### Abstract

With the increase in global pollution and electricity use, a clean energy sources and energy conversion technologies are needed. An attractive alternative is using a fuel cell to convert chemical energy into electrical energy. Still, a durability is a critical concern for fuel cell development. In this thesis, two degradation concerns related to the materials in the fuel cell are investigated by density functional theory (DFT).

Firstly, the stability of a single metal atom catalyst (M/N/C) is investigated. The M/N/C catalyst is a promising catalyst at the cathode of the fuel cell. However, under an acid condition of the fuel cell, it has poor stability. The thermodynamic model of the dissolution reaction for the M/N/C catalyst with various local carbon structures and metal atoms is investigated. The results reveal a significant role of both local carbon structure and the metal atom in the stability. The computational screening considering both activity and stability suggests the MN<sub>4</sub> site on the bulk graphene, and graphene edge with M = Fe, Co, and Ru as a stable catalyze in the activity and stability calculations for the MN<sub>4</sub> site on bulk graphene and graphene edge. Under the ORR-related condition, the electrolyte anions compete with water on the single metal site, in some cases either poisoning or modifying the catalyst activity and thermodynamic stability. The catalytic activity and stability descriptor suggest promising electrolyte and metal atom combinations that result in an active and durable catalyst.

Finally, the alkaline stability of the polybenzimidazole molecule is investigated. The polybenzimidazole molecule is a promising material for anion exchange membranes in alkaline fuel cells, but the degradation at a higher KOH concentration limits its practical use. It is found that the polybenzimidazole molecule undergoes deprotonation, forming the ionized molecule in an alkaline solution. In highly alkaline conditions, the fully deprotonated molecule is dominant and unlikely to degrade. In contrast, the non- and partially deprotonated molecules can undergo degradation. The effective energy barrier depends on the KOH concentration and becomes lower as the concentration increases. Also, it is found that the barrier along the reaction pathway and the availability of the vulnerable species in the solution both can affect the degradation rate, suggesting a significant role of  $pK_a$  value in the degradation.

### Résumé

Med stigningen i den globale forurening og elektricitetsforbrug er der behov for rene energikilder samt teknologi til energikonvertering. Et attraktivt alternativ er at bruge en brændselscelle til at omdanne kemisk energi til elektrisk energi. Durabiliteten er dog stadig et kritisk problem for udviklingen af brændselsceller. I denne afhandling undersøges to nedbrydningsproblemer relateret til materialerne i brændselsceller ved hjælp af tæthedsfunktionalteori (DFT).

Først undersøges stabiliteten af en single-metalatom katalysator (M/N/C). M/N/C-katalysatoren er en lovende katalysator ved brændselscellens katode. Under sure betingelser i brændselscellen har den dog dårlig stabilitet. Den termodynamiske model for opløsningsreaktionen for M/N/C-katalysatoren med forskellige lokale carbonstrukturer og metalatomer undersøges. Resultaterne afslører at både den lokale carbonstruktur og metalatomet spiller væsentlige roller i forhold til at afgøre stabiliteten. Den beregningsbaserede screening, der tager både aktivitet og stabilitet i betragtning, antyder at MN<sub>4</sub>-sitet på bulk grafen og grafenkanten med M = Fe, Co og Ru er stabile katalysatorer under sure betingelser. Adsorption af anionen i elektrolytten er yderligere inkluderet i aktivitets- og stabilitetsberegningen for MN<sub>4</sub>-sitet på bulk grafen og grafenkanten. Under ORR-relevante betingelser konkurrerer elektrolytanionerne med vand om single-metalsitet, hvilket i nogle tilfælde kan lede til enten blokering eller modificering af katalysatoraktiviteten og den termodynamiske stabilitet. Den katalytiske aktivitet- og- stabilitetsdeskriptor antyder lovende elektrolytog metalatomkombinationer, der resulterer i en aktiv og holdbar katalysator.

