value of the converged magnetization projected on the metal center in the MN<sub>4</sub> site is found on both bulk graphene and graphene edge. Thus, the metal center in both structures should have a similar electronic configuration in their d-orbitals.

**Figure 4.10:** Spin-polarized density of states for: (a-b) the pristine  $CoN_4C_{10}$  and  $CoN_4C_A$  site projected onto Co 3d, N 2p orbital. (c-d) The  $CoN_4C_{10}$  and  $CoN_4C_A$  site with \*OH projected onto Co 3d, N 2p and O 2p (\*OH) orbital. (e-f) The  $CoN_4C_{10}$  and  $CoN_4C_A$  with \*COOH projected onto Co 3d, N 2p and C 2p (\*COOH) orbital.

**Figure 4.11:** Illustration of d-orbital splitting and possible electron configurations for a single metal atom on bulk graphene ( $MN_4C_{10}$ ) in square pyramidal geometry (with one adsorbate), octahedral geometry (two adsorbates): (a) Cr, (b) Mn, (c) Fe and (d) Co. The possible electron configuration is based on the converged magnetization projected on the metal center (number of spin-up - number of spin-down), and it is assumed that the oxidation of the metal center atom of the pristine structure (without adsorbates) is 2+. Only electrons in the black arrows remain on the metal center atom, while the electrons in the grey arrows are donated to the adsorbates. The relative position of energy level is qualitative only.

## 4.10 Conclusions

The effect of electrolyte anion adsorption on the stability and activity of single metal atom catalysts was studied. We considered two structural models of the M/N/C catalysts: the  $MN_4$  motif on the bulk graphene terrace and the graphene edge with 3d, 4d, 5d, or p-block (Sn, Sb, and Bi) metal atoms. It was found that the armchair edge is thermodynamically favored to form the MN<sub>4</sub> site compared to the bulk graphene, especially for 3d transition metals. Under ORR conditions, various electrolyte anions can compete with water and adsorb on the single metal site. The electrolyte anion adsorption depends on the nature of the metal atom and local carbon structure around the  $MN_4$  site. The ORR activity is either poisoned or altered by the electrolyte anion. If the electrolyte anion adsorbs on the single metal site, the single metal site can be further stabilized against dissolution in acid environments, compared to the stability in the pure water environment. It would be interesting to include the electrolyte stabilization effect on other MN<sub>4</sub> sites with different local carbon structures, although the sites considered here are expected to be among the most stable sites. Considering both stability in acid conditions and ORR activity, a single metal site based on Ir, Cu, Rh, Zn, Au, Os, Cr, and p-block elements (Sb, Sn, and Bi), especially on the graphene edge, has comparable ORR activity and stability to a single metal atom based on Fe and Co. Under the CO<sub>2</sub>RR condition, most considered electrolyte anions, except in 0.1 M H<sub>2</sub>CO<sub>3</sub> solution, do not interact with the single metal site. Still, water and gas molecules may form ligands on various single metal sites under the CO<sub>2</sub>RR condition. It was found that the activity trend for the reduction of  $CO_2$  to CO on the single metal site with the ligand from the solution compares well with the experimental trends. Besides the single-atom catalysts based on Fe, Co, Mn and Ni, we suggested promising single metal sites (Cr, Ru, W, Re, Os, Rh, Bi, Sb, Mo, Zn, and Ir) by including the adsorbate ligand from the solution. These promising candidates have comparable stability and activity to the Fe and Co-based catalysts. This study illustrated that the nature of the metal atom, the local carbon structure, and the chemical environment (i.e., electrolyte anions) play a critical role in the activity and stability of a single-atom electrocatalyst. A careful combination of electrolyte or gas ligand and a single metal atom with various local carbon structures could be a possible way to achieve an active and durable electrocatalyst.

## Chapter 5

# Degradation of Polybenzimidazole in Alkaline Solution

This chapter is based on the work presented in Paper III as given in Appendix D. The alkaline stability of the polybenzimidazole molecule is investigated as the polybenzimidazole molecule is a promising material for anion exchange membranes in alkaline fuel cells. This chapter covers the main points and results.

## 5.1 Introduction

Alkaline anion exchange membranes have gained increased attention due to their potential integration with a wide range of electrochemical energy storage and conversion devices, such as fuel cells and electrolyzers. Generally, in order to allow hydroxide ion conduction in an anion exchange membrane, cations, such as ammonium [11, 48], imidazolium cation [49–52] and benzimidazolium [50, 53, 54] are commonly attached to the polymer backbone. However, the hydroxide ion can react irreversibly with the polymer backbone and cations, causing the loss of ionic conductivity [55–57]. As a result, a chemical stability remains a significant challenge for anion exchange membranes. An alternative is an ion-solvating membrane where an aqueous electrolyte is dissolved in a polymer matrix, utilizing the uptake of the aqueous electrolyte to achieve ionic conductivity. Thus, there is no need for cation moieties [47, 60].

The poly(2,2-(m-phenylene)-5,5-bibenzimidazole) (mPBI) equilibrated in potassium hydroxide (KOH) solution can result in the ion-solvating membrane, consisting of KOH and water dissolved in the polymer matrix [66]. This alkaline doped mPBI system has high ionic conductivity, and excellent chemical stability in an alkaline condition [60, 66]. Also, it has been tested as an anion exchange membrane in direct alkaline alcohol fuel cells [167], alkaline fuel cells [159, 168], alkaline water electrolyzers [60, 62, 169], and vanadium redox flow batteries [170] with remarkable performance.

The composition of the alkaline doped mPBI system strongly depends on the KOH concentration, which significantly determines the ionic conductivity of the membrane. The mPBI undergoes deprotonation when it is immersed in an alkaline solution.

The acid-base equilibrium of mPBI in KOH solution is shown as reaction (0) in Figure 5.1. The system exhibits high ionic conductivity and chemical stability at low concentration (5 - 10 wt% KOH at T = 88°C) [60, 61]. Further increasing KOH concentration enhances the ionic conductivity [60, 61] but causes the degradation of the polymer as the gradually reduced molecular weight, mechanical strength, ionic conductivity, and structural change have also been reported [60, 61]. Thus, the actual use is still limited.

The mPBI-based membrane in an alkaline solution may degrade via a hydrolysis reaction [60, 61, 69]. Figure 5.1 shows the postulated degradation pathway. Reaction (1) is the nucleophilic addition of hydroxide ions at the benzimidazole ring. The following reactions are (2) ring-opening and (3) chain scissions [46, 61, 68]. The postulated degradation pathway is similar to the degradation of imidazolium and benzimidazolium cations [56, 57, 171, 172]. As shown in Figure 5.1, the negative charge may be delocalized over the benzimidazole ring after the deprotonation. The interaction between the deprotonated mPBI molecule and hydroxide ion in reaction (1) could differ from that of cations. Also, the following degradation reaction could be different. However, the degradation mechanism of the mPBI molecule in an alkaline solution has not been presented in detail. On top of that, it is still unclear which form of mPBI molecule undergoes the degradation in an alkaline solution since the equilibrium of the reaction (0) in Figure 5.1 strongly depends on the KOH concentration [64, 66].

In this chapter, we use the DFT calculations to evaluate the predominant species and the degradation mechanism of mPBI molecule in an alkaline solution. The postulated degradation pathway of the mPBI molecule, as shown in Figure 5.1, is investigated. The effect of explicit water molecules and hydroxide ion concentration on the degradation is considered. A comparison between experiment and theory is achieved by computing the effective energy barrier for the degradation against those estimated from experimental results.

**Figure 5.1:** Schematic illustration: Reaction (0) is an acid-base equilibrium of mPBI molecule in KOH solution, and reaction (1)-(3) is a postulated degradation pathway of mPBI in alkaline solution

### 5.2 Computational Details

In this chapter, the DFT calculations were performed using the B3LYP functional [81] and 6-311++G(d, p) basis sets as implemented in Q-Chem 5.2 [173] for both optimized geometries and calculated energies. The threshold for the maximum gradient and the self-consistent field (SCF) energy change between consecutive optimization cycles was  $3.0 \times 10^{-3}$  Hartree/Bohr and  $1.0 \times 10^{-8}$  Hartree, respectively. The geometry optimizations for intermediate and transition states were carried out in gas phase. A freezing string method (FSM) [174, 175] was used to approximate the path connecting each intermediate state pair. The highest energy point on the path was taken as the first approximation for a transition state. The refined transition state was found using Baker's partitioned rational-function optimization (P-RFO) algorithm [176] also implemented in Q-chem 5.2. Each transition state was verified to connect the designated reactant and product by performing intrinsic reaction coordinate (IRC) [177] calculations. The vibrational frequencies were calculated to confirm the local minima on the potential energy surface with no imaginary frequencies for the reaction intermediates and one single imaginary frequency for the transition states. Single point energies were computed with the conductor-like polarization continuum model (C-PCM) [178-180] based on the optimized gas-phase geometries, and a dielectric constant of 78.39 corresponding to the bulk water was used to include the effect of the surrounding water medium.

Reaction free energy and free energy barrier are calculated at  $T = 88^{\circ}C$  and pressure = 1 atm, which is the same as the experimental condition [61]. The free energy (G) of the model compound is the calculated DFT energy (E<sub>DFT</sub>) included zero-point energy (ZPE), enthalpy contribution (H = H<sub>vibration</sub> + H<sub>rotation</sub> + H<sub>translation</sub>), and entropy contribution (S = S<sub>vibration</sub> + S<sub>rotation</sub> + S<sub>translation</sub>) calculated in the gas phase. The vibration calculations assume harmonic approximation. The reaction free energy in the solution phase is, for the example, given by

$$A + B \rightarrow C$$

$$\Delta G_{(\text{sol})} = G(C_{(\text{sol})}) - G(A_{(\text{sol})}) - G(B_{(\text{sol})})$$
(5.1)

$$=\Delta E_{(sol)} + \Delta ZPE_{(gas)} + \Delta H_{(gas)} - T\Delta S_{(gas)}$$
(5.2)

where 
$$\Delta E_{(sol)} = E(C_{(sol)}) - E(A_{(sol)}) - E(B_{(sol)})$$
 (5.3)

$$\Delta ZPE_{(gas)} = ZPE(C_{(gas)}) - ZPE(A_{(gas)}) - ZPE(B_{(gas)})$$
(5.4)

$$\Delta H_{(gas)} = H(C_{(gas)}) - H(A_{(gas)}) - H(B_{(gas)})$$
(5.5)

$$\Delta S_{(gas)} = S(C_{(gas)}) - S(A_{(gas)}) - S(B_{(gas)})$$
(5.6)

where  $E(X_{(sol)})$  is the single point energy of species X (where X = A, B) computed with the presents of the implicit solvation based on the optimized gas-phase geometry. ZPE, H, and S are calculated in the gas phase.

#### 5.3 Deprotonation Reaction

The mPBI-based membrane has been found to undergo deprotonation when it was soaked in KOH solution, and the ionized form has been found as a major species at high concentration [66]. At the same time the degradation has also been observed at high KOH concentration. Thus, it has been suggested that the degradation of the mPBI starts from the ionized species [66]. The pK<sub>a</sub> of the mPBI molecule is firstly considered here to identify a predominant species at the high pH range, where degradation occurs.

**Figure 5.2:** Thermodynamic cycle for calculation of the first deprotonation reaction. Abbreviation in brackets: (gas) = gas phase and (sol) = solution phase (implicit solvation)

Two possible protons are deprotonated in mPBI molecule. The stepwise dissociation constant is defined for losing a single proton as illustrated in the reaction (0a) and (0b) in Figure 5.1. The dissociation constant for the first proton is denoted as  $pK_a^1$ , and the successive proton is  $pK_a^2$ . The acid deprotonation reaction of the mPBI molecule can be expressed as follows

$$mPBI(0) \rightleftharpoons mPBI(-1) + H^+ \rightleftharpoons mPBI(-2) + 2H^+$$

The number in parenthesis indicates the total charge on the molecule. Thus, mPBI(0) is the non-deprotonated form, mPBI(-1) is the partially deprotonated form after losing one proton, and mPBI(-2) is the fully deprotonated form after losing two protons. The  $pK_a$  is calculated from the deprotonation free energy in the solution phase.

$$pK_a = \frac{1}{2.303 \text{RT}} \Delta G_{\text{(sol)}}^{\text{Deprotonation}}$$
(5.7)

where  $\Delta G_{(sol)}^{Deprotonation}$  is calculated from the thermodynamic cycle in Figure 5.2 and can be expressed as follows

$$\Delta G_{(sol)}^{\text{Deprotonation}} = \Delta G_{(gas)}^{\text{Deprotonation}} + \Delta m PBI(-1)_{sol} + \Delta H_{sol}^{+} - \Delta m PBI(0)_{sol}$$
(5.8)

where  $\Delta G_{(gas)}^{Deprotonation}$  is the deprotonation free energy in gas phase.

$$\Delta G_{(gas)}^{\text{Deprotonation}} = G(\text{mPBI}(-1)_{(gas)}) + G(H_{(gas)}^{+}) - G(\text{mPBI}(0)_{(gas)})$$
(5.9)

where  $G(mPBI(-1)_{(gas)})$  and  $G(mPBI(0)_{(gas)})$  are the free energy of the mPBI(-1) and mPBI(0) molecule in gas phase.  $\Delta mPBI(0)_{sol}$  and  $\Delta mPBI(-1)_{sol}$  are the solvation energy of mPBI(0) and mPBI(-1) molecule, respectively, and can be calculated as

$$\Delta mPBI(0)_{sol} = E(mPBI(0)_{(sol)}) - E(mPBI(0)_{(gas)})$$
(5.10)

$$\Delta mPBI(-1)_{sol} = E(mPBI(-1)_{(sol)}) - E(mPBI(-1)_{(gas)})$$
(5.11)

where  $E(mPBI(0)_{(gas)})$  and  $E(mPBI(-1)_{(gas)})$  are the calculated DFT energy of mPBI(0), mPBI(-1) molecule in gas phase.  $E(mPBI(0)_{(sol)})$  and  $E(mPBI(-1)_{(sol)})$  are the single point energy of mPBI(0), mPBI(-1) molecule computed with the presence of the implicit solvation based on the optimized gas-phase geometry.  $G(H^+_{(gas)})$  is the free energy of the proton in the gas phase, which is calculated as

$$G(H^{+}_{(gas)}) = E(H^{+}_{(gas)}) + H(H^{+}_{(gas)}) - TS(H^{+}_{(gas)})$$
(5.12)

where  $E(H^+_{(gas)}) = 0.00 \text{ eV}$ ,  $H(H^+_{(gas)}) = \frac{5}{2}RT = 0.08 \text{ eV}$  and  $S(H^+_{(gas)}) = 0.41 \text{ eV}$  taken from the literature [181].  $\Delta H^+_{sol}$  is a solvation correction for a proton in solution phase, which is calculated as

$$\Delta H_{sol}^{+} = \Delta G_{1atm \to 1M} + \Delta G(H^{+})_{solvation}$$
(5.13)

where  $\Delta G_{1atm \rightarrow 1M}$  (= 0.08 eV) is the correction corresponding to the change in state from 1 atm to 1 M taken from the literature [181].  $\Delta G(H^+)_{solvation}$  (= -11.53 eV) is solvation free energy for proton taken from the literature [181].

For the mPBI molecule, we find that  $pK_a^1 = 12.46$  and  $pK_a^2 = 12.85$ , suggesting that the mPBI(-2) molecule is the major species at high pH (high KOH concentration). Since there is a slight difference between successive  $pK_a$  values, there can be an overlap between the pH range and the existence of these three species. The mole fraction of the mPBI molecule in each deprotonation state is approximated using the relationship between pH and  $pK_a$  as described by the Henderson-Hasselbalch equation [182].

$$pH = pK_a^1 + \log(\frac{[mPBI(-1)]}{[mPBI(0)]})$$
(5.14)

$$pH = pK_a^2 + \log(\frac{[mPBI(-2)]}{[mPBI(-1)]})$$
(5.15)

$$E_0 = 1/(1+10^{(pH-pKa_1)}+10^{(pH-pKa_1)}10^{(pH-pKa_2)})$$
(5.16)

$$f_1 = f_0 10^{(pH-pKa_1)}$$
(5.17)

$$f_2 = f_1 10^{(pH-pKa_2)}$$
(5.18)

The square brackets indicate the concentration of mPBI molecule in each deprotonation state.  $f_0$ ,  $f_1$  and  $f_2$  is the mole fraction of mPBI(0), mPBI(-1) and mPBI(-2), respectively, and  $f_0 + f_1 + f_2 = 1$  at any pH. The conversion between pH and KOH concentration is calculated as follows

$$pH = pK_w + log[OH^-]$$
 where  $[OH^-] = \frac{0.01X_{wt}D_{KOH}}{m_{KOH}}$  (5.19)

where X<sub>wt</sub> is KOH concentration (in %wt KOH). D<sub>KOH</sub> is the density of the KOH solution (in g/L). The density of KOH solution at each KOH concentration is taken from the literature (at T = 70°C [183]). m<sub>KOH</sub> is the molar mass of KOH (= 56.11 g/mol). pK<sub>w</sub> is the acid dissociation constant of water taken from literature (pK<sub>w</sub> = 12.46 at T = 80°C [184])

Figure 5.3 shows the calculated mole fraction of mPBI molecule in each deprotonation state as a function of KOH concentration (and pH) at  $T = 88^{\circ}C$ . The mole fraction of the mPBI(-1) and mPBI(-2) molecule increases as the KOH concentration increase from 0 to 10 %wt KOH, while the mole fraction of the mPBI(0) molecule decreases. At a higher concentration than 15 %wt KOH, mPBI(-2) becomes the predominant species. At the same time, the number of mPBI(0) and mPBI(-1) molecules keeps decreasing when the KOH concentration is higher than 15 %wt KOH. All three mPBI species can also be found at 5 - 15 wt% KOH. At 15 wt% KOH, there are approximately 10% of mPBI(0), 40% of mPBI(-1) and 50% of mPBI(-2) in the solution. At 50 wt % KOH, there are still approximately 10% of mPBI(-1) mixed with 90% of mPBI(-2) in the solution.

**Figure 5.3:** Calculated mole fraction of mPBI molecule in each deprotonated state as a function of KOH concentration (and pH) at  $T = 88^{\circ}C$ .

It can be seen that the concentration of the ionized molecules increases with pH. Therefore, the ion conductivity can become higher by increasing KOH concentration. These calculation results are in line with a previous experiment by Kraglund *et al.*, which has reported an increase in the ionic conductivity of the mPBI-based membrane at  $T = 80^{\circ}$ C of about two orders of magnitude from 0.7 to 72 mS/cm when the KOH concentration has been changed from 5 to 15 wt% KOH [60]. The ionic conductivity was further increased and peaked at the concentration around 20 - 25 wt% KOH; however, there were signs of structural change [60].

It should be noted that the bulk KOH concentration might not be directly applicable to the alkaline doped mPBI system. A previous study by Hou *et al.* has suggested that protons from the mPBI molecule can combine with hydroxide ions in the environment and form a more stable water molecule while the  $K^+$  ion can integrate into the membrane [64, 185]. Therefore, due to water and  $K^+$  uptake, the internal KOH concentration of the alkaline-doped mPBI system could be slightly different from the bulk KOH concentration.

## 5.4 Nucleophilic Addition

The degradation of mPBI-based membranes in alkaline solutions has been suggested to take place via hydrolysis reaction [46]. The first reaction involves nucleophilic addition at the carbon atom of the five-membered ring [46, 171]. Since all three forms of the mPBI molecule can be present in the alkaline solution at a high KOH concentration (> 15 %wt KOH), where the degradation is expected [46, 60, 61, 171], the reaction free energy of the first nucleophilic addition ( $\Delta G_1$ ) for all three forms of the mPBI molecule is investigated as follows

$$\Delta G_1 = G(OHmPBI(n))_{(sol)} - G(mPBI(n)_{(sol)}) - G(OH_{(sol)}^-)$$
(5.20)

where OHmPBI(n) is the mPBI(n) molecule with a hydroxide ion bound with one of the carbon atoms of the five-membered ring and n = 0, -1, -2 for the non-, partially, and fully deprotonated mPBI molecule, respectively. There are three possible distinct carbon atoms of the five-membered ring of the mPBI(0) molecule, marked as C2, C4, and C5 in Figure 5.4, where hydroxide ions can attack. There are five possible positions in the mPBI(-1) molecule at C2, C4, C5, C2\*, and C4\*. The \* denotes atoms located at the deprotonated part of the molecule. For the mPBI(-2) molecule, hydroxide attack on the carbon atom at the C2\* or C5\* position is possible. While the carbon atoms at C4\* and C5\* are symmetry equivalent.

As shown in Table 5.1, the hydroxide ion attack at the C2 position in the mPBI(0) and mPBI(-1) is more accessible than in other positions. Since these carbon atoms are located between two nitrogen atoms with higher negativity, these carbon atoms are more positively charged than the others. The more positive charge, the more favorably hydroxide ions attack. The deprotonated part is less vulnerable to hydroxide ions. The hydroxide ion attack at the C2<sup>\*</sup> position in the mPBI(-1) molecule is more difficult than those at the C2 position. The lowest unoccupied molecular orbital (LUMO) energy of the molecule increases after deprotonation, and the atomic charge of atoms near the deprotonated part becomes slightly more negative. Figure 5.4 shows LUMO isosurfaces for mPBI molecules in different protonation states. The LUMO isosurface distributes all over the structure, including the C2 position on both sides in the mPBI(0) molecule. In comparison, the LUMO isosurface localizes in the C2 position in mPBI(-1) molecule. For the mPBI(-2) molecule, the LUMO energy is the highest among considered species, and the attack by hydroxide ion is also the most difficult. These results suggest that the susceptibility to hydroxide anion attack of the mPBI molecule can be related to the LUMO energy and isosurface [49, 186] and the formation of the deprotonated molecule can suppress the hydroxide ion attack.

**Figure 5.4:** NBO atomic charge [187]: (a) mPBI(0), (b) mPBI(-1), (c) mPBI(-2). LUMO isosurface: (d) mPBI(0), (e) mPBI(-1), (f) mPBI(-2). (H = white, C = gray, N = blue)

**Table 5.1:**  $\Delta G_1$  (in eV) at the five-membered ring in mPBI molecule in each deprotonated state at T = 88 °C and atomic charge on the atom (in electron)

molecule	position	atomic charge	$\Delta G_1$
	C2	0.20	1.31
mPBI(0)	C4	0.06	1.99
	C5	0.06	2.26
	C2*	0.17	2.43
	C4*	0.04	2.88
mPBI(-1)	C2	0.20	1.38
	C4	0.06	2.02
	C5	0.06	2.25
mDBI(2)	C2*	0.17	2.66
IIII DI(-2)	C4*	0.05	2.99

For the nucleophilic addition reaction at the C2 position, the free energy barrier is 1.42 eV for the mPBI(-1) and 1.35 eV for the mPBI(0) molecule. The free energy barrier for other positions in the mPBI(0) and mPBI(-1) molecule and in the mPBI(-2) molecule is 2.0 eV or greater, making the degradation unlikely. As there are more percentages of mPBI(-1) in solution than mPBI(0) at a high pH (pH > 13), the degradation could significantly be due to the mPBI(-1) species. Further investigation is continued from the hydroxide ion bond with the C2 position in the mPBI(-1) molecule.

## 5.5 Ring-opening Reaction

A ring-opening reaction follows the hydroxide ion attack. The possible mechanism for the mPBI(-1) molecule is that a hydroxyl proton at the C2 position is transferred to the nitrogen atom either at the N1 or N3 position, followed by a C-N bond breaking. The free energy barriers and rate constant along these two possible paths are calculated to identify the minimum reaction pathway.

For the calculated free energy barrier, an estimate of the reaction rate constant (k) is obtained from transition state theory [188].

$$k = \frac{k_{\rm B}T}{h} \exp(\frac{-\Delta G^{\rm TS}}{RT})$$
(5.21)

where  $k_B$  is Boltzmann's constant, h is Planck's constant,  $\Delta G^{TS}$  is the free energy barrier, R is the gas constant, and T is the temperature (K).

Due to its small mass, a hydrogen atom can be considered a wave packet, and it can penetrate regions forbidden for classical particles. During a hydrogen atom or proton transfer, the tunneling effects can increase the rate constant [189]. Thus, we also consider the tunneling effect for the reaction involving the hydrogen atom or proton transfer. Assuming the reaction path and the tunneling path coincide, the tunneling effect is included in the rate constant to obtain a tunneling corrected rate constants [190] as follows

$$k_{\text{tunnelling}} = \varkappa \frac{k_{\text{B}}T}{h} \exp(\frac{-\Delta G^{\text{TS}}}{RT})$$
(5.22)

where x is a tunneling correction adjusted the rate constant to include the tunneling effect along the reaction coordinate. Furthermore, assuming the shape of the potential energy barrier of the reaction is an inverted parabola. The probability of a particle with mass **m** and energy **E** penetrating the energy barrier with height **V** is approximated using the Wentzel-Kramers-Brillouin (WKB) approximation, leading to the following expression [191, 192].

$$P(E) = \exp(-\frac{\pi^2 \omega}{h} \sqrt{2m(V - E)}); 0 < E < V$$

$$P(E) = 1; E > V$$
(5.23)

where P(E) is the probability to find a particle on the other side of the barrier.  $\omega$  is the energy barrier width estimated from the reaction path obtained from the IRC calculations.  $\times$  is the ratio between the quantum-mechanical rate to the classical rate [191].

Considering the particle with mass **m** and energy **E** moving toward the energy barrier with height **V**, if  $J_0$  is the total flux of the inward particle to the barrier, the rate J at which particle appears on the other side of the barrier is given by

$$J = \frac{J_0}{k_B T} \int_0^\infty P(E) \exp(\frac{-E}{k_B T}) dE$$
(5.24)

For classical mechanism, P(E) = 0 for E < V and P(E) = 1 for E > V. Thus,  $J_C$  which is the classical flux of particle on the other side of the barrier is given by

$$J_{\rm C} = \frac{J_0}{k_{\rm B}T} \int_{\rm V}^{\infty} \exp(\frac{-E}{k_{\rm B}T}) dE = J_0 \exp(\frac{-\rm V}{k_{\rm B}T})$$
(5.25)

Therefore, x can be expressed as follows

$$\varkappa = \frac{J}{J_c} = \exp(\frac{V}{k_B T}) \int_0^\infty \frac{1}{k_B T} \exp(\frac{-E}{k_B T}) P(E) dE$$
(5.26)

If x = 1, there is no tunneling effect, and if x > 1, the tunneling effect contributes to the rate constant.

Let us consider the hydroxyl proton at the C2 position transfer to the nitrogen atom at the N3 position (see Figure 5.5). The ring-opening reaction occurs as a single step in path 1.1. The reaction goes through TS2-1.1 with a free energy barrier of 0.83 eV. The hydrogen tunneling effect in this step is negligible as x = 1.00. Alternatively, as the degradation occurs in an alkaline solution, water molecules and hydroxide ions are available in the environment, and both can participate in the reaction [171, 172]. The ring-opening with the presence of a hydroxide ion and a water molecule is shown as paths 1.2 and 1.3 in Figure 5.5, respectively.

For path 1.2, one hydroxide ion is explicitly added. This additional hydroxide ion spontaneously reacts with the hydroxyl proton at the C2 position, resulting in BX1-1.2, where one water molecule is formed. A transition state between intermediate B and BX1-1.2 could not be found. It is seen that the BX1-1.2 state is 0.31 eV less stable than the B state. The resulting water molecule further participates in the C2-N3 bond breaking, resulting in the ring-opening product C and one hydroxide ion. Compared to path 1.1, the additional hydroxide ion acts as a catalyst, lowering the energy barrier in path 1.2. The last reaction involves proton transfer from the water molecule to the nitrogen atom at the N3 position, where the tunneling correction is 1.07. Thus, the proton transfer rate constant increase from  $1.33 \times 10^9$  s<sup>-1</sup> to  $1.43 \times 10^9$  s<sup>-1</sup>.

For path 1.3, the reaction goes through TSY1-1.3, leading to the breaking of the C2-N3 bond. The free energy barrier for this step is 1.18 eV, including 0.25 eV for hydrogenbond formation between structure B and the water molecule. After that, the hydroxyl proton at the C2 position is transferred to the nitrogen atom at the N3 position via the water molecule. The reaction gives the ring-opening product C and a water molecule. The free energy barrier for the hydroxyl proton transfer is only 0.02 eV, and the hydrogen tunneling correction for this step is 1.73. Thus, hydrogen tunneling significantly contributes to the rate constant which is increased from  $3.67 \times 10^{12} \text{ s}^{-1}$  to  $6.36 \times 10^{12} \text{ s}^{-1}$ . However, the highest transition state in path 1.3 is even higher than in the previous paths.

**Figure 5.5:** (a) Reaction energy profile for the ring-opening reaction of mPBI(-1) via path 1.1, 1.2 and 1.3 at T = 88 °C. The reference zero energy state for energies reported is A+OH<sup>-</sup>, and the relative energies are in eV. The insets show the intermediate and transition state structure in (a) path 1.1, (b) path 1.2 and (c) path 1.3 (H = white, C = grey, N = blue, O = red).

Figure 5.6 shows an alternative path for the ring-opening reaction. First, the hydroxyl proton at the C2 position is transferred to a nitrogen atom at the N1 position. Then the C2-N1 (or C2-N3) bond is broken. It should be noted that after the hydroxyl proton transfer to the N2 position, the C2-N1 bond is equivalent to the C2-N3 bond.

We first consider the intramolecular proton transfer process (path 2.1). The hydroxyl proton at the C2 position is directly transferred to the nitrogen atom at the N1 position. A free energy barrier is found to be 0.91 eV. Due to the hydrogen tunneling effect (x = 1.04), the rate constant of 1.43 s<sup>-1</sup> is increased to 1.48 s<sup>-1</sup>

The hydroxyl proton transfer to the nitrogen atom at the N1 position via a hydroxide ion or water molecule is considered in paths 2.2 and 2.3, respectively. In path 2.2, the reaction goes through TS2-2.2. The water molecule donates one of its protons to the nitrogen atom at the N1 position, and then the hydroxide ion is obtained. The resulting hydroxide ion reacts with the hydroxyl proton at the C2 position, resulting in the intermediate C and water molecule. The free energy barrier for the hydroxyl proton transfer is 0.37 eV, including 0.25 eV for the hydrogen-bond formation between structure B and the water molecule. The TS2-2.2 state is about 0.54 eV lower than the TS2-2.1 state. Including the hydrogen tunneling correction of 1.26, the rate constant for the hydroxyl proton transfer is  $5.55 \times 10^7$  s<sup>-1</sup>, faster than the previous intramolecular proton transfer.

**Figure 5.6:** (a) Reaction energy profile for the ring-opening reaction of mPBI(-1) via path 2.1, 2.2 and 2.3 at T = 88 °C. The reference zero energy state for energies reported is A+OH<sup>-</sup>, and the relative energies are in eV. The insets show the intermediate and transition state structure related to the hydroxyl proton transfer: (b) path 2.1, (c) path 2.2 and (d) path 2.3 (H = white, C = grey, N = blue, O = red)

In path 2.3, the additional hydroxide ion reacts with the hydroxyl proton at the C2 position, producing one water molecule. This water molecule later donates one of its protons to the nitrogen atom at the N1 position, resulting in the intermediate C and hydroxide ion. The reaction goes through TS2-2.3, and the free energy barrier is 0.25 eV, 0.66 eV lower than TS2-2.1, and 0.13 eV lower than TS2-2.2. Including the hydrogen

tunneling correction, the rate constant for the hydroxyl proton transfer is  $3.57 \times 10^9$  s<sup>-1</sup>, faster than previous considerations.

The next step involves breaking the C-N bond (either C2-N1 or C2-N3 bond), resulting in an unstable N dangling bond in the structure D. This unstable N dangling bond can be stabilized by receiving a proton from a water molecule in its environment. The reaction gives the ring-opening product E and the hydroxide ion. The free energy barrier for the C-N bond breaking is 0.68 eV, including 0.23 eV for hydrogen-bond formation between the structure C and the water molecule. The free energy barrier for the proton transfer from the water molecule to the unstable N dangling atom is only 0.02 eV. With the hydrogen tunnelling correction of 1.33, the rate constant of the last step is  $4.65 \times 10^{12} \text{ s}^{-1}$ .

It can be seen that path 2.2 and 2.3 has lower energy barrier than path 2.1. The highest transition state in path 2.2 and 2.3 is TS3 which is also lower than TSX1-1.2 in path 1. Thus, the ring-opening reaction of the mPBI(-1) molecules possibly occurs through path 2.2 or 2.3 with the assistance of water or hydroxide ions.

It should be noted that the hydroxide ion is unstable as it spontaneously reacts with the hydroxyl proton at the C2 position. It is also possible to spontaneously combine with the potassium ion instead of catalyzing the reaction if the explicit potassium ion is added. Still, the ring opening can occur via the water-assisted path.

### 5.6 Chain scission

The C2-N1 bond (amide linkage) in the structure E can be further hydrolyzed, leading to complete chain scission. As the degradation occurs in an alkaline solution, the hydroxide ion involves in the reaction. For path 3.1 in Figure 5.7 (b), the reaction begins with the nucleophilic addition at the C2 carbon atom in the structure E as it is the most positively charged position. The reaction goes through TS5 with a free energy barrier of 1.03 eV. The next step involves the C2-N1 bond cleavage, where the reaction goes through TS6-3.1 with a free energy barrier of 0.40 eV. The transition state mainly relates to the C2-N1 bond breaking. Then, the hydroxyl proton at the C2 position is transferred to the nitrogen atom at the N1 position without a transition state. The final product G is at -1.25 eV in the reaction energy profile and it is more stable than the E+OH<sup>-</sup> state.

The effect of explicit water on the energy profile is shown as path 3.2 in Figure 5.7 (b). One explicit water molecule is placed near the C2-N1 bond in structure E. The reaction goes through TS6-3.2 which relates to the C2-N1 bond breaking. The hydroxyl proton at the C2 position is spontaneously transferred to the nitrogen atom at the N1 position. The hydroxyl proton transfer can occur by passing the proton through the explicit water molecule but it is also barrierless. Thus, the tunneling correction is not taken into account in this step. The free energy barrier for the C2-N1 bond cleavage along path 3.2 is 0.70 eV, including 0.31 eV for hydrogen-bond formation between the structure F and water molecule. The free energy barrier is lowered by about 0.01 eV with the presence of explicit water molecules.

**Figure 5.7:** (a) NBO atomic charges on the structure E. (b) Reaction energy profile for the chain scission reaction of mPBI(-1) at T = 88 °C. The reference zero energy state for energies reported is  $E+OH^-$ , and the relative energies are in eV. The insets show structures for the intermediate and transition states in path 3.1. Structures for the intermediate and transition states (c) path 3.2 (d) path 3.3 (H = white, C = grey, N = blue, O = red).

With an additional hydroxide ion (path 3.3), the additional hydroxide ion spontaneously reacts with a hydroxyl proton at the C2 position, forming a water molecule. The hydroxyl proton abstraction leads to the cleavage of the C2-N1 bond. The hydrogen atom (H4) is transferred back and forth between the nitrogen atom at the N3 position and the oxygen atom at the O2 position. The reaction goes through TS6-3.3 with a free energy barrier of 0.98 eV. The hydrogen tunneling correction for this step is only 1.02. The C2-N1 bond breaking creates an unstable N-dangling bond at the N2 position in structure FX2-3.3. A hydrogen atom can be transferred from the water molecule to stabilize this N-dangling bond. The free energy barrier for this step is only 0.01 eV and it results in the rate constant of  $5.58 \times 10^{12} \text{ s}^{-1}$ . The hydrogen tunneling correction of

1.51 results in  $8.45 \times 10^{12}$  s<sup>-1</sup>, implying that hydrogen transfer occurs very fast. The final products G and one hydroxide ion are obtained at the end. The free energy barrier in path 3.3 is higher than the previous paths.

**Figure 5.8:** Reaction energy profile for the degradation path at  $T = 88 \degree C$  with a different number of explicit water molecules: (a) mPBI(-1) and (b) mPBI(0). The reference zero energy state for energies reported is A+OH<sup>-</sup>, and the relative energies are in eV.

In summary, the degradation path for the mPBI(-1) is shown as the black line in Figure 5.8 (a). A water molecule catalyzes the pathway during the ring-opening reaction. The highest transition state along the degradation path is the TS6-3.1, located at 2.04 eV in the reaction profile. This state is the rate-limiting state. Therefore, the effective barrier for the degradation reaction which is calculated from the free energy of the TS6-3.1 relative to the initial state (A+OH<sup>-</sup>), is found to be 2.04 eV. The final products from the chain scission contain free amino groups and a carbonyl group which are in line with the experimental study by Aili et al. [66] and Kraglund et al. [60]. For the mPBI(0) molecule, the degradation path is the same as the mPBI(-1) molecule and is given in Figure 5.8 (b) in the black line. The highest transition state is TS6-3.1 and the effective energy barrier is found to be 2.02 eV for the mPBI(0) molecule.