Til sidst undersøges den basiske stabilitet af polybenzimidazolmolekylet. Polybenzimidazol-molekylet er et lovende materiale til anion exchangemembraner i basiske brændselsceller, men nedbrydningen ved højere KOH-koncentration begrænser dets praktiske anvendelse. Det findes, at polybenzimidazol-molekylet gennemgår deprotonering og danner det ioniserede molekyle i basisk opløsning. Under stærkt basiske betingelser er det fuldt deprotonerede molekyle dominerende og vil sandsynligvis ikke nedbrydes. Derimod kan de ikke- og delvist deprotonerede molekyler undergå nedbrydning. Den effektive energibarriere afhænger af KOH-koncentrationen og bliver lavere, når koncentrationen stiger. Det findes endvidere, at barrieren langs reaktionsvejen og tilgængeligheden af de sårbare molekyler i opløsningen begge kan påvirke nedbrydningshastigheden, hvilket tyder på at pKa-værdien spiller en væsentlig rolle i nedbrydningen.

### Preface

This thesis is submitted in candidacy for a Ph.D. from Technical University of Denmark (DTU). The work was conducted between October 2019 and October 2022 at the Section of Atomic Scale Modelling and Materials at the Department of energy conversion and storage. The studies have been supervised by Heine Anton Hansen and Tejs Vegge. The Ph.D. project was financially supported by the Ministry of Science and Technology, Royal Thai Government.

I am thankful for many people I met during my time at DTU. First and foremost, I would like to thank my supervisor, Heine Anton Hansen, for his continuous support and guidance. I am thankful for his patience in explaining things to me, and I appreciate all the help and advice he has given. I also would like to thank my co-supervisor, Tejs Vegge, for his suggestions and kindness over the past three years.

Many thanks to all current and past members of the Atomic Scale Materials Modelling (ASM) and Autonomous Materials Discovery (AMD) section. I would like to thank Changzhi Ai, Benjamin Heckscher Sjølin, Nis Fisker-Bødker, Smobin Vincent, and Williams Agyei Appiah for the positive working environments in the office. In addition, I am very thankful to Arghya Bhowmik and Peter Bjørn Jørgensen for their help and discussion. It was a pleasure to meet and work with Haobo Li during my virtually external stay at Fritz-Haber-Institut der Max-Planck-Gesellscha, Germany. I am grateful to David Aili, Dmytro Serhiichuk, and Yang Hu for their valuable discussion of experimental findings. Special thanks to Pernille Pedersen for her help translating the abstract to Danish. I would also like to thank Changzhi Ai, Benjamin Heckscher Sjølin, Surajit Nandi, Xueping Qin, Leonardo Evaristo de Sousa, Xin Yang, and Xiaotong Zhang for proofreading the thesis and providing valuable suggestions for improvements.

Last but not least, many thanks to my parents, sister, and friends for always supporting and encouraging me. I appreciate your time with me, hearing me out, and cheering me up.

# Chapter 1 Introduction

### 1.1 Fuel Cell Technology

Growing concerns about global pollution and increasing electricity use drive us to find less polluting energy sources and clean energy conversion technology. An attractive alternative is a conversion of chemical energy into electrical energy. A fuel cell is an electrochemical device that can convert the chemical energy of H<sub>2</sub> into electricity [1]. Among the different types of fuel cells, a proton exchange membrane fuel cell (PEMFC) and anion exchange membrane fuel cell (AMFC) are perceived as promising fuel cells, especially for mobile applications, due to their high energy efficiency and zero emission [1]. The PEMFC and AMFC are similar in principle. The main difference is that a solid membrane separates an anode and a cathode. As shown in Figure 1.1, protons conduct through a proton exchange membrane from the anode to the cathode in the PEMFC. In the AMFC, hydroxide ions are transported through an anion exchange membrane from the cathode to the anode. Under an acid condition of the PEMFC, the hydrogen oxidation reaction (HOR) occurs at the anode, and the oxygen reduction reaction (ORR) occurs at the cathode, which can be expressed as follows

HOR : 
$$H_2 \rightarrow 2H^+ + 2e^-$$
  
ORR :  $\frac{1}{2}O_2 + 2e^- + 2H^+ \rightarrow H_2O$  (1.1)

Similarly, the HOR at the anode and the ORR at the cathode under an alkaline condition in the AMFC can be written as follows

HOR : 
$$H_2 + 2OH^- \rightarrow 2H_2O + 2e^-$$
  
ORR :  $\frac{1}{2}O_2 + H_2O + 2e^- \rightarrow 2OH^-$  (1.2)

Both types of fuel cells lead to the same overall reaction, which is

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O \tag{1.3}$$

However, some differences can be seen in the fuel cell electrode reactions, and both types have their advantages and disadvantages.