## 5.7 Reaction Path with Implicit-explicit Solvation

The implicit solvation model with the PCM is used in previous calculations to consider the effect of the surrounding water medium. However, it does not incorporate a shortrange interaction between solutes and solvents, i.e., hydrogen bonding which can be important in the reaction path [181, 193]. In the following section, the combination between the explicit water molecules and the PCM implicit solvation is considered.

#### **One Explicit Water Molecule**

The first hydroxide ion attack at the C2 carbon atom in the mPBI(-1) molecule with one explicit water molecule at different hydrogen-bonding sites is considered. Among the considered positions in Figure C.1 of Appendix C. the explicit water molecule near the N1 position gives the lowest energy of  $\Delta G_1$ . Thus, when we consider the reaction path with one explicit water molecule, the explicit water molecule is placed near the N1 position of the mPBI(-1) molecule. This position is also close to where the degradation occurs, and the explicit water molecule participates in the reaction as a reactant.

The free energy profile for the mPBI(-1) with one explicit water molecule is shown as the red line in Figure 5.8 (a). In this cases,  $\Delta G_1$  is 0.11 eV lower than that without the explicit water molecule. The free energy barrier for the water-assisted hydroxyl proton transfer ( $\Delta G^{TS2-2.2}$ ) and the C-N bound breaking ( $\Delta G^{TS3}$ ) during the ring-opening step is 0.25 and 0.23 eV lower than that without the explicit water molecule. The  $\Delta G^{TS4}$ and other reaction free energies during the chain scission are still the same as the path without the explicit water molecule. The highest transition state with one explicit water molecule is TS6-3.1, and the effective energy barrier is 1.69 eV, 0.35 eV lower than the path without the explicit water molecule.

#### Two and Three Explicit Water Molecules

When we consider more explicit water molecules in the reaction path, one explicit water molecule is placed near the N1 position and thus participates as a reactant. Then, additional explicit water molecules are placed near the N3<sup>\*</sup> or N1<sup>\*</sup> position, forming a hydrogen bond with the deprotonated site. The additional explicit water molecules are placed in the way to keep forming the hydrogen bond at the same site throughout the degradation path. With two explicit water molecules, it is found that the configuration with at least one explicit water molecule near the N1 position results in lower energy for  $\Delta G_1$  (see Table C.1). An increasing number of explicit water molecules from zero to three with at least one water molecule near the N1 position reduced  $\Delta G_1$  from 1.38 to 1.24 eV.

The reaction profile of the mPBI(-1) molecule with two and three explicit water molecules is given in the blue and green line in Figure 5.8 (a), and it is similar to the energy profile with one explicit water molecule. However, the reaction free energy for the proton transfer between structures D and E with two and three explicit water molecules is about 0.14 eV less negative than that with one explicit water molecule. The free energy barrier and reaction free energy for the second nucleophilic addition step (from E+OH<sup>-</sup> to F) with two and three explicit water molecules are about 0.15 and 0.14 eV lower than those with one explicit water molecule. The free energy difference in each step along the reaction path, with two and three explicit water molecules, is less than 0.1 eV. These results suggest that a further increase in explicit water molecules may have no practical effect on the reaction profile. The highest transition state along the degradation pathway with two and three explicit water molecules is the TS6-3.1 state, which is only 0.1 eV lower than the degradation pathway with one explicit water molecules.

Additionally, the degradation pathway for the mPBI(0) with up to two explicit water molecules using the PCM implicit solvation is given in Figure 5.8 (b). The highest transition state is TS6-3.1, regardless of the number of explicit water molecules. The effective energy barrier in the reaction with zero, one, and two explicit water molecules is 2.02 eV, 1.63 eV, and 1.60 eV, respectively.

We employed the SMD implicit solvation model to test the sensitivity to the choice of implicit solvation model [194]. We use the same optimized structures in the gas phase and keep water as a solvent for the SMD implicit solvation. As shown in Figure C.2 (a) of Appendix C, the paths obtained from both implicit solvation models are similar, but the SMD implicit solvation results in higher reaction energy and energy barrier. As shown in Figure C.2 (b) of Appendix C, the effective barrier with the SMD implicit solvation also becomes smaller when including the explicit water molecules.

It is important to note that the effective energy barrier was approximated with specific static configurations and a limited amount of explicit water molecules around the mPBI molecule. A more elaborate model would require more number of explicit water molecules. A computational study of hydrolysis of imidazole-ylidenes by Hollóczki et al. has suggested that by increasing the number of water molecules, the calculated energy barriers trend agrees with the experimental results [195]. Also, it has been suggested that the alkaline stability of the imidazolium-based cation is determined by the hydration level, which is the number of water molecules per cation molecule [196–198]. Furthermore, a recent study by Wu et al. [198] investigating the distribution of water molecules and hydroxide ions around imidazolium-based molecules by molecular dynamic (MD) simulations with about 100 - 400 explicit water molecules has found that the alkaline stability of the imidazolium-based molecules significantly depends on the distribution of water molecules and hydroxide ions around the imidazolium structures. In our study, further increasing the number of explicit water molecules to complete the hydration shell for the mPBI molecule along the degradation by performing MD simulations would be required to achieve higher accuracy. However, such a simulation requires significantly more computational cost and time.

#### 5.8 Effect of Hydroxide Ion Concentration

Previous experimental studies by Aili *et al.*[66] and Kraglund *et al.* [60] have reported that the mPBI-based membrane was stable at low KOH concentration (up to 5 wt% KOH at T = 80 - 88 °C) but it degraded when the KOH concentration was increased. In this following section, we consider the hydroxide ion concentration in the reaction free energy and free barrier calculations. The reaction free energy is, for example, calculated as follows

 $\mathrm{A} + \mathrm{OH}^- \to \mathrm{C}$ 

$$\Delta G(pH) = \Delta G_{(sol)} - RT \ln[OH^{-}] = \Delta G_{(sol)} - 2.303RT(pH - pK_w)$$
(5.27)

$$\Delta G_{(sol)} = G(C_{(sol)}) - G(A_{(sol)}) - G(OH_{(sol)}^{-})$$
(5.28)

where  $\Delta G_{(sol)}$  is the reaction free energy at standard condition in solution phase where  $[A] = [OH^-] = [C] = 1$  M, and it is calculated in the same way as described in Section 5.2. pK<sub>w</sub> is the acid dissociation constant of water taken from the literature (pK<sub>w</sub> = 12.46 at T = 80°C [184]). It should be noted that the previous calculations apply for pH = 12.46.

Figure 5.9 (a) shows the reaction profile for the mPBI(-1) degradation with two explicit water molecules at different pH. For all considered pH values, the degradation rate is still determined by the TS6-3.1 state but the effective energy barrier becomes lower as pH increases, suggesting that the degradation becomes easier as the KOH concentrations is higher.

It should be noted that even though at a high pH range (pH > 13), the dominant species is mPBI(-2) which is unlikely to degrade, the degradation still can occur through the mPBI(-1) species which accounts for 10 - 20% of the mPBI molecules. The number of mPBI(-1) in the solution can be quickly reduced as the degradation reaction is also facile at this high pH. The mPBI(-2) species can then change to mPBI(-1) to maintain the equilibrium between all three mPBI species. The degradation can proceed further. Due to the degradation, the number of ionized species and mobile hydroxide ions in the solution is reduced. Thus, the reduction in the ionic conductivity and the changes in membrane structure are unavoidable. Working at a lower pH range to minimize degradation can be possible. However, this comes with a lower ionic conductivity as the percentage of the ionized form in the solution becomes lower at a lower pH [60].

#### 5.9 Comparison with Experiment

An apparent free energy barrier can be approximated from a given experimental reaction rate. The apparent degradation rate is derived from the molecular weight loss of the mPBI membrane after being soaked in 5, 10, 25, 50 wt% KOH at T = 88 °C for 200 days reported by Aili *et al.* [66]. Therefore, the molecular weight loss rate of the mPBI at a specific KOH concentration (in s<sup>-1</sup>) is approximated as follows

rate = 
$$\frac{1}{\Delta t} (1 - \frac{m_{200}}{m_1}) = k(f_0 + f_1) = k_0 f_0 + k_1 f_1$$
 (5.29)

**Figure 5.9:** (a) Reaction energy profile for the mPBI(-1) degradation at T = 88 °C with two explicit water molecules and the PCM implicit solvation model at different pH. The reference zero energy state for energies reported is A+OH<sup>-</sup>, and the relative energies are in eV. (b) The effective free energy barrier and the apparent energy barrier from the experiments at different KOH concentrations and T = 88 °C

where k is the apparent reaction rate constant (in s<sup>-1</sup>).  $k_0$ ,  $k_1$  is the reaction rate constant (in s<sup>-1</sup>) for the degradation of mPBI(0), and mPBI(-1), respectively.  $f_0$ ,  $f_1$  are the mole fraction of mPBI(0), and mPBI(-1), respectively.  $\Delta t$  is the duration for storing the mPBI in KOH solution (= 200 days);  $m_1$  and  $m_{200}$  are the molecular weight of mPBI (in g/mol) before storing in KOH solution (day1) and after storing in KOH solution for 200 days, respectively. The apparent free energy barrier is calculated using Equation 5.21 with the approximated k from Equation 5.29.

The (total) effective barrier ( $\Delta G^{TST}$ ) from the theoretical model is a weighted average value, taking the mole fraction of mPBI(0) and mPBI(-1) at each KOH concentration into account, and can be expressed as follows

$$\Delta G^{\text{TST}} = -RT \ln(\frac{hk_{avg}}{k_BT}) \text{ and } k_{avg} = \frac{k_0 f_0}{f_0 + f_1} + \frac{k_1 f_1}{f_0 + f_1}$$
(5.30)

where  $k_0$ ,  $k_1$  are calculated from the effective energy barrier for the degradation of the mPBI(-1) and mPBI(0) molecule using Equation 5.21.

Figure 5.9 (b) shows the apparent energy barrier derived from the experimental results and the effective free energy barrier from different implicit-explicit solvation models. Without the explicit water molecules, the PCM implicit solvation model predicts a much larger effective free energy barrier than the experiments, resulting in a mean absolute value (MAE) of 0.43 eV. However, the MAE is reduced to below 0.1 eV when including explicit water molecules in the simulation. On top of that, it is seen that both the apparent and effective free energy barriers decrease as the KOH concentration increases.

It should be noted that the contribution from the mPBI(-2) molecule to the total degradation rate is considered insignificant and is not included in the previous approximation. We find that the reaction free energy for the first nucleophilic addition reaction at the C2 position in the mPBI(-2) molecule is more than 2 eV, higher than those of the mPBI(-1) and mPBI(0) molecule. Thus, we consdiered that the mPBI(-2) molecule is unlikely to degrade. The approximated degradation rate includes the mPBI(-2) contribution as given in Figure C.3 (a) of Appendix C, demonstrating that there is no further improvement in the approximated rate.

Figure C.3 (b) in Appendix C show the approximated degradation (rate =  $k_1f_1 + k_0f_0$ ) from the calculation model with different number of explicit water molecule. Like the effective energy barrier, the approximated degradation rate approaches the experimental results when explicit water molecules are included. The results show that the combined implicit and explicit solvation makes the predicted degradation rate and effective barrier move toward the experimental results, and at least two explicit water molecules should be considered along the degradation pathway.

The degradation rate becomes higher with KOH concentration, especially from 0 to 15 %wt KOH. After that, the degradation rate is slightly lower, mainly due to the reduced number of mPBI(0) molecules as the KOH concentration increase. Simultaneously, the degradation rate contribution from the mPBI(-1) molecule keeps increasing with the KOH concentration, see Figure C.3 (a) in Appendix C. These results suggest that both effective barriers and  $pK_a$  value play a significant role in the stability of the mPBI molecule in an alkaline solution.

### 5.10 Conclusions

This chapter investigated the degradation mechanism of the mPBI molecule in an alkaline solution. The mPBI molecule deprotonates when submerged in an alkaline solution. The fully deprotonated molecule (mPBI(-2)) is the predominant species at the high KOH concentration where degradation is expected. However, the formation of the fully deprotonated molecule suppresses the hydroxide ion attack. Still, the degradation possibly proceeds from the small fraction of non- and partially deprotonated molecules (mPBI(0) and mPBI(-1)). The hydroxide ion can attack the carbon atom at the C2 position in the non- and partially deprotonated molecule, initiating the degradation. The following reaction is the ring-opening reaction, where the hydroxyl proton transfer occurs via an ancillary hydroxide ion or water molecule. The product from the ring-opening reaction undergoes alkaline hydrolysis, leading to complete chain scission. The rate-determining state is associated with the amide cleavage during the chain scission reaction. An implicit solvation model predicts a relatively largest deviation of the degradation rate and effective barrier compared to the experiment. Combining explicit water molecules and implicit solvation lowers the effective barrier for the degradation, giving more agreement between the experiment and the calculations. The model additionally captures the experimental trend in which the degradation rate increases with KOH concentration.

## **Chapter 6**

## **Summary and Outlook**

In this thesis, the stabilities of carbon-based materials used in the fuel cell were studied by DFT calculations. These included the degradation of the M/N/C electrocatalyst in an acid solution and the degradation of the mPBI molecule in an alkaline solution.

We considered the stability of the M/N/C catalyst from the propensity of the metal center to dissolve from the carbon substrate. It was found that the local carbon structures around the metal center play a crucial role in its stability under the acid condition. Depending on the local carbon structures, the basicity of the atoms incorporated with the metal center and the bonding strength between the metal center and the carbon substrate influence the stability of the M/N/C structure under the acid condition. The choice of a metal center is also crucial to determining stability. We found that metal oxidation causes a significant difference in the acid stability among the 3d metal element. Using the computational screening approach, we suggested that the MN<sub>4</sub> sites on the bulk graphene and graphene edge with M = Fe, Co, and Ru are stable electrocatalysts in the acid condition.

Furthermore, the adsorption of the relevant species in the electrolytes was included in the stability and activity calculations for the  $MN_4$  site on the bulk graphene and graphene edge. It was found that the electrolyte anions can compete with water and adsorb on the single metal site under the ORR-related condition. Then the single metal site can be further thermodynamically stabilized against dissolution, compared to the stability in the pure water environment. Unlike the ORR-related condition, most electrolyte anions do not adsorb on the single metal site at the lower potentials for the  $CO_2RR$ . Still, the adsorption of water and gas molecules can occur under  $CO_2RR$ related conditions, resulting in modified catalytic activity. Through the catalytic activity and stability descriptor, we suggested promising combinations of the electrolyte and the metal center that result in an active and durable catalyst for the ORR and  $CO_2RR$ .

The stability calculations of the M/N/C catalyst in this thesis were based on the thermodynamic model. A kinetic analysis would be required for a better understanding and a complete stability descriptor. Also, the metal center can dynamically interact with the water and solvent molecules at the electrode-liquid interface. These interactions could affect the dissolution mechanism and the kinetic barrier. Thus the proper

configurations of water and solvent molecules at the catalyst interface should be explicitly considered. The other reactions leading to the degradation of the M/N/C catalyst may occur in parallel during durability testing of the fuel cell, while only the demetallation was considered in this thesis. Therefore, the calculation models should be extended to consider other possible reactions, such as carbon surface oxidation and carbon corrosion. Also, it is interesting to study the stability of the M/N/C materials in other geometries, such as the dual metal site embedded in the graphene.

Apart from the stability of the M/N/C catalyst, we considered the stability of the mPBI molecule in an alkaline solution. The mPBI-based membrane is a promising material for anion exchange membranes in the alkaline fuel cell, but the degradation at high KOH concentrations limits its practical use. Under the alkaline condition, it was found that the mPBI molecule is deprotonated and thus forms the ionized molecule. The fully deprotonated molecule is the dominant species under the highly alkaline condition and is unlikely to be degraded. At the same time, the non- and partiallydeprotonated molecules are vulnerable to hydroxide ion attack. Thus, the degradation possibly proceeds from the small fraction of non- and partially-deprotonated molecules. Furthermore, we found that the effective energy barrier depends on the KOH concentration and becomes lower as the KOH concentration increases, suggesting that degradation can become easier when the KOH concentration is higher. It was also found that the availability of vulnerable species in the solution can affect the degradation rate. These results suggested that the pK<sub>a</sub> value is a crucial factor affecting the stability of the mPBI molecule. Finally, it was found that the calculation with the implicit-explicit solvation model agrees with the experiment more than the calculation with only the implicit solvation, and at least two explicit water molecules should be included along the degradation pathway.

Further investigating the distribution of explicit water molecules and hydroxide ions around the mPBI structures along the degradation would give a more accurate model and a better understanding of the degradation. Additionally, recent experiments have been carried out with derivatives of mPBI that are linked with steric trimethylphenyl units [69] or bulky naphthalene groups [70] and suggested improved stability in an alkaline solution. Further exploration of the degradation pathway of the derivatives will provide helpful information for designing new derivatives with improved long-term stability in alkaline solutions.

#### Appendix A

### **Supplementary material I**

**Table A.1:** Reaction free energy for the dissolution of the bulk metal (G( $M^{x+}$ )) and calculated DFT energy per atom of the metal in their bulk structure ( $E_M$ (bulk)).  $E_0$  is in  $V_{SHE}$  and  $E_M$ (bulk) is in eV/atom. The square brackets indicate the concentration of the dissolved metal ions.

ion	$G(M^{X+})$	E <sub>0</sub>	E <sub>M</sub> (bulk)
Cr <sup>2+</sup>	$E_{Cr}(bulk) + 2(E_0 + (0.059/2) \log[Cr^{2+}])$	$E_0 = -0.91$	
Cr <sup>3+</sup>	$E_{Cr}(bulk) + 3(E_0 + (0.059/3) \log[Cr^{3+}])$	$E_0 = -0.74$	-7.17
CrOH <sup>2+</sup>	$G(Cr^{3+}) + G(H_2O) - (1/2)G(H_2) + 2.303 k_BTpH_0$	$pH_0 = 3.81$	
Mn <sup>2+</sup>	$E_{Mn}(bulk) + 2(E_0 + (0.059/2) \log[Mn^{2+}])$	$E_0 = -1.19$	6.45
Mn <sup>3+</sup>	$G(Mn^{2+}) + E_0 + (0.059) \log([Mn^{3+}]/[Mn^{2+}])$	$E_0 = 1.54$	-0.45
Fe <sup>2+</sup>	$E_{Fe}(bulk) + 2(E_0 + (0.059/2) \log[Fe^{2+}])$	$E_0 = -0.45$	
Fe <sup>3+</sup>	$E_{Fe}(bulk) + 3(E_0 + (0.059/3) \log[Fe^{3+}])$	$E_0 = -0.04$	-5.65
FeOH <sup>2+</sup>	$G(Fe^{3+}) + G(H_2O) - (1/2)G(H_2) + 2.303 k_BTpH_0$	$pH_0 = 2.43$	
Co <sup>2+</sup>	$E_{Co}(bulk) + 2(E_0 + (0.059/2) \log[Co^{2+}])$	$E_0 = -0.28$	4 29
Co <sup>3+</sup>	$G(Co^{2+}) + E_0 + (0.059) \log([Co^{3+}]/[Co^{2+}])$	$E_0 = 1.92$	-4.29
Ni <sup>2+</sup>	$E_{Ni}(bulk) + 2(E_0 + (0.059/2) \log[Ni^{2+}])$	$E_0 = -0.26$	2 53
Ni <sup>3+</sup>	$G(Ni^{2+}) + E_0 + (0.059) \log([Ni^{3+}]/[Ni^{2+}])$	$E_0 = 2.30$	-2.55
Ru <sup>2+</sup>	$E_{Ru}(bulk) + 2(E_0 + (0.059/2) \log[Ru^{2+}])$	$E_0 = 0.46$	-6.26
Ru <sup>3+</sup>	$G(Ru^{2+}) + E_0 + (0.059) \log([Ru^{3+}]/[Ru^{2+}])$	$E_0 = 0.25$	-0.20

**Figure A.1:** The minimum energy structures of the dissolved-metal  $N_yCH_n$  carbon cavity with n = 0 - 4: (a)  $N_4C_{10}H_n$ , (b)  $N_4C_{12}H_n$ , (c)  $N_4C_8H_n$ , (d)  $N_4C_2H_n$ , (e)  $N_4C_AH_n$ , (f)  $N_3C_{10}H_n$ , (g)  $N_3C_ZH_n$ , (h)  $N_3C_AH_n$ . (C = gray, N = blue, H = white, M = orange).

**Figure A.2:** Reaction free energy for protonation at the metal-dissolved carbon cavity  $(\Delta G_{\text{protonate-cavity}})$  as a function of numer of H<sup>+</sup> at pH = 0 and U = 0.8 V<sub>SHE</sub>.

**Figure A.3:** (top) Stability diagram and (bottom)  $\Delta G_R$  at pH = 0 of the considered Fe/N/C structures without and with the adsorbate (Fe, \*OH-Fe, and \*O-Fe) obtained from two sizes of unit cell (b = bigger unit cell): (a) FeN<sub>4</sub>C<sub>10</sub>, (b) FeN<sub>4</sub>C<sub>12</sub>, (c) FeN<sub>4</sub>C<sub>8</sub>, (d) FeN<sub>4</sub>C<sub>Z</sub>, and (e) FeN<sub>4</sub>C<sub>A</sub>. The insets show the structural models used in the calculations (C = gray, N = blue, H = white, Fe = orange).

**Figure A.4:** Stability diagram and  $\Delta G_R$  at pH = 0 of the considered Fe/N/C structures without and with the adsorbate (Fe, \*OH-Fe, and \*O-Fe) obtained from different solvation (v = vacuum, w = explicit solvation): (a) FeN<sub>4</sub>C<sub>10</sub>, (b) FeN<sub>4</sub>C<sub>12</sub>, (c) FeN<sub>4</sub>C<sub>8</sub>, and (d) FeN<sub>4</sub>C<sub>2</sub>. The insets show the structural models used in the calculations (C = gray, N = blue, H = white, Fe = orange).

**Figure A.5:** (top) Stability diagram and (bottom)  $\Delta G_R$  at pH = 0 of the considered Cr/N/C structures without and with the adsorbate (Cr, \*OH-Cr, and \*O-Cr): (a) CrN<sub>4</sub>C<sub>10</sub>, (b) CrN<sub>4</sub>C<sub>12</sub>, (c) CrN<sub>4</sub>C<sub>8</sub>, (d) CrN<sub>4</sub>C<sub>2</sub>, (e) CrN<sub>4</sub>C<sub>A</sub>, (f) CrN<sub>3</sub>C<sub>10</sub>, (g) CrN<sub>3</sub>C<sub>Z</sub>, and (h) CrN<sub>3</sub>C<sub>A</sub>

**Figure A.6:** (top) Stability diagram and (bottom)  $\Delta G_R$  at pH = 0 of the considered Mn/N/C structures without and with the adsorbate (Mn, \*OH-Mn, and \*O-Mn): (a) MnN<sub>4</sub>C<sub>10</sub>, (b) MnN<sub>4</sub>C<sub>12</sub>, (c) MnN<sub>4</sub>C<sub>8</sub>, (d) MnN<sub>4</sub>C<sub>2</sub>, (e) MnN<sub>4</sub>C<sub>A</sub>, (f) MnN<sub>3</sub>C<sub>10</sub>, (g) MnN<sub>3</sub>C<sub>2</sub>, and (h) MnN<sub>3</sub>C<sub>A</sub>

**Figure A.7:** (top) Stability diagram and (bottom)  $\Delta G_R$  at pH = 0 of the considered Co/N/C structures without and with the adsorbate (Co, \*OH-Co, and \*O-Co): (a) CoN<sub>4</sub>C<sub>10</sub>, (b) CoN<sub>4</sub>C<sub>12</sub>, (c) CoN<sub>4</sub>C<sub>8</sub>, (d) CoN<sub>4</sub>C<sub>2</sub>, (e) CoN<sub>4</sub>C<sub>A</sub>, (f) CoN<sub>3</sub>C<sub>10</sub>, (g) CoN<sub>3</sub>C<sub>2</sub>, and (h) CoN<sub>3</sub>C<sub>A</sub>

**Figure A.8:** (top) Stability diagram and (bottom)  $\Delta G_R$  at pH = 0 of the considered Ni/N/C structures without and with the adsorbate (Ni, \*OH-Ni, and \*O-Ni): (a) NiN<sub>4</sub>C<sub>10</sub>, (b) NiN<sub>4</sub>C<sub>12</sub>, (c) NiN<sub>4</sub>C<sub>8</sub>, (d) NiN<sub>4</sub>C<sub>2</sub>, (e) NiN<sub>4</sub>C<sub>A</sub>, (f) NiN<sub>3</sub>C<sub>10</sub>, (g) NiN<sub>3</sub>C<sub>Z</sub>, and (h) NiN<sub>3</sub>C<sub>A</sub>

**Figure A.9:** (top) Stability diagram and (bottom)  $\Delta G_R$  at pH = 0 of the considered Ru/N/C structures without and with the adsorbate (Ru, \*OH-Ru, and \*O-Ru): (a) RuN<sub>4</sub>C<sub>10</sub>, (b) RuN<sub>4</sub>C<sub>12</sub>, (c) RuN<sub>4</sub>C<sub>8</sub>, (d) RuN<sub>4</sub>C<sub>2</sub>, (e) RuN<sub>4</sub>C<sub>A</sub>, (f) RuN<sub>3</sub>C<sub>10</sub>, (g) RuN<sub>3</sub>C<sub>Z</sub>, and (h) RuN<sub>3</sub>C<sub>A</sub>

**Figure A.10:** Reaction free energy for the formation of \*OH and \*O on the FeN<sub>4</sub> center (in dashed lines) and carbon atoms adjacent to the FeN<sub>4</sub> center (in solid lines) at pH = 0;  $\Delta G(*X)$  where X = O, OH: (a) FeN<sub>4</sub>C<sub>10b</sub>, (b) FeN<sub>4</sub>C<sub>12b</sub> and (c) FeN<sub>4</sub>C<sub>Zb</sub>. The insets show the minimum energy positions for \*OH and \*O on the carbon atoms (C = gray, N = blue, H = white, Fe = orange).

**Figure A.11:** Stability diagram and  $\Delta G_R$  at pH = 0 of the considered FeN<sub>4</sub>C<sub>10</sub> structures without and with the adsorbate (Fe, \*OH-Fe, and \*O-Fe): (a) FeN<sub>4</sub>C<sub>10b</sub>, (b) FeN<sub>4</sub>C<sub>10b</sub> with near by \*OH, (c) FeN<sub>4</sub>C<sub>10b</sub> with near by \*O, (d) FeN<sub>4</sub>C<sub>10</sub>, (e) FeN<sub>4</sub>C<sub>10</sub> with nearby graphitic N atoms (configuration 1) and (f) FeN<sub>4</sub>C<sub>10</sub> with nearby graphitic N atoms (configuration 2). The insets show the structural models used in the calculations (C = gray, N = blue, H = white, Fe = orange).

**Figure A.12:** The d-orbital splitting and electronic configuration for the metal atom in  $^{*}OH-MN_{4}C_{10}$  and  $^{*}OH-MN_{4}C_{8}$  structure: (a) M = Cr, (b) M = Mn, (c) M = Ru, (d) M = Co, and (e) M = Co. The electron donated to the adsorbate is red, and the remaining electrons in the d-orbitals are black.

**Figure B.1:** Scaling relation between  $\Delta G(^*O)$  vs.  $\Delta G(^*OH)$  and  $\Delta G(^*OOH)$  vs.  $\Delta G(^*OH)$  on the bare metal site: (a)  $MN_4C_{10}$ , (b)  $MN_4C_A$ . Activity volcano plot as a function of  $\Delta G(^*O)$  for the bare metal site: (c)  $MN_4C_{10}$  and (d)  $MN_4C_A$ .

**Figure B.2:**  $\Delta G_f$  (in eV) as a function of  $\mu_N(n)$ : (a)  $MN_4C_{10}$  at  $T = 1100 \ ^\circ$ C, (b)  $MN_4C_{10}$  at  $T = 25 \ ^\circ$ C, (c)  $MN_4C_A$  at  $T = 1100 \ ^\circ$ C, (d)  $MN_4C_A$  at  $T = 25 \ ^\circ$ C. At n = 0,  $\mu_N(n = 0)$  is that of the  $N_2$  molecule at 1 bar and at considered temperature in each subplot ( $T = 1100 \ ^\circ$ C for (a) and (c);  $T = 25 \ ^\circ$ C for (b) and (d)). Lower formation energy (brighter colour background) indicates more thermodynamically favourable to form.

**Figure B.3:** (a) Stability diagrams for the CoN<sub>4</sub>C<sub>A</sub> site in 0.1 M solutions. (b)  $\Delta G_R$  for the sites at specific pH, and (c) Stability diagrams for the CoN<sub>4</sub>C<sub>A</sub> site showing the most stable surface, and the background color corresponds to the value of  $\Delta G_R$ 

**Figure B.4:** (a) Stability diagrams for the FeN<sub>4</sub>C<sub>10</sub> site in 0.1 M solutions. (b)  $\Delta G_R$  for the sites at specific pH, and (c) Stability diagrams for the FeN<sub>4</sub>C<sub>10</sub> site showing the most stable surface, and the background color corresponds to the value of  $\Delta G_R$ 

**Figure B.5:** (a) Stability diagrams for the FeN<sub>4</sub>C<sub>A</sub> site in 0.1 M solutions. (b)  $\Delta G_R$  for the sites at specific pH, and (c) Stability diagrams for the FeN<sub>4</sub>C<sub>A</sub> site showing the most stable surface, and the background color corresponds to the value of  $\Delta G_R$

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          | $\cdot \frac{4539}{9} \frac{1}{9} \frac{1}{9} \frac{5}{9} \frac{1}{9} \frac{1}{9}$                                          | $\cdot \frac{3592}{500} \frac{D+2}{D+2} \frac{3}{2} \frac{5}{2} \frac$ |

(a)  $MN_4C_{10}$ :  $\Delta G_{max}(pH = 1, U = 0.8 V_{SHE}) / eV$ 

**Figure B.6:**  $\Delta G_{max}$  along the ORR pathway at U = 0.80 V<sub>SHE</sub> and pH = 1 in 0.1 M electrolytes on: (a) MN<sub>4</sub>C<sub>10</sub>, (b) MN<sub>4</sub>C<sub>A</sub>. In each cell, the inserted text in the 1<sup>st</sup> row shows the adsorbate ligand on the back side of the metal atom participating in the reaction. The adsorbate ligand is considered to be the most stable adsorbate on the MN<sub>4</sub> site at pH = 1, U = 0.80 V<sub>SHE</sub>. The inserted text in the 2<sup>nd</sup> row shows the determining reaction states for  $\Delta G_{max}$  at pH = 1, U = 0.80 V<sub>SHE</sub>. The number 0-6 is referred to the reaction state in Figure 4.5. The inserted number in the 3<sup>rd</sup> row is  $\Delta G_{max}$  value at pH = 1, U = 0.80 V<sub>SHE</sub> in eV. The insert **X** in the 3<sup>rd</sup> row means the second adsorbate moves away from the metal site with a distance > 3.0 Å; thus, the metal site is considered to be inactive for the ORR. The background color corresponds to the  $\Delta G_{max}$  value. The brighter the background color, the lower the thermodynamic barrier.

(a)  $MN_4C_{10}$ :  $U_L(pH = 1) / V_{SHE}$ 

**Figure B.7:** U<sub>L</sub> of the ORR in 0.1 M electrolyte at pH = 1 on: (a)  $MN_4C_{10}$ , (b)  $MN_4C_A$ . In each cell, the inserted text in the 1<sup>st</sup> row shows the adsorbate ligand on the back side of the metal atom participating in the reaction. The adsorbate ligand is considered to be the most stable adsorbate on the  $MN_4$  site at pH = 1, U = 0.80 V<sub>SHE</sub>. The inserted text in the 2<sup>nd</sup> row shows the potential determining states for U<sub>L</sub> at pH = 1. The number 0-6 is referred to the reaction state in Figure 4.5. The inserted number in the 3<sup>rd</sup> row is U<sub>L</sub> value at pH = 1 in V<sub>SHE</sub>. The insert **X** in the 3<sup>rd</sup> row means the second adsorbate moves away from the metal site with a distance > 3.0 Å; thus, the metal site is considered to be inactive for the ORR or the neutral gas molecules are thermodynamically favorable on both sides of the metal atom. The background color corresponds to the value of U<sub>L</sub>. The brighter the background color, the higher the limiting potential.

**Figure B.8:** Free energy diagram of the CO<sub>2</sub>RR to CO at pH = 7, U = -1.0 V<sub>SHE</sub> on: (a)  $MN_4C_{10}$ , (b)  $MN_4C_A$  structure in 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO solution, where M = Mn, Fe, Co, Ni, Zn, Cu and Sn. The ligand on the back side of the metal atom is the most adsorbate at pH = 7, U = -1.0 V<sub>SHE</sub>. The insets show the side view of the \*COOH/\*H and \*CO/\*H on the CoN<sub>4</sub> site. (C = gray, N = blue, H = white, O = red, Co = pink)

(a)  $MN_4C_{10}$ :  $\Delta G_{max}(pH = 7, -0.80 V_{SHE}) / eV$ 

**Figure B.9:**  $\Delta G_{max}$  along the CO<sub>2</sub>RR to CO pathway at U = -0.80 V<sub>SHE</sub> and pH = 7 in 0.1 M electrolytes on: (a) MN<sub>4</sub>C<sub>10</sub>, (b) MN<sub>4</sub>C<sub>A</sub>. In each cell, the inserted text in the 1<sup>st</sup> row shows the adsorbate ligand on the back side of the metal atom participating in the reaction. The adsorbate ligand is considered to be the most stable adsorbate on the MN<sub>4</sub> site at pH = 7, U = -0.80 V<sub>SHE</sub>. For other considered electrolytes, except 0.1 M H<sub>2</sub>CO<sub>3</sub>, their catalytic activity under the CO<sub>2</sub>RR-related condition is the same as in H<sub>2</sub>O. The inserted text in the 2<sup>nd</sup> row shows the determining reaction states for  $\Delta G_{max}$  at pH = 7, U = -0.80 V<sub>SHE</sub>. The number 0-5 is referred to the reaction state in Figure 4.7. The inserted number in the 3<sup>rd</sup> row is  $\Delta G_{max}$  value at pH = 7, U = -0.80 V<sub>SHE</sub> in eV. The insert X in the 3<sup>rd</sup> row means the second adsorbate moves away from the metal site with a distance > 3.0 Angstrom. Thus, the metal site is considered to be inactive for the CO<sub>2</sub>RR. The lower the thermodynamic barrier of the limiting step.

ABSTRACT: M	etal—nitrogen carbon (M–N–(	C) catalysts, atomically dispersed and	0, 🕶 👞

hitogen-coordinated  $MN_x$  sites embedded in carbon planes, have exhibited encouraging oxygen reduction reaction activity in an acidic environment. However, one challenge for these materials is their insufficient long-term stability in the acid environment. Herein, we systematically investigate both catalytic activity toward ORR and stability under acid conditions using density functional theory (DFT). Various local atomic structures around the  $MN_x$  site and different metal atoms (M = Cr, Mn, Fe, Co, Ni, and Ru) are considered in this study to understand the relation between atomic structures, stability, and catalytic activity. The stability of the M-N-C catalyst is considered from the propensity of the metal atom center to dissolve from the carbon host structure. The calculations reveal that the considered  $MN_x$  sites are thermodynamically unstable in acid ORR conditions. However, based on the calculated thermodynamic driving force toward the metal dissolution, the  $MN_4$  sites with Fe, Co, Ni, and Ru metal atoms embedded on the

graphene plane and at the graphene edge are more stable in the acid ORR condition than the other considered  $MN_x$  structures. Combining the stability and catalytic activity descriptor, we propose some acid-stable and active  $MN_x$  structures toward ORR. This computational study provides helpful guidance for the rational modification of the carbon matrix hosting  $MN_x$  moieties and the appropriate selection of a metal atom for optimizing the activity and stability toward the ORR reaction.

#### 1. INTRODUCTION

The proton exchange membrane fuel cell (PEMFC) is a highly efficient clean energy conversion device that requires a highly active catalyst for the oxygen reduction reaction (ORR) at the cathode. Platinum-based catalysts now reach high activity and durability.<sup>1</sup> However, considering the high cost and lack of platinum-based catalysts, the catalyst-free platinum group remains an alternative catalyst for cost and sustainability reasons.