#### 1.2 Degradation of M/N/C Electrocattalyst

The PEMFC has attracted attention due to its favorable power-to-weight ratio, quick start-up, and low operating temperature [3, 4]. The development of the PEMFC for commercialization has also made significant progress. Still, its large-scale commercialization is hampered by high cost and low performance. A highly efficient electrocatalyst is required to drive the sluggish ORR at the cathode. Carbon-support platinumbased particles are the most efficient and commercialized ORR catalysts. However, due to the high Pt-loading required at the cathode and the scarcity of Pt, the catalyst cost is the largest component of the PEMFC stack [5]. In addition, a lack of durability can also lead to the limited performance of the PEMFC. Under the acidic condition of the PEMFC, the corrosion of the carbon-based material, dissolution of catalyst, and polymer decomposition are the degradation that can be observed [6, 7]. Hence, it still has room to be improved regarding durability. In this thesis, the focus is on the catalyst component.

In developing advanced Pt-free cathode catalysts, the requirements for inexpensive but more active and durable ORR electrocatalysts are challenging. A single metal site incorporated in N-doped carbon (M/N/C catalyst) has emerged as a promising low-cost ORR catalyst. Many experimental and theoretical studies have already demon-

**Figure 1.2:** Schematic illustration of the degradation of M/N/C electrocatalysts via the demetallation and oxidation of the carbon matrix. Reproduced from [8], Copyright 2021, with permission from Elsevier.

strated the impressive utilization and initial ORR activity of the M/N/C catalyst, especially Fe/N/C catalysts [9–12]. However, a significant challenge of the M/N/C electrocatalysts is their poor stability, especially in acidic media.

Several possible degradation processes have been proposed to cause the instability of the Fe/N/C catalysts, e.g., the leaching of the metal atom from the  $MN_yC_x$  motif [13, 14], the carbon surface oxidation [15, 16] and the corrosion of the carbon matrix [17]. These mechanisms may occur parallel during the fuel cell operation and may be interrelated [18, 19]. For example, as shown in Figure 1.2, the demetallation could cause a direct loss of the active site density, and the leached metal ion could indirectly catalyze the oxidation of carbon materials. In addition, the oxidation of the carbon matrix could further accelerate the demetallation. Still, the dominating factor contributing to the M/N/C catalyst degradation is elusive and needs further investigation.

The carbon oxidation can occur by the direct electrochemical carbon oxidation at a higher potential [16, 20], leading to the destruction of the  $MN_yC_x$  site and the removal of the metal center atom. Its kinetics depend on temperature and defects in the carbon matrix. The carbon corrosion rate increases with temperature [16, 20], and the rate becomes faster on the graphene edge than on the basal plane [16]. As a result, the micropore-hosted  $MN_yC_x$  site could be eliminated faster than the bulk-hosted site [16]. The chemical oxidation of M/N/C catalysts surface by H<sub>2</sub>O<sub>2</sub>-derived radicals rather than by electrochemical carbon oxidation has been proposed as one of the degradation mechanisms of the Fe/N/C catalyst during the fuel cell operation [15, 21]. H<sub>2</sub>O<sub>2</sub> can be electrochemically generated by ORR [22–24], and the reactions between H<sub>2</sub>O<sub>2</sub> and dissolved metal ions or MN<sub>y</sub> site, especially Fe ions and FeN<sub>y</sub> site, lead to active oxygen species (ROS). The ROS has higher oxidative strength than H<sub>2</sub>O<sub>2</sub> and can oxidize carbon matrix [15, 21, 25]. Upon damaging the carbon matrix, the metal atom could be more prone to detach from the M/N/C structures [15, 26], reducing the active site density. The ROS can also modify the carbon surface near the active site, reducing the turnover frequency (TOF) of the Fe/N/C catalyst [17]. The latter effect is partially reversible upon reduction of the carbon surface [17].