Among the catalysts free of platinum group metals, metal– nitrogen carbon (M–N–C) catalysts, where atomically dispersed and nitrogen-coordinate  $MN_x$  sites are embedded in carbon planes, have gained much attention because of their high initial activity toward the ORR in acid media, especially Fe–N–C catalysts.<sup>2–4</sup> However, the issue facing the Fe–N–C catalyst is an insufficiency of long-term stability. The Fe–N–C catalyst tends to degrade quickly in the acidic PEMFC environment,<sup>5</sup> but the degradation mechanism remains elusive; therefore, further investigations and improvements for the M– N–C catalysts are still needed. However, various degradation mechanisms have been proposed to degrade M–N–C catalysts, such as carbon oxidation by hydroxyl or hydroperoxyl radicals,<sup>6,7</sup> demetalation of metal sites,<sup>8,9</sup> and carbon corrosion.<sup>10</sup>

On top of that, the synthetic approaches that involve pyrolysis of the mixture of metal, nitrogen, and carbon precursor often result in the various local environment for the MN<sub>x</sub> site,<sup>11,12</sup> and thus, the ORR catalytic activity and stability of the M-N-C materials is highly dependent on the synthesis path. Different configurations of the MN<sub>x</sub> sites have been proposed as an active site for the ORR by experimental and theoretical studies,  $^{13-15}$  but the specific MN<sub>x</sub> sites, which are active and durable under working conditions, should be preferred targets for synthesis. The Fe-N-C catalyst prepared via pyrolysis in flowing NH<sub>3</sub> has been reported to have higher initial ORR activity in acid and alkaline conditions than similarly prepared Fe-N-C pyrolyzed in an inert atmosphere.<sup>12,13</sup> However, the NH<sub>3</sub> pyrolyzed Fe-N-C catalyst results in about 10 times enhanced Fe leaching rate than the inert gas pyrolyzed catalyst in acid.<sup>12,13</sup> It has been reported that the  $NH_3$  pyrolysis promotes high basicity and porosity in the Fe–N–C catalyst surface.<sup>12,13,16</sup> The introduction of

Figure 1. M-N-C model structures: (a)  $MN_4C_{10'}$  (b)  $MN_4C_{12'}$  (c)  $MN_4C_{8'}$  (d)  $MN_4C_{2'}$  (e)  $MN_4C_{A'}$  (f)  $MN_3C_{10'}$  (g)  $FeN_3C_{Z'}$  (h)  $FeN_3C_{A'}$ . Color codes for atom: C-gray, N-blue, H-white, M (= metal atom)-orange.

micropores has been suggested to enhance the catalytic activity for ORR.<sup>17,18</sup> In contrast, the initial ORR performance loss has also been proposed due to the demetalation of the FeN4 site located in the micropore.<sup>16</sup> In addition, a recent experimental study by Li et al.<sup>19</sup> using operando X-ray absorption spectroscopy has reported that there are two types of FeN4 sites identified in the Fe-N-C catalyst. These are FeN<sub>4</sub>C<sub>10</sub>, and FeN<sub>4</sub>C<sub>12</sub> sites, surrounded by a different local carbon structure. Both sites initially contribute to the ORR activity of the Fe–N–C in an acidic medium. However, the FeN<sub>4</sub>C<sub>12</sub> site is not durable under operation, rapidly converting into inactive ferric oxide particles as there is a decreasing ORR activity, decreasing numbers of this site, and increasing ferric oxide formation. The  $\text{FeN}_4C_{10}$  site is stable under the acid condition with no measurable decrease in the numbers of this active site after 50 h of operating at 0.5 V.<sup>19</sup> Therefore, the local atomic structures of the MN<sub>x</sub> have been suggested to play a significant role in ORR catalytic activity and demetalation of the active site.<sup>10,17,19,20</sup>

Besides the Fe-N-C catalyst, the Co-N-C catalyst has been the most investigated as a replacement for Fe since the dissolved Fe ions from the Fe-N-C catalysts can further deteriorate the membrane durability by catalyzing the formation of radicals from  $H_2O_2$ , which degrade the membrane.<sup>6,21</sup> Thus, metal atom sites which do not promote the formation of H<sub>2</sub>O<sub>2</sub> radicals are also needed. A previous study by Xie et al. has reported that the Co-N-C catalyst has inferior catalytic activity toward ORR and lower activity for promoting radicals from H<sub>2</sub>O<sub>2</sub> but has significant resistance to demetalation in acid condition.<sup>22</sup> Since various CoN<sub>x</sub> sites can be simultaneously formed during the synthesis,<sup>23</sup> specific knowledge of the detailed structures of the active and durable  $CoN_x$  site would be valuable. Furthermore, other M–N–C catalysts have also been reported to have structural stability under acid conditions, such as the Ru-N-C system.<sup>2</sup> Therefore, the insightful understanding of how catalytic activity and degradation of the  $MN_x$  site related to its electronic structures and local atomic configuration is critical for designing M–N–C catalyst.

Advancements in computing capability have helped to expand predictions from first-principles simulations of materials. While the materials screening for ORR to date have focused on the electrocatalytic activity,  $^{25-27}$  stability under working conditions is also an essential criterion.<sup>28–31</sup> The demetalation of the metal atom center due to proton attack has been calculated and used to determine the acid

stability of the M–N–C catalyst, identifying a specific potential or pH when the dissolution of the metal center is thermodynamically favorable.<sup>32–34</sup> Also, the embedding energy, indicating the bonding strength between the embedded isolated metal atom with N-doped carbon structure against the cohesion energy of the bulk metal, is often calculated and used to represent thermodynamic stability for the M–N–C cattalyts.<sup>27,33,35</sup> Previous work on the thermodynamic dissolution of the FeN<sub>4</sub> structures on two different local carbon structures toward aqueous Fe<sup>2+</sup> has been studied by Glibin et al.,<sup>36</sup> suggesting acid stability of the FeN<sub>4</sub> site.<sup>36</sup> In contrast, Holby et al. found FeN<sub>4</sub> site, and the absolute thermodynamic stability of FeN<sub>4</sub> sites remains controversial.<sup>37,38</sup>

Various degradation mechanisms of the M-N-C catalyst have been suggested. The carbon oxidation is most probably from H<sub>2</sub>O<sub>2</sub>-derived radicals during the oxygen reduction, which leads to various oxygen functional groups on the carbon surface that can deactivate the metal site<sup>7</sup> and trigger irreversible leaching of the metal site.<sup>19,39</sup> This might depend on the morphology of the carbon surface.<sup>19,39</sup> However, the carbon surface oxidation is reversible, and the ORR activity can be recovered by electrochemical cycling or chemical treatment.<sup>7,22</sup> Additionally, carbon corrosion can occur and leads to carbon loss surrounding the FeN<sub>x</sub> site, eventually resulting in metal site leaching.<sup>10</sup> The demetalation itself has also been proposed to cause fast activity decay of the Fe-N-C catalyst.<sup>16</sup> Thus, the degradation of M-N-C catalysts may have more than one cause. Nonetheless, how the M-N-C structure affects the stability against demetalation can be the first step to understand the M-N-C degradation, and it is a focus in this work. The relation between the structure and demetalation will be addressed before introducing other possible degradation pathways.

The thermodynamic understanding of dissolution in aqueous media can be obtained from the so-called Pourbaix diagrams, which indicates the potential and pH ranges where the different component oxidation state of materials exist.<sup>29,30,40</sup> A recent study by Holby et al. has proposed a dissolution reaction to determine the stability of FeN<sub>4</sub> embedded on a graphene layer as a function of pH and applied potential,<sup>38</sup> indicating the acid instability and like-lihood to dissolution to further study the stability of MN<sub>x</sub> with various local atomic structures and various metal atoms to understand how local atomic structures and different metal

atoms affect the stability of M-N-C catalysts. Furthermore, the acid stability descriptor of the  $MN_x$  site under PEMFC conditions is determined by computing the relative stability with respect to the most stable species in the stability diagram, and it is used as a comparative stability descriptor. Thus, the stability descriptor can offer insight into how the M-N-C structure affects stability. The stability descriptor is then used along with the catalytic activity descriptor to identify promising acid-stable and active  $MN_x$  sites toward ORR.

#### 2. METHODS

**2.1. Computation Details.** Spin-polarized density functional theory calculations are performed using the Vienna ab initio simulation package (VASP)<sup>41</sup> and project augmented wave (PAW)<sup>42</sup> pseudopotential. Structures are set up and analyzed using the atomic simulation environment (ASE).<sup>43</sup> The exchange and correlation energy are described using the BEEF-vdW functional to include the effects of dispersive interactions.<sup>44</sup> A plane-wave cutoff of 600 eV is used. The self-consistent electron density loop is converged to  $10^{-5}$  eV, and the structures are relaxed until all forces are below 0.025 eV Å<sup>-1</sup>. The calculations are submitted, managed, and received using the MyQueue<sup>45</sup> workflow tool, a python front-end to the job scheduler.

Eight different M-N-C model structures with different local atomic structure surrounding the metal site are investigated in this study and shown in Figure 1. The MN<sub>4</sub>C<sub>10</sub> structure is an MN<sub>4</sub> site embedded in an intact graphitic layer where the MN<sub>4</sub> site is surrounded by 10 carbon atoms, where M is a single metal atom. The  $MN_4C_Z$  and MN<sub>4</sub>C<sub>A</sub> structure represent the MN<sub>4</sub> site near the zigzag and armchair graphitic edge, respectively. For the active sites hosted in a micropore, we consider a MN<sub>4</sub>C<sub>12</sub> site near the micropore with a porphyrin-like structure and a MN<sub>4</sub>C<sub>8</sub> site where the  $MN_4$  moiety is bridging two adjacent armchair edges. The  ${\rm FeN_4C_{12}}$  site has been identified by X-ray absorption spectroscopy and has been proposed as the active site toward the ORR reaction by Zitolo et al.<sup>13</sup> The  $FeN_4C_8$ site has been proposed as the most active site in such Fe–N–C catalyst.  $^{14,15,18,46}$  Li et al. have reported that the Fe–N–C catalyst initially comprises two distinct  $FeN_4$  sites identified as the  $FeN_4C_{10}$  and  $FeN_4C_{12}$  structure.<sup>19</sup> Also, we further consider two defective sites derived from the MN<sub>4</sub>C<sub>Z</sub> and MN<sub>4</sub>C<sub>A</sub> structure, namely, MN<sub>3</sub>C<sub>Z</sub> and MN<sub>3</sub>C<sub>A</sub>. These edgeanchored unsaturated MN<sub>3</sub> structures are possible to form under a synthesis environment, as reported by Cheng et al.<sup>47</sup> The unit cell dimensions in the catalyst plane are  $16.9 \times 9.8$  Å on average, with minor variations for the different metal atoms M (where M = Cr, Mn, Fe, Co, Ni, and Ru) and different local atomic structures. The vacuum layer in a perpendicular direction to the catalyst plane is about 15 Å, and a dipole correction is used in the perpendicular direction to the catalyst plane to decouple the electrostatic potentials on the two sides of the catalyst plane. The Brillouin zone is sampled with a  $(3 \times$  $3 \times 1$ ) MonkhorstPack k-point mesh.<sup>44</sup>

Solvent effects on the surface and adsorbates are included using the implicit solvent model implemented in VASPsol with a dielectric constant of  $80^{49,50}$  representing water medium. Additional calculations with an explicit solvation effect are performed with one explicit water layer. First, the explicit water layer structure (16 H<sub>2</sub>O molecules) and the explicit water layer with ORR intermediate structure (15 H<sub>2</sub>O molecules surrounding an intermediate) on the FeN<sub>4</sub>C<sub>10</sub> structure are

determined by the minima hopping algorithm implemented in ASE.<sup>51–53</sup> The minima hopping algorithm is performed to find at least about 30 local minima with the convergence criterion of maximum force on each atom less than 0.05 eV Å<sup>-1</sup>. Next, the lowest energy local minima structure and the local minima structure within 0.1 eV of the lowest structure are relaxed further with maximum force on each atom less than 0.025 eV Å<sup>-1</sup>. Then, the water layer structure with the lowest energy is used in the calculations for the FeN<sub>4</sub>C<sub>10</sub> and other Fe–N–C structures.

The change in reaction free energy with an applied potential, U, and pH was calculated using the computational hydrogen electrode (CHE),<sup>1,54</sup> the free energy of the reaction at a potential of U versus the reversible hydrogen electrode (SHE), and pH is given by

$$\Delta G(U, \text{ pH}) = \Delta G(U = 0, \text{ pH} = 0) - neU$$
$$+ nk_{\text{B}}T\text{pHln}(10)$$
(1)

where *n* is the number of electrons involved in the reaction, *e* is the numerical charge of an electron, and  $k_{\rm B}$  is the Boltzmann constant.

$$\Delta G(U = 0, \text{ pH} = 0) = \Delta E_{\text{DFT}} + \Delta E_{\text{ZPE}} + \Delta U_{\text{vib}}(T)$$
  
-  $T\Delta S_{\text{vib}}(T)$  (2)

where  $\Delta G(U = 0, \text{ pH} = 0)$  is calculated from DFT and includes the change in electronic energy ( $\Delta E_{\text{DFT}}$ ), zero-point energy ( $\Delta E_{\text{ZPE}}$ ), vibration energy ( $\Delta U_{\text{vib}}(T)$ ), and entropy ( $\Delta S_{\text{vib}}(T)$ ) at T = 298.15K. In the case of adsorbates on the catalyst surface, only the vibration frequencies of adsorbate are considered, and the free energy is calculated following the quantum mechanical harmonic approximation.

The energy of O<sub>2</sub> in the gas phase is poorly described by DFT calculations;<sup>44</sup> thus, it is corrected to reproduce experimental free energy of liquid water formation (2H<sub>2</sub> + O<sub>2</sub>  $\rightarrow$  2H<sub>2</sub>O;  $\Delta G_{\rm H_2O} = -4.92$  eV). Furthermore, according to the Christensen scheme,<sup>55,56</sup> the error in the energy levels of the ORR intermediates specific to the BEEF-vdW functional are corrected as follows

$$\Delta E(O-O) = 0.20 \text{ eV} \tag{3}$$

$$\Delta E(\mathrm{H}_2\mathrm{O}) = -0.03 \text{ eV} \tag{4}$$

$$\Delta E(\mathrm{H}_2) = 0.09 \text{ eV} \tag{5}$$

**2.2. Stability Calculations.** Our current investigation follows previous work on a dissolution reaction for the FeN<sub>4</sub> site on the bilayer graphene-host structure (which is similar to the FeN<sub>4</sub>C<sub>10</sub> structure defined in this study) by Holby et al.<sup>38</sup> During the dissolution, the Fe metal atom can leave the FeN<sub>4</sub> site on the carbon host structure (FeN<sub>4</sub>C) and becomes an aqueous Fe ion, Fe<sup>\*+</sup><sub>(aq)</sub> with a charge *x*, given the resulting metal-dissolved carbon host cavity with various possible degrees of protonation under the acid environment of the dangling bond, N<sub>4</sub>CH<sub>n</sub> as a product where *n* is the number of protons bonded with the carbon host cavity. It has been reported that the FeN<sub>4</sub> site embedded in graphene without ligands or ORR intermediates is unstable in acid conditions, whereas the adsorption of OH on FeN<sub>4</sub> makes the FeN<sub>4</sub> site thermodynamically stable.<sup>38</sup>

In this work, we employ the above dissolution mechanism to further investigate the stability trend of the M-N-C systems

Figure 2. (a-c) Stability diagram of FeN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>12</sub>, and FeN<sub>4</sub>C<sub>8</sub> structure as a function of applied potential (*U*) and pH. (d-f) The relative stability ( $\Delta G_R$ ) for Fe, \*OH-Fe, and \*O-Fe phase as a function of potential *U* at pH = 0 for FeN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>12</sub>, and FeN<sub>4</sub>C<sub>8</sub> structure, the most energetically favorable dissolved species are superimposed as horizontal bars at the bottom of each relative stability plot. (g) Relative stability for Fe, \*OH-Fe, and \*O-Fe phase of different considered FeN<sub>4</sub>C structures in Figure 1 at *U* = 0.8 V<sub>SHE</sub> and pH = 0.

with different local atomic structures surrounding the metal site, as shown in Figure 1 and different metal atoms. The free energy of  $MN_yC$ , \*OH- $MN_yC$ , and \*O- $MN_yC$  phase relative to dissolved species as a function of potential U and pH are defined by using H<sub>2</sub>O in a liquid phase and H<sub>2</sub> in a gas phase as a reference to avoid O<sub>2</sub> calculation and can be written as eqs 7–9. Note that y is the number of N atoms ligating the metal atom. The  $MN_yC$  denotes the bare metal site structure, while the \*OH- $MN_yC$  and \*O- $MN_yC$  denote one \*OH and \*O adsorbate bond with the metal site, respectively. It is assumed that the catalyst surface is in equilibrium with protons, electrons, and liquid water at T = 298.15 K, such that oxygen and hydroxyl may be exchanged between the surface and a reference electrolyte through Equation 6.<sup>29</sup>

$$MN_{y}C + H_{2}O(l) \rightleftharpoons *OH-MN_{y}C + (H^{+}_{(aq)} + e^{-})$$
$$\rightleftharpoons *O-MN_{y}C + 2(H^{+}_{(aq)} + e^{-})$$
(6)

$$\begin{split} MN_{y}C + nH_{(aq)}^{+} &\to M_{(aq)}^{*+} + N_{y}CH_{n} + (x - n)e^{-} \\ \Delta G(MN_{y}C) &= G(M_{(aq)}^{*+}) + G(N_{y}CH_{n}) - G(MN_{y}C) \\ &- \frac{n}{2}G(H_{2}) - (x - n)U + nk_{B}Tln(10)pH \\ &\quad *OH-MN_{y}C + (n + 1)H_{(aq)}^{+} \\ &\to M_{(aq)}^{*+} + N_{y}CH_{n} + (x - n - 1)e^{-} + H_{2}O \end{split}$$

$$\Delta G(*OH-MN_yC) = G(M_{(aq)}^{x+}) + G(N_yCH_n) + G(H_2O)$$

$$-G(MN_yC) - \frac{(n-1)}{2}G(H_2) - (x - n - 1)U + (n - 1)k_BTln(10)pH$$
(8)

$$\Delta G(*OH-MN_{u}C) = G(M_{(aa)}^{x+}) + G(N_{u}CH_{u}) + G(H_{2}O)$$

$$-G(MN_{y}C) - \frac{(n-2)}{2}G(H_{2})$$
$$-(x-n-2)U + (n-2)k_{B}T\ln(10)pH$$
(9)

where  $\Delta G(MN_yC)$ ,  $\Delta G(*OH-MN_yC)$ ,  $\Delta G(*O-MN_yC)$  are the free energy of the catalyst surface without and with one \*OH, and one \*O at the metal site, respectively.  $\Delta G(N_yCH_n)$ is the free energy of the metal-dissolved carbon cavity with *n* H atoms bonded at the cavity. We consider from *n* = 0 up to *n* = 4 for the dissolution reaction in eqs 7–9. The optimized structures of *n*H-bond carbon cavity are shown in Figure S1.  $G(M^{+x})$  is the free energy of the dissolved metal ion, is estimated as follows:

$$G(M^{+x}) = E_{DFT(bulk)} + \Delta G_x$$
<sup>(10)</sup>

where  $E_{\text{DFT(bulk)}}$  is the total energy per metal atom in the bulk structure obtained from DFT calculations.  $\Delta G_x$  is the free reaction energy of the dissolution reaction of the bulk metal, which is taken from the literature.<sup>57–59</sup> Table S1 shows the free energy of the dissolved metal ion and the dissolution potential used in each approximation  $\Delta G_x$ . The free energy of the dissolved ion depends on the metal ion concentration, which is assumed to be  $10^{-6}$  M for all dissolved metal ions in this work and all calculations are at T = 298.15 K.

**2.3. ORR Catalyst Activity.** We employ purely thermodynamic models when considering the ORR activity by assuming that all element steps have to be exergonic for the ORR to run and neglect the kinetic barrier for each elementary step. The ORR catalytic activity of the different surface structures is estimated by determining the theoretical overpotential and the potential-determining step in the four-electron associative mechanism with \*O, \*OH, and \*OOH intermediates<sup>60</sup> as shown in eqs 11–14. The metal site is considered as the active site, so all ORR intermediates bond with the metal site. The potential and pH dependence of each reaction step is calculated by employing the CHE as shown in eq 1.

$$O_2(g) + H^+ + e^- + * \to *OOH ; \Delta G_1$$
 (11)

\*OOH + H<sup>+</sup> + e<sup>-</sup> 
$$\rightarrow$$
 \*O + H<sub>2</sub>O(l) ;  $\Delta G_2$  (12)

$$*O + H^+ + e^- + * \rightarrow *OH \qquad ; \Delta G_3 \tag{13}$$

13106

$$OH + H^{+} + e^{-} \rightarrow * + H_2O(l) \qquad ; \Delta G_4 \qquad (14)$$

where \* denotes the active metal site. The limiting potential  $(U_L)$  is defined as the highest potential at which all four reaction steps are downhill in free energy.

overpotential = 
$$1.23 \text{ V} - U_{\text{L}}$$

= 1

.23 V - max{
$$\Delta G_1$$
,  $\Delta G_2$ ,  $\Delta G_3$ ,  $\Delta G_4$ }/e
(15)

Adsorption energies of \*O, \*OH, and \*OOH intermediate are defined relative to a water molecule from the following reactions.

$$* + H_2O \rightarrow *O + H_2 \qquad ; \Delta G(*O) \tag{16}$$

\* + H<sub>2</sub>O 
$$\rightarrow$$
 \*OH +  $\frac{1}{2}$ H<sub>2</sub> ;  $\Delta G$ (\*OH) (17)

\* + 2H<sub>2</sub>O 
$$\rightarrow$$
 \*OOH +  $\frac{3}{2}$ H<sub>2</sub> ;  $\Delta G$ (\*OOH) (18)

### 3. RESULTS AND DISCUSSION

3.1. Stability Diagram and Thermodynamic Driving Force toward Metal Dissolution. We first consider the Fe-N-C system. Figure 2 shows the stability diagram of the  $FeN_4C_{10},\ FeN_4C_{12},\ and\ FeN_4C_8$  structures as a function of applied potential, U, and pH. The stability diagrams for other FeN<sub>v</sub>C structures are shown in Figure S2. At acidic ORR relevant conditions ( $U \sim 0.6-0.8 \text{ V}_{\text{SHE}}$  and pH = 0), the most stable phase is the dissolved Fe ions for all considered structures, so the single Fe metal atom is prone to leach. At the same potential range in alkaline conditions, \*OH or \*O can be formed from water on the Fe metal site on the  $FeN_4C_{10}$ ,  $FeN_4C_{12}$ ,  $FeN_4C_A$ ,  $FeN_4C_Z$ , and  $FeN_3C_{10}$  structure and results in stabilization of the Fe metal site against the dissolution. However, the FeN<sub>4</sub>C<sub>8</sub>, FeN<sub>3</sub>C<sub>Z</sub>, and FeN<sub>3</sub>C<sub>A</sub> structures are still prone to dissolution even in alkaline conditions, as the most stable phase is still a dissolved Fe compound ion. In general, the calculation reveals that the dissolution is a greater problem in acidic than alkaline conditions, as reported by previous experiments.<sup>12,61</sup>

To further extend the stability diagram, we consider a thermodynamic driving force toward the dissolution. A previous study by Singh et al. suggests that materials with predicted free energy up to 0.5 eV/atom greater than the most stable species in the Pourbaix diagram can be stable against the corrosion in experiments due to a large kinetic barrier for structural reorganization.<sup>40</sup> We define the relative dissolution free energy ( $\Delta G_{\rm R}$ ), which is the free energy difference between the most stable Fe, \*OH-Fe, or \*O-Fe phase and the most stable dissolved species at pH = 0. The  $\Delta G_{\rm R}$  represents a thermodynamic driving force for each phase toward the dissolution and is shown in Figure 2d-f, where the most stable dissolved species are superimposed as horizontal bars at the bottom. The phase with a higher driving force is likely to dissolve into the electrolyte, as reported by the previously combined experimental and theoretical study.

For the considered FeN<sub>y</sub>C structures, the relative dissolution free energy ( $\Delta G_R$ ) value of the bare Fe metal phase order at  $U = 0.8 V_{SHE}$  and pH = 0 is FeN<sub>4</sub>C<sub>A</sub> < FeN<sub>4</sub>C<sub>Z</sub> < FeN<sub>4</sub>C<sub>10</sub> < FeN<sub>3</sub>C<sub>10</sub> < FeN<sub>4</sub>C<sub>12</sub> < FeN<sub>3</sub>C<sub>Z</sub> < FeN<sub>4</sub>C<sub>8</sub> < FeN<sub>3</sub>C<sub>A</sub>, see Figure 2g, suggesting that the stability against the dissolution decreases from FeN<sub>4</sub>C<sub>A</sub> to FeN<sub>3</sub>C<sub>A</sub>. **Figure 3.** (a) Schematic illustration of possible dissolution mechanism of  $\text{FeN}_4C_{10}$  structure. Color codes for atoms are the same as Figure 1. (b) Free energy diagram related to possible dissolution mechanisms of  $\text{FeN}_4C_{10}$  structure with up to  $3\text{H}^+$  at  $U = 0.8 \text{ V}_{\text{SHE}}$  and pH = 0. (c) Protonation free reaction energy ( $\Delta G_{\text{protonate}}$ ) at the atoms surrounding the Fe metal site and (d) demetalation free reaction energy ( $\Delta G_{\text{dem}}$ ) for Fe metal atom from the considered host carbon structures to dissolved Fe<sup>3+</sup> ion as a function of H<sup>+</sup> number at pH = 0 and  $U = 0.8 \text{ V}_{\text{SHE}}$ . (e) The relative stability ( $\Delta G_{\text{R}}$ ) of the bare metal phase and (f) the most stable phase MN<sub>y</sub>C structures at  $U = 0.8 \text{ V}_{\text{SHE}}$  and pH = 0. The symbols for the surface: \*M = circle, \*OH-M = square, \*O-M = triangle.

\*OH and \*O on the bare Fe metal site at higher potential thermodynamically stabilizes the Fe metal atom against the dissolution. At  $U = 0.8 \text{ V}_{\text{SHE}}$  and pH = 0, the relative free energy ( $\Delta G_{\text{R}}$ ) order of the most stable phase is found to be \*O-FeN<sub>4</sub>C<sub>A</sub> < \*O-FeN<sub>4</sub>C<sub>Z</sub> < \*O-FeN<sub>4</sub>C<sub>10</sub> < \*OH-FeN<sub>3</sub>C<sub>10</sub> < \*O-FeN<sub>4</sub>C<sub>12</sub> < \*O-FeN<sub>3</sub>C<sub>Z</sub> < \*O-FeN<sub>3</sub>C<sub>A</sub> < \*OH-FeN<sub>4</sub>C<sub>8</sub>, see Figure 2g.

At potentials in the range of 0.2–0.9  $V_{SHE}$  and pH = 0, we find that the FeN<sub>4</sub>C<sub>10</sub> structure is more stable than the FeN<sub>4</sub>C<sub>12</sub> site as the thermodynamic driving force for the most stable phase of the FeN<sub>4</sub>C<sub>12</sub> structure is about 0.70 eV greater than that of the FeN<sub>4</sub>C<sub>10</sub> structure, on average. These results agree with the experimental results reported by Li et al.<sup>19</sup>

The horizontal bars at the bottom of each relative stability plot indicate the most energetically favorable dissolved species, suggesting that the dissolution reactions depend not only on the working condition (U and pH) but also on the local atomic structure around the metal site. For example, for the FeN<sub>4</sub>C<sub>8</sub>,  $\text{FeN}_4\text{C}_A$ , and  $\text{FeN}_4\text{C}_Z$  structures, the dissolution reaction results in 0 or one proton transferred to the cavity site, while 1–3 protons are transferred to the cavity site of the other structures.

Considering the dissolution reaction in more detail, we find that the protonation at the metal-dissolved host carbon structure is thermodynamically favorable for the  $N_4C_{12}$ ,  $N_3C_{10}$ ,  $N_4C_Z$ ,  $N_4C_A$ ,  $N_4C_{10}$ , and  $N_3C_Z$  structure, but it is endothermic for the  $N_3C_A$  and  $N_4C_8$  structure (Figure S3). However, these proton transfers might not necessarily affect the kinetic dissolution rate if they occur late in the exothermic process. During the dissolution, we therefore also consider that the protonation reaction occurs at the atoms surrounding the Fe metal atom and is followed by the demetalation reaction, as eqs 19 and 20. Figure 3a,b illustrates the possible dissolution mechanism and corresponding free energy diagram of the dissolution process. From a thermodynamic perspective, whether the protonation reaction occurs before or after the demetalation leads to the same overall dissolution reaction as eq 7 and the same relative stability.

$$\operatorname{FeN}_{y}C + n(\mathrm{H}^{+} + e^{-}) \to \operatorname{FeN}_{y}C\mathrm{H}_{n}$$
<sup>(19)</sup>

$$\text{FeN}_{v}\text{CH}_{n} \rightarrow \text{Fe}^{+m} + \text{N}_{v}\text{CH}_{n} + me^{-}$$
 (20)

We find that the protonation at the atoms surrounding the Fe metal atom is endothermic and becomes more difficult as the potential increases or more protons are added (Figure 3c). At the potential  $U = 0.8 V_{SHE}$  and pH = 0, the order of the protonation (from easy to difficult) is  $\text{FeN}_4\text{C}_2 > \text{FeN}_4\text{C}_{12} \sim$  $FeN_3C_{10} \sim FeN_3C_A > FeN_3C_Z \sim FeN_4C_A > FeN_4C_{10} > FeN_4C_8$ . On the other hand, the demetalation reaction becomes more favorable after the atoms surrounding the Fe metal atoms are protonated and become more favorable as potential increases or more protons are added (Figure 3d). The order of the demetalation at  $U = 0.8 V_{SHE}$  and pH = 0(from easy to difficult), regardless of the number of additional protons before the demetalation is  $FeN_4C_8 \sim FeN_3C_A >$  $FeN_3C_Z > FeN_4C_{10} > FeN_4C_A \sim FeN_3C_{10} \sim FeN_4C_{12} >$  $FeN_4C_Z$ . Additionally, we find that the Fe metal atom in the  $FeN_4C_8\text{, }FeN_3C_Z\text{, and }FeN_3C_A$  structure bond quite weakly with the host carbon structure compared with the others, as reported by Tan et al.<sup>39</sup> Therefore, the Fe metal atom in these structures can more easily leave the host carbon structure.

The demetalation reaction relates to the bond strength between the Fe metal atom and the host carbon structure. The protonation at the ligand atoms surrounding the Fe metal atom can weaken the bond between the Fe and the surrounding ligand atoms, resulting in the following demetalation step being facile. Consequently, the basicity of ligand atoms contributes to the stability of the Fe–N–C catalyst in the acidic condtion <sup>12,20</sup> as same as the bonding strength between the metal atom with the carbon host structure. The different trade-offs between the demetalation reaction and the protonation reaction due to the different local atomic structures surrounding the Fe metal site enable different *n* values for the dissolution reaction.

It is important to note that the real degradation mechanism is still unknown, and other possible mechanisms such as carbon corrosion,<sup>10,18</sup> hydroxyl radical attraction,<sup>6,62</sup> and carbon oxidation<sup>7</sup> have been proposed as a degradation mechanism of the Fe–N–C catalyst can simultaneously occur and might be coupled. Also, the stability is here analyzed from thermodynamic trends, whereas the rate of metal leaching is determined by the kinetic activation energy. Thus, a kinetic analysis of the dissolution mechanism would be required for a complete theoretical description.

Furthermore, Holby et al. suggest the computational unit cell size and a graphene underlayer to host the FeN<sub>4</sub> actives site influence the calculated stability.<sup>38</sup> To assess the sensitivity to these choices, we performed additional stability calculations for some Fe–N–C structures with a bigger unit cell (Figure S5). Table S4 shows the dissolution potential to Fe<sup>2+</sup> ion obtained from two sizes of a unit cell. The size of the unit cell can lead to variation in the dissolution potential of about 0.08  $V_{SHE}$ . However, we find the same trend in the dissolution potential obtained from both sizes of unit cells which is FeN<sub>4</sub>C<sub>8</sub> ( $-1.09 V_{SHE}$ ) < FeN<sub>4</sub>C<sub>10</sub> ( $0.35 V_{SHE}$ ) < FeN<sub>4</sub>C<sub>A</sub> ( $0.65 V_{SHE}$ ) < FeN<sub>4</sub>C<sub>12</sub> ( $0.79 V_{SHE}$ ) < FeN<sub>4</sub>C<sub>2</sub> ( $0.94 V_{SHE}$ ) for the unit cell in Figure 1 and FeN<sub>4</sub>C<sub>8b</sub> ( $-0.98 V_{SHE}$ ) < FeN<sub>4</sub>C<sub>10b</sub> ( $0.27 V_{SHE}$ ) < FeN<sub>4</sub>C<sub>Ab</sub> ( $0.52 V_{SHE}$ ) < FeN<sub>4</sub>C<sub>12b</sub> ( $0.73 V_{SHE}$ ) <

 $FeN_4C_{Zb}$  (0.97  $V_{SHE}$ ) for the bigger unit cell in Figure S5. This dissolution trend agrees with the trend reported by Tan et al.<sup>39</sup> However, we find the dissolution to  $Fe^{2+}$  ion of 0.35  $V_{SHE}$  and 0.27  $V_{\text{SHE}}$  for the  $\text{FeN}_4C_{10}$  and  $\text{FeN}_4C_{10b}$  structure, respectively, which are quite different from the value reported by Holby et al. using the  $FeN_4C_{10}$  structure on a 6  $\times$  6 graphene monolayer structure in a vacuum, in which the dissolution potential is 0.57  $\mathrm{V}_{\mathrm{SHE}}.$  We find that the dissolution potential of 0.47  $V_{SHE}$  for the FeN<sub>4</sub>C<sub>10</sub> structure (Table S5) in a vacuum. Thus, there may be some influence of solvation on the calculated stability as well as the strain associated with the smaller cell.<sup>38</sup> The variation in \*O and \*OH free adsorption energy due to the size of the unit cell is 0.08 and 0.07 eV on average for both \*O and \*OH, respectively. The trend in the relative dissolution free energy  $(\Delta G_{\rm R})$  value of the most stable phase at  $U = 0.8 V_{SHE}$  and pH = 0 obtained from the bigger unit cell is  $*O-FeN_4C_{Ab} < *O-FeN_4C_{10b} < *O-FeN_4C_{Zb} < *O-FEN_$  $FeN_4C_{12b}$  < \*OH-FeN<sub>4</sub>C<sub>8b</sub>, largely in agreement with results on the unit cell in Figure 1. Therefore, the unit cells in Figure 1 are used in our further calculations.

Besides the stabilization by the graphene underlayer reported by Holby et al., the dissolution potential of 0.65  $V_{SHE}$  has been reported for the FeN<sub>4</sub>C<sub>10</sub> configuration on a 6 × 6 graphene bilayer structure (0.08 higher than the monolayer structure).<sup>38</sup> Thus, it has been recommended to use a larger and bilayer graphene structure for the stability calculation.<sup>38</sup> However, we find that different local atomic structures around the Fe metal site cause the change in the dissolution potential in the range of 0.30–1.43 V<sub>SHE</sub>, which is greater than the effect of a graphene underlayer. Thus, only a monolayer structure is considered here.