The demetallation could process by direct leaching of the Fe center [13, 14] or the loss of FeN<sub>x</sub> species due to carbon corrosion [15, 16]. The demetallation of the Fe ion from the Fe/N/C catalyst is dominating at low potential (< 0.7 V) [20]. Using density functional theory (DFT) calculations to study the dissolution reaction of the FeN<sub>4</sub> sited embedded on a bilayer-graphene, Holby *et al.* suggested the demetallation of the FeN<sub>4</sub> site is thermodynamically favored under the PEMFC-relevant environment [27]. In contrast to the thermodynamic dissolution of the FeN<sub>4</sub> structures toward aqueous Fe<sup>2+</sup> studied by Glibin *et al.* [28] and Chenitz *et al.* [29], the FeN<sub>4</sub> structures are thermodynamically stable in acidic conditions, but they can be demetallated by the driving force of water running into the micropores [29]. This specific demetallation has been proposed as the cause of the initial loss of ORR activity, especially for highly microporous catalysts[29].

The atomic structures and working environments play essential roles in the stability and catalytic activity of the Fe/N/C catalyzes [18, 29, 30]. While, the structure of pyrolyzed Fe/N/C materials highly depends on the synthetic path where various Fe species may form at high temperatures, ranging from metallic, metal-carbide, and metal-nitride Fe particles to FeN<sub>x</sub> moieties. Many detail structures of the FeN<sub>4</sub> sites with different local carbon structure have been proposed as the active site for the ORR by both experimental and theoretical studies (e.g., FeN<sub>4</sub>C<sub>8</sub> [31, 32], FeN<sub>4</sub>C<sub>10</sub> [18, 33], FeN<sub>4</sub>C<sub>12</sub> [9, 18, 33], edge-hosted FeN<sub>4</sub> [34]).

In a previous experiment by Santori *el al.*, two Fe/N/C catalysts comprising only atomically dispersed FeN<sub>y</sub> moieties; one is an NH<sub>3</sub>-pyrolyzed Fe/N/C catalyst, and the other is the Ar-pyrolyzed Fe/N/C catalyst [14]. The NH<sub>3</sub>-pyrolyzed Fe/N/C catalyst results in a higher ORR activity in alkaline electrolyte and approximately ten times higher Fe leaching in the acid electrolyte relative to the Ar-pyrolyzed Fe/N/C catalyst. Furthermore, the Fe leaching rate is strongly enhanced when the potential is 0.75 to 0.3 V<sub>RHE</sub>. By using operando X-ray absorption spectroscopy (XAS), Santori *el al.* has also suggested that the instability in the acidic medium of the NH<sub>3</sub>-pyrolyzed catalysts relates to the lower oxidation state of the Fe atom litigated with highly basic nitrogen ligands [14].

Recent studies have shown that two FeN<sub>4</sub> sites with different local carbon structures have different stability under the operation in the acid eletrolyte[18]. Combining operando <sup>57</sup>Fe Mössbauer spectroscopy and XAS, Li *et al.* have identified two initial types of FeN<sub>4</sub> sites in the Fe/N/C catalysts, including a high-spin FeN<sub>4</sub>C<sub>12</sub> moiety (S1) and a low- or intermediate-spin FeN<sub>4</sub>C<sub>10</sub> moiety (S2), as shown in Figure 1.3. Both sites initially contribute to the ORR activity in the acid electrolyte. However, the FeN<sub>4</sub>C<sub>12</sub> site, which is more active for the ORR, irreversibly converts to inactive ferric oxides during the operation, especially at low potentials [18]. In contrast, the FeN<sub>4</sub>C<sub>10</sub> site, which has relatively low activity, is found to be more stable against demetallation and insensitive to local carbon surface oxidation [18]. This study has suggested a significant role of the local carbon around the FeN<sub>4</sub> sites in their stability, bringing up a potential pathway to achieve a Fe/N/C catalyst with activity and stability by regulating the local carbon structure. Nonetheless, the underlying driving force for different stability of these two FeN<sub>4</sub> sites is still unclear, and there is a wide debate about the active and stable site of the Fe/N/C catalysts [26, 35–37].