So far, the solvent effect is considered implicitly in this work. We further investigate the effect of the explicit water layer on the stability calculation. We consider the explicit water layer only on the same side of the catalyst as the \*O and \*OH adsorbates (Figure S6). A previous study by Svane et al.<sup>63</sup> studied the explicit solvation effect on a CoN<sub>4</sub>C<sub>12</sub> structure suggests that the explicit water on the same side of the adsorbate can result in stabilization about 0.27 eV for \*OH relative to a solvent-free model. However, there is no further stabilization effect when adding explicit water layers on both sides of the catalyst surface, as the stabilization is only about 0.1 eV for \*O, \*OH, and \*OOH relative to the one explicit water on the same side with the adsorbates. Table S5 shows the dissolution potential to Fe<sup>2+</sup> obtained from different solvation models. The dissolution potentials obtained from implicit solvation are 0.14  $\mathrm{V}_{\mathrm{SHE}}$  lower, on average, than those obtained in a vacuum. The dissolution potential with the explicit solvation is close to those in a vacuum with a variation of 0.06  $V_{SHE}$ , on average. However, there is a big difference in dissolution potential between FeN<sub>4</sub>C<sub>Z</sub> in a vacuum and explicit solvation. We find that, in the optimized structure of the N<sub>4</sub>C<sub>Zw</sub>H<sub>0</sub> structure with one explicit water layer, the nitrogen atoms are out of a carbon plane while the nitrogen atoms in a vacuum and implicit solvation model remain in the carbon plane. The distortion with the explicit solvation leads to 0.20  $V_{\text{SHE}}$  lower dissolution potential for the  $\text{FeN}_4\text{C}_{\text{Zw}}$  compared with the solvation-free model. The explicit water layer surrounding \*O and \*OH adsorbates leads to stabilization relative to the vacuum of 0.41 and 0.22 eV, respectively. The stabilization relative to the vacuum due to the implicit solvation is 0.30 and 0.22 eV for \*O and \*OH, respectively. Thus, the stabilization is similar in magnitude for implicit and

explicit solvation. For the most stable phase at  $U = 0.8 V_{SHE}$ and pH = 0, the relative dissolution free energy ( $\Delta G_R$ ) value with explicit solvation is \*O-FeN4C10<sub>Zw</sub> < \*O-FeN4C<sub>10w</sub> < \*O-FeN4C<sub>12w</sub> < \*O-FeN4C<sub>8w</sub>. Meanwhile, we find the relative dissolution free energy ( $\Delta G_R$ ) value in a vacuum to be \*OH-FeN<sub>4</sub>C10<sub>Zv</sub> < \*OH-FeN4C<sub>10v</sub> < \*OH-FeN4C<sub>12v</sub> < \*OH-FeN4C<sub>8v</sub>. The difference in the relative stability of the most stable phase is mainly due to the different stabilization effects on \*O and \*OH via different solvation models. There is an obvious influence of solvation on the stability calculation; to avoid the structural distortion in the calculations, we use the implicit solvation, which leads to a similar solvation stabilization as the explicit solvation in our further calculations.

We further extend the thermodynamic stability analysis with different metal atoms, changing the metal atom to Cr, Mn, Co, Ni, and Ru. The stability diagrams are shown in Figures S10-\$15, indicating that all considered  $MN_x$  sites on the considered structures prefer to dissolve under the acid condition as the most stable species at pH = 0 are an aqueous metal ion. Figure 3e shows the relative stability for the bare metal site at U = 0.8 $V_{SHE}$  and pH = 0; the MN<sub>4</sub>C<sub>8</sub>, MN<sub>3</sub>C<sub>Z</sub>, and MN<sub>3</sub>C<sub>A</sub> structures, regardless of the metal atom, are less stable than other structures. On the other hand, the  $MN_4C_A$  structure is the most stable structure against the dissolution under the same acid conditions, regardless of the metal atoms. The general trend in the thermodynamic driving force toward the dissolution of the bare metal site at  $U = 0.8 V_{SHE}$  and pH = 0 is Cr > Mn > Ru > Fe > Co > Ni. To understand this trend, we have considered the dissolution of the bare MN<sub>x</sub> site without the protonation at the cavity. We first consider the energy of the metal atom being in the  $MN_x$  site on the carbon host structure against the formation of metal atom in the bulk structure by the following equation:

$$\Delta G_{\text{bulk}} = E_{\text{M}} + E(N_x C_y) - E(M N_x C_y)$$
<sup>(21)</sup>

where  $E_{\rm M}$  is the total energy per atom of the metal in bulk structure,  $E({\rm MN}_x C_y)$  is the total energy of the MN<sub>4</sub> structure and  $E({\rm N}_x C_y)$  is the total energy of the metal-dissolved cavity structure  $({\rm N}_x C_y)$ . The calculated  $\Delta E_{\rm metal}$  for different metal centers on different carbon host structures are shown in Figure S16a and Table S6. The  $\Delta E_{\rm metal}$  values indicate that the metal atom in the MN<sub>4</sub>C<sub>8</sub>, MN<sub>3</sub>C<sub>2</sub>, and MN<sub>3</sub>C<sub>A</sub> structure is unstable and prefers to form the bulk metal rather than be embedded in the carbon host structure compared with other structures. Second, we consider the energy for oxidizing the metal atom at a working potential ( $U = 0.8 V_{\rm SHE}$ ) by the following equation:

$$\Delta E_{\text{oxidize}} = G(M^{+x}) - xU - E_M$$
(22)

where  $G(M^{+x})$  is free energy of the most stable dissoved metal ion at the considered condition (x = 2 for M = Co and Ni; x =3 for M = Cr, Mn, Ru and Fe). The calculated  $\Delta E_{\text{oxidize}}$  is shown in Figure S16b and Table S6. The oxidization trend of the metal (from easy to difficult) is Cr < Mn < Fe < Co < Ni. For these 3d metals, the metal oxidation energy ( $\Delta E_{\text{oxidize}}$ ) plays an important role in the dissolution reaction, causing a significant difference in the acid stability among 3d elements. The stability of the bare MN<sub>x</sub> site toward a dissolved metal cation is Cr < Mn < Fe < Co < Ni, following the oxidation trend.

For Ru, the bond strength between the Ru atom and the carbon hosts is weaker than other metal elements within the same carbon host structure. However, Ru is also more difficult to oxidize, and overall, the stability of the  $\operatorname{RuN}_x$  site is between Mn and Fe.

The formation of one \*O and \*OH from water mostly on Cr, Mn, Ru, and Fe metal sites at pH = 0 and  $U = 0.8 V_{SHE}$  is thermodynamically favorable on most of the considered structures, resulting in increased stability under acid conditions. However, under the same conditions, the most stable phase of the considered CoN<sub>y</sub>C and NiN<sub>y</sub>C structures is mostly the bare metal site (Figure 3f).

We consider the M–N–C catalyst by choosing M = Cr, Mn, Fe, Ru, Co, and Ni because these elements are either relatively cheap and abundant 3d metals or have shown promising ORR activity and stability. The thermodynamic stability analysis of the Pt–N–C structures is also considered and shown in Figure S17. Most of the considered Pt–N–C structures, except PtN<sub>4</sub>C<sub>8</sub>, are thermodynamically stable against dissolution at pH = 0, U = 0.8 V<sub>RHE</sub>, and even more stable than other considered metal elements. However, all considered Pt–N–C structures are inactive toward the ORR as the overpotential of all considered Pt–N–C structures is more than 1.00 eV (Table S18).

In general, we find that the metal atom on the graphene plane ( $MN_4C_{10}$  or  $MN_3C_{10}$ ) and the  $MN_4$  site on the graphene edge ( $MN_4C_Z$  and  $MN_4C_A$ ) are more stable than the  $MN_4$  site hosted near micropores ( $MN_4C_{12}$ ) or bridging between two zigzag edges ( $MN_4C_8$ ) and the  $MN_3$  structures at the graphene edge ( $MN_3C_Z$  and  $MN_3C_A$ ).

The Fe, Co, Ru, and Ni metal atoms on the  $MN_4C_{10}$ , MN<sub>4</sub>C<sub>Z</sub>, and MN<sub>4</sub>C<sub>A</sub> can well be kinetically stable under acid conditions as the thermodynamic driving force is less than 0.70 eV at  $U = 0.8 V_{SHE}$  and pH = 0. On top of that, the Ru metal atom on the  $MN_4C_{Z^\prime}\,MN_4C_A$  structure, and Ni metal atom on the MN<sub>4</sub>C<sub>A</sub> structure are the most promising stable structure under the acid condition as the thermodynamic driving force toward the dissolution is less than 0.2 eV. Previous experimental results have found that the Ru-N-C catalyst is rather stable in the acid environment with a dissolution rate of less than 5% over 30 h of operation at 1.5 V<sub>SHE</sub>.<sup>24</sup> Meanwhile, the Cr and Mn metal atoms on considered structures have a considerable driving force toward dissolution (>0.7 eV), so these catalysts are unstable during the PEMFC operation. A previous experimental study has reported that the Mn-N-C catalyst is likely to lose its ORR catalytic activity more than the Fe-N-C catalyst in acid and alkaline conditions during the stability test cycling the potential between 0.5 and 1.3 V<sub>SHE</sub>.<sup>61</sup> Furthermore, the previous experiments have suggested that the Co-N-C catalyst has significantly enhanced resistance to demetalation compared to the Fe-N-C catalyst in acid conditions, especially under  $O_2$  purged testing.<sup>22</sup> For the FeN<sub>v</sub>C and CoN<sub>v</sub>C structure without any adsorbate, the thermodynamic driving force of the bare Fe metal atom toward the dissolution is about 0.56 eV bigger than for the bare Co metal site, on average. With the formation of one \*OH or \*O on the metal site, the relative stabilities of the most stable phase under acid conditions for both metal atoms are comparable. This suggests that other mechanisms such as carbon surface oxidation  $^7$  as well as the  $\rm H_2O_2$  derived radicals attack stabilized \*OH or \*O ligand  $^{22,62}$  possibly occur along with the demetalation reaction or deactivate the active site. These possible processes should be included in the calculation model to get a complete theoretical description.

Different metal atoms on the same carbon structure dissolve with the same dissolution reaction; the same n value in eqs

7–9). With the n = 0 dissolution reaction, the primary contribution to acid instability is the bond strength between the single metal atom and the host carbon structure. However, with increasing n, more contributions from the protonation reaction at the atom surrounding the metal site are included. Thus, the thermodynamic acid stability of the M-N-C catalyst is determined by both the bonding strength of the metal atom with the host carbon structure and the basicity of the ligand atom around the metal atoms. In the Fe-N-C system, the FeN<sub>4</sub>C<sub>12</sub> has strong bonding between the Fe metal atom and the host carbon structure, but the nitrogen atoms around the Fe metal site are vulnerable to proton attack. The nitrogen ligand in the FeN<sub>4</sub>C<sub>8</sub> structure can resist the action of protons in acid solution, but the bonding between the Fe metal atom and the carbon host structure is too weak. Consequently, both structures are predicted to be less stable than the FeN<sub>4</sub>C<sub>10</sub> structure under the same acid conditions.

Additionally, previous studies by Zhang et al.<sup>64</sup> and Jung et al.<sup>65</sup> have suggested that the oxygen functional groups near the CoN<sub>4</sub> site can be formed via electrochemical or chemical treatment. The formation energies of \*O from water on various carbon sites near the CoN<sub>4</sub>C<sub>10</sub> structure reported by Zhang et al.<sup>64</sup> and Jung et al.<sup>65</sup> are more than 2.8 eV, suggesting weak adsorption of \*O on the adjacent carbons. The oxidation of the surface carbon adjacent to the FeN<sub>4</sub> sites has also been reported, decreasing the four-electron ORR activity. However, the deactivation is reversible, and the ORR activity can be recovered upon electrochemical reduction of the carbon surface.<sup>7</sup> We consider \*O or \*OH formation on carbon adjacent to the Fe center on the  $FeN_4C_{10b}$ ,  $FeN_4C_{12b}$ , and FeN<sub>4</sub>C<sub>Zb</sub> structures, assuming that the catalyst surface is in equilibrium with protons, electrons, and liquid water at T =298.15 K (Figure S19). The \*O or \*OH on adjacent carbon is not thermodynamically favored in the potential range of 0-1.2V<sub>SHE</sub>. Thus, we exclude the formation of \*O and \*OH next to the MN<sub>r</sub> site from our further considerations.

However, the surface carbon oxidation can possibly occur via other such as the dissociation of  $H_2O_2^{-7}$  or \*OOH.<sup>39</sup> The surface carbon oxidation may directly or indirectly affect the dissolution of the  $MN_x$  site.<sup>19</sup> Tan et al.<sup>39</sup> has suggested that the stable oxygen functional group site next to the FeN<sub>4</sub> site can be different, depending on the local carbon structure.

We consider the effect of nearby \*O and \*OH on the dissolution reaction for some specific Fe-N-C structures. The carbon surface oxidation potentially affects the stability of the  $MN_x$  site and the dissolution reaction. As shown in Table S8, the bond strength between Fe and carbon host in the FeN<sub>4</sub>C<sub>10</sub> structure and bond strength between one H with the carbon cavity in the N<sub>4</sub>C<sub>10</sub> structure is strengthened by the nearby \*OH functional but weakened by the nearby \*O functional. Breaking the Fe-N bonds require more energy with nearby \*OH; however, the H binding with the cavity is also more energetically favorable in the final product. Overall, at pH = 0and  $U = 0.8 V_{SHE}$ , the pristine FeN<sub>4</sub>C<sub>10</sub> with the nearby \*OH has the same dissolution (n = 1) reaction product as the pristine FeN<sub>4</sub>C<sub>10</sub> structure but the dissolution reaction is more thermodynamically favorable than the pristine  $FeN_4C_{10}$ structure (Figure S20). The thermodynamic driving force toward the dissolution of the pristine  $FeN_4C10_{bOH}$  is found to be 1.58 eV, 0.37 eV higher than that of the pristine  $\text{FeN}_4C_{10}$ . For the  $FeN_4C_{10}$  with nearby \*O functional, the Fe-N and H–N bonding become weak. At pH = 0 and  $U = 0.8 V_{SHE}$ , the overall dissolution reaction is more thermodynamically

favorable to occur via the n = 0 reaction for the pristine  $FeN_4C10_{bO}$ , and it is more thermodynamically favorable than the pristine  $FeN_4C_{10}$  structure. The thermodynamic driving force toward the dissolution for the pristine  $FeN4C_{10bO}$  is 1.87 eV, 0.66 eV higher than the pristine  $FeN_4C_{10}$  structure.

In the cases of the pristine  $\text{FeN}_4\text{C}_{12}$ , the Fe–N and H–N bond strength are weakened by both the nearby \*O and \*OH functional groups. The same dissolution (n = 2) reaction as the pristine FeN<sub>4</sub>C<sub>12</sub> structure becomes more energetically favorable with nearby \*O and \*OH. The thermodynamic driving force toward the dissolution is 2.01, 1.98 eV for the pristine FeN<sub>4</sub>C<sub>12bOH</sub> and FeN<sub>4</sub>C<sub>12bO</sub> structure (0.36, 0.33 eV higher than that of the pristine FeN<sub>4</sub>C<sub>12</sub>).

At the same time, the formation site of these stable oxygen functional groups can depend on the carbon structure around the active site (Table S7). Therefore, the effect of the carbon surface oxidation on the stability of the  $MN_x$  site can vary for different local carbon structures.<sup>39</sup> How carbon surface oxidation forms on various carbon structures and its corresponding effect on the dissolution reaction of the  $MN_x$  active site would certainly be interesting to study. However, such an investigation is beyond the scope of the current study.

In addition to the carbon surface oxidation resulting in \*O or \*OH on the adjacent carbon atoms to the FeN<sub>x</sub> site, the carbon surface could possibly contain additional N heteroatoms. The graphitic N atoms surrounding the  $FeN_x$  site have been reported to improve ORR activity in both alkaline and acidic electrolyte. It has been reported that the neighboring graphitic nitrogen induces a higher filling degree of d-orbit and decreases on-site magnetic, which can optimize the binding energy of the ORR intermediates.<sup>66</sup> The stability diagrams of some structures with one and two graphitic N atoms are shown in Figure S22. The structures show no distortion because of the added graphitic N atoms (Figure S23). However, the Fe-N bond strength and the first H-N bonding strength on the cavity are weakened due to the added graphic N (Table S9). Consequently, the additional graphitic N atoms are likely to destabilize the surface and increase the thermodynamic driving force toward the dissolution. At pH = 0,  $U = 0.8 V_{SHE}$ , the thermodynamic driving force toward dissolution increases 0.09 and 0.26 eV on average for the FeN<sub>4</sub>C<sub>12</sub> structures with one and two graphitic N atoms, respectively. For the  $\mbox{FeN}_4\mbox{C}_{10}$ structure, the thermodynamic driving force toward the dissolution at pH = 0 and  $U = 0.8 V_{SHE}$  increase from 1.25 eV to 1.56 and 1.83 eV on average with one and two graphitic N atoms, respectively. Note that only some specific configurations of the graphitic N on the carbon plane are considered here; different configurations could affect the measured activity<sup>66</sup> and stability. However, the exploration of all such configurations is beyond the scope of this work.

The anion-selective adsorption on the active site of the M– N–C catalyst can occur, and it has been previously reported<sup>25,67</sup> that the effect of anions on the Pt and the Fe– N–C catalyst is different. For Pt, the anion in the electrolyte solution can block the active site, decreasing ORR activity. While the M–N–C catalyst is a two-dimensional material, both sides of the catalyst can be exposed to the electrolyte with anions adsorbing on one or both sides of the catalyst. The adsorption of various anions has been reported to be competitive with formation of \*O, \*OH on the MN<sub>4</sub>C<sub>12</sub> structure (where M = Fe, Cr, Mn, and Co) and can even promote the ORR activity, depending on the metal center as previously reported Svane et al.<sup>25</sup>

The most stable phase at pH = 0 and U = 0.8 V<sub>SHE</sub> are filled color and symbol for the surface: \*M = circle, \*O-M = square, \*OH-M = triangle in the volcano plot. The most stable phases are marks with a yellow star in the overpotential plot.

**3.2. ORR Catalytic Activity.** As previously seen from the thermodynamic stability results, the formation of one \*OH and \*O adsorbate from water on the metal site is thermodynamic favorable and stabilizes the metal site against the dissolution. Due to the two-dimensional structure of the

 $MN_y$  motif, when the formation of one \*OH or \*O adsorbate from water occurs on the metal site, it can become a part of the active metal site where the other side of the metal atom is still available for the ORR intermediates to react. Thus, in this work, we consider that both metal sides can bond with the

Research Article

adsorbate. At a relevant PEMFC condition, we can identify the most stable adsorbate, which is likely to occupy one of the metal atom sides and become a part of the active metal site, as shown in Figure 3f.

In general, we find that one \*O or \*OH adsorbate is absorbed strongly on the metal site in the  $MN_4C_8$ ,  $MN_3C_2$ , and  $MN_3C_A$  structures compared with other  $MN_yC$  structures, even in the case of inactive Ni metal atoms. Thus, one \*O or \*OH mostly becomes a part of the active metal site in these structures, regardless of the metal atom.

Having identified the most stable phase of the considered  $MN_yC$  structures, we investigate how the ORR activity was affected by the local atomic structure around the metal atom as well as the presence of \*O and \*OH adsorbate as a part of the active metal site. The adsorption free energy of the reaction intermediate \*OOH, \*O, and \*OH and the limiting potential for the associative ORR pathway is calculated as defined in the Methods section. An initial chemical step of O<sub>2</sub> adsorption is not explicitly considered. Liu et al.<sup>17</sup> reported that the activation energy for the direct O<sub>2</sub> dissociation reaction is always higher for the OOH dissociation reaction on the FeN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>12</sub>, and FeN<sub>4</sub>C<sub>8</sub> structure; thus, the OOH dissociation path is kinetically more feasible than the O<sub>2</sub> dissociation pathway.

The  $MN_yC$  catalyst follows the scaling relation between the adsorption energies of the \*OH and \*OOH intermediates, which is known for metal and oxide surface.<sup>68</sup>

$$\Delta G(*OOH) = \Delta G(*OH) + 3.23, \text{ MEA} = 0.11 \text{ eV}$$
(23)

A similar scaling relation obtained from the MN<sub>4</sub> catalyst has been previously reported by Svane et al.<sup>25</sup> This scaling relationship implies that the best liming potential is 0.83 V<sub>SHE</sub>, resulting in the minimum overpotential of 0.4 V<sub>SHE</sub>. The limiting potential plotted as a function of  $\Delta G(*OH)$  for each metal atom, and the corresponding ORR overpotential is shown in Figure 4.

We first consider the Fe-N-C system, the bare Fe metal site bond with \*OH intermediate quite strongly, so the reaction is limited by the reduction of \*OH (Equation 14) for the considered carbon host structures. The trend in ORR overpotential for the bare Fe metal site is found to be FeN<sub>4</sub>C<sub>12</sub> <  $FeN_4C_A$  <  $FeN_4C_{10}$  <  $FeN_4C_Z$  <  $FeN_3C_{10}$  <  $FeN_4C_8$  <  $FeN_3C_Z$  <  $FeN_3C_A$ . This trend agrees with a previous theoretical prediction by Yang et al.<sup>69</sup> At  $U = 0.8 V_{SHE}$  and pH = 0, we find that one side of the Fe atom is likely to be ligated by either \*OH or \*O adsorbate. The active site with the \*O or \*OH ligand is denoted as \*OH-Fe and \*O-Fe in Figure 4. The ORR intermediate binds with the Fe metal site more weakly with the presence of \*OH ligand, compared with those on the bare Fe metal site. The ORR intermediate binding becomes even weaker with the presence of the \*O ligand. The \*OH ligand is found to improve ORR activity on the  $\text{FeN}_4\text{C}_{10}$ ,  $\text{FeN}_4\text{C}_{12}$ ,  $\text{FeN}_4\text{C}_8$ ,  $\text{FeN}_4\text{C}_2$ , and  $\text{FeN}_3\text{C}_{10}$ structure as reported by previous studies.<sup>69–72</sup> However, the \*O ligand promotes the ORR activity on the FeN<sub>3</sub>C<sub>Z</sub> and FeN<sub>3</sub>C<sub>A</sub> structures. Considering the ORR activity on the most stable phase under the PEMFC relevant condition in Figure 3f, we find the ORR overpotential trend to be \*OH-FeN4C8  $(0.43) < *O-FeN_3C_Z (0.54) \sim *OH-FeN_3C_{10} (0.54) < *O \text{FeN}_{3}C_{A}(0.56) < *\text{O-FeN}_{4}C_{10}(0.63) < *\text{O-FeN}_{4}C_{12}(0.80) <$  $*O-FeN_4C_A (0.81) < *O-FeN_4C_Z (1.06).$ 

We find that the ORR intermediates bind strongly on the bare metal site for Cr, Mn, and Ru metal atoms, especially on the  $MN_4C_{8}$ ,  $MN_3C_2$ , and  $MN_3C_A$  structures. Thus, the ORR activity of the bare metal site locates on the left leg of the volcano plot, and the desorption of the \*OH step restricts the reaction ( $\Delta G_4$ ). The \*OH and \*O ligands are found to decrease the ORR adsorption strength on the metal site, as previously found in the FeN<sub>y</sub>C system. We find that the formation of OH ligand at the metal site enhance the ORR activity for the  $MN_4C_{10}$ ,  $MN_4C_2$ ,  $MN_4C_A$ , and  $MN_3C_{10}$  structure with the Mn and Cr metal atom, while the \*O ligand positively affects the ORR activity on the  $MN_4C_8$ ,  $MN_3C_2$ , and the  $MN_3C_A$  structure with the Mn and Cr metal atom.

For the RuN<sub>y</sub>C structures, we find that the formation of one \*OH and \*O ligand, which is expected under the working condition, is also beneficial for the ORR activity, especially \*O. It turns out that the \*O-Ru site has higher ORR activity than the bare metal site or the \*OH-Ru site for the  $RuN_4C_{10}$ ,  $RuN_4C_8$ ,  $RuN_4C_Z$ ,  $RuN_4C_A$ ,  $RuN_3C_Z$ , and  $RuN_3C_A$  structure.

The ORR intermediate adsorption on the bare Co metal site is weaker than the previous metal atoms. Still, the ORR intermediate strongly binds on the bare metal site in the MN<sub>4</sub>C<sub>8</sub>, MN<sub>3</sub>C<sub>Z</sub>, and MN<sub>3</sub>C<sub>A</sub> structures. For the Co bare metal site, the ORR activity is still on the left leg of the volcano plot but locates near the peak of the volcano plot. The strong bonding of the \*OH has restricted the reaction, except for the  $CoN_4C_{12}$  structure where  $\Delta G_1$  limits the reaction. The \*OH and \*O ligands are found to decrease the ORR adsorption strength on the Co metal site. Unlike previously considered metal atoms, the effect of \*OH and \*O ligands on the Co metal site negatively affects the ORR activity on the CoN<sub>4</sub>C<sub>12</sub>,  $CoN_4C_{Z'}$  and  $CoN_4C_A$  structure because the activity of the Co bare metal site is already near the top of the activity volcano. With \*OH and \*O ligands on these structures, the \*OH adsorption strength is decreased, moving the active sites to the right leg of the volcano plot. However, under working conditions, the \*OH ligand is expected to spontaneously evolve only on the Co metal site in the  $CoN_3C_{10}$ ,  $CoN_3C_Z$ , and CoN<sub>3</sub>C<sub>A</sub> structure which can substantially enhance the ORR activity.

In the NiN<sub>y</sub>C structures, the ORR intermediate bond is too weak with the bare Ni metal site in most considered host carbon structures, and no \*O and \*OH ligands are expected on most NiN<sub>y</sub>C sites. Thus, the first reaction step restricts the reaction ( $O_2 \rightarrow$  \*OOH;  $\Delta G_1$ ), and most NiN<sub>y</sub>C structures are less active toward the ORR than other metal atoms, except for the NiN<sub>4</sub>C<sub>8</sub> structure. The NiN<sub>4</sub>C<sub>8</sub> structure turns out to have high ORR activity with the overpotential of 0.45 V<sub>SHE</sub>. This is due to the stronger bonding between the Ni metal and the ORR intermediate on the NiN<sub>4</sub>C<sub>8</sub> compared with other host structures.

For the bare metal site, the binding energy of the ORR intermediate in the same carbon host structure is likely to follow the ordering (from strong to weak): Cr > Mn > Ru > Fe > Co > Ni. Among the different carbon host structures, the bare metal atom on the  $MN_4C_8$ ,  $MN_3C_7$ ,  $MN_3C_A$  structure is likely to bond with the adsorbate too strongly. We find that in the optimized structure of the  $MN_4C_8$  with an adsorbate, the metal atom is likely to lay above the basal plane, forming a distorted square-pyramidal geometry instead of a square-pyramidal geometry. Also, we find that the metal atom (with adsorbate) in this distorted square-pyramidal geometry prefers

a higher spin state than in other structures with a squarepyramidal geometry.

Consider the  $FeN_4C_{12}$ ,  $FeN_4C_{10}$ , and  $FeN_4C_8$  structures as an example in Figure S24. The optimized structures of the  $FeN_4C_{12},\ FeN_4C_{10},\ and\ FeN_4C_8$  are in a square planar geometry. The  $Fe^{2^+}$  have a spin configuration with two (or almost two) unpaired d electrons in these structures. Due to the \*OH adsorption, the d electron in the highest level is transferred to the \*OH adsorbate. The \*OH-FeN<sub>4</sub>C<sub>12</sub> and  $^{*}OH\text{-}FeN_{4}C_{10}$  structures are in the square pyramidal geometry where the Fe  $^{3+}$  has only one unpaired electron in their orbital configuration. For the \*OH-FeN<sub>4</sub>C<sub>8</sub> structure, the \*OH adsorption causes the elevation of the Fe metal about 0.80 Å above the N<sub>4</sub> plane. The distortion could lead to a different orbital configuration, as suggested by Jurca et al.<sup>73</sup> The possible d electron configuration in an orbital configuration associated with the distortion has three unpaired d electrons, resulting in a higher spin state configuration. The electron configuration in the \*OH-FeN<sub>4</sub>C<sub>8</sub> structure has lower energy than those in the  $*OH-FeN_4C_{12}$  and  $*OH-FeN_4C_{10}$  structure. Therefore, the \*OH adsorption on the FeN<sub>4</sub>C<sub>8</sub> is more energetically favorable than the  $FeN_4C_{12}$  and  $FeN_4C_{10}$ structure. The degree of distortion depends on the choice of the metal center. The distorted square-pyramidal geometry upon the intermediate adsorption also causes the high spin configuration on the Mn<sup>3+</sup> and Co<sup>3+</sup>, which also has strong binding energy with the adsorbate (Figure S25). There is no significant difference in the spin state of Cr3+ in the \*OH-CrN<sub>4</sub>C<sub>8</sub>, \*OH-CrN<sub>4</sub>C<sub>12</sub>, and \*OH-CrN<sub>4</sub>C<sub>10</sub> structure since both geometries have the same three unpaired d-electrons; however, the elevation of the Cr metal atom in the \*OH-CrN<sub>4</sub>C<sub>8</sub> is relatively higher and the \*OH adsorption is stronger compared with that of the CrN<sub>4</sub>C<sub>10</sub> and CrN<sub>4</sub>C<sub>12</sub> structure (Figure S26). The distorted square-pyramidal geometry may be the energetically favored structure. Like the Cr-N-C system, the Ni<sup>3+</sup> has the same d electron configuration for both distorted and undistorted square-pyramidal geometry; thus, there is no different spin state among considered structures as observed in the previous Fe-N-C system, but the Ni site in the NiN<sub>4</sub>C<sub>8</sub> structure still bonds with the adsorbate stronger than other structures. However, the Ni metal atom is unlikely to react with the ORR intermediate, so the evaluation of the Ni atom out of the  $\mathrm{N}_4$  plane upon the intermediate adsorption is relatively small compared to other MN<sub>4</sub>C<sub>8</sub> structures. For the \*OH-RuN<sub>4</sub>C<sub>8</sub>, the Ru metal atom with \*OH adsorbate is about 0.97 Å above the  $N_4$  plane (Figure S27). The Ru<sup>3+</sup> in the RuN<sub>4</sub>C<sub>8</sub> structure also has a higher spin state and stronger \*OH bonding than in the \*OH-RuN<sub>4</sub> $C_{12}$  and \*OH-RuN<sub>4</sub> $C_{10}$ structure.

Note that the pristine structure of the bulk-host  $(MN_4C_{10})$ and edge-hosted  $MN_4$  site  $(MN_4C_Z \text{ and } MN_4C_A)$  is a square planar geometry. The metal center in these pristine structures has a similar converged magnetic moment on the metal atom (Table S10), implying a similar spin state. For the Fe–N–C system, the magnetic moment is 1.83, 1.92, and 1.91 for the pristine FeN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>Z</sub>, and FeN<sub>4</sub>C<sub>A</sub> structures, respectively. The change in the d band center due the change in structure from the bulk-hosted MN<sub>4</sub> site to the edge-hosted MN<sub>4</sub> sites varies with the metal center element (Table S10). In the Fe–N–C system, the d-band center shifts up from –1.13 eV to –0.91 and –0.94 eV when the structure changes from the FeN<sub>4</sub>C<sub>10</sub> to the FeN<sub>4</sub>C<sub>Z</sub> and FeN<sub>4</sub>C<sub>A</sub> structure, respectively. While the \*OH adsorption free energy is 0.40,

0.28, and 0.46 eV for the  $FeN_4C_{10}$ ,  $FeN_4C_Z$ , and  $FeN_4C_A$ structure, respectively. In these cases, the adsorption of \*OH is more energetically favorable on the zigzag edge host  $(\mbox{FeN}_4\mbox{C}_Z)$ structure than the others (FeN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>A</sub>). After one \*OH adsorption, the bulk-hosted MN<sub>x</sub> site and edge-hosted MN<sub>x</sub> sites adopt a square-pyramidal geometry. In the case of the Fe-N-C system, the elevation of the metal center upon the \*OH adsorption is 0.28, 0.45, and 0.26 Å for the \*OH-FeN<sub>4</sub>C<sub>10</sub>, \*OH-FeN<sub>4</sub>C<sub>Z</sub>, and \*OH-FeN<sub>4</sub>C<sub>A</sub> structures, respectively (Figure S28) This elevation is significantly smaller than the elevation in the \*OH-FeN<sub>4</sub>C<sub>8</sub> structure, which is 0.80 Å. The magnetic moment on the metal atom is 1.17, 1.70, and 1.00 for the \*OH-FeN<sub>4</sub>C<sub>10</sub>, \*OH-FeN<sub>4</sub>C<sub>7</sub>, and \*OH-FeN<sub>4</sub>C<sub>A</sub> structures, respectively, resulting in a low spin configuration. The ORR activity can be found in Table S14 for the Fe-N-C system. The pristine  $\mathrm{FeN}_4\mathrm{C}_\mathrm{A}$  structure, which the  $\mathrm{FeN}_4$  site located at the armchair edge, is slightly more active toward the ORR than the bulk-host FeN<sub>4</sub> site (overpotential is 0.08 V lower than the  $FeN_4C_{10}$  site). However, the ORR activity also depends on the \*OH and \*O ligands which can form in closed potential. With the \*OH, the FeN4 site at the armchair edge still has better ORR activity than the bulk-hosted one (overpotential is 0.08 V lower than the  $*OH-FeN_4C_{10}$ site)-however, the ORR activity order changes with the \*O ligand. The formation energies of the bulk-hosted and edgedhost  $MN_4$  sites are calculated and presented in Table S10. Our results suggest that forming the MN<sub>4</sub> site at the edge, either on a zigzag or armchair edge, is energetically favorable compared to forming it on the graphene bulk structure for all considered metal elements.

The  $MN_{3}C_{\rm Z}$  and  $MN_{3}C_{\rm A}$  structures are also likely to bond with the adsorbate strongly, regardless of the metal atom. This is possible because the metal atom has a possible oxidation state of +1 in these two structures. Thus, the metal atom prefers to form at least one more bond with the adsorbate, changing the oxidation from +1 to +2 or +3, which is generally favorable for transition metal atoms. To consider the NiN<sub>3</sub>C<sub>A</sub> and NiN<sub>3</sub>C<sub>Z</sub> structures as examples, see Table S11, we find that the pristine structures are converted into +1 spin states (one unpaired electron). The \*O and \*OH bond strongly with the bare Ni metal site in the  $NiN_3C_A$  and  $NiN_3C_{Z'}$  and the spin states become +0, which is the same as other  $NiN_4C_{\nu}$ structures without adsorbates. The bonding with another ORR intermediate as a second adsorbate on the NiN<sub>3</sub>C<sub>A</sub> and NiN<sub>3</sub>C<sub>Z</sub> structure becomes too weak, and it is comparable to that on the bare Ni atom on other  $NiN_4C_{\nu}$  structures. In other words, the metal atom in the  $MN_3C_A$  and  $MN_3C_Z$  structure is unsaturated and prefers to form a bond with the adsorbate. The preference of \*O and \*OH on these unsaturated structures is advantageous for Fe and Co catalysts. We find that \*O strongly adsorbs on the  $\text{FeN}_3\text{C}_{\text{Z}}$  and  $\text{FeN}_3\text{C}_{\text{A}}$ structures and becomes a part of the active site where the theoretical overpotential can be as low as 0.54 and 0.56  $\mathrm{V}_{\mathrm{SHE}}$ respectively. Similarly, the \*OH-CoN<sub>3</sub>C<sub>Z</sub> and \*OH-CoN<sub>3</sub>C<sub>A</sub> active sites can reach as low theoretical overpotential as 0.54 and 0.37 V<sub>SHE</sub>

**3.3. Stability vs Activity.** Combining the acid stability and activity descriptors, we plot the relative stability of the most stable phase at  $U = 0.8 \text{ V}_{\text{SHE}}$ , pH = 0 against the ORR activity in Figure 5. We consider the structure with the relative stability lower than 1 eV and the overpotential less than 1 V<sub>SHE</sub>. The stable and active sites shown in Figure 5 are from the Fe, Co, Ni, and Ru metal atom mainly on the graphene plane (both

**Figure 5.** Relative stability of the most stable phase at  $U = 0.8 V_{SHE}$  and pH = 0 vs theoretical ORR overpotential with nonadsorbing electrolyte ions. The catalysts close to the bottom left corner are expected to be active toward ORR and stable in acid conditions.

 $MN_4C_{10}$  and  $MN_3C_{10}$  structure) and at the edge of the graphene (Table 1). The  $MN_yC$  structure with Cr ad Mn metal

$NiN_3C_{10}$	*Ni	0.45	0.51

atoms is predicted to be unstable under the considered condition as the thermodynamic driving force toward the dissolution is greater than 1 eV. Also, most  $MN_yC$  structures hosted by the micropore and the unsaturated  $MN_y$  structures that exhibit higher catalytic activity than the active site on the graphene plane for some metal atoms are not in Figure 5 because of the same reason.

Besides the well-known Fe–N–C catalyst, the Ru–N– $C_{,7^{4,75}}$  Co–N– $C_{,2^{22,23,76,77}}$  and Mn–N– $C^{7^{8,79}}$  catalysts have already been synthesized and tested as an ORR catalyst in acid conditions. However, when we compare theoretical and experimental results, we need to keep in mind that the variation in catalyst preparation and different metal precursor<sup>80</sup> can possibly lead to a different configuration of MN<sub>y</sub> site for different metal atoms.

Xiao et al. have reported that the RuN<sub>4</sub> single-atom catalyst exhibits oxygen reduction reaction turnover frequency in 0.1 M

 $\rm HClO_4$  exceeding the  $\rm FeN_4$  single atom in the same solution while the activity loss is less than that of the  $\rm FeN_4$  single atom.<sup>74</sup> Furthermore, the \*OH-RuN<sub>4</sub> site has be suggested as an active site for the ORR activity in acid conditions.<sup>74</sup> The experimental study by Cao et al.<sup>24</sup> and Zhang et al.<sup>75</sup> suggests that under working potential in acid solution, the active and stable site for the RuN<sub>4</sub> single-atom catalyst is the Ru metal site bond with an oxygen atom, in agreement with our finding. Furthermore, Zitolo et al.<sup>23</sup> has suggested that the Fe-based moieties experience a structural change and an electronic-state change, implying that the \*O and \*OH ligand originating from H<sub>2</sub>O can exist under operating while it does not occur for the Co-based moieties. This partially agrees with this study. Most of the Fe–N–C sites have either one \*O or \*OH on one side of the Fe metal, while only some of the Co–N–C sites have the \*O or \*OH ligand at the ORR relevant condition.

We find that the stable CoN<sub>v</sub>C structures in Table 1 and Figure 5 are more active than the stable  $FeN_{\nu}C$  structures. Previous experimental studies have reported that the Co-N-C catalyst exhibits high stability in acid condition.<sup>22,77</sup> However, Martinez et al. have found the ORR activity order in 0.5  $H_2SO_4$  to be Fe > Co > Mn.<sup>78</sup> To match the experimental results and DFT calculations, Martinez et al. have also suggested that the \*OH ligand must be adsorbed on one side of the metal atom in the MN<sub>4</sub>C<sub>A</sub>. While not included in this study, it is well-known that impurities or anions from the electrolyte can be adsorbed on an  $\mathrm{MN}_4$  motif site and can either enhance or deteriorate the catalytic activity.<sup>67,81</sup> The computational study by Svane et al. has found that the ligand under H<sub>2</sub>SO<sub>4</sub> solution for the FeN<sub>4</sub>C<sub>12</sub> and MnN<sub>4</sub>C<sub>12</sub> structure is HSO<sub>4</sub> and H<sub>2</sub>O for CoN<sub>4</sub>C<sub>12</sub> structure, giving good ORR catalytic activity (Fe > Co > Mn)<sup>25</sup> in agreement with the experimental trend in the same solution reported by Martinez et al.<sup>78</sup> The interaction of the single metal site on different local carbon structures with the relevant species in the electrolyte should be further considered to create a model that can accurately describe both the catalytic activity and stability under experimental conditions.<sup>25,67</sup> Another possible explanation for this could be that the Co-N-C catalyst is highly selective for the two-electron pathway, potentially lowering catalytic activity for the four-electron pathway. Martinez et al. has reported that the Fe-N-C catalyst has a half-wave potential of 0.80  $V_{RHE}$  and a selectivity for the fourelectron pathway more than 95% while the Co-N-C catalyst has a lower half-wave potential of 0.77  $V_{\text{RHE}}$  and a lower selectivity for the four-electron path (90%).<sup>78</sup> Similarly, Gao et al. has reported that the Co-N-C and Fe-N-C catalyst both show high onset potential at around 0.7  $\mathrm{V}_{\mathrm{RHE}}$  but the Co–N– C catalyst is more selective for the two-electron pathway than the Fe-N-C catalyst,<sup>82</sup> also agreeing with Zitolo et al.

Some of the promising stable and active structures in acid condition are the FeN<sub>3</sub>C<sub>10</sub>, CoN<sub>3</sub>C<sub>10</sub>, and NiN<sub>3</sub>C<sub>10</sub> structures, suggesting that the catalytic activity of the MN<sub>x</sub> on the graphene plane can be tuned by the nearest neighbor interaction; therefore, careful manipulation of the heteroatoms around the active site can possibly further improve the catalytic activity of the MN<sub>y</sub>C<sub>10</sub> structure while maintaining acid stability. Additionally, for the design strategies to achieve both active site and stable M–N–C catalyst, the synthesized aim should be increasing the site density of MN<sub>x</sub> bulk-hosted structures (MN<sub>4</sub>C<sub>10</sub> or MN<sub>3</sub>C<sub>10</sub>) or the MN<sub>4</sub> on the edgehosted graphene structure. Also, avoiding the formation of unsaturated MN<sub>3</sub>C<sub>Z</sub> or MN<sub>3</sub>C<sub>A</sub> structure as well as the MN<sub>4</sub>C<sub>8</sub> site, which bridged between two armchair edges, will increase the stability of the M–N–C catalyst under acid conditions. Further stability improvement for the active M–N–C structures hosted by the micropores ( $MN_4C_{12}$ ,  $MN_4C_8$ ) or the unsaturated structure ( $MN_3C_7$ ,  $MN_3C_A$ ) might be achieved by forming these active structures over another graphitic layer. The metal choice also significantly affects both stability and activity and should be considered when designing the catalyst. Integrating Fe, Co, and Ru metal elements into graphitic carbon supports like the  $MN_xC_{10}$  structure would be a promising catalyst for the ORR in acid conditions.

## 4. CONCLUSION

To summarize, we have systematically investigated stabilities and ORR catalytic activity of the MN, site on different local atomic structures in acid conditions using DFT calculations, which reveal that the local atomic structure plays a crucial role in both stability and ORR catalytic activity. The stability is here considered from the tendency of a single metal atom to dissolve into the electrolyte. The calculation reveals that all considered MN<sub>x</sub> structures are thermodynamically unstable in acid ORR conditions. The thermodynamic driving forces toward the dissolution suggest that the single metal site on the graphene plane and at the edge of the graphene ( $MN_4C_{10}$ ,  $MN_4C_{A\!\prime}$  and  $MN_4C_Z)$  are more stable against the dissolution than the single metal sites host by the microporous (i.e.,  $MN_4C_{12}$ ,  $MN_4C_8$ ) or in the unsaturated single metal site at the edge  $(MN_3C_Z \text{ and } MN_3C_A)$ . The stability also depends on the choice of metal site. The MN<sub>x</sub> sites with Fe, Co, Ni, and Ru metal atoms are more stable under the acid conditions than those with Mn and Cr metal atoms. Under reaction conditions, we predict the most stable phase of the active site in which \*O or \*OH ligands occur and become a part of the active site. The ORR activity also depends on the choice of metal and the local atomic structure around the metal site. The MN<sub>4</sub>C<sub>8</sub>, MN<sub>3</sub>C<sub>7</sub>, and MN<sub>3</sub>C<sub>A</sub> structures are likely to bond with the intermediate too strongly, generally having one \*O or \*OH ligand on the metal site. For different metal atoms, the Cr, Mn, Ru, and Fe metal bond with the ORR intermediate quite strongly, and the ORR occurs with \*O or \*OH ligands. The bonding strength becomes weak for the Ni metal atom compared to other considered metal atoms, and most considered structures with Ni are not active toward ORR. Combining both stability and activity descriptors, we identify that single Fe, Co, and Ru metal atoms mostly on the  $MN_4C_{10}\!\!\!,\,MN_4C_Z\!\!\!,\,MN_4C_A\!\!\!,$  and MN<sub>3</sub>C<sub>10</sub> structure are the promising acid-stable active ORR catalyst. Therefore, rational modification of carbon matrix hosting MN<sub>v</sub> moieties and appropriate selection of a metal atom could be carefully used to optimize the activity and stability toward the reaction. This computational study provides useful guidance to rational design and controlled synthesis of M-N-C electrocatalyst to achieve both active and stable catalyst under working conditions not only for the ORR but also the OER due to their similar operating conditions and reaction intermediates. Our study highlights the improved stability of  $MN_4C_{10}$ ,  $MN_4C_Z$ , and  $MN_4C_A$  sites against the demetalation and metal clustering compared to, e.g.,  $MN_4C_8$  and  $MN_4C_{12}$  sites. The approach can be further applied to the  $N_2^{83}$  and  $CO_2$  reduction reactions,<sup>84,85</sup> and refined by including relevant reaction intermediates such as \*H, \*CO, and \*NH<sub>3</sub> at the more reducing reaction conditions. Figure S30 is an example of extending stability diagrams and relative stability plots at different pH, showing that the

approach is flexible and can be applied for varied electrochemical environments. Furthermore, these computational approaches are of interest to the further understanding of acid stability of other geometries of M-N-C materials, such as the dual metal site embedded on the graphene<sup>61,63,86</sup> or a diporphyrin complex.<sup>84,87</sup>

## ABSTRACT

A single metal site incorporated in N-doped carbon (M/N/C) is a promising electrocatalyst. Here, we perform a computation investigation of the effect of electrolyte anion adsorption on the activity and stability of single-atom catalysts (MN<sub>4</sub>) with M as transition metal and p-block metal. The MN<sub>4</sub> site on two different graphene structures (bulk graphene and graphene edge) is studied under electrochemical conditions for the oxygen reduction reaction (ORR) and the CO<sub>2</sub> reduction reaction (CO<sub>2</sub>RR). Because of the two-dimensional nature of the catalyst, reaction intermediates and electrolyte ions can interact with both sides of the single-atom catalyst. As a result, the electrolyte anions compete with water and adsorbate on the single metal site, in some cases either poisoning or modifying the catalyst activity and thermodynamic stability. We find most electrolyte anions adsorbs on the single metal site under ORR conditions but not at the lower potentials for the CO<sub>2</sub>RR. Still, the adsorption of water and gas molecules can occur under CO<sub>2</sub>RR conditions. For example, under ORR conditions, the thermodynamic driving force of the \*SO<sub>4</sub>-FeN<sub>4</sub> site in the 0.1 M H<sub>2</sub>SO<sub>4</sub> solution is about 0.47-0.56 eV lower than the \*O-FeN<sub>4</sub> site in water, depending on the local carbon structure. Additionally, the stabilization by electrolyte anions depends on the nature of the metal atom. Our study demonstrates the important role of electrolytes and the coordination environment for the activity and stability of the M/N/C catalyst.

## INTRODUCTION

Single metal atom coordinated N-doped carbon (M/N/C) has been recognized as an efficient electrocatalyst. Compared to the bulk metal, the single-atom catalyst maximizes the metal atom utilization, thus exhibiting impressively high activity and selectivity. In many experimental and theoretical studies, the Fe/N/C and Co/N/C materials have been identified as active ORR catalysts in acid electrolytes<sup>1–5</sup>. More recent studies showed that the M/N/C catalyst is also an efficient catalyst for the  $CO_2RR^{6-8}$ . The metal centers are crucial for the reaction, and the MN<sub>y</sub> site is suggested as the active site for the ORR<sup>4</sup> and  $CO_2RR^9$ . In addition, the coordination environment is suggested to play an important role in both catalytic activity and stability<sup>10,11</sup>. Many studies have been made to determine the detailed structure and map the relationship between catalyst structure, activity, and stability. Many structures of the MN<sub>4</sub> site with different local carbon structures (i.e.,  $MN_4C_8^{3,12,13}$ ,  $MN_4C_{10}^{11,14}$ ,  $MN_4C_{12}^{2,4,14}$ ) have been proposed from experimental and theoretical studies. Still, there is a wide debate about the active and stable site in the M/N/C materials.<sup>11,15–21</sup>

Additionally, possessing two-dimensional structures, the M/N/C catalyst is distinct from the bulk materials, where only one exposed side is responsible for its catalytic activity. Ideally, both sides of the M/N/C catalyst are exposed to electrolyte so both sides can interact with an adsorbate. An electrolyte anion or a gas molecule from the environment may adsorb on one side of the MN<sub>y</sub> site while the other side is still available for the reaction to proceed.<sup>22,23</sup> The presence of the adsorbate on one side of the single metal atom will modify its electronic states, affecting the binding of the second adsorbate on the

other side<sup>24,25</sup>. Experimental and theoretical studies have considered the effect of anions from the electrolyte or a gas molecule impurity on ORR activity. For instance, Holst-Olesen *et al.* found that the presence of anions from  $H_3PO_4$  or  $CH_3COOH$ -containing electrolytes is beneficial for the ORR activity on the Fe/N/C catalyst<sup>22,23</sup>. Various combinations of the electrolyte anion ligand and the single metal center in the MN<sub>4</sub>C<sub>12</sub> structure (M = Cr, Mn, Fe, and Co) for improving the ORR activity have also been suggested in a previous theoretical study by Svane *et al.*<sup>24</sup> Recently, studies have also reported that the introduction of axial oxygen<sup>26,27</sup> or halogen atom<sup>25</sup> on the MN<sub>4</sub>C structure can achieve an efficient catalyst for the CO<sub>2</sub>RR.

Besides the catalytic activity, the stability of the  $MN_4$  site with the presence of a fifth ligand was recently discussed. Glibin et al. have previously studied the dissolution reaction of two different FeN4 sites with \*F ligand based on a thermodynamic model and suggested that the fluorination on the FeN4 sites increases the resistance of the single metal site against acid leaching<sup>28</sup>. Density functional theory (DFT) calculations have been used to study the dissolution reaction of the FeN4 site embedded on a bilayer-graphene by Holby et al.<sup>19</sup> This study has suggested the presence of \*OH ligand on the FeN<sub>4</sub>C<sub>10</sub> site thermodynamically prevents the single Fe metal site from dissolution<sup>19</sup>. Using in situ Raman spectroscopy of molecule Fe phthalocyanine (FePc) model and pyrolyzed Fe/N/C catalyst, Wei et al. have reported the structural dynamics of the FeN<sub>4</sub> active site in acid solution (0.1 M HClO<sub>4</sub>). At high potential (1.0 V<sub>RHE</sub>), a non-planar structure is induced by the presence of an adsorbate on the FeN<sub>4</sub> site, and the structure is stable against the dissolution. In contrast, the irreversible attenuation of the planar Fe-N vibration after staying at a lower potential for a long time (at 0.05 V<sub>RHE</sub> for 15 min) has been suggested as evidence for the dissolution of the Fe center<sup>29</sup>. Using DFT simulations with <sup>57</sup>Fe Mössbaur spectroscopy data, Nematollahi et al. have compared the DFT calculated and experimental quadrupole splitting energy of doublets ( $\Delta E_{QS}$ ) for different FeN<sub>4</sub> structures (FeN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>12</sub>, FeN<sub>4</sub>C<sub>8</sub>) both with and without ligands. They have suggested the  $FeN_4C_8$  structure with a fifth ligand such as OH<sup>-</sup> and NH<sub>2</sub><sup>-</sup> could be an active and durable site for the ORR in acid conditions<sup>20</sup>.

Here, we systematically explore the effect of electrolyte anion adsorption on the stability and activity of a single metal atom with N ligands doped into a bulk graphene terrace ( $MN_4C_{10}$ ) and a graphene edge ( $MN_4C_A$ ) with M = 3d, 4d, 5d, or p-block (Sn, Sb, and Bi) metal atoms. These graphene sites are selected because they are among the most stable type of sites<sup>18</sup>. We determine the interaction between the single metal site with the electrolyte anion and evaluate how the electrolyte adsorption thermodynamically influences the dissolution of the single metal site under electrochemical conditions relevant to the ORR and CO<sub>2</sub>RR. We then investigate the catalytic activity with the presence of an electrolyte anion ligand for the ORR and CO<sub>2</sub>RR. Finally, the results are used to suggest combinations of a metal atom, local carbon structure, and electrolyte for active and stable catalysts under working conditions. We show how the chemical environment around the single-atom site plays a crucial role in determining the activity and stability of the catalyst.

## **RESULTS AND DISCUSSION**

**Figure 1** (a) Single atom site in bulk graphene ( $MN_4C_{10}$ ) and a graphene edge ( $MN_4C_A$ ) (C = grey, N = blue, H = white, M = pink). (b)  $\Delta G_f$  for  $MN_4C_{10}$  and  $MN_4C_A$  sites. (c) Stability diagrams for the CoN<sub>4</sub>C<sub>10</sub> site in 0.1 M solutions. (d)  $\Delta G_R$  for the sites at specific pH and (e) Stability diagrams for the CoN<sub>4</sub>C<sub>10</sub> site showing the most stable surface.

Here we consider the structural models of the  $MN_4C_{10}$  and  $MN_4C_A$  sites, as shown in **Figure 1 (a)**. The  $MN_4C_{10}$  site was previously reported as a durable site in acid<sup>11,18,30</sup>. Also, the  $MN_4C_A$  site, which represents the  $MN_4$  site at the armchair edge is included in this study as previously found to be a stable and active site for the ORR under acid conditions<sup>18,31</sup>. We calculate the formation free energy of the single metal atom doped into bulk graphene and the graphene edge as follows:

$$\Delta G_{f} = E(MN_{4}C) - (E(C) - 6\mu_{C} - \mu_{M} - 4\mu_{N})$$
 Equation 1

E(MN<sub>4</sub>C) is the total energy of the single metal atom doped into graphene. E(C) is the total energy of a pristine graphene sheet or pristine graphene nanoribbon.  $\mu_{C}$  is the total energy of the pristine graphene sheet per carbon atom.  $\mu_{M}$  is the total energy of metal in its bulk structure per metal atom. The nitrogen chemical potential ( $\mu_{N}$ ) is treated as a parameter to account for the use of different nitrogen precursors in experiments<sup>7,8,14,32–35</sup>.  $\mu_{N}$  is referenced to NH<sub>3</sub>, N<sub>2</sub>, and H<sub>2</sub> at 1 bar and can be expressed as  $\mu_{N}(n) = n[G(NH_3) - (3/2)G(H_2)] + (1/2)(1 - n)G(N_2)$  where n is an integer. Thus, when n = 0, the nitrogen reference source is the N<sub>2</sub> gas molecule at 1 bar, and when n = 1, the nitrogen reference source is the NH<sub>3</sub> gas molecule. The nitrogen chemical potential can vary as a function of N<sub>2</sub>, H<sub>2</sub>, and NH<sub>3</sub> content in the environment gas during the synthesis. The n < 0 situation corresponds to synthesis under the high pressure of N<sub>2</sub> + H<sub>2</sub>, and the n > 1 situation corresponds to the synthesis under the high pressure of NH<sub>3</sub>.

**Figure 1 (b)** shows the  $\Delta G_f$  of MN<sub>4</sub>C<sub>10</sub> and MN<sub>4</sub>C<sub>A</sub> at two different  $\mu_N(n)$  with n=1,3. The temperature is considered at T=1100 °C, a typical temperature in the M/N/C synthesis<sup>4,6,36</sup>. Regardless of the metal atom and  $\mu_N(n)$ , the single atom site is thermodynamically preferred to form at the graphene edge over bulk graphene. We find that a pyridine vacancy (PorN<sub>4</sub>) is more stable on the graphene edge than the bulk graphene, and it is likely to be further stabilized if the bulk metal atom is supplied, forming the MN<sub>4</sub> site. Most 3d elements are thermodynamically more favorable to dope into the pyridine vacancy than the 4d-5d elements and p-elements. The formation at T=1100 °C, becomes thermodynamic favorable when n increase from 1 to 3 (e.g., under the elevated NH<sub>3</sub> partial pressure). Figure S1 (b) shows that the nitrogen chemical potential changes with temperature. Thus, the formation free energies depend on temperature and the nitrogen chemical potential. Let us consider the formation free energy of the  $CoN_4C_{10}$  site as an example, as shown in **Figure S1 (c)**. Increasing temperature makes the formation more favorable when n > 1. In other words, the synthesis under the high NH<sub>3</sub> partial pressure and high temperature (T > 500 °C) is favorable for the single atom formation. At low temperatures (T < 100 °C), the formation becomes thermodynamic favourable when n < 0 (e.g., under high N<sub>2</sub>+H<sub>2</sub> content). Figure S2 shows the formation free energy of all considered MN<sub>4</sub> structures at T=25°C and 1100 °C as a function of  $\mu_{N}$ , suggesting that the considered single metal sites doped into graphene can be synthesized in a controlled experiment.

We then consider the stability of the MN<sub>4</sub> site in an electrochemical environment where the single metal atom can interact with anions from the electrolyte or reaction intermediates. We consider anions from commonly used electrolytes for the ORR or the  $CO_2RR^{37-39}$ , *e.g.*,  $H_2PO_4^-$ ,  $HPO_4^{2-}$ ,  $PO_4^{3-}$  in  $H_3PO_4$  solution;  $HSO_4^-$ ,  $SO_4^{2-}$  in  $H_2SO_4$  solution;  $CI^-$  in HCI solution;  $CIO_4^-$  in HCIO<sub>4</sub> solution;  $NO_3^-$  in HNO<sub>3</sub> solution;  $HCO_3^-$  and  $CO_3^{2-}$  in  $H_2CO_3$  solution. Furthermore, NO and CO gas molecules and  $CN^-$  in HCN solution are included as they have been found to affect the catalytic activity<sup>40-42</sup>. The complete list of the considered electrolyte anion and poisoning gas molecules is given in **Table S2** and **Table S3**. The adsorption of CO and NO on the single metal site considered in this study does not depend on pH and potential. We consider that the electrolyte anion adsorption on the single metal atom can compete with

the water molecule. In each solution, the adsorption of anion or gas molecules on the single metal site competes with the formation of \*OH, \*O, and \*H from water oxidation or reduction. The adsorption free energy of electrolyte anions is calculated using the thermodynamic cycle<sup>23,24</sup> shown in **Figure S3**, with additional calculation details in **Section 3** of the Supporting Information. Along with the adsorption of the adsorbate, the dissolution of the single metal atom from the graphene host into the electrolyte, resulting in dissolved metal ion (M<sup>x+</sup>) and the graphene host cavity (N<sub>4</sub>CH<sub>n</sub>) is considered as follows<sup>19</sup>:

$$MN_4C + nH^{+}_{(aq)} \rightarrow M^{x+}_{(aq)} + N_4CH_n + (x-n)e^{-}$$
 Equation 2

More calculation details about the dissolution reaction can be found in **Section 4** of the supporting information. However, other possible degradation reactions besides the demetalltion<sup>43,44</sup> have been proposed to cause instability of the Fe/N/C catalyst, especially in an acidic environment. These include carbon corrosion<sup>45</sup>, and carbon surface oxidation by  $H_2O_2$ -derived free radicals<sup>45,46</sup>. These possible degradation mechanisms might coincide and be interrelated<sup>45</sup>. Understanding the degradation mechanism is a prerequisite for the rational design of durable and stable M/N/C catalysts. We believe that the relation between the chemical environment, i.e., electrolyte and local carbon structure around the MN<sub>y</sub> site with the demetallation, provides a better understanding of the degradation and is useful for designing intrinsic stable and active catalysts.

For example, Figure 1 (c) shows the stability diagram of the CoN<sub>4</sub>C<sub>10</sub> site in 0.1 M solutions. Only the most stable phase at each condition is shown in the stability diagram. It is seen that the electrolyte anion competes with water adsorption and becomes the most favorable adsorbate on a single Co atom. We further consider the relative stability ( $\Delta G_R$ ), which we define as the free energy difference between the M/N/C catalyst surface (either with or without the adsorbate) and the most stable dissolved species (the dissolved metal ion and carbon host cavity)<sup>47</sup>. Therefore,  $\Delta G_R$  indicates the thermodynamic driving force for the dissolution of the metal atom. The more positive relative stability, the less stable the single metal atom is against dissolution. Figure 1 (d) shows  $\Delta G_R$  as a function of applied potential at specific pH (pH = 1 for  $H_3PO_4$ ,  $H_2SO_4$ , and  $HCIO_4$  solution and pH = 7 for  $H_2CO_3+CO$  solution). The most stable dissolved species for each potential used as a reference for  $\Delta G_R$  are superimposed as horizontal bars at the bottom in **Figure 1 (d)**. At potentials above 0.6  $V_{SHE}$  and pH=1, in 0.1 M H<sub>3</sub>PO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>, and HClO<sub>4</sub> solution, it is seen that \*HPO<sub>4</sub>, \*SO<sub>4</sub>, and \*ClO<sub>4</sub> are thermodynamically preferred on the single Co atom and further reduces the thermodynamic driving force toward dissolution compared to \*OH on the single Co atom in H<sub>2</sub>O. The relative stability of the CoN<sub>4</sub>C<sub>A</sub> site and the FeN<sub>4</sub> site on both bulk graphene and the graphene edge can be found in **Section 5** of the supplementary information, where similar trends are found. The electrolyte anion becomes thermodynamically stable on the single metal site as potential increases. Simultaneously, the corresponding thermodynamic force becomes lower than the same single metal site in  $H_2O$ . Furthermore, it is seen that the thermodynamic driving force toward the dissolution is likely to decrease as the potential increase, suggesting that the demetallation could be dominant at the low potential region in the acid condition. This is in line with the experimental study by Choi et al., where the Fe demetallation from the Fe/N/C catalyst in 0.1 M HClO<sub>4</sub> was observed at potentials below 0.7  $V_{RHE}^{44}$ .

At pH = 7 in 0.1 M H<sub>2</sub>CO<sub>3</sub> solution with CO<sup>6,39</sup>, at potentials below -0.4 V<sub>SHE</sub>, \*H is thermodynamically favorable on the single Co atom. When the potential increases, the anions become the most stable adsorbate on the Co atom (\*HCO<sub>3</sub> at potential around -0.6 to 0.4 V<sub>SHE</sub> and \*CO<sub>3</sub> at potential above 0.4 V<sub>SHE</sub>). The thermodynamic driving force is lowered by 0.46 eV when the \*HCO<sub>3</sub> is

stabilized on the Co atom (U = -0.6 to 0.4  $V_{SHE}$ ), and it is lowered by 2.18 eV when the \*CO<sub>3</sub> is stabilized on the Co atom (U = 0.4 - 1.6  $V_{SHE}$ ), compared to the \*CO-CoN<sub>4</sub>C<sub>10</sub> site in H<sub>2</sub>O+CO solution at the same potential ranges.

The  $\Delta G_R$  of the most stable MN<sub>4</sub>C<sub>10</sub> and MN<sub>4</sub>C<sub>A</sub> surface in 0.1 M electrolytes under the ORR condition (pH=1, and U=0.80 V<sub>SHE</sub>) is shown in Figure 2(a) and Figure S9, respectively. Except for  $PtN_4C_{x=10,A}$ ,  $PdN_4C_{x=10,A}$ , and  $AuN_4C_{x=10,A}$  sites, the other MN<sub>4</sub> sites are likely to be stabilized by the adsorbate. Therefore the thermodynamic driving force is reduced compared to the bare metal site. The PtN<sub>4</sub>C<sub>x=10,A</sub>, PdN<sub>4</sub>C<sub>x=10,A</sub>, and AuN<sub>4</sub>C<sub>x=10,A</sub> sites weakly interact with electrolyte anions and water molecules. However, they are stable against dissolutions in a wide range of pH and potentials, even without any adsorbate. The stability of the Pt center is consistent with a previous experimental study by Li et al.<sup>48</sup>, where a negligible change in the current density of a Pt/N/C catalyst under accelerated durability tests in 0.5 M  $H_2SO_4$  has been reported. The relative stability of  $IrN_4C_{x=10,A}$  is found to be lower than zero in the considered electrolytes, so it is stable under the considered ORR condition. This agrees with experiments where the Ir/N/C catalyst retains 97% of the current density during a durability test in 0.1 M HCIO<sub>4</sub><sup>49</sup>. For CrN<sub>4</sub>C<sub>x=10,A</sub>, MoN<sub>4</sub>C<sub>x=10,A</sub>, RuN<sub>4</sub>C<sub>x=10,A</sub>, ReN<sub>4</sub>C<sub>x=10,A</sub>, and OsN<sub>4</sub>C<sub>x=10,A</sub> sites, the binding strength of the anion is likely weaker than \*O in most considered electrolytes. Thus, these metal sites are covered by \*O. According to experimental studies by Zhang et al.<sup>50</sup> and Xiao et al.<sup>51</sup> testing the ORR performance of the Ru/N/C catalyst in 0.1 M HClO<sub>4</sub>, the active RuN<sub>4</sub> site has been suggested to bond with axial \*O or \*OH.

Furthermore, a previous experimental study has shown a higher activity loss of the Mn/N/C catalyst than the Fe/N/C catalyst in 0.1 M HClO<sub>4</sub> under an accelerated stress test where the potential is cycled between 0.5 and 1.3  $V_{RHE}^{52}$ . In agreement with this experiment, in 0.1 M HClO<sub>4</sub> in the potential range of 0.5–1.3  $V_{RHE}$  (0.44-1.25  $V_{SHE}$  at pH = 1), we find the thermodynamic force toward the dissolution of the MnN<sub>4</sub> site on bulk graphene and graphene edge is about 0.78 eV and 0.57 eV higher than those of the FeN<sub>4</sub> site on bulk graphene and graphene edge, respectively. At U = 0.5–1.0  $V_{RHE}$  in 0.1 M HClO<sub>4</sub>, the MnN<sub>4</sub> and FeN<sub>4</sub> sites are stabilized by ClO<sub>4</sub>. Then,  $\Delta G_R$  is about 0.25 eV and 0.13 eV lower than in H<sub>2</sub>O, respectively. However, in both H<sub>2</sub>O and 0.1 M HClO<sub>4</sub>, the MnN<sub>4</sub> site is found to be less stable than the FeN<sub>4</sub> site.

Another experimental study by Xie *et al.*<sup>53</sup> has determined the amount of metal leached out from the Fe/N/C and Co/N/C catalyst when the potential is cycled between 0.6–1.0 V<sub>RHE</sub> in 0.5 M H<sub>2</sub>SO<sub>4</sub>. They have found a lower amount of metal leaching from the Co/N/C catalyst, compared to the Fe/N/C catalyst, especially when purged with  $O_2$ .<sup>53</sup> At U = 0.6–1.0 V<sub>RHE</sub> (U=0.55–0.96 V<sub>SHE</sub> at pH=1), we find that the FeN<sub>4</sub> and CoN<sub>4</sub> site on both bulk graphene and the graphene edge in 0.1 M H<sub>2</sub>SO<sub>4</sub> are occupied by \*SO<sub>4</sub>. The thermodynamic driving force toward the dissolution of the \*SO<sub>4</sub>-CoN<sub>4</sub> site on bulk graphene and graphene edge is about 0.14 eV and 0.13 eV lower than the \*SO<sub>4</sub>-FeN<sub>4</sub> site, agreeing with the experiment. In our previous study<sup>18</sup>, the electrolyte anion adsorption was not included. At the same condition, the \*O-FeN<sub>4</sub> and \*OH-CoN<sub>4</sub> is the most stable phase of the FeN<sub>4</sub> and CoN<sub>4</sub> site on both bulk and armchair edge in H<sub>2</sub>O. The thermodynamic driving toward the dissolution of the most stable phase of the FeN<sub>4</sub> site. This suggests that our stability calculations, including the electrolyte anion adsorption, compare well with the experimental results for M/N/C catalysts.

For CO adsorption, CO chemisorption experiments on the M/N/C catalyst (M = Fe and Mn) have suggested a stronger CO binding on the Fe-containing site over the Mn-containing site<sup>52</sup>. In agreement with these experiments, we find a stronger CO adsorption on the FeN<sub>4</sub> site than on the MnN<sub>4</sub> site on both bulk graphene and the graphene edge. Similar results have been reported by Svane *et al.*<sup>54</sup> where the

 $MN_4$  structure is modeled based on the  $MN_4C_{12}$  structure. In addition, the stability against dissolution is also determined by the local carbon structure. We find that the  $MN_4$  site on the graphene edge is more stable against dissolution than that on the bulk graphene. The thermodynamic driving at U = 0.8 V<sub>SHE</sub>, pH = 1 of the most stable  $MN_4$  site on the graphene edge is about 0.52 eV lower than those on the bulk graphene, on average.

Since the MN<sub>4</sub> site is embedded in a two-dimensional carbon sheet, the adsorbates may interact with the metal atom from both sides. The electrolyte anion can strongly adsorb on two sides, blocking the metal site from the intermediate adsorbates. Alternatively, if the interaction is weak, the electrolyte anion will adsorb only on one side, allowing the intermediate adsorbates to interact from the other. In the case of weak interaction, i.e.,  $PdN_4C_x$ ,  $PtN_4C_x$ , and  $AuN_4C_x$ , the bare metal site is responsible for their catalytic activity. In this work, the ORR is considered to proceed through a four-electron associative pathway, and the metal site is considered the active site. Most of the considered MN<sub>4</sub> sites interact with the electrolyte anion under the ORR condition. Thus, the activity of the MN<sub>4</sub> site toward the ORR by considering the following reaction mechanism<sup>23</sup> on the catalyst surface:

; ∆G(ORR)₀	Equation 3
; ∆G(ORR)1	Equation 4
; ∆G(ORR)₂	Equation 5
; ∆G(ORR)₃	Equation 6
; ∆G(ORR)₄	Equation 7
	; ∆G(ORR)₀ ; ∆G(ORR)₁ ; ∆G(ORR)₂ ; ∆G(ORR)₃ ; ∆G(ORR)₄

\*A<sup>n</sup>/\*A<sup>n</sup> is the electrolyte anions (or gas molecules with n = 0) adsorbed on both sides. \*X/\*A<sup>n</sup> stands for the electrolyte anion adsorbs on one side and the reaction intermediate on another, where \*X = \*O, \*OH, \*OOH.  $\Delta G(*O/*A^n)$  and  $\Delta G(*OOH/*A^n)$  are obtained from a scaling relation established for  $\Delta G(*O)$  vs.  $\Delta G(*OH)$  and  $\Delta G(*OH)$  vs.  $\Delta G(*OOH)$  on the bare metal site (**Figure S12**), respectively. Thus, only  $\Delta G(*OH/*A^n)$  is explicitly calculated in this study. The possible electrolyte anion participating in the reaction is considered the most stable adsorbate at pH = 1 and U = 0.80 V<sub>SHE</sub>, as shown in Figures 2 (a) and **S9**. The corresponding ORR activity is also calculated at this condition. The change in free reaction energy with an applied potential (U<sub>SHE</sub>) and pH is calculated using the computational hydrogen electrode (CHE)<sup>55</sup>. The thermodynamic barrier of the limiting step ( $\Delta G_{max}$ ) along the ORR pathway at pH = 1, U = 0.80 V<sub>SHE</sub> is considered the ORR activity descriptor, which is given in **Figure S14-S15**. The limiting potential (U<sub>L</sub>) is also calculated if all elementary steps are electrochemical, as shown in **Figure S16-S17**. This includes when NO and CO gas molecules are not thermodynamically stable on both sides of the metal atom.

The ORR activity of the FeN<sub>4</sub> site in 0.1 M H<sub>3</sub>PO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>, HCIO<sub>4</sub>, and HCI is firstly discussed. At U = 0.8 V<sub>SHE</sub> and pH = 1, one electrolyte anion (HPO<sub>4</sub><sup>2-</sup>, SO<sub>4</sub><sup>2-</sup>, CIO<sub>4</sub><sup>--</sup> and Cl<sup>-</sup>) bonds with the FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> sites stronger than the water molecule, so the electrolyte anion can affect the ORR. **Figure S13** shows free energy diagrams of the ORR on the FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> sites at U = 0.80 V<sub>SHE</sub> and pH = 1. The anion removal step limits the ORR on the FeN<sub>4</sub>C<sub>10</sub> site in 0.1 M HCIO<sub>4</sub> and HCI. In 0.1 H<sub>3</sub>PO<sub>4</sub>, the thermodynamic barrier of the limiting step is the barrier of the anion removal plus the barrier of the formation \*OOH on the FeN<sub>4</sub>C<sub>10</sub> site. While in 0.1 M H<sub>2</sub>SO<sub>4</sub>, the ORR is limited by the reduction of \*OH to H<sub>2</sub>O. The lowest  $\Delta G_{max}$  at U = 0.80 V<sub>SHE</sub> and pH = 1 for the FeN<sub>4</sub>C<sub>10</sub> site in these electrolytes is found for H<sub>2</sub>SO<sub>4</sub> (0.02 eV) < HCIO<sub>4</sub> (0.13 eV) < H<sub>3</sub>PO<sub>4</sub> (0.26 eV) < HCI (0.56 eV). The U<sub>L</sub> with the most stable adsorbate at U = 0.80 V<sub>SHE</sub> and pH = 1 as the ligand on the FeN<sub>4</sub>C<sub>10</sub> site is found in the following order:

 $H_2SO_4(0.78 V_{SHE}) > HCIO_4(0.67 V_{SHE}) > H_3PO_4(0.60 V_{SHE}) > HCI(0.24 V_{SHE})$ . These results suggest that the ORR activity of the FeN<sub>4</sub>C<sub>10</sub> site is in the following order:  $H_2SO_4 > HCIO_4 > H_3PO_4 > HCI$ .