**Figure 1.3:** Schematic illustration of the conversion of two types of FeN<sub>4</sub> sites under acidic fuel cell operation. The highly active  $\text{FeN}_4\text{C}_{12}$  site (S1) is not durable and quickly converts into inactive ferric oxide. The less-active  $\text{FeN}_4\text{C}_{10}$  site is durable and retain fuel cell performance. Reproduced from [18], Copyright 2020, with permission from Springer Nature.

Since the dissolved Fe ions from the Fe/N/C catalyst and the Fe/N/C site itself can catalyze the formation of radicals from  $H_2O_2$  [21, 25, 38], further deteriorating the catalyst surface and proton exchange membrane [17, 39]. The replacement of Fe with other metals that do not promote the formation of  $H_2O_2$ -derived radicals are also desirable. A previous study by Xie *et al.* [19] has reported a similar catalytic activity toward ORR of the Co/N/C catalyst to the Fe/N/C catalyst. In contrast, the Co/N/C catalyst has lower metal reaching and lower activity for promoting radicals from  $H_2O_2$ , resulting in significant resistance to demetallation and carbon surface oxidation under acid conditions, compared to the Fe/N/C catalysts [19]. By using X-ray absorption nearedge structure (XANES), extended X-ray absorption fine structure of the Co/N/C catalyst

lysts has been identified by Zitolo *et al.* [12]. Like the Fe/N/C catalyst, the  $CoN_yC_x$  moieties are an active site toward the ORR. Unlike the FeN<sub>y</sub>C<sub>x</sub> moieties, the  $CoN_yC_x$  moieties do not experience structural and electronic-state changes under the ORR operation. In addition to the Co/N/C catalysts, the excellent structural stability of Ru/N/C catalyst in acid electrolytes has also been reported. Cao *el al.* have detected the Ru dissolution ratio of as low as 5% within 30 hours operation for Ru/N/C catalyst in O<sub>2</sub>-saturated 0.5 M H<sub>2</sub>SO<sub>4</sub> electrolyte [40]. Also, using transmission electron microscopy (TEM), X-ray diffraction (XRD), and EXAFS, they have found that the morphology and structure of the Ru/N/C catalyst remain nearly unchanged after the operation.

Understanding the degradation mechanism of the Fe/N/C catalyst is beneficial for the rational design of durable M/N/C catalysts. However, the complexity of the degradation becomes a big challenge to reveal the underlying dominant one. In this thesis, we try to understand how the nature of the metal atoms, the local carbon structures, and chemical environments, i.e., electrolyte anions affect the demetallation of the single metal atom and its catalytic activity. Although other degradation reactions could occur and contribute to the degradation, the ambiguous interaction between each possible degradation reaction makes it hard to explore simultaneously. We believe that the relation between the atomic structure and chemical environment of the MN<sub>y</sub> motif with the demetallation will provide a better understanding of the degradation reactions could be further included.

The development of new materials using the first principle calculations has been possible thanks to the increased computational power over the decades. As a result, a computational screen process can rapidly reduce the number of candidates to investigate experimentally. The DFT calculations have been successfully used for describing the electronic structure, and catalytic activity of the single atom catalyst [41–44]. This thesis uses the DFT calculations to study the relationship between the demetallation of the  $MN_yC$  motifs with their structure and chemical environments, i.e., electrolyte adsorption. Using the computation screening approach, we also suggest interesting candidates that can result in active and stable M/N/C catalysts.

#### **1.3 Degradation of Polybenzimidazole Membrane**

The AMFC is effectively an alkaline analogy of the PEMFC. Working under alkaline conditions offers several advantages over the PEMFC, including low dissolution rates of catalysts, less expensive Pt-free electrocatalysts, and wide selections of materials and components that are stable at high pH [45]. However, there are still concerns regarding the performance achieved by the AMFC. The most critical concern is the poor ionic conductivity and stability of the anion exchange membranes [2].