For the FeN<sub>4</sub>C<sub>A</sub> site in 0.1 M H<sub>3</sub>PO<sub>4</sub>, and HCl, the ORR at U = 0.80 V<sub>SHE</sub>, and pH = 1 is limited by the anion removal step. In 0.1 M H<sub>2</sub>SO<sub>4</sub>, the thermodynamic barrier of the limiting step is the barrier of the anion removal plus the formation of \*OOH on the FeN<sub>4</sub>C<sub>A</sub> site. The ORR is limited by the reduction of \*OH to H<sub>2</sub>O for the FeN<sub>4</sub>C<sub>A</sub> site in 0.1 M HClO<sub>4</sub>. The lowest  $\Delta G_{max}$  at U = 0.80 V<sub>SHE</sub> and pH = 1 for the FeN<sub>4</sub>C<sub>A</sub> site in these electrolytes is found to be H<sub>3</sub>PO<sub>4</sub> (0.01 eV) < H<sub>2</sub>SO<sub>4</sub> (0.08 eV) < HClO<sub>4</sub> (0.13 eV) < HCl (0.54 eV). The U<sub>L</sub> is found in the following order: H<sub>3</sub>PO<sub>4</sub> (0.79 V<sub>SHE</sub>) > H<sub>2</sub>SO<sub>4</sub> (0.76 V<sub>SHE</sub>) > HClO<sub>4</sub> (0.67 V<sub>SHE</sub>) > HCl (0.26 V<sub>SHE</sub>). These results suggest that the ORR activity of the FeN<sub>4</sub>C<sub>A</sub> site is in the following order: H<sub>3</sub>PO<sub>4</sub> > HCl (0.12 eV) = H<sub>2</sub>SO<sub>4</sub> + HClO<sub>4</sub> + HClO<sub>4</sub> = HClO<sub>4</sub> = HClO<sub>4</sub> + HClO<sub>4</sub> = HCl

Previous experimental results by Holst-Olesen et al.23 and Hu et al.56 have reported that the ORR activity of the Fe/N/C catalyst in H<sub>3</sub>PO<sub>4</sub> is higher than in the other considered electrolytes. Holst-Olesen et al.<sup>23</sup> reported the ORR activity in the following order:  $H_3PO_4 > HCIO_4 \approx H_2SO_4 > HCI in 0.5$  M electrolyte. At 0.8 V<sub>RHE</sub>, Hu et al.<sup>56</sup> reported the ORR activity of the Fe/N/C catalyst in the following order: H<sub>3</sub>PO<sub>4</sub> >  $H_2SO_4 > HCIO_4 > HCI.$  Modeling the Fe/N/C catalyst by the FeN<sub>4</sub>C<sub>12</sub> structure, Holst-Olesen et al.<sup>23</sup> have reported a good agreement between the theoretical and experimental ORR activity trend. Our calculation results obtained from the FeN<sub>4</sub>C<sub>A</sub> site agree with the experiments by Hu et al.<sup>56</sup> and Holst-Olesen et al.<sup>23</sup>. Both experimental studies by Holst-Olesen et al.23 and Hu et al.56 have suggested a strong poison effect on the Fe/N/C catalyst by Cl<sup>-</sup> in HCl solution. In our findings, the thermodynamic barrier of the limiting step in 0.1 M HCl is also higher than in 0.1 M HClO<sub>4</sub> and H<sub>2</sub>SO<sub>4</sub> solution. Additionally, Hu et al.<sup>56</sup> have also suggested that the catalytic activity of the Fe/N/C catalyst can be poisoned by CIO<sub>4</sub><sup>-</sup> in the HCIO<sub>4</sub> solution. Our calculation results show that the  $ClO_4$  can be adsorbed on the FeN<sub>4</sub> site on bulk graphene and graphene edge at U = 0.80 V<sub>SHE</sub> and pH = 1. Also, we find that the CIO<sub>4</sub> anions thermodynamically block the FeN<sub>4</sub>C<sub>10</sub> site at this condition. These results disagree with previous theoretical and experimental studies<sup>22,24</sup> based on the MN<sub>4</sub>C<sub>12</sub> (M = Cr, Fe, Mn, Co) structure where the CIO<sub>4</sub><sup>-</sup> anion has been found not to adsorb on the MN<sub>4</sub> site at U = 0.75 V in 0.5 M HClO<sub>4</sub>. As discussed previously, the discrepancy could be due to the different coordination environments around the MN<sub>4</sub> site, which could be different in each experiment, depending on the synthesis process.

**Figure 2**  $\Delta G_R$  of the most stable adsorbate on MN<sub>4</sub>C<sub>10</sub> in 0.1 M electrolytes at: (a) pH=1, U=0.80 V<sub>SHE</sub>. (b) pH=7, U=-0.80 V<sub>SHE</sub>. The text insert indicates the most stable adsorbate on the metal site and its corresponding  $\Delta G_R$  in eV. (c) U<sub>L</sub> for the ORR on MN<sub>4</sub>C<sub>10</sub> (circle) and MN<sub>4</sub>C<sub>A</sub> (square) at pH=1 with M = Mn, Fe, and Co and (d)  $\Delta G_{max}$  for the CO<sub>2</sub>RR to CO on MN<sub>4</sub>C<sub>10</sub> (circle) and MN<sub>4</sub>C<sub>A</sub> (square) at pH=7 and U=-0.8 V<sub>SHE</sub> with M = Mn, Fe, Co, Ni, Cu, Zn, and Sn.

Evaluating the ORR catalytic activity in 0.5 M H<sub>2</sub>SO<sub>4</sub>, Martinez *et al.*<sup>57</sup> have reported the following order of onset for the M/N/C catalyst: Mn < Co < Fe and their theoretical study has suggested an \*OH ligand as a part of the active site. The theoretical studies by Svane *et al.*<sup>24</sup> based on the MN<sub>4</sub>C<sub>12</sub> structure have reported the same order for the liming potential in 0.5 M H<sub>2</sub>SO<sub>4</sub>. They have found \*HSO<sub>4</sub> as a ligand on the FeN<sub>4</sub>C<sub>12</sub> and MnN<sub>4</sub>C<sub>12</sub> site while \*H<sub>2</sub>O on the CoN<sub>4</sub>C<sub>12</sub> site in 0.5 M H<sub>2</sub>SO<sub>4</sub><sup>24</sup>. According to our calculations, the ligand on MnN<sub>4</sub>, FeN<sub>4</sub>, and CoN<sub>4</sub> sites on both bulk graphene and graphene edge in 0.1 M H<sub>2</sub>SO<sub>4</sub> is \*SO<sub>4</sub>. As shown in **Figure 2 (c)**, the U<sub>L</sub> on the MN<sub>4</sub>C<sub>10</sub> structure for these three elements in 0.1 M H<sub>2</sub>SO<sub>4</sub> at pH = 1 differs by 0.01 V<sub>SHE</sub>, and the U<sub>L</sub> order is Mn (0.77 V<sub>SHE</sub>) < Fe (0.78 V<sub>SHE</sub>) < Co (0.79 V<sub>SHE</sub>). While U<sub>L</sub> calculated from the MN<sub>4</sub>C<sub>A</sub> structure in 0.1 M H<sub>2</sub>SO<sub>4</sub> is in the following order: Mn (0.70 V<sub>SHE</sub>) < Co (0.71 V<sub>SHE</sub>) < (0.76 V<sub>SHE</sub>), agreeing with the onset potential order from the experiments. Another experimental study testing the ORR performance of the Co/N/C and Mn/N/C catalyst in 0.1 M HClO<sub>4</sub> solution has reported the onset potential order as Mn < Co<sup>58</sup>. For both MN<sub>4</sub>C<sub>10</sub> and MN<sub>4</sub>C<sub>A</sub> sties in 0.1 M HClO<sub>4</sub>, we find \*ClO<sub>4</sub>-MnN<sub>4</sub> and \*ClO<sub>4</sub>-CoN<sub>4</sub> sites serve as the active center, and the U<sub>L</sub> is Co < Mn. Based on the MN<sub>4</sub>C<sub>12</sub> structure studied by Svane *et al.*, the ligand is \*OH and \*H<sub>2</sub>O on MnN<sub>4</sub>C<sub>12</sub> and CoN<sub>4</sub>C<sub>12</sub>, respectively, and the U<sub>L</sub> is Mn < Co<sup>2424</sup>.

Previous experimental results have shown a poisoning of Fe/N/C catalysts by CN<sup>-</sup> in an acid environment<sup>59</sup>. This is consistent with our calculations on FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> structures and the FeN<sub>4</sub>C<sub>12</sub> site in the previous computational study<sup>24</sup>. At U > 0 V<sub>SHE</sub>, pH = 1, the ORR on the FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> sites process by the least thermodynamic barrier for removing one \*CN anion from the FeN<sub>4</sub> sites. The Fe site and other metal sites such as Mn, Co, Ru, Rh, Os, and Ir on both bulk graphene and graphene edge where two \*CN can limit the ORR anions by blocking the metal site at U > 0 V<sub>SHE</sub>, pH = 1. Additionally, we find that NO gas molecules are thermodynamically favorable on both sides of the IrN<sub>4</sub>C<sub>10</sub> and IrN<sub>4</sub>C<sub>A</sub> structure. In the potential range of 0 - 0.8 V<sub>SHE</sub> and pH = 1, the ORR proceeds with the least thermodynamic hindrance for removing one \*NO from the IrN<sub>4</sub> site. We find that both CO and NO gas molecules are thermodynamically stable on both sides of the RuN<sub>4</sub>C<sub>A</sub> and OsN<sub>4</sub>C<sub>A</sub> structures. However, at U = 0.80 V<sub>SHE</sub>, pH = 1, the binding of \*OH is stronger than the 2<sup>nd</sup> \*CO or \*NO. As a result, the ORR is thermodynamically limited by the reduction of \*OH to H<sub>2</sub>O.

Comparing our present calculation results with the previous studies<sup>23,24</sup>, it is seen that the nature of the metal center of the M/N/C catalyst and the coordination environment plays a crucial role in determining the electrolyte adsorption and its corresponding catalytic performance in acid environments.

**Figures 2 (b)** and **S10-S11** show  $\Delta G_R$  of the most stable MN<sub>4</sub>C<sub>10</sub> and MN<sub>4</sub>C<sub>A</sub> surface in 0.1 M electrolytes under the CO<sub>2</sub>RR condition (pH = 7, and U = -0.8 V<sub>SHE</sub>). At this condition, we include 0.1 M H<sub>2</sub>CO<sub>3</sub> solution as the electrolyte used in the experiments<sup>6,8,39</sup>. In contrast to the ORR conditions, the anion from most of the considered electrolytes, except from 0.1 M H<sub>2</sub>CO<sub>3</sub>, do not bind with the single metal site. Thus, most considered electrolytes possibly have little impact on catalytic activity and stability of the MN<sub>4</sub> site under the CO<sub>2</sub>RR. For all considered electrolytes, except 0.1 M H<sub>2</sub>CO<sub>3</sub>, the stability under the CO<sub>2</sub>RR-related condition is the same as in H<sub>2</sub>O. We find that \*H can occupy the CoN<sub>4</sub>, RuN<sub>4</sub>, RhN<sub>4</sub>, OsN<sub>4</sub>, and IrN<sub>4</sub> sites on both bulk graphene and the graphene edge in H<sub>2</sub>O. While the MoN<sub>4</sub>C<sub>x=10,A</sub>, WN<sub>4</sub>C<sub>x=10,A</sub>, and ReN<sub>4</sub>C<sub>10</sub> sites are occupied by \*O. This is the same as under the ORR condition but with a lower thermodynamic driving force toward the dissolution. It is also seen that \*CO (in H<sub>2</sub>O+CO solution) and \*NO (in H<sub>2</sub>O+CO+NO solution) can be thermodynamically stable on many metal sites both on bulk graphene and the graphene and the graphene than CO to the metal site. The binding of CN<sup>-</sup> is weaker than that of CO. Then CN<sup>-</sup> is unlikely to either block the metal site or affect the CO<sub>2</sub>RR. In 0.1 M H<sub>2</sub>CO<sub>3</sub>, the MoN<sub>4</sub>C<sub>x=10,A</sub>, WN<sub>4</sub>C<sub>x=10,A</sub>, and ReN<sub>4</sub>C<sub>10</sub> sites or affect the CO<sub>2</sub>RR. In 0.1 M H<sub>2</sub>CO<sub>3</sub>, the MoN<sub>4</sub>C<sub>x=10,A</sub>, WN<sub>4</sub>C<sub>x=10,A</sub>, and ReN<sub>4</sub>C<sub>10</sub> sites bind with the \*CO<sub>3</sub> via two

oxygen atoms. For other metal sites, we find that  $^{*}HCO_{3}$  is thermodynamically stable on  $CrN_{4}C_{x=10,A}$ ,  $MnN_{4}C_{x=10,A}$ ,  $FeN_{4}C_{10}$ ,  $ZnN_{4}C_{10}$ ,  $SbN_{4}C_{x=10,A}$ , and  $BiN_{4}C_{x=10,A}$  sites. When the CO gas molecule is present (such as in 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO), the  $^{*}CO$  can compete with  $^{*}HCO_{3}$  and  $^{*}CO_{3}$  and bind to the metal sites. It can be seen that the most stable adsorbate on both  $MN_{4}C_{10}$  and  $MN_{4}C_{A}$  sites in H<sub>2</sub>O+CO and 0.1 M H<sub>2</sub>CO<sub>3</sub>+CO is slightly different. Like the ORR above conditions, the NiN<sub>4</sub>, CuN<sub>4</sub>, PdN<sub>4</sub>, PtN<sub>4</sub>, and AuN<sub>4</sub> sites on both bulk graphene and the graphene edge are unoccupied by an adsorbate.

Recently, a kinetic model fit the experimental data by Zeng et al.<sup>60</sup> demonstrated the role of the bicarbonate (HCO<sub>3</sub>) buffer on the electrochemical CO<sub>2</sub>RR catalyzed by cobalt phthalocyanine (CoPC). They suggested that the active site can be poisoned by HCO<sub>3</sub><sup>-</sup> via electrosorption at low overpotential while the bicarbonate acts as a proton donor at higher overpotential. Defining the onset potential for CO production to be the applied electrode potential at which the TOF of the CO formation exceeds 0.2 mmol/(h m<sup>2</sup><sub>active</sub>), the experiments have found that the Co/N/C catalyst starts producing CO at around -0.36  $V_{RHE}^{6}$  (-0.77  $V_{SHE}$  at pH = 7). Around this potential, it is seen from our calculations in **Figure 1 (c)** and **Figure S5** that \*H, \*CO, and \*HCO<sub>3</sub> could be absorbed on the CoN<sub>4</sub> site on both bulk graphene and the graphene edge. At more negative potential (high overpotential), the \*H is more stable than \*CO and \*HCO<sub>3</sub>. At a more positive potential (low overpotential), the \*HCO<sub>3</sub> becomes the most favorable adsorbate. Furthermore, a series of M/N/C catalysts (M = Mn<sup>3+</sup>, Fe<sup>3+</sup>, Co<sup>2+</sup>, Ni<sup>2+</sup>, Cu<sup>2+</sup>, Zn<sup>2+</sup>, and Sn<sup>2+</sup>) have been synthesized and evaluated for electrochemical CO2 reduction in aqueous electrolyte (0.5 M KHCO<sub>3</sub> and 0.5 M K<sub>2</sub>SO<sub>4</sub>) by Paul et al.<sup>8</sup>. They have found that the Cu/N/C catalyst can produce hydrocarbon products in significant amounts which have also been demonstrated to correlate with a partial reduction of Cu<sup>2+</sup> to Cu<sup>0</sup> accompanied by a partial demetallation of the CuN<sub>4</sub> site. According to our calculation at CO<sub>2</sub>RR condition in 0.1 M H<sub>2</sub>CO<sub>3</sub>+CO, both the CuN<sub>4</sub> site and the MnN<sub>4</sub> site on both bulk graphene and the graphene edge have a relatively higher thermodynamic driving force than other metal elements. While our calculation agrees with the experiments for the CuN<sub>4</sub> site by Paul et al.<sup>8</sup>, it is inconclusive for the MnN<sub>4</sub> site since there are no available experiments on the transformation of the Mn/N/C catalyst during the CO<sub>2</sub>RR.

Similar to the ORR mechanism with the electrolyte anion ligand, the following mechanism for CO<sub>2</sub> to CO formation is considered:

$A^n/A^n + ne^- \rightarrow A^n + A^{n-1}$	; ∆G(CO₂RR)₀	Equation 8
*/* $A^n$ + CO <sub>2</sub> + (H <sup>+</sup> + e <sup>-</sup> ) $\rightarrow$ *COOH/* $A^n$	; ∆G(CO₂RR)₁	Equation 9
*COOH/*A <sup>n</sup> + (H <sup>+</sup> + e <sup>-</sup> ) $\rightarrow$ *CO/*A <sup>n</sup> + H <sub>2</sub> O	; ∆G(CO <sub>2</sub> RR) <sub>2</sub>	Equation 10
$CO/A^n \rightarrow CO(g) + A^n$	; ∆G(CO₂RR)₃	Equation 11

The possible electrolyte anion participating in the reaction is considered to be the most stable adsorbate at pH = 7 and U = -0.8 V<sub>SHE</sub>. The CO<sub>2</sub> to CO formation activity is also considered in this condition. **Figure S19-S20** shows the thermodynamic barrier of the limiting step ( $\Delta G_{max}$ ) for the CO<sub>2</sub> to CO formation at pH = 7 and U = -0.8 V<sub>SHE</sub> on the MN<sub>4</sub> site. We find that the NO gas molecules thermodynamically prefer both sides of the IrN<sub>4</sub>C<sub>10</sub>, IrN<sub>4</sub>C<sub>A</sub>, and ReN<sub>4</sub>C<sub>A</sub> structures. In the H<sub>2</sub>CO<sub>3</sub> + CO + NO solution at pH = 7 and U = -0.8 V<sub>SHE</sub>, the limiting step is removing one NO gas molecule plus forming \*COOH on these metal sites. Similarly, the CO gas molecules can be thermodynamically stable on both sites of ReN<sub>4</sub>C<sub>x=10,A</sub>, OsN<sub>4</sub>C<sub>x=10,A</sub>, RuN<sub>4</sub>C<sub>A</sub>, and WN<sub>4</sub>C<sub>A</sub> sites. In H<sub>2</sub>CO<sub>3</sub> + CO solution at pH = 7 and U = -0.8 V<sub>SHE</sub>, the limiting step is necessarily the CO gas molecules can be thermodynamically stable on both sites of ReN<sub>4</sub>C<sub>x=10,A</sub>, OsN<sub>4</sub>C<sub>x=10,A</sub>, RuN<sub>4</sub>C<sub>A</sub>, and WN<sub>4</sub>C<sub>A</sub> sites. In H<sub>2</sub>CO<sub>3</sub> + CO solution at pH = 7 and U = -0.8 V<sub>SHE</sub>, the limiting step is necessarily the CO gas molecule plus the removal of one CO gas molecule plus the formation \*COOH.

We compare our calculation results with the experimental studies shown in Figure 2 (d). An experimental study by Ju et al.6. has evaluated the electrochemical performance of the M/N/C catalyst (M=Mn. Fe. Co, Ni, and Cu) for CO<sub>2</sub> to CO formation and reported the order of the onset potential in 0.1 M KHCO<sub>3</sub> as follows: Co (-0.36 V<sub>RHE</sub>) > Fe (-0.37 V<sub>RHE</sub>) > Mn (-0.41 V<sub>RHE</sub>) > Cu (-0.52 V<sub>RHE</sub>) > Ni (-0.36  $V_{RHE}$ ). Their theoretical results have also suggested that the potential-determining step on these M/N/C catalysts is the first proton-coupled electron transfer reduction of CO<sub>2</sub> to form \*COOH<sup>6</sup>. The experimental onset potentials reported by Ju et al. are marked with red stars in Figure 2 (d) and use the y-axis on the right. In 0.1 M  $H_2CO_3$  with CO, the CO<sub>2</sub> to CO formation on the MN<sub>4</sub>C<sub>10</sub> structure is thermodynamically limited by the reduction of  $CO_2$  to \*COOH, as shown in **Figure S18** (a). The thermodynamic barrier of the limiting step for the CO<sub>2</sub> to CO formation at U = -0.80  $V_{SHE}$ , and pH = 7 is found to be in the following order: Co (0.46 eV) < Fe (0.59 eV) < Mn (0.70 eV) < Cu (0.79 eV) < Ni (1.16 eV), agreeing with the onset potential order reported by Ju et al.<sup>6</sup>. It should be noted that at this condition in 0.1 M H<sub>2</sub>CO<sub>3</sub>+CO, the ligand is found to be \*CO on the CoN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>10</sub> and MnN<sub>4</sub>C<sub>10</sub> sites. In contrast, the CuN<sub>4</sub>C<sub>10</sub> and NiN<sub>4</sub>C<sub>10</sub> site has no ligand on the metal site at this condition. For the MN<sub>4</sub>C<sub>A</sub> structure in 0.1 M H<sub>2</sub>CO<sub>3</sub> with CO, the ligand at U = -0.80 V<sub>SHE</sub>, and pH = 7 is \*H on the CoN<sub>4</sub>C<sub>A</sub> site and \*CO on the FeN<sub>4</sub>C<sub>A</sub> and MnN<sub>4</sub>C<sub>A</sub> sites. There is also no ligand on both CuN<sub>4</sub>C<sub>A</sub> and NiN<sub>4</sub>C<sub>A</sub> under this condition. The CO<sub>2</sub>RR to CO on these metal sites are also limited by the reduction of CO<sub>2</sub> to \*COOH, as shown in Figure S18 (b), and the thermodynamic barrier of the limiting step at U = -0.80  $V_{SHE}$ , and pH = 7 is in the following order: Fe (0.67 eV) < Mn (0.70 eV) < Cu (0.94 eV) < Co (0.95 eV) < Ni (1.21 eV), deviating from the experimental trend.

Furthermore, Li et al.<sup>7</sup> have synthesized and evaluated the activity toward CO formation in 0.1 M KHCO<sub>3</sub> for the M/N/C catalysts with M = Mn, Fe, Co, Ni, and Cu. They have reported the following order of CO partial current density at U =  $-0.6 V_{RHE}$ : Co > Fe > Ni > Cu > Mn. Our thermodynamic barrier on the MN<sub>4</sub>C<sub>10</sub> structure agrees with this experiment only for the relative order between Co, Fe, and Mn. In another experimental study by Paul et al.<sup>8</sup>, the M/N/C catalyst with M = Mn, Fe, Co, Ni, Cu, Zn, and Sn was synthesized and tested for the CO<sub>2</sub>RR in gas diffusion electrodes. The experimental onset potential for the CO formation in 0.5 M KHCO<sub>3</sub>+0.5 M K<sub>2</sub>SO<sub>4</sub> at pH=7.5 has been reported in the following order: Fe (-0.27 V<sub>RHE</sub>) > Co (-0.35 V<sub>RHE</sub>) > Mn (-0.36 V<sub>RHE</sub>) > Cu (-0.46 V<sub>RHE</sub>) > Ni (-0.56 V<sub>RHE</sub>) > Zn (-0.83 V<sub>RHE</sub>) > Sn (-0.92 V<sub>RHE</sub>). The experiential onset potentials reported by Paul *et al.*<sup>8</sup> are marked with blue stars in Figure 2 (d). Our thermodynamic barrier based on the MN<sub>4</sub>C<sub>10</sub> and MN<sub>4</sub>C<sub>A</sub> structure in 0.1 M H<sub>2</sub>CO<sub>3</sub> with CO does not give the exact order as the experimental results by Paul et al.<sup>8</sup> It should be noted that other possible sites with different coordination environments<sup>60-62</sup> could be involved in the catalytic process and that the distribution of active sites could be different in each experiment, depending on the synthesis process. Also, the onset potential is defined differently in these two experiments, and we assume that the CO<sub>2</sub>RR to CO in the experiments is limited by the reduction of CO<sub>2</sub> to \*COOH, similar to our calculations.

On top of that, the ligand on the metal site is defined to be the most stable adsorbate at U = -0.8  $V_{SHE}$  and pH = 7. The most stable ligand could be different when the potential slightly deviates from U = -0.8  $V_{SHE}$  on some metal sites, i.e., the CoN<sub>4</sub>C<sub>10</sub> site. In **Figure S22**, we consider the thermodynamic barrier of the limiting step on the metal site in 0.1 M H<sub>2</sub>CO<sub>3</sub>+CO at -1.0  $V_{SHE}$  and pH = 7, and the most stable adsorbate at U=-1.0  $V_{SHE}$ , pH = 7 is considered to be a ligand on the metal site. At this condition, most of the considered MN<sub>4</sub>C<sub>10</sub> sites still have the same ligand, except the CoN<sub>4</sub>C<sub>10</sub> site, where the ligand is now \*H. For the MN<sub>4</sub>C<sub>10</sub> structure, the limiting step is still the reduction of CO<sub>2</sub> to \*COOH step, as shown in **Figure S21(a)**. The thermodynamic barrier of the limiting step at U = -1.0  $V_{SHE}$ , pH = 7 is found in the following order: Fe < Mn < Co < Cu < Ni < Sn < Zn. Due to the ligand change, the most active site

among the considered  $MN_4C_{10}$  structures is shifted from the  $CoN_4C_{10}$  site to the FeN<sub>4</sub>C<sub>10</sub> site. Still, this order differs slightly from the experimental trend reported by Paul *et al.*<sup>8</sup>

It should be noted that the oxidation state on the single metal atom in the pristine MN<sub>4</sub> structure is considered to be +2 in this work. Our calculations give a relatively high thermodynamic barrier for the NiN<sub>4</sub> site on both bulk graphene and graphene edge, compared to the FeN<sub>4</sub> site. In contrast, the Fe/N/C and particularly Ni/N/C catalyst have been suggested as highly promising for selective CO production<sup>6–8</sup>. One possible explanation is that the Ni<sup>2+</sup>N<sub>4</sub> site is not active for the CO<sub>2</sub>RR. According to a previous study by Li *et al.*, the Ni<sup>1+</sup>N<sub>4</sub>C<sub>10</sub> site bind with CO<sub>2</sub> more strongly than the Ni<sup>2+</sup>N<sub>4</sub>C<sub>10</sub>, so the Ni<sup>1+</sup>N<sub>4</sub>C<sub>10</sub> site is predicted to have higher activity toward CO formation than the Ni<sup>2+</sup>N<sub>4</sub>C<sub>10</sub> site. In fact, by DFT calculations, they have found that the Ni<sup>1+</sup>N<sub>4</sub>C<sub>10</sub> site has the highest activity among the considered MN<sub>4</sub> sites in their study where M = Mn<sup>2+</sup>(\*O), Fe<sup>2+</sup>(\*H<sub>2</sub>O), Co<sup>2+</sup>(\*H<sub>2</sub>O), Ni<sup>1+</sup>, and Cu<sup>2+</sup>. the letter in parentheses is the ligand considered in their study<sup>7</sup>.

The local environment could also influence catalytic activity. For example, according to a previous study by Yang *et al.*, the NiN<sub>3</sub> sites have been calculated to be more active than the NiN<sub>4</sub> site<sup>63</sup>. Furthermore, it has been suggested that the NiN<sub>y</sub> site has a weaker binding of \*H than the CoN<sub>y</sub> site, making the hydrogen evolution reaction (HER) unfavorable for the Ni/N/C catalyst. Also, the \*CO selectivity is higher for the Ni/N/C catalyst than the Co/N/C catalyst<sup>6</sup>. As shown in **Figure S23**, the binding energy of \*H on the NiN<sub>4</sub> site is weaker than on the CoN<sub>4</sub> site. Thus the NiN<sub>4</sub> site in our calculation is also expected to have higher selectivity toward CO formation than the CoN<sub>4</sub> sites.

In order to identify the promising catalysts that are electrochemically stable and active based on our computational analysis, the  $\Delta G_R$  of the most stable phase is plotted against its corresponding thermodynamic barrier of the limiting step on that most stable phase at the same condition. We considered the ORR catalyst in acid at U = 0.80  $V_{SHE}$  and pH = 1, as shown in Figures 3 (a) and 3 (b). It is seen that the FeN<sub>4</sub>, CoN<sub>4</sub>, MnN<sub>4</sub>, and RuN<sub>4</sub> sites on both bulk graphene and the graphene edge emerge as a promising candidates in many electrolytes, in agreement with several previous experimental studies<sup>2,53,64,65</sup>. In our previous study, where electrolyte adsorption was not included, the MnN<sub>4</sub>C<sub>10</sub> structure was not a promising candidate for the ORR in acid<sup>18</sup>. The MnN<sub>4</sub> site, however, becomes more stable against dissolution through electrolyte adsorption in the current study. We also identify new promising combinations between metal elements for acid electrolytes with  $\Delta G_R < 1$  eV and  $\Delta G_{max} < 0.8$ eV. These are IrN<sub>4</sub>C<sub>10</sub> in H<sub>3</sub>PO<sub>4</sub>, HClO<sub>4</sub>, H<sub>2</sub>O+NO, or non-adsorbing electrolyte (*e.g.*, HF); IrN<sub>4</sub>C<sub>A</sub> in H<sub>3</sub>PO<sub>4</sub>,  $H_2O+NO$  or non-adsorbing electrolyte (e.g., HCIO<sub>4</sub>, HF, HCOOH); CuN<sub>4</sub>C<sub>A</sub> in a non-adsorbing electrolyte (e.g., HClO<sub>4</sub>, HNO<sub>3</sub>); CuN<sub>4</sub>C<sub>10</sub> in H<sub>2</sub>SO<sub>4</sub>, H<sub>3</sub>PO<sub>4</sub>, non-adsorbing electrolyte (e.g., HClO<sub>4</sub>, HNO<sub>3</sub>); RhN<sub>4</sub>C<sub>10</sub> in H<sub>2</sub>O+CO, HClO<sub>4</sub>, H<sub>3</sub>PO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>, H<sub>2</sub>O+NO; RhN<sub>4</sub>C<sub>A</sub> in H<sub>2</sub>SO<sub>4</sub>, H<sub>2</sub>O+NO, H<sub>3</sub>PO<sub>4</sub> or non-adsorbing electrolyte (e.g., HCIO<sub>4</sub>, HF, HCOOH); AgN<sub>4</sub>C<sub>A</sub> in H<sub>3</sub>PO<sub>4</sub>; AuN<sub>4</sub>C<sub>x=10,A</sub> in a non-adsorbing electrolyte (e.g., all considered electrolytes in this study); ZnN<sub>4</sub>C<sub>10</sub> in HClO<sub>4</sub>, HNO<sub>3</sub>; ZnN<sub>4</sub>C<sub>A</sub> in HClO<sub>4</sub>, HNO<sub>3</sub>, HCOOH, HCI; OsN<sub>4</sub>C<sub>10</sub> in H<sub>3</sub>PO<sub>4</sub> and H<sub>2</sub>O+CO; BiN<sub>4</sub>C<sub>A</sub> in H<sub>3</sub>PO<sub>4</sub>, HClO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>, HCOOH; CrN<sub>4</sub>C<sub>A</sub> in H<sub>2</sub>O+NO, H<sub>2</sub>SO<sub>4</sub>, or non-adsorbing electrolyte (e.g., HClO<sub>4</sub>, HCl, HCOOH); SnN<sub>4</sub>C<sub>A</sub> in H<sub>2</sub>SO<sub>4</sub>, H<sub>3</sub>PO<sub>4</sub>; and SbN<sub>4</sub>C<sub>A</sub> in HCOOH, HCI, H<sub>3</sub>PO<sub>4</sub>. It is seen that the p-block metals, mostly on the graphene edge, have comparable stability and activity to the transition metal sites. The Sn/N/C catalyst has been successfully synthesized, and it exhibits similar activity and selectivity for four-electron ORR to a Fe/N/C catalyst in 0.1 M HClO<sub>4</sub><sup>66</sup>. The Sb/N/C catalyst has also been synthesized and exhibits promising activity toward the ORR, although in 0.1 M KOH<sup>67</sup>.

**Figure 3**  $\Delta G_R$  vs.  $\Delta G_{max}$  for the ORR on the most stable surface in the different electrolytes at pH = 1 at U = 0.8 V<sub>SHE</sub>: (a) MN<sub>4</sub>C<sub>10</sub> (b) MN<sub>4</sub>C<sub>A</sub>.  $\Delta G_R$  vs.  $\Delta G_{max}$  for the CO<sub>2</sub>RR to CO on the most stable surface in different electrolytes at pH = 7 and U = -0.8 V<sub>SHE</sub>: (c) MN<sub>4</sub>C<sub>10</sub> and (d) MN<sub>4</sub>C<sub>A</sub>. Classification plot for possible CO<sub>2</sub>RR products of promising candidates: (e) MN<sub>4</sub>C<sub>10</sub> and (f) MN<sub>4</sub>C<sub>A</sub>.

For the CO<sub>2</sub>RR toward CO, we consider the condition at U = -0.80 V<sub>SHE</sub> and pH = 7, as shown in **Figure 3 (c)** and **(d)**. Besides the MnN<sub>4</sub>, FeN<sub>4</sub>, CoN<sub>4</sub>, and NiN<sub>4</sub> which has been experimentally suggested for CO production<sup>6–8</sup>, we show promising combinations (with  $\Delta$ G<sub>R</sub> < 1 eV and  $\Delta$ G<sub>max</sub> < 0.8 eV): OsN<sub>4</sub>C<sub>x=10,A</sub>,

IrN<sub>4</sub>C<sub>x=10,A</sub>, RuN<sub>4</sub>C<sub>x=10,A</sub>, RhN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>10</sub>, ReN<sub>4</sub>C<sub>x=10,A</sub>, and WN<sub>4</sub>C<sub>A</sub> in H<sub>2</sub>CO<sub>3</sub> (or H<sub>2</sub>O) with NO or CO; BiN<sub>4</sub>C<sub>x=10,A</sub> and SbN<sub>4</sub>C<sub>x=10,A</sub> in non-adsorbing electrolyte (*e.g.* H<sub>2</sub>O); ZnN<sub>4</sub>C<sub>10</sub> in H<sub>2</sub>O with CO; CrN<sub>4</sub>C<sub>x=10,A</sub> in H<sub>2</sub>CO<sub>3</sub> with CO, H<sub>2</sub>O with CO; MoN<sub>4</sub>C<sub>A</sub> in H<sub>2</sub>CO<sub>3</sub> with CO or NO; and MoN<sub>4</sub>C<sub>A</sub> in H<sub>2</sub>O with CO.

In addition to reducing CO<sub>2</sub> to CO, the competing HER is crucial in determining catalytic efficiency. It has been shown that the binding strength of \*CO and \*H are a descriptor of CO<sub>2</sub>RR selectivity for both on transition metal surface<sup>68</sup> and single site porphyrin-like structure<sup>69</sup>. **Figure 3 (e)** and **(f)** show the classification of possible products from CO<sub>2</sub>RR on the single metal sites, based on the binding energy of \*CO and \*H criteria suggested by Bagger *et al.*<sup>69</sup>. It is seen that the identified promising candidates are selective toward CO production over H<sub>2</sub> production. The effect of the ligand is seen on the MoN<sub>4</sub>, RuN<sub>4</sub>, WN<sub>4</sub>, ReN<sub>4</sub>, and OsN<sub>4</sub> sites, where the bare metal site strongly bonds with \*H and will be highly selective for the HER. The binding of \*CO and \*H becomes weaker with the ligand; thus, the competing HER can be suppressed, as shown in **Figure S23**. Among the promising candidates, IrN<sub>4</sub>C<sub>x=10,A</sub> in H<sub>2</sub>CO<sub>3</sub>+CO solution potentially reduces CO<sub>2</sub> to the product beyond CO. Other promising candidates that can produce products beyond CO are RuN<sub>4</sub>C<sub>x=10,A</sub>, RhN<sub>4</sub>C<sub>10</sub>, and OsN<sub>4</sub>C<sub>10</sub> in H<sub>2</sub>CO<sub>3</sub>+CO solution; ReN<sub>4</sub>C<sub>A</sub> and WN<sub>4</sub>C<sub>A</sub> in H<sub>2</sub>CO<sub>3</sub>+CO (or H<sub>2</sub>CO<sub>3</sub>+CO+NO solution); and CrN<sub>4</sub>C<sub>A</sub> and MoN<sub>4</sub>C<sub>A</sub> in H<sub>2</sub>O+CO solution.

For the transition metal single atom considered in this study, we find that the reaction intermediate binding on the MN<sub>4</sub> site on the graphene edge is generally weaker than that on the MN<sub>4</sub> site on the bulk graphene. **Figure S24** illustrates the projected density of states (PDOS) for the CoN<sub>4</sub>C<sub>10</sub> and CoN<sub>4</sub>C<sub>A</sub> sites without and with adsorbate (either one \*OH or \*COOH adsorbate). In the pristine structure of the CoN<sub>4</sub>C<sub>10</sub> site, we observe that the 3d<sub>xy</sub> hybridization with the 2p orbital of the surrounding N atoms forms the Co-N bonds, while the other 3d orbitals are non-binding orbitals. For the pristine structure of the CoN<sub>4</sub>C<sub>A</sub> site, not only 3d<sub>xy</sub> but also 3d<sub>x2-y2</sub> overlap with the 2p orbital for the surrounding N atoms. When \*OH or \*COOH adsorb on the Co atom, the 2p orbital of \*OH or \*COOH overlaps with the 3d<sub>z2</sub> and 3d<sub>yz</sub> orbital of the Co 3d<sub>xy</sub> locates above the Fermi energy. The opposite situation is found for the CoN<sub>4</sub>C<sub>A</sub> site, where the Co 3d<sub>x2</sub> orbital locates below while the Co 3d<sub>xy</sub> locates above the Fermi energy. A similar calculated PDOS pattern is found for other single metal atoms. Thus, it appears that the difference in d-orbitals located near the Fermi level, possibly caused by different local carbon atoms, affects the binding strength of the adsorbates<sup>10</sup>.

Furthermore, with the presence of the ligand on the other side of the single metal atom, we find that the adsorption of the reaction intermediate likely weakens. The change in adsorption behavior of the ORR intermediate with the ligand on the  $CrN_4C_{12}$  and the  $CoN_4C_{12}$  structure has been previously explained by Svane *et al.*<sup>24,70</sup> using crystal field theory. In **Figure S25**, we show the possible electronic configuration in the d-orbital of the single metal atom in the MN<sub>4</sub>C<sub>10</sub> (M = Cr, Mn, Fe, and Co) structure with one and two adsorbates based on the converged magnetization and crystal field theory. The MN<sub>4</sub> site with two adsorbates adopts an octahedral structure, and the d-orbitals of the metal atom are split into two different energy levels,  $t_{2g}$  and  $e_g$ . For a Co<sup>2+</sup> ion with a low spin configuration in the octahedral geometry, transferring more than one electron to the adsorbates may not be thermodynamically favorable since after the first unpaired electron is transferred from higher  $e_g$  d-orbitals, the remaining electrons are paired electrons and fully placed in the lower  $t_{2g}$  d-orbital.

Similarly, for a  $Fe^{2+}$  ion in the octahedral geometry with a low spin configuration, all d-electrons are placed in the lower  $t_{2g}$  d-orbital. Removing electrons from this fully occupied orbital may not be thermodynamically favorable. This could result in the destabilization of \*COOH or \*OH when binding as

the second adsorbate. We find a similar value of the final magnetization for the MN<sub>4</sub> site on both bulk graphene and graphene edge; thus, we expect that both structure sites should have a similar d-orbital splitting pattern.

## CONCLUSION

We have investigated the effect of electrolyte anion adsorption on the stability and activity of single metal atoms doped on two different graphenes: the bulk graphene terrace and a graphene edge with 3d, 4d, 5d, or p-block (Sn, Sb, and Bi) metal atoms. We find that the armchair edge is thermodynamically favored to form the MN<sub>4</sub> site compared to the bulk graphene, especially for 3d transition metals. Under ORR conditions (pH=1 and U=0.80 V<sub>SHE</sub>), we find that various electrolyte anions can compete with water and adsorb on the single metal site. The electrolyte anion adsorption depends on the nature of the metal atom and local carbon around the MN<sub>4</sub> site. The ORR activity is either poisoned or altered by the electrolyte anion. If the electrolyte anion adsorbs on the single metal site, the single metal site can be further stabilized against dissolution in acid environments, compared to the stability in the pure water environment. We also find that the MN<sub>4</sub> site on the armchair edge is more stable than on the bulk graphene. Therefore, it would be interesting to include the electrolyte stabilization effect on other  $MN_4$ sites with different local carbon structures, although the sites considered here are expected to be among the most stable sites. Considering both stability in acid conditions and ORR activity, we find a single metal site based on Ir, Cu, Rh, Zn, Au, Os, Cr, and p-block elements (Sb, Sn, and Bi), especially on the graphene edge, has comparable ORR activity and stability to a single metal atom based on Fe and Co. Under the CO<sub>2</sub>RR condition (pH = 7 and U =  $-0.8 V_{SHE}$ ), most considered electrolyte anions, except in  $0.1 \text{ M H}_2\text{CO}_3$  solution, do not interact with the single metal site. Still, water and gas molecules may form ligands on various single metal sites under CO<sub>2</sub>RR conditions. We find that the activity trend for reducing  $CO_2$  to CO on the single metal site with the ligand from the solution compares well with the experimental trends. Besides the single atom catalyst-based Fe, Co, and Ni, we have identified promising single metal sites (Cr, Ru, W, Re, Os, Rh, Bi, Sb, Mo, Zn, and Ir), by including the adsorbate ligand from the solution. These promising candidates have comparable stability and activity to the Fe and Co-based catalysts. Our results illustrate that the nature of the metal atom, the local carbon structure, and the chemical environment, such as electrolytes, play a critical role in the activity and stability of a single-atom electrocatalyst. A careful combination of electrolyte or gas ligand and a single metal atom with various local carbon could be a possible way to achieve an active and durable electrocatalyst.

## DATA AVAILABILITY

The data that supports the findings of this study are available within the article and its supplementary material. The DFT-optimized structures and calculation details in this study can be accessed from an online repository: DOI:10.5281/zenodo.7071450

# Supporting Information

# Effects of Electrolyte Anion Adsorption on the Activity and Stability of Single Atom Electrocatalysts

Tipaporn Patniboon and Heine Anton Hansen Department of Energy Conversion and Storage, Technical University of Denmark Anker Engelunds Vej, 2800 Kongens Lyngby, Denmark

#### 1. Computational Details

The spin-polarized density functional theory calculations are performed using the Vienna ab initio simulation package (VASP)<sup>1</sup> and projector augmented wave (PAW)<sup>2</sup> is used to describe the core electrons. A plane-wave basis function with a kinetic energy cutoff of 600 eV is used to describe the valence electrons. The Fermi smearing is used with a width of 0.1 eV. The exchange and correlation energy are described using the BEEF-vdW<sup>3</sup> functional to include the effects of dispersive interactions. The self-consistent electron density loop is converged to 10<sup>-5</sup> eV. The structure is prepared using the Atomic Simulation Environments (ASE)<sup>4</sup> package and the bare M/N/C catalyst models are similar to those used in our previous study<sup>5</sup>. The unit cell dimensions in the catalyst plane are 16.9 x 9.8 Å on average, with variations for the different metal atoms. The lattice relaxation of the single metal atom on bulk graphene (MN<sub>4</sub>C<sub>10</sub>) and graphene edged (MN<sub>4</sub>C<sub>A</sub>) are relaxed in a vacuum until all forces are below 0.025 eV Å<sup>-</sup> and a dipole correction is used in the perpendicular direction to the catalyst plane to decouple the electrostatic potentials on the two sides of the catalyst plane. The Brillouin zone is sampled with a (3×3×1) Monkhorst Pack k-point mesh<sup>6</sup>. For binding energy calculations, the solvent effect is included during the relaxation, using the implicit solvent model implemented in VASPsol<sup>6</sup> with a dielectric constant of 80, representing the water medium. The calculations are submitted, managed, and received using the MyQueue<sup>7</sup> workflow tool, a python front-end to the job scheduler.

The free energy for the adsorbate is calculated from DFT energy ( $E_{DFT}$ ), including zero-point energy (ZPE), vibrational internal energy ( $U_{vib}$ ), and vibrational entropy ( $S_{vib}$ ) as a thermal correction.

$$G = E_{DFT} + ZPE + U_{vib} - TS_{vib} = E_{DFT} + Thermal correction$$
 Equation S1

The thermal correction term (ZPE +  $U_{vib} - TS_{vib}$ ) is calculated only for the adsorbates on the FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> sites and applied to other single metal sites with the same local carbon structure. The thermal corrections for adsorbates are listed in Table S1. In the case of the adsorbates on the catalyst surface, only the vibration of the adsorbate is calculated, following the quantum mechanical harmonic approximation, by using the thermochemistry class in the ASE package<sup>4</sup>. For the gas molecule, the free energy the DFT energy is corrected by including ZPE, enthalpy (H), and entropy (S). These values (ZPE, H, S) for the gas molecules are taken from the thermochemical database<sup>8</sup> (if available). The free energy of O<sub>2</sub> is not directly obtained from the DFT calculation, it is calculated in the way to reproduce the experimental free energy of liquid water formation (2H<sub>2</sub> + O<sub>2</sub>  $\rightarrow$  2H<sub>2</sub>O;  $\Delta G_{H2O} = -4.92 \text{ eV}^9$ ).

The change in free reaction energy with an applied potential ( $U_{SHE}$ ) and pH is calculated using the computational hydrogen electrode (CHE)<sup>10</sup>. By the definition of the standard hydrogen electrode (SHE)

at 0 V<sub>SHE</sub>, there is an equilibrium between hydrogen molecules in the gas phase with solvated protons and electrons.

Thus, the free energy of hydrogen adsorption on the catalysts surface at any considered potential  $(U_{SHE})$  and pH can for the example given by follows.

$$\Delta G_{*H}(U_{SHE}, pH) = G(*H) - G(*) - (1/2)G(H_2) + eU_{SHE} + k_BT pH \ln(10)$$
Equation S2

$$\Delta G_{H}(U_{SHE}, pH) = G(H) - G(L) - (1/2)G(H_2) - \Delta G_H - \Delta G_e$$
 Equation S3

where \* denoted the adsorbed site on the catalyst surface,  $\Delta G_H = -k_B T \text{ pH In}(10)$  and  $\Delta G_e = -eU_{SHE}$ , where e is the numerical charge of an electron,  $k_B$  is the Boltzmann constant and T is the temperature (in K). Furthermore, according to the Christensen scheme<sup>11,12</sup>, the energies of molecular CO<sub>2</sub>, CO, H<sub>2</sub>, and H<sub>2</sub>O are corrected by +0.3, +0.15, +0.09, and -0.03 eV, respectively, which is specific to the BEEF-vdW functional. When  $\Delta G(*OOH)$  is calculated, it is also corrected by  $\Delta E(O-O) = 0.20 \text{ eV}$ , for the same reason.

## 2. Formation Energy Calculation

**Figure S1** (a) Single metal atom site and pyridine vacancy site doped on bulk graphene ( $MN_4C_{10}$ ,  $PorN_4C_{10}$ ) and on graphene edge ( $MN_4C_A$ ,  $PorN_4C_A$ ) (C = grey, N = blue, H = white, M = pink). (b)  $\mu_N(n)$  at different temperatures (c)  $\Delta G_f$  of the  $CoN_4C_{10}$  structure at different  $\mu_N(n)$  and temperatures.

**Figure S2**  $\Delta G_f$  (in eV) as a function of  $\mu_N(n)$ : (a) MN<sub>4</sub>C<sub>10</sub> at T=1100 °C, (b) MN<sub>4</sub>C<sub>10</sub> at T=25 °C, (c) MN<sub>4</sub>C<sub>A</sub> at T=1100 °C, (d) MN<sub>4</sub>C<sub>A</sub> at T=25 °C. At n = 0,  $\mu_N(n=0)$  is that of the N<sub>2</sub> molecule at 1 bar and at considered temperature in each subplot (T=1100 °C for (a) and (c); T=25°C for (b) and (d)). Lower formation energy (brighter colour background) indicates more thermodynamically favourable to form.

## 3. Electrolyte Anion Adsorption

**Figure S3** Thermodynamic cycle for the calculation of the free adsorption energy of the electrolyte anion in 0.1 M electrolyte:  $\Delta G(*A^{n})^{13,14}$ 

The adsorption free energy of the electrolyte anion in added 0.1 M electrolyte at T = 298.25 K is calculated from:

$$\Delta G(*A^{n-}) = G(*A) - neU_{SHE} - n pH k_BT ln(10) - G(*) - G_{dilute}(A^{n-})$$
 Equation S4

 $\Delta G_{sol}(H_nA)$  is the free energy for dissolving gaseous  $H_nA$  (at 1 bar) in water to form anion and proton at the standards state where  $[A^{n-}_{(aq)}] = [H^+_{(aq)}] = 1M$ .

$$\Delta G_{sol}(H_nA) = G(A^{n-}_{(aq, 1M)}) + (n/2)G(H_2) - G(H_nA_{(gas)}) = \Delta G_f(A^{n-}_{(aq, 1M)}) - \Delta G_f(HA_{(gas)})$$
 Equation S5

where  $\Delta G_f(H_nA_{(gas)})$ ,  $\Delta G_f(A^{n-}_{(aq, 1M)})$  are formation energy of  $H_nA$  in gas phase and  $A^{n-}$  is solution phase at 1 M, respectively.  $\Delta G_{dilute}(A^{n-})$  is the free energy for concentration difference from the standard state.

$$\Delta G_{\text{dilute}}(A^{n-}) = G(A^{n-}_{\text{(dilute)}}) - G(A^{n-}_{(aq, 1M)}) = RT \times \ln((a_{H}^{+})^{n} \times a_{A}^{n-}) = RT \times \ln((a_{H}^{+})^{n} \times \gamma[A^{n-}]) \text{ Equation S6}$$

where  $a_{H^+}$ ,  $a_{A^{n^-}}$  are the activity of H<sup>+</sup> and A<sup>n-</sup>, respective.  $\gamma$  is activity coefficient of A<sup>n-</sup>, and [A<sup>n-</sup>] is the concentration of the electrolyte anion. The concentration of the added electrolyte is taken to be 0.1 M and the poisoning gas molecule is considered at 1 bar. At different pH, we assume that pH is adjusted by adding non-adsorbing acid and  $a_{H^+}$  is calculated from pH =  $-\log(a_{H^+})$ . The concentration of each electrolyte anion species in the 0.1 M solution at each pH is calculated based on its pK<sub>a</sub> value. Then G<sub>dilute</sub>(A<sup>n-</sup>) in Equation S4 can be expressed as:

$$G_{dilute}(A^{n-}) = \Delta G_{sol}(H_nA) + \Delta G_{dilute}(A^{n-}) - (n/2)G(H_2) + G(H_nA_{(gas)})$$
Equation S7

Finally, the adsorption free energy of electrolyte anion can be calculated using the thermodynamic cycle in Figure S3 and can be expressed as follows:

$$\Delta G(^*A^{n-}) = \Delta_{CHE}G(^*A) - \Delta G_{sol}(H_nA) - \Delta G_{dilute}(A^{n-})$$
 Equation S8

where  $\Delta_{CHE}G(^*A) = G(^*A) + (1/2)G(H_2) + n\Delta G_H + n\Delta G_e - G(^*) - G(H_nA_{(gas)})$  and  $\Delta G_H = -k_BT$  pH In(10) and  $\Delta G_e = -eU_{SHE}$ . All the relevant values ( $\gamma$ ,  $\Delta G_f$ , pK<sub>a</sub>) are taken from literature and listed in Table S2 and Table S3.

Table S3 Electrolyte anions:  $pK_a$ , solvation free energy, and activity coefficient for 0.1 M  $H_nA$ .

<sup>a</sup> only enthalpy data was available. The entropy is calculated using thermochemistry class in ASE package, treating a molecule as an ideal gas and the formation energy in the gas phase is calculated from the following reaction:  $H_2CO_{3(gas)} \rightarrow H_2O_{(gas)} + CO_{2(gas)}$ <sup>b</sup> The activity coefficients are estimated by using the Davies equation<sup>17</sup>.

#### 4. Dissolution Reaction

The dissolution of the single metal atom from the graphene host into the electrolyte, resulting in dissolved metal ion ( $M^{x+}$ ) and the graphene host cavity ( $N_4CH_n$ ) is considered as follows:

 $MN_4C + nH^+_{(aq)} \rightarrow M^{x+}_{(aq)} + N_4CH_n + (x-n)e^-$ 

The reaction free energy for dissolving a single metal atom from the graphene host structure at the potential  $U_{SHE}$  and pH is considered as follows<sup>18</sup>:

$$\Delta G_{diss} = G(M^{x+}_{(aq)}) + G(N_4CH_n) + (x-n)\Delta G_e - G(MN_4C) - n\Delta G_H - (1/2)G(H_2)$$
 Equation S9

 $N_4CH_n$  is the graphene host after the single metal is dissolved and can have different protonation degrees at the N dangling bonds. We considered  $N_4CH_n$  with n = 0.4 for  $N_4C_{10}H_n$  and  $N_4C_AH_n$ , where their free energy is taken from the previous study<sup>5</sup>.  $M^{x+}$  is a dissolved metal ion,  $U_{SHE}$  is the applied potential vs SHE and  $G(M^{x+}_{(aq)}) = E_M(bulk) + \Delta G_x$ , where  $E_M(bulk)$  is energy per atom of the metal in their bulk structure and  $\Delta G_x$  is the free reaction energy of the dissolution reaction of the bulk metal taken from literature and shown in Table S4. In this work, the concentration of dissolved metal ion is  $10^{-6}$  M and T = 298.15 K.

**Figure S8**  $\Delta G_R$  of the most stable surface of MN<sub>4</sub>C<sub>10</sub> in 0.1 M electrolytes under ORR-related conditions (pH=1, U=0.80 V<sub>SHE</sub>). The text insert shows the most stable adsorbate on the metal atom and its corresponding relative stability in eV. The background color corresponds to the  $\Delta G_R$  value. The brighter the background color, the more stable the MN<sub>4</sub>C<sub>10</sub> site is against the dissolution.

**Figure S9**  $\Delta G_R$  of the most stable surface of MN<sub>4</sub>C<sub>A</sub> in 0.1 M electrolytes under ORR-related conditions (pH=1, U=0.80 V<sub>SHE</sub>). The text insert shows the most stable adsorbate on the metal atom and its corresponding relative stability in eV. The background color corresponds to the  $\Delta G_R$  value. The brighter the background color, the more stable the MN<sub>4</sub>C<sub>A</sub> site is against the dissolution.

 $\Delta G_{max}(pH = 1, U = 0.80V_{SHE}) / eV$ 

**Figure S14**  $\Delta G_{max}$  along the ORR pathway at U = 0.80 V<sub>SHE</sub>, pH = 1 on the MN<sub>4</sub>C<sub>10</sub> site in 0.1 M electrolyte. In each cell, the inserted text in the 1<sup>st</sup> row shows the electrolyte anion participating in the reaction which is the most stable adsorbate on the MN<sub>4</sub>C<sub>10</sub> site at pH = 1, U = 0.80 V<sub>SHE</sub>. The inserted text in the 2<sup>nd</sup> row shows the determining states for  $\Delta G_{max}$  (number 0-6 is referred to a state in Figure S13). The inserted number in the 3<sup>rd</sup> row is  $\Delta G_{max}$  value in eV. The insert 'X' means the second adsorbate moves away from the metal site with a distance > 3.0 Å, thus we consider the metal site is inactive for the ORR. The later cases occur especially on the SbN<sub>4</sub>C<sub>10</sub> and BiN<sub>4</sub>C<sub>10</sub> site. The background color corresponds to the  $\Delta G_{max}$  value. The brighter the background color, the lower the thermodynamic barrier of the limiting step.

	ΔG <sub>max</sub> (pH = 1, U = 0.80V <sub>SHE</sub> ) / eV

**Figure S16** U<sub>L</sub> for ORR on MN<sub>4</sub>C<sub>10</sub> in 0.1 M electrolyte at pH = 1. In each cell, the inserted text in the 1<sup>st</sup> row shows the electrolyte anion participating in the reaction which is the most stable adsorbate on the MN<sub>4</sub>C<sub>10</sub> site at pH=1, U=0.80 V<sub>SHE</sub>. The inserted text in the 2<sup>nd</sup> row shows the potential determining states for U<sub>L</sub> (the number 0-6 is referred a state in Figure S13). The inserted number in the 3<sup>rd</sup> row is U<sub>L</sub> value in V<sub>SHE</sub>. The insert 'X' means the neutral gas molecules are thermodynamic stable on both sides of the metal atom or the second adsorbate moves away from the metal site with the distance > 3.0 Å, thus we considered the metal site is inactive for the ORR. The later cases occur especially on the SbN<sub>4</sub>C<sub>10</sub> and BiN<sub>4</sub>C<sub>10</sub> sites, The background color corresponds to the U<sub>L</sub> value. The brighter the background color, the higher the limiting potential.

	U <sub>L</sub> (pH = 1) / V <sub>SHE</sub>

**Figure S19**  $\Delta G_{max}$  along the CO<sub>2</sub>RR to CO pathway at U=-0.80 V<sub>SHE</sub>, pH=7 on the MN<sub>4</sub>C<sub>10</sub> site in 0.1 M electrolyte. In each cell, the inserted text in the 1<sup>st</sup> row shows the electrolyte anion participating in the reaction which is the most stable adsorbate on the MN<sub>4</sub>C<sub>10</sub> site at pH=7, U=-0.80 V<sub>SHE</sub>. The inserted text in the 2<sup>nd</sup> row shows the determining states for  $\Delta G_{max}$  (number 0-5 is referred to state in Figure S18). The inserted number in the 3<sup>rd</sup> row is  $\Delta G_{max}$  value in eV. The insert 'X' means the second adsorbate moves away from the metal site with the distance > 3.0 Å, thus we considered the metal site is inactive for the ORR. The later cases occur especially on the SbN<sub>4</sub>C<sub>10</sub> and BiN<sub>4</sub>C<sub>10</sub> site.

Keywords: Density Functional Theory Polybenzimidazole Solvation Degradation Electrolysis

# ABSTRACT

Membrane-based polybenzimidazole (mPBI) emerges as an exciting electrolyte membrane for alkaline fuel cells and water electrolyzers due to its useful ion conductivity range after being doped with aqueous KOH. However, the polymer degradation at highly alkaline concentrations limits its practical use. Herein, the density functional theory (DFT) calculations are used to study the degradation mechanism of mPBI molecule in an alkaline solution. The pristine mPBI molecule deprotonates to form an ionized molecule in an alkaline solution, with the ionized form being predominant at high pH. The nucleophilic hydroxide at the C2 position initiates the degradation, whereas the formation of the fully deprotonated ionic form suppresses the hydroxide ion attack. The degradation reaction then proceeds by ring-opening and chain scission reactions. The ring-opening reaction is preferred with an ancillary hydroxide ion or water molecule during the proton transfer process. The rate-determining state is the transition state involving the amide cleavage during the chain scission. Combining implicit-explicit solvation models is found to stabilize intermediate and transition states, lowering the energy barrier. With one or two explicit water molecules, the free energy barrier agrees well with experimental polymer lifetimes. An increase in KOH concentration increases the degradation rate, agreeing with experiments.

## 1. Introduction

Alkaline anion exchange membranes have gained increased attention due to their potential to integrate with a wide range of electrochemical energy storage and conversion technologies. The advantage of an alkaline condition is a broad selection of electrocatalysts based on abundant and cheap materials, in contrast to noble metal-based electrocatalysts required in acidic conditions [1].

In the cell design, the electrodes are separated by an electrolyte membrane where hydroxide ions are transported. Cations, such as ammonium [2,3] and imidazolium cation [4–6], are commonly attached to the polymer backbone to allow hydroxide ion-conduction. However, the hydroxide ion can react irreversibly with the polymer backbone and cations, causing ionic conductivity degradation over time [7–9]. Therefore, chemical stability remains a significant challenge for anion conducting membranes. An alternative is to use an ion-solvating membrane where an aqueous electrolyte is dissolved in a polymer matrix [10] so that it utilizes the uptake of an aqueous alkaline to achieve ionic conductivity and does no need for cation moieties [11,12].

The poly(2,2'-(m-phenylene)-5,5'-bibenzimidazole) (mPBI) equilibrated in aqueous potassium hydroxide (KOH) can form an ion-solvating polymer system composed of KOH and water dissolved in the polymer matrix; the ternary mPBI/KOH/H<sub>2</sub>O electrolyte system [13]. This alkaline doped mPBI system has been reported to have high ionic conductivity and excellent chemical stability in alkaline conditions. It has been tested as an anion exchange membrane in direct alkaline alcohol fuel cells [14,15], al-kaline fuel cells [16–18], water electrolyzers [10,19], and vanadium redox flow batteries [20] with remarkable performance.

The ternary mPBI/KOH/H<sub>2</sub>O electrolyte composite is strongly dependent on the KOH concentration, which significantly determines the ionic conductivity of the membrane. The system exhibits high ionic conductivity and chemical stability at low KOH concentration (5–10 wt% KOH at 88 °C). The ionic conductivity can be increased by two orders of magnitude and reach a peak at 20–25 wt% KOH [21]. However, increasing KOH concentration enhances the degradation of the polymer, as evidenced by the gradually reduced molecular weight, mechanical strength, ionic conductivity, and structural change [10,21]. Thus, the actual use is limited.

Experimental studies have suggested that the polybenzimidazole-based membrane may degrade in an alkaline environment by a hydrolysis reaction [10,21,22]. The postulated

Fig. 1. Schematic illustration: (0) acid-base equilibrium of mPBI and (1)-(3) postulated degradation pathway of mPBI in aqueous KOH.

degradation pathway is shown in Fig. 1, where (1) the nucleophilic addition of hydroxide ions at the benzimidazole ring initiates the degradation, followed by (2) the ring-opening and (3) chain scissors [11,23]. This postulated reaction path is similar to the degradation of imidazolium and benzendazolium cations [8,9,24,25], which have also been suggested as a promising candidate for anion exchange membranes. However, the degradation mechanism of the mPBI membrane in alkaline solution has not been presented in detail. Additionally, the mPBI has been reported to deprotonate when submerged in aqueous KOH [13]. The equilibrium between the pristine and deprotonated form is shown as reaction (0a) and (0b) in Fig. 1. Unlike the imidazole cation, the negative charge may be delocalized over the benzimidazole ring of the deprotonated mPBI. Thus, the mPBI and hydroxide ion interaction may differ from that occurs with the imidazolium cations, resulting in different degradation mechanisms and degradation rates. Also, it is unclear which form of mPBI is most vulnerable and undergoes degradation in an alkaline environment as the equilibrium between the pristine and deprotonated forms strongly depends on the KOH concentration [13,26].

In this work, we use first-principles modeling with density functional theory (DFT) to evaluate the predominant species and the degradation mechanism of mPBI in an alkaline solution. The postulated degradation pathway of the mPBI, as shown in Fig. 1, is investigated where the first step of the degradation involves the nucleophilic addition reaction, followed by the ring-opening and chain scission. A low-barrier degradation pathway for mPBI molecules in an alkaline solution is catalyzed by hydroxide ions or water molecules. We study the role of explicit water molecules on the free energy barrier in each reaction step and investigate the effect of hydroxide ion concentration on the degradation rate. Comparing experiment and theory is achieved by computing the theoretical free energy barrier against those estimated from the experimental results. Our investigation provides a clearer understating of how the mPBI-based membranes degrade in an alkaline environment.

# 2. Computational details

All calculations are performed using B3LYP [27] functional and 6-311++G(d, p) basis sets as implement in Q-Chem 5.2 [28] for both optimized geometries and calculated energies. The threshold for the maximum gradient and the self-consistent field (SCF) energy change between consecutive optimization cycles is  $3.0 \times 10^{-3}$  Hartree/Bohr and  $1 \times 10^{-8}$  Hartree, respectively. The geometry optimizations for intermediate and transition states are carried out in the gas phase. A freezing string method (FSM) [29,30] is used to approximate the reaction path connecting each intermediate state pair. The highest energy point on the reaction path is taken as the first approximation for a transition state which is then refined to the actual transition state by using the Baker's partitioned rational-

function optimization (P-RFO) algorithm [31] implemented in Qchem 5.2. Each transition state is verified to connect the designated reactant and product by performing an intrinsic reaction coordinate (IRC) calculation [32]. The vibrational frequencies are calculated to confirm the local minima on the potential energy surface with no imaginary frequencies for all intermediates and one single imaginary frequencies for all transition states. Single point energies are computed with the conductor-like polarization continuum model (C-PCM) [33–35] based on the optimized gas-phase geometries. A dielectric constant of 78.39 corresponds to the bulk water used to include the surrounding water medium.

Free reaction energy and free energy barrier are calculated at T = 88 °C and 1 atm, which is the same as the experimental condition [21]. For the reaction between A and B, the reaction goes through a transition state TS and results in the product C.

$$A + B \rightarrow TS \rightarrow C \tag{1}$$

The free energy reaction ( $\Delta G_{(sol)}$ ) and the free energy barrier ( $\Delta G^{TS}_{(sol)}$ ) in the solution are defined as follows.

$$\Delta G_{(sol)} = G(C_{(sol)}) - G(A_{(sol)}) - G(B_{(sol)}) = \Delta E_{(sol)} + \Delta G_{(gas)}^{corr}$$
(2)

$$\Delta G_{(sol)}^{TS} = G(TS_{(sol)}) - G(A_{(sol)}) - G(B_{(sol)}) = \Delta E_{(sol)}^{TS} + \Delta G_{(gas)}^{TScorr}$$
(3)

where

$$\Delta E_{(\text{sol})} = E(C_{(\text{sol})}) - E(A_{(\text{sol})}) - E(B_{(\text{sol})})$$
(4)

$$\Delta E_{(sol)}^{TS} = E(TS_{(sol)}) - E(A_{(sol)}) - E(B_{(sol)})$$
(5)

 $\Delta E_{(sol)}$  and  $\Delta E^{TS}_{(sol)}$  are the reaction energy and the energy barrier, respectively, computed as the energy difference between the species in the gas phase geometry with the presence of the continuum solvent.  $\Delta G^{corr}_{(gas)}$  (= $\Delta H_{(gas)}$  -  $T\Delta S_{(gas)}$ ) and  $\Delta G^{TScorr}_{(gas)}$  are thermal corrections, including zero-point vibration energy (ZPVE) and vibrational, translational, and rotational entropies and enthalpies computed from the vibration analysis assuming vibrational modes are non-interacting quantum mechanical harmonic oscillators.

An estimate of the reaction rate constant is obtained from transition state theory.

$$k = \frac{k_{\rm B}T}{h} e^{\frac{-\Delta G^{\rm TS}}{RT}} \tag{6}$$

k is the rate constant for a given reaction,  $k_B$  is Boltzmann's constant, h is Planck's constant,  $\Delta G^{TS}$  is the free energy difference between the transition state and the reactants, R is the gas constant, and T is the temperature.

As a hydrogen atom can be described as a wave packet, it can penetrate regions forbidden for classical particles. The inclusion of quantum mechanical tunnelling effects in the calculations has been reported to increases the proton transfer rate [36]. Therefore, in our calculations, a proton tunnelling effect is included in the rate constant involved in the proton transfer reaction. The reaction rate constant, including the tunnelling effect, can be written as follows.

$$k = \kappa \frac{k_{\rm B}T}{h} e^{\frac{-\Delta c^{\rm TS}}{RT}}$$
<sup>(7)</sup>

 $\kappa$  is tunnelling correction used to account for the tunnelling effect along the reaction coordinate and obtained as the ratio between the quantum mechanical and the classical rate constant. If  $\kappa = 1$ , there is no tunnelling, and if  $\kappa > 1$ , the tunnelling effect contributes to the rate constant. The tunnelling correction ( $\kappa$ ) [37] is defined as follows.

$$\kappa = e^{\left(\frac{\Delta E^{TS}}{k_{B}T}\right)} \int_{0}^{\infty} \frac{1}{k_{B}T} e^{\left(\frac{-E}{k_{B}T}\right)} P(E) dE$$
(8)

P(E) is a tunnelling probability of a particle with mass m and energy E to penetrate the barrier with height  $\Delta E^{TS}$ . In this work, P(E) is approximated by using WKB approximation [38] and can be written as follows.

$$P(E) = e^{-\frac{\pi^2 w}{h} \sqrt{2m \left(\Delta E^{TS} - E\right)}}; 0 < E < \Delta E^{TS}$$
(9)

$$P(E) = 1; E > \Delta E^{TS}$$
<sup>(10)</sup>

w is barrier width,  $\Delta E^{TS} - E$  is the energy deficiency of the proton with respect to the top of the barrier. The barrier width (w) is estimated from the reaction path obtained from the IRC calculations.

#### 3. Results and discussion

#### 3.1. Deprotonation reaction of mPBI in alkaline solution

The dissociation of an acidic proton of the mPBI-based molecule in KOH solution has been observed in experiments, and the ionized form has been found to dominate at concentrations higher than 15 wt% KOH [13]. The ionized form leads to the ternary mPBI/KOH/H<sub>2</sub>O electrolyte system, which is responsible for a high ionic conductivity of the membrane. Further increasing the KOH concentration has been found to cause membrane degradation [13]; thus, the degradation has been suggested to start from the ionized form of the mPBI [11,22].

To identify the predominant form of the mPBI in the alkaline solution where the degradation occurs, we first consider an acid dissociation constant ( $pK_a$ ) of the mPBI molecule. The stepwise dissociation constant is defined for losing a single proton and is illustrated as reaction (0a) and (0b) in Fig. 1. The dissociation constant for the first proton is denoted as  $pK_{a1}$ , and the successive proton is  $pK_{a2}$ . Thus, the acid deprotonation reaction of the mPBI molecule can be written as follows.

$$mPBI(0) \rightleftharpoons mPBI(1) + H^+ \rightleftharpoons mPBI(2) + 2H^+$$
(11)

The number in parenthesis indicates the total negative charge on the molecule; thus, mPBI(0) is the pristine molecule, mPBI(1) is the first ionized form after losing one proton, and mPBI(2) is the second ionized form after losing two protons. The pK<sub>a</sub> can be calculated from the Gibbs free energy of the deprotonation reaction.

$$pK_{a} = \frac{\Delta G_{dep(sol)}}{2.303 RT}$$
(12)

 $\Delta G_{dep(sol)}$  is the Gibbs free energy of the deprotonation reaction in the solution obtained from a thermodynamic cycle as shown in Figure S1.

**Table 1** Calculated  $\Delta G_{dep}$  and pK<sub>a</sub> value for mPBI molecule at  $T = 88 \ ^{\circ}C$ .

	$\Delta G_{dep}$ (eV)	pka
mPBI(0) mPBI(1)	0.89 0.92	$\begin{array}{l} pK_{a1}=12.46\\ pK_{a2}=12.85 \end{array}$

Table 1 shows the calculated pK<sub>a</sub> for the mPBI(0) and mPBI(1), implying that the mPBI(2) is the major species at high pH. However, there is a slight difference between successive pK<sub>a</sub> values, so there can be an overlap between the species' pH range and existence. Figure S2 shows the calculated percentage of formation for each mPBI species as a function of pH at T = 88 °C. The mPBI(1) starts to form at pH ~ 10. The mPBI(2) begins to form at pH ~ 12 and becomes the predominant species at pH > 13 (about 5 wt% KOH [39,40]). Still, all three mPBI species can be found in the solution at pH between 12–13. At pH = 13, approximately 10% of mPBI(0) and 40% of mPBI(1) are in the solution and at pH = 14, the solution consists of approximately 10% of mPBI(1) and 90% of mPBI(2).

The concentration of the ionized form (mPBI(1) + mPBI(2)) increases as pH increases. Therefore, by increasing KOH bulk concentration, the ion conductivity can be expected to increase. In the experimental study by Kraglund et al., the ionic conductivity of the mPBI based-membrane at T = 80 °C increases by two orders of magnitude from 0.7 to 72 mS•cm<sup>-1</sup> when the bulk solution concentration is increased from 5 to 15 wt% KOH with limited structural changes and the ionic conductivity can be peak at KOH concentration around 20–25 wt% KOH while the membrane shows signs of structural change [10].

The conversion between the pH and KOH bulk concentration in the above approximation might not be directly applicable to the ternary mPBI/KOH/H<sub>2</sub>O system. Hou et al. suggest that protons from the mPBI molecule can combine with hydroxide ions in the environment and form a more stable water molecule [41]. At the same time, potassium ions could interact with the negatively charged nitrogen or carbon atom, subsequently integrating with the mPBI molecule [26,42]. Therefore, the internal KOH concentration of the ternary mPBI/KOH/H<sub>2</sub>O system can slightly be different from the bulk solution [21].

# 4. Nucleophilic addition reaction

The degradation of mPBI based membranes in alkaline solutions has been suggested via hydrolysis reaction [23]. The first reaction step involves the nucleophilic addition at the carbon atom of the five-membered ring [11,21]. A carbon atom at the C2 position [11,22,24] (Fig. 2a) has been suggested as the susceptible point of the mPBI to hydroxide ion attack.

All three forms of the mPBI molecule can be present in the alkaline solution at a high pH range (pH  $\sim$  12-14) where the degradation has been reported; thus, we first consider the free reaction energy for the first reaction step ( $\Delta G_1$ ) for all three mPBI forms as follows.

$$\Delta G_{1} = G(OHmPBI(n)_{(sol)}) - G(mPBI(n)_{(sol)}) - G(OH_{(sol)}^{-})$$
(13)

OHmPBI denotes the mPBI molecule with a hydroxide ion bound to one of the carbon atoms of the five-membered ring.

There are three possible distinct carbon atoms, marked as C2, C4, and C5 in Fig. 2b, where hydroxide ions can attack the mPBI(0) molecule. There are five possible positions for the mPBI(1) molecule at C2, C4, C5, C2\*, and C4\*, where the \* denotes atoms located at the ionized part of the mPBI molecule. For the mPBI(2) molecule, hydroxide attack on the carbon atom at the C2\* or C5\*

Table 2				
$\Delta G_1$ for hydroxide ion attack at different carbon atoms of the five-				
membered ring for each species of mPBI at $T = 88$ °C.				

molecule	attack position	Atomic partial charge (electron)	$\Delta G_1 (eV)$
mPBI(0)	C2	0.20	1.31
	C4	0.06	1.99
	C5	0.06	2.26
mPBI(1)	C2*	0.17	2.43
	C4*	0.04	2.88
	C2	0.20	1.38
	C4	0.06	2.02
	C5	0.06	2.25
mPBI(2)	C2*	0.17	2.66
	C4*	0.05	2.99

position is possible, while the carbon atoms at C4 $^{*}$  and C5 $^{*}$  are symmetry equivalent.

Table 2 presents calculated  $\Delta G_1$  at different carbon positions. The hydroxide ion attack at the C2 position in either the mPBI(0) or mPBI(1) is more accessible than in other positions. Since carbon at the C2 (or C2<sup>\*</sup>) position is between two nitrogen atoms, which has higher electronegativity, the atomic charges obtained from the natural bond orbital analysis (NBO) analysis [43] on these carbon atoms are more positive than the others (Fig. 2). The more positive charge can make the attack of the hydroxide anions more favorable. On the contrary, the ionized part of the molecule is less vulnerable to hydroxide ions. Considering the mPBI(1), the hydroxide ion attacks at the C2\* position are more difficult than those at the C2 position. After deprotonation, the lowest unoccupied molecular orbital (LUMO) energy of the ionized molecule increases, and the atomic charge of atoms near the ionized position becomes more negative. Fig. 2(d-f) shows LUMO isosurfaces for mPBI molecules in different protonation states. The LUMO isosurface has weight on carbon atoms at the C2 position of the mPBI(0). For the mPBI(1), the LUMO isosurface has mainly weight near the C2 position and not on the ionized part near the C2\* position. However, the LUMO+1 isosurface with higher energy localizes on the carbon atom at the C2\* position. For the mPBI(2), the LUMO energy is highest among considered species, and the attack by hydroxide ion is also most difficult. This suggests that the susceptibility to hydroxide anion attack of the mPBI based-molecule can be related to the LUMO energy and the LUMO isosurface [4,44], and the formation of the deprotonated mPBI form can suppress hydroxide ion attack.

For the nucleophilic addition reaction at the C2 position, the forward free energy barrier is 1.42 eV for the mPBI(1) and 1.35 eV for the mPBI(0) but only 0.04 eV for both mPBI(1) and mPBI(0) in the reverse direction. Thus, the first step is highly reversible. The free energy barrier for the nucleophilic addition reaction at the other positions of the mPBI(0) and mPBI(1) as well as at the mPBI(2) molecule is 2.0 eV or greater, making the degradation from the other parts and the mPBI(2) unlikely. As there are more percentages of mPBI(1) in solution than mPBI(0) at high pH range, we think that the overall degradation is significantly due to the degradation from the other mPBI(1) species, and we investigate the further degradation reaction from the mPBI(1).

# 5. Ring-opening reaction

A ring-opening reaction follows the hydroxide ion attack. The possible mechanism for the mPBI(1) degradation is that a hydroxyl proton at the C2 position is transferred to the nitrogen atom at the N1 or N3 position, followed by a C-N bond breaking.

# 5.1. Hydroxyl proton transferred to the nitrogen atom at the N3 position

We first consider that the hydroxyl proton is transferred to the nitrogen atom at the N3 position, followed by a C2-N3 bond breaking, as shown in Fig. 3.

First, we consider that this ring-opening reaction occurs in a single step, as shown in reaction path 1.1, Fig. 3. The free energy barrier for this single-step reaction is 0.83 eV, and a transition state TS2-1.1 locates at 2.22 eV in the quantitative reaction profile. The hydrogen tunnelling effect in this single-step reaction is negligible as we find the calculated tunnelling correction ( $\kappa$ ) of 1.00 (Table S1).

Alternatively, as the degradation occurs in an alkaline solution, water molecules and hydroxide ions are available in the environment, and both can participate and assist the reaction [24,25].

For reaction path 1.2 in Fig. 3, one hydroxide ion is added into the simulation explicitly. The additional hydroxide ion spon-

**Fig. 3.** (a) Quantitative reaction profile for the ring-opening reaction of mPBI(1) via reaction path 1 at T = 88 °C. The reference zero energy state for energies reported is A+OH<sup>-,</sup> and the relative energies of the intermediates and transition state are in eV. The insets show optimized structures for intermediate and transition states involved in the reaction path 1.1. The optimized structures for intermediate and transition states involved: (b) reaction path 1.2 and (c) 1.3. Colors code for atoms: H-white, C-grey, N-blue, O-red.

taneously reacts with the hydroxyl proton at the C2 position, resulting in intermediate state BX1-1.2, where one water molecule is formed. A transition state between the intermediate B and BX1-1.2 cannot be found. However, the intermediate BX1-1.2 state is 0.31 eV, less stable than the intermediate state B. The resulting water molecule further participates in the C2-N3 bond breaking, giving intermediate state C and one hydroxide ion. Thus, the additional hydroxide ion acts as a catalyst in this reaction path. For the two successive reactions, free energy barriers  $\Delta G^{TSX1-1.2}$  and  $\Delta G^{TSX2-1.2}$  are 0.26 and 0.27 eV, respectively. The last step for the  $BX2-1.2 \rightarrow C+OH^{-}$  step involves the proton transfer from the water molecule to the N3 nitrogen atom, where we find the tunnelling correction ( $\kappa$ ) of 1.07. Thus, the proton tunnelling contributes to the rate constant increased from 1.33  $\times$  10<sup>9</sup> s<sup>-1</sup> to  $1.43 \times 10^9 \text{ s}^{-1}$  when including the tunnelling correction. The highest transition state along this reaction path is TSX1-1.2, locating at 1.96 eV in the quantitative reaction profile. Although the TSX1-1.2 is lower than the TS2-1.1 in the quantitative reaction profile, the energy relative to the initial reactant is still high.

For reaction path 1.3 in Fig. 3, we consider the hydroxyl proton transfer through one explicit water molecule. The reaction first goes through a transition state TSY1-1.3, where the C2-N3 bond is broken. The transition vector of a single imaginary frequency of the TSY1-1.3 state relates to the C-N bond breaking (Fig. S3a). The free energy barrier for this step is 1.18 eV which includes the free formation energy for hydrogen-bond structure between the intermediate structure B and one explicit water of 0.25 eV. After that, the hydroxyl proton at the C2 position is transferred to the nitrogen atom at the N3 position via the additional water molecule, giving the intermediate C and one water molecule at the end of the process. The free energy barrier for the hydroxyl proton transfer is only 0.02 eV, and the tunnelling correction ( $\kappa$ ) for the BY1-1.3  $\rightarrow$  C+H<sub>2</sub>O step is 1.73, implying that the proton tunnelling can significantly contribute to the rate constant. The rate constant before applying the tunnelling correction is 3.67  $\times$  10<sup>12</sup> s<sup>-1</sup>, and it is increased to 6.36  $\times$  10<sup>12</sup> s<sup>-1</sup> after applying the tunnelling correction. However, the highest transition state in the reaction path 1.3, which is the TSY1-1.3 locating at 2.56 eV in the quantitative reaction profile, is higher than the previously considered reaction path.

# 5.2. Hydroxyl proton transferred to the nitrogen atom at the N1 position

An alternative path for the ring-opening reaction is shown in Fig. 4. The hydroxyl proton is transferred to a nitrogen atom at the N1 position. Then either the C2-N1 or C2-N3 bond is broken.

We first consider the intramolecular proton transfer process where the hydroxyl proton at the C2 position is directly transferred to the nitrogen atom at the N1 position, as shown in reaction path 2.1, Fig. 4. The optimized structures related to this reaction path are shown in Fig. 5a. A relatively high free energy barrier (0.91 eV) is found for this intramolecular proton transfer process, and a TS2-2.1 state locates at 2.29 eV in the quantitative reaction profile. The rate constant for the proton transfer along this reaction path (for  $B \rightarrow C$  step) is 1.43 s<sup>-1</sup>, and the inclusion of the tunnelling effect gives a rate constant of 1.48 s<sup>-1</sup> ( $\kappa = 1.04$ ).

We also investigate whether the hydroxyl proton is transferred to the nitrogen atom at the N1 position via a nearby hydroxide ion or water molecule.

The quantitative reaction profile for the hydroxyl proton transfer through the water molecule is shown in reaction path 2.2, Fig. 4. A single imaginary frequency transition vector for a tran-

**Fig. 4.** Quantitative reaction profile for the ring-opening reaction of mPBI(1) via reaction path 2 at T = 88 °C. The reference zero energy state for energies reported is A+OH<sup>-</sup> and the relative energies of the intermediates and transition state are in eV. The insets show optimized structures for the intermediate and transition states involved in the reaction path. Colors code for atoms: H-white, C-grey, N-blue, O-red

Fig. 5. Optimized structures for the intermediate and transition states related to the hydroxyl proton transfer for mPBI(1) during the ring-opening reaction path: (a) 2.1 (b) 2.2 and (c) 2.3. Colors code for atoms: H-white, C-grey, N-blue, O-red

sition state TS2-2.1 corresponds to a proton transfer via a water molecule (Fig. S4b). First, the water molecule donates one of its protons to the nitrogen atom at the N1 position, and then one hydroxide ion is obtained. After that, the resulting hydroxide ion reacts with the hydroxyl proton at the C2 position, giving intermediate structure C and a water molecule at the end of the process. The optimized structures along this reaction path are shown in Fig. 5b. The free energy barrier for the hydroxyl proton transfer is 0.37 eV, including the free formation energy for hydrogenbond structure between intermediate structure B and one explicit water of 0.25 eV. Therefore, the TS2-2.1 state is 0.54 eV lower than TS2-2.1 in the quantitative reaction profile, and the rate constant (for  $B+H_2O\rightarrow C+H_2O$  step) without the tunnelling correction  $(k = 4.42 \times 10^7 \text{ s}^{-1})$  is already higher than that of the intermolecular proton transfer. Furthermore, in this reaction path, the tunnelling correction ( $\kappa$ ) is 1.26, resulting in a higher rate constant for the hydroxyl proton transfer of 5.55  $\times$  10<sup>7</sup> s<sup>-1</sup> when the proton tunnelling effect is included.

For the hydroxyl proton transfer through a hydroxide ion, the qualitative reaction profile is shown in reaction path 2.3, Fig. 4.

First, the additional hydroxide ion reacts with the hydroxyl proton at the C2 position, produces one water molecule. This water molecule later donates one of its protons to the nitrogen atom at the N1 position (Fig. 5c). Then, the intermediate state *C* and a hydroxide ion are obtained. The transition vector for a single imaginary frequency of a transition state TS2-2.3 mainly corresponds to a proton transfer from the produced water molecule to the nitrogen atom at the N1 position (Fig. S4c). The free energy barrier for this hydroxyl proton transfer is 0.25 eV (0.66 eV lower than the TS2-2.1 and only 0.13 eV lower than the TS2-2.2 in the qualitative reaction profile). Like the previous water assists the process, the rate constant (for B+OH<sup>-</sup>→C+OH<sup>-</sup> step) without tunnelling correction ( $k = 2.68 \times 10^9 \text{ s}^{-1}$ ) is higher than the intermolecular proton transfer. Also, the tunnelling correction ( $\kappa$ ) of 1.33 along this reaction path increases the rate constant to 3.57  $\times 10^9 \text{ s}^{-1}$ .

The results show that the water molecule and hydroxide ion play an important role in reducing the energy barrier for the hydroxyl proton transfer during the ring-opening reaction. Also, along a water molecule or hydroxide ion-assisted pathway, the proton can tunnel through the energy barrier. Thus, the tunnelling in-

#### T. Patniboon and H.A. Hansen

creases the rate constant, improving the ability of water or hydroxide to facilitate the process (Table S2).

After forming the intermediate state C, the next step involves breaking the C-N bond. Note that for the intermediate structure C, the C2-N1 bond is symmetric with the C2-N3 bond. The cleavage of the C-N bond creates an unstable N dangling bond in the intermediate structure D. This unstable N dangling bond can be stabilized by receiving a proton from an available water molecule in its environment. Thus, the next ring-opening step involves the intermediate C and water molecules. This process results in an intermediate structure E and a hydroxide ion. The free energy barrier for breaking the C-N bond is 0.68 eV, including the free formation energy for hydrogen-bond structure between intermediate structure C and one explicit water of 0.23 eV. The free energy barrier for the proton transfer from the water molecule to the unstable N dangling bond is only 0.02 eV, with the tunnelling correction ( $\kappa$ ) of 1.33. Thus, the proton tunnelling effect also contributes to the reaction rate constant in this step, increasing the rate constant from 3.50  $\times$  10^{12} s^{-1} to 4.65  $\times$  10^{12} s^{-1}

For reaction path 2.2 and 2.3 in Fig. 4, the highest transition state is TS3 which locates at 1.78 eV in the quantitative reaction profile, and it relates to the C-N bond-breaking. The highest transition state along this reaction path is lower than reaction path 1 in Fig. 3. Thus, the ring-opening reaction of the mPBI(1) molecules possibly occurs through reaction path 2.2 or 2.3 with the assistance of either a water molecule or hydroxide ion. However, the additional hydroxide ion is unstable for the latter case as it is likely to spontaneously react with the hydroxyl proton at the C2 position. It is also possible that if we added an explicit potassium ion, this additional hydroxide ion could spontaneously combine with the potassium ion instead of catalyzing the reaction. Still, as there are available water molecules in the environment, the reaction is expected to occur with the assistance of a water molecule.

We also investigate the ring-opening reaction for the mPBI(0) as shown in Figure S6a and S6b. The results conclude that the ringopening reaction is likely to occur via reaction path 2.2 or 2.3. In reaction path 2 for the mPBI(0), the TS2-2.2 and TS2-2.3 are 0.52 and 0.67 eV lower than the TS2-2.1 in the quantitative reaction profile. Also, the highest transition state along the ring-opening reaction (reaction path 2.2 or 2.3) for the mPBI(0) is the TS3.

#### 6. Chain scission reaction

The C2-N1 bond in the intermediate E is the amide linkage (Fig. 6a) which can be further hydrolyzed, leading to complete chain scission. As the degradation occurs in an alkaline solution, we consider the chain scission involving hydroxide ions. In Fig. 6b, the chain scission begins with the nucleophilic hydroxide ion attack at the C2 carbon atom in the intermediate structure E as it has the most positive charge. The nucleophilic addition goes through a transition state TS5 with the free energy barrier of 1.03 eV in the forward direction and only 0.13 eV in the reverse direction. Thus, this step is highly reversible. The next step involves the amide cleavage, as shown in reaction path 3.1, Fig. 6b. The reaction goes through a transition state TS6-3.1 with a free energy barrier of 0.40 eV. The transition vector corresponded to a single imaginary frequency for the TS6-3.1 state mainly relates to the C2-N1 bond breaking (Fig. S5a). After the C2-N1 bond is broken, the hydroxyl proton at the C2 position transferred to the nitrogen atom at the N1 position occurs without a transition state, so no tunnelling effect is considered along this reaction step. The final product G is 1.25 eV, more stable than the intermediate E+OH<sup>-</sup> state.

The chain scission reaction considered here is the same as the alkaline hydrolysis of an amide [45,46]. A previous study by Lopez et al. has suggested that the explicit water molecule lowers the energy barrier by either acting as a proton bridge between hy-

droxyl and nitrogen or stabilizing the molecule via hydrogen bonding [45]. Cheshmedzhieva et al. conducted a theoretical study on alkaline hydrolysis of three different secondary amides. They found that the stabilization, whether via proton bridging or hydrogen bonds, depending on the molecular structure containing the amide bond [46].

We consider the effect of explicit water on the amide cleavage energy profile as shown in reaction path 3.2, Fig. 6b. One explicit water molecule is placed near the amide linkage in the intermediate E structure. The amide cleavage goes through a transition state TS6-3.2. The transition vector corresponded to a single imaginary frequency for TS6-3.2 still mainly relates to the C2-N1 bond breaking (Fig. S5b) similar to the previous TS6-3.1 state. After the C2-N1 bond is broken, the hydroxyl proton at the C2 position is also spontaneously transferred to the N1 nitrogen atom. The hydroxyl proton transfer can occur either with or without passing the proton through the explicit water molecule; still, they are a barrierless and exothermic process. The free energy barrier for the C2-N1 bond cleavage along the reaction path 3.2 is 0.70 eV, including the free formation energy for hydrogen-bond structure between intermediate structure F and one explicit water molecule of 0.31 eV. The free energy barrier is lowered by  $\sim$  0.01 eV with the presence of one explicit water molecule. Thus the explicit water molecule has a minor effect on the amid cleavage energy barrier for the mPBI(1).

Furthermore, we consider the amid cleavage with an additional hydroxide ion as shown in reaction path 3.3, Fig. 6b. We find that the additional hydroxide ion near the amide linkage in the intermediate E spontaneously reacts with a hydroxyl proton at the C2 position, forming a water molecule. The hydroxyl proton abstraction leads to the cleavage of the C2-N1 bond, and the H4 hydrogen atom is transferred back and forth between the N3 nitrogen atom and the O2 oxygen atom along this process (Fig. 6d). The reaction undergoes a transition state TS6-3.3, locating at 1.88 eV in the quantitative reaction profile. The tunnelling correction ( $\kappa$ ) along this reaction step is 1.02, resulting in the rate constant of  $1.50 \times 10^{-1} \ s^{-1}.$  The breaking of the C2-N1 bond creates an unstable N dangling bond at the N1 position in intermediate structure FX2-3.3. This unstable N dangling bond can be stabilized by receiving a proton from an available water molecule in its environment. The free energy barrier of the last step is found to be only 0.01 eV with the tunnelling correction of 1.51, implying a significant proton tunnelling facilitating this step. The final products, structure G, and one hydroxide ion are obtained at the end of the process. However, along reaction path 3.3 in Fig. 6b, the free energy barrier for the amide breaking is higher than the previous considerations. Therefore, the rate constant for the amide cleavage (for  $F \rightarrow G$  step) along the reaction path 3.3, even including the proton tunnelling effect, is much lower than the others (Table S3).

The chain scission reaction of the mPBI(0) is shown in Fig. S6c. Like the amide cleavage of the mPBI(1), the transition vector corresponded to a single imaginary frequency for TS6-3.1 and TS6-3.2 state of the mPBI(0) mainly relates to the C2-N1 bond breaking (Fig. S10). Also, the hydroxyl proton transfer from the C2 carbon atom to the N1 nitrogen atom spontaneously occurs after the C-N bond breaking. The free energy barrier for the amide cleavage without explicit water molecules is 0.48 eV. In comparison, the free energy barrier for the amide cleavage with one explicit water molecule is 0.86 eV, including the free formation energy for hydrogen-bond structure between intermediate structure F and explicit water of 0.41 eV. Thus, the free energies barrier is lower  $\sim$  0.03 eV with the presence of one explicit water molecule.

The final product from the chain scion reaction contains free amino groups and a carbonyl group, agreeing with the experimental results by Aili et al., where the mPBI membrane structures soaked in KOH solution at T = 88 °C were studied with FTIR

**Fig. 6.** (a) Optimized structure and NBO atomic charges on intermediate structure E. (b) Quantitative reaction profile for the chain scission reaction of mPBI(1) at T = 88 °C. The reference zero energy state for energies reported is E+OH<sup>-,</sup> and the relative energies of the intermediates and transition states are in eV. The insets show optimized structures for the intermediate and transition states involved in the reaction path 3.1. (c-d) Optimized structures for the intermediate and transition state related to the

and <sup>1</sup>H NMR spectra. The mPBI structures soaked in 15–50 wt% KOH for 200 days were reported to the structure changes assigned to the free amino group formation [21]. Kraglund et al. also reported forming free amino groups and carbonyl moieties in the mPBI membrane structure after operating in a water electrolyzer at 2.0 V in 30 wt% KOH, 80°C for 48h [10].

G + OH

C2-N1 bond cleavage along reaction path: (c) 3.2 (d) 3.3. Colors code for atoms: H-white, C-grey, N-blue, O-red.

The quantitative reaction profile for the entire degradation process of the mPBI(1), is shown in the black line, Fig. 7a. A water molecule catalyzes this reaction pathway during the ring-opening reaction, and there is no explicit water included during the chain scission reaction. The highest transition state is the TS6-3.1 located at 2.04 eV in the quantitative reaction profile. This state is predicted to be the rate-limiting state and the effective barrier for the degradation reaction is 2.04 eV.

The same reaction path for the entire degradation reaction of mPBI(0) is shown in Fig. S11 (the black line). The highest transition state, in this case, is also the TS6-3.1 (TS6) located at 2.02 eV in the quantitative reaction profile, so the effective energy barrier for the degradation reaction differs only by 0.02 eV from that of the mPBI(1).

When the chain scission occurs, the reaction is irreversible. The hydroxide ion is consumed during the degradation as well as the mPBI(1) partially loses the ability to hold the aqueous KOH. Eventually, the degradation reaction can lead to the gradual drop of the ionic conductivity of the membrane. Also, the degradation reaction can lead to a reduced molecular weight of the mPBI polymer, as evidenced by the experimental results by Aili et al. [21]. The stability study of mPBI membrane in KOH solution at T = 88 °C has been found that the average molecular weight of mPBI soaked in 50 wt% KOH for 200 days was about 21-25% of the initial molecular weight [21].

#### 7. Reaction with implicit-explicit solvation model

TS6X2-3.3

So far, we employ the PCM implicit solvation model to approximately account for the effect of a dielectric constant surrounding the reaction center. However, it does not incorporate specific short-range solute-solvent interactions such as hydrogen bonding, which can be particularly important for anions [47–49]. A combined implicit-explicit solvation approach by including few explicit

**Fig. 7.** Quantitative reactive profile for the degradation path of mPBI(1) at T = 88 °C (a) with a different number of explicit water molecules using PCM implicit solvation model and (b) with two explicit water molecules using PCM and SMD implicit solvation model. The reference zero energy state for energies reported is A+OH<sup>-</sup>, and the relative energies of the intermediates and transition state are in eV.

water molecules in the implicit solvation model has been found to improve the agreement between theoretical calculations and experimental data such as solvation energies and  $pK_a$  for neutral, cation, and anion molecules [47–51]. For alkaline hydrolysis of amide bonds, the explicit water molecule has been reported to assist the proton-transfer process and stabilize the critical transition states via hydrogen bonding [45,46]. Subsequently, the explicit water molecule alters the activation energy.

#### 7.1. Reaction with one explicit water molecule

The first hydroxide ion attack at the C2 carbon atom of the mPBI(1) or  $\Delta G_1$  with one explicit water molecule at different hydrogen-bonding sites is shown in Table S7. The results clearly show that a hydrogen bonding site can contribute significantly to  $\Delta G_1$  while placing one explicit water molecule near the N1 position gives the lowest energy for  $\Delta G_1$ . Thus, when we consider the entire degradation pathway of the mPBI(1) with one explicit water

molecule, the explicit water molecule is placed near the nitrogen atom at the N1 position in structure A which is also close to where the expected degradation reaction occurs and participates in the reaction as a reactant.

With one explicit water molecule through the entire degradation process, only the initial reactant structure A, intermediate structure B, C, and transition structure TS1 are different from those previously considered. The optimized structures for the entire degradation process with one explicit water molecule are shown in Fig. S13.

The free energy diagram of mPBI(1) degradation with one explicit water molecule is plotted in Fig. 7a (the red lines). The one explicit water molecule does not substantially affect the free energy barrier during the first nucleophile addition reaction, but it still lowers the free reaction energy for this step (0.11 eV lower than without explicit water molecule). The free energy barrier related to the water-assisted hydroxyl proton transfer ( $\Delta G^{TS2-2.2}$ ) and the cleavage of the C2-N1 bond ( $\Delta G^{TS3}$ ) during the ring-opening

reaction is about 0.25 and 0.23 eV lower than that in the reaction path without explicit water molecule. The  $\Delta G^{TS4}$  and other relative free energies during the chain scissor reaction are the same as the previous consideration since the explicit water molecule is not included in these steps. The highest transition state for the entire degradation pathway with one explicit solvation for the mPBI(1) is TS6-3.1, locating at 1.69 eV in the quantitative reaction profile, which is 0.35 eV lower than the degradation pathway without the explicit water molecule. The explicit water molecule lowers the energy barrier by stabilizing via hydrogen bonds with the intermediate state structure along the reaction path.

#### 7.2. Reaction with two and three explicit water molecules

More water molecules (up to three water molecules) were explicitly included in the simulation. With two explicit water molecules, we find that the configuration with at least one explicit water molecule near the nitrogen at the N1 position results in lower energy for  $\Delta G_1$  (Table S7). An increasing number of explicit water molecules from zero to three (with at least one explicit water molecules from zero to three (with at least one explicit water molecule is near the N1 nitrogen atom) reduced  $\Delta G_1$  from 1.38 to 1.24 eV. Thus, when we add more explicit water molecules along the simulated reaction path, the first explicit water molecule is placed near the nitrogen atom at the N1 position and participates as a reactant. The second and third water molecules are placed near the nitrogen bond with deprotonated site. Besides, the additional explicit water molecules keep forming the hydrogen bond at the same site throughout the degradation process.

It is important to mention that we only consider some specific configurations between the limited amount of explicit water molecules and the mPBI(1) molecule in the reaction pathway. More explicit water molecules and other possible hydrogen bonding positions would require considering a more elaborate model. Increasing the number of explicit water molecules to achieve at least the first solvation shell has been reported to agree with the experimental results as it can provide a more accurate treatment of the short-range solvation interactio [52–54]. The complete first solvation shell can be obtained by ab initio molecular dynamics simulations, which typically require a large number of water molecules ( $\sim$ 10–100 molecules) and long simulation times [55,56]; such calculations are beyond the scope of the present study.

The quantitative reaction profile for the mPBI(1) degradation with two and three explicit water molecules is shown in Fig. 7a (the blue and green line, respectively), exhibiting a similar reaction profile to that with one explicit water molecule. However, the free reaction energy for the proton transfer reaction (for  $D \rightarrow E + OH^{-}$ step) along the degradation with two and three explicit water molecules is about 0.14 less negative than that with one explicit water molecule. Also, the free energy barrier and free energy reaction for the second nucleophilic addition step (for  $E+OH^- \rightarrow TS5 \rightarrow F$ step) along the reaction path with two and three explicit water molecules are about 0.15 and 0.14 eV lower than those in the reaction pathway with one explicit water molecule, respectively. This is results can imply that the specific hydrogen bonding at the deprotonate site significantly affects these steps. Hydrogen bonds between the explicit water molecules and the structure along the reaction path are likely to result in a lower energy barrier.

The free energy difference for each reaction step along the degradation pathway with two and three explicit water molecules is less than 0.1 eV. This can suggest that a further increase in explicit water molecules may have no practical effect on the reaction profile. The highest transition state along the degradation pathway with two and three explicit water molecules is the TS6-3.1 state, which is only 0.1 eV lower than that of the degradation pathway

with one explicit water molecule, but it is 0.36 eV lower than the degradation pathway without the explicit water molecule.

To test the sensitivity to the choice of implicit solvation model, we employed the SMD implicit solvation model [57] based on the same optimized structures in the gas phase, and the solvent remains water. Fig. 7b presents the quantitative reaction profile for the degradation pathway of the mPBI(1) molecule with two explicit water molecules using PCM and SMD implicit solvation. The reaction profiles obtained from both implicit solvation are similar, except that all states from the SMD implicit solvation are higher in the quantitative reaction profile. Still, the highest transition state with the SMD implicit solvation is the TS6-3.1 state but locates at 0.33 eV higher than that obtained from the PCM implicit solvation. However, similar results in which the effective barrier becomes smaller when including the explicit water molecules along the reaction pathway are also found for the SMD implicit solvation (Fig. S16).

The same degradation pathway for the mPBI(0) with up to two explicit water molecules using the PCM implicit solvation is shown in Fig. S11, leading to the same conclusion. The rate-determining state is the TS6-3.1 (TS6) state, regardless of the number of explicit water molecules. The effective free energy barrier along the degradation pathway for the mPBI(0) is reduced from 2.02 eV to 1.63 and 1.60 eV when the number of explicit water molecules increases from zero to one and two, respectively.

# 8. Comparison with experimental degradation rates

The degradation of the mPBI membrane depends on the KOH concentration. The experimental studies by Aili et al. [21] and Kraglund et al. [10] both reported that the mPBI membrane was stable at low KOH concentration (up to 5 wt% KOH at T = 80-88 °C). At higher KOH concentrations, the mPBI membrane degrades, and the degradation rate increases with increasing KOH concentration. To consider the KOH concentration dependency, we take the hydroxide ion concentration into account and reconsider the free reaction energy ( $\Delta G$ ) and free energy barrier ( $\Delta G^{TS}$ ), i.e., for the first nucleophilic reaction between structure A and OH<sup>-</sup>, the reaction goes through TS1 and results in intermediate B.

$$A + OH^{-} \rightarrow TS1 \rightarrow B$$
 (14)

$$\Delta G_1 = \Delta G_1^c - RT \ln \left[ OH^- \right] = \Delta G_1^c - 2.303 RT (pH - pK_w)$$
(15)

$$\Delta G^{TS1} = \Delta G^{TS1c} - RT \ln \left[ OH^{-} \right] = \Delta G^{TS1c} - 2.303RT(pH - pK_w)$$
(16)

 $\Delta G^c$  and  $\Delta G^{TSc}$  are the free reaction energy and free energy barrier at a standard concentration, pK<sub>w</sub> is the acid dissociation constant of water at T = 88 °C which is taken from the literature (pK<sub>w</sub> = 12.46 [40]).

Based on the above calculation, the free reaction energy along the water-assisted degradation pathway in the first, fourth and fifth reaction steps depends on pH, and only the first and the fifth free energy barrier changes with pH. Besides, all previous calculations are applied for pH = 12.46.

Fig. 8a shows the quantitative reaction profile for the mPBI(1) degradation with two explicit water molecules at different pH. For all considered pH values, the overall degradation rate is still determined by the TS6-3.1 state, which is decreased as pH increases. Thus, the effective energy barrier is reduced, and the degradation of mPBI(1) becomes more facile with increased hydroxide ion concentration.

Even though at a high pH range (pH= 13–14), the dominant species is mPBI(2) which is unlikely to degrade, the degradation

Electrochimica Acta 398 (2021) 139329

**Fig. 8.** (a) Quantitative reaction profile for the mPBI(1) degradation at T = 88 °C with two explicit water molecules and the PCM implicit solvation model at different pH. The reference zero energy state for energies reported is A+OH<sup>-</sup> and the relative energies of the intermediates and transition state are in eV. (b) the calculated effective free energy barrier and the apparent energy barrier from the experiments [21] ( $\Delta G^{TST}$ ) at different KOH concentrations and T = 88 °C.

still occurs through the mPBI(1) species which accounts for 10–20% of the PBI molecules. The number of mPBI(1) in the solution can be quickly reduced as the degradation reaction is also facile at this high pH. Some mPBI(2) species then can change to mPBI(1) species to maintain the equilibrium between all mPBI species. The degradation can further proceed, and the number of ionized species and mobile hydroxide ions in the solution is also reduced. Thus, the reduction in the ionic conductivity and the changes in membrane structure are unavoidable. Working at a lower pH range to minimize degradation can be possible. However, this comes with a lower ionic conductivity as the percentage of the ionized form in the solution becomes lower at a lower pH.

The reaction rate constant can be estimated from transition state theory, as shown in Eq. (6). The effective rate constant for the over degradation is calculated from the effective free energy barrier, the free energy difference between the highest transition state (TS6-3.1) and the initial reactant state ( $A+OH^{-}$ ).

Furthermore, given an experimentally observed reaction rate, one could estimate an apparent free energy barrier. The apparent free energy barrier is derived from the molecular weight loss of the mPBI membrane after being soaked in 5, 10, 25, 50 wt% KOH at T = 88 °C for 200 days reported by Aili et al. [21]. The rate of the molecular weight loss of the mPBI at a specific KOH concentration (in s<sup>-1</sup> unit) is approximated as follows.

$$rate = \frac{1}{\Delta t} \left( 1 - \frac{m_{200}}{m_1} \right) = k_0 f_{mPBI(0)} + k_1 f_{mPBI(1)}$$
(17)

where  $k_0$ , and  $k_1$ , are an apparent reaction rate constant (in s<sup>-1</sup> units) for the degradation of mPBI(0), and mPBI(1), respectively;  $f_{mPBI(0)}$ ,  $f_{mPBI(1)}$  are the mole fraction of mPBI(0), and mPBI(1) at considered KOH concentrations, respectively;  $\Delta t$  is the duration for storing the mPBI in KOH solution ( $\Delta t$ = 200 days);  $m_1$  and  $m_{200}$  are a molecular weight of mPBI before storing in KOH solution (day1) and after storing in KOH solution for 200 days (in g mol<sup>-1</sup>).

The mPBI(2) molecule is unlikely to degrade with the initial degradation step on the mPBI(2) molecule > 2 eV, about 1.30 eV higher than those of the mPBI(1) and mPBI(0). For simplicity, we assume that the contribution of the mPBI(2) to the total rate constant is insignificant, and we neglect the apparent reaction rate and the mole fraction of the mPBI(2) into Eq. (17). Fig. S17 shows the approximated rate including the mPBI(2) contribution, demonstrating that there is no further improvement in the approximated rate compared to the rate using Eq. 17.

Fig. 8b shows the apparent energy barrier derived from the experimental results and the effective free energy barrier from dif-

ferent implicit-explicit solvation models (Table S11). The effective energy barrier from the theoretical model is a weighted average value, taking the mole fraction of mPBI(0) and mPBI(1) at each KOH concentration into account. We find that both the apparent and effective free energy barriers decrease as the KOH concentration increases, implying the increasing degradation rate of mPBI as the KOH concentration increases. Without the explicit water molecules, the PCM implicit solvation model predicts a much larger effective free energy barrier than the experiments, resulting in an MAE of 0.43 eV. The MAE is reduced to below 0.1 eV when including explicit water molecules in the simulation. The results clearly show that the combination of implicit and explicit solvation models makes the predicted effective free energy barrier move toward the experimental results.

#### 9. Conclusion

A comprehensive DFT study of the degradation mechanism of the mPBI molecule in an alkaline solution is carried out in this work. The impact of continuum solvation and explicit water molecules on the reaction mechanism and energy profile is examined. The theoretical results are compared to the experimental work by determining the activation energy barrier for the degradation reaction.

The mPBI molecule deprotonates when submerged into an alkaline solution. At the high pH where the degradation occurs, the ionized forms, mPBI(2), is the predominant species, but the degradation is possibly initiated by the hydroxide ion attack at the C2 carbon position in the mPBI(1) or mPBI(0). The formation of a fully ionized molecule suppresses the hydroxide ion attack. The following ring-opening reaction is associated with hydroxyl proton transfer, the C-N bond breaking, and the stabilization of the N dangling bond. The hydroxyl proton transfer during the ringopening reaction likely occurs via an ancillary hydroxide ion or water molecule. The amide linkage is a product from the ring-opening reaction, which subsequently undergoes alkaline hydrolysis, leading to a complete chain scissor. The rate-determining state is associated with the amide cleavage during the chain scission reaction. A continuum solvation model predicts a relatively high effective barrier compared to the experiment. While combining explicit water molecules and implicit solvation lower the calculated effective barrier for the degradation, giving a good agreement between experiment and theoretical results. The explicit water molecules reduce the energy barrier mainly by forming hydrogen bonds with the intermediate state structure along the reaction path. The pro-

#### T. Patniboon and H.A. Hansen

posed model additionally captures the experimental trend in which the degradation rate increased with increased KOH concentration.

These studies point to the dominant degradation pathway for the mPBI membranes in alkaline solution and the importance of evaluating the reaction pathway with explicit water molecules. This insight is expected to be useful in designing degradationresistant anion exchange membranes for alkaline water electrolyzers and fuel cells. In addition, a polymer structure optimization of the polybenzimidazole membrane is expected to affect the alkaline stability of the membrane.