As shown in Figure 1.4 (a), the electrodes are separated by an aqueous potassium hydroxide solution confined in a porous diaphragm. The porous diaphragm is a separator material made from a stable, inert polymer, solely relying on a liquid electrolyte to establish percolating pathways throughout the porous structure. The diaphragm

must have a significant thickness to secure gas separation. However, this, unfortunately, causes the increased ohmic resistance [46]. Replacing the diaphragm with an ion-conducting membrane reduces inter-electrode thickness, thus reducing the internal resistance [47]. A typical anion exchange membrane comprises polymer backbones with pendant fixed organic cations such as ammonium [11, 48], imidazolium cation [49–52], benzimidazolium [50, 53, 54] to allow hydroxide-ion conduction. However, both polymer backbones and organic cations could be potentially attacked by hydroxide ions, leading to the loss of mechanical strength and ion conductivity [55–58].

**Figure 1.4:** Three approaches towards hydroxide conducting separators: (a) a porous diaphragm, (b) an anion exchange membrane, (c) an ion-solvating membrane [47]

An alternative is an ion-solvating membrane which consists of a water-soluble polymer and a hydroxide salt (i.e., potassium hydroxide) [47, 59]. These combinations have the mechanical properties of the polymer and conductive properties of the alkaline salt. The polymer contains electronegative heteroatoms such as oxygen, nitrogen, or sulfur, which interact with the cations of the salt. Ionic conduction within the structure is based on these heteroatom-cation interactions, so it does not need the cation moieties [59] and can be prepared as thin as other polymeric membranes [47, 60].

Recently, the ion-solvating membrane based on polybenzimidazoles (mPBI) have been studied for the AMFC, and alkaline water electrolysis [60–63]. As shown in Figure 1.5, when combined with a strong concentrated base, the mPBI undergoes ionization, forming the polybenzimidazolides that allow the uptake of water and base to facilitate the hydroxide-ion transport in the membranes [64–66]. Compared to a porous separator such as Zirfon, the mPBI-based membrane has a lower ohmic polarization and hydrogen crossover but a higher ionic conductivity [60, 67]. The composite of the mPBI-based membrane depends on the KOH concentration. The mPBI-based membrane exhibits high ionic conductivity and chemical stability at low concentration (5 - 10 wt% KOH at T = 88°) [61]. The ionic conductivity can be further increased by two orders of magnitude and peaks at 20 - 25 % KOH [61]. However, a long-term operation at this high KOH concentration can lead to the degradation of the mPBI-based polymer [60, 61, 68]. Thus, the practical use is still limited. A structure optimization has been found as a possible way to improve the alkaline stability of the mPBI-based membrane. The chemical stability of mPBI has been studied by Aili *et al.* [68], and they have found no change in the mPBI structure under 6 M KOH at 85 °C for 116 days. A polybenzimidazole derivative, poly(2,2-(m-mesitylene)-5,5-bibenzimidazole) (mesPBI), has been synthesized and was stable in 0 - 10 wt% KOH at T = 88 °C for 207 days [69]. Recently, a poly(2,2-(1,4-naphthalene)-5,5-bibenzimidazole) (NPBI); also a polybenzimidazole derivative, was successfully synthesized and used in alkaline water electrolysis by Hu *et al.* [70] and they have found no chemical degradation at T = 80 °C in 6 M KOH for 180 days.

**Figure 1.5:** Formation of polybenzimidazolides in the alkaline solution. Reproduced from [71], Copyright 2020, with permission from Royal Society of Chemistry.

The degradation of the mPBI-based membrane could happen via a nucleophilic attack by hydroxide ions at the benzimidazole ring, similar to that of imidazolium cation [68–70]. However, under an alkaline condition, the mPBI undergoes deprotonation. The negative charge could be localized at the benzimidazole ring of the mPBI; thus, a predominant degradation mechanism could differ from the imidazolium cation. In order to develop mitigating degradation, a detailed mapping of the degradation pathway is needed. This thesis uses the DFT calculations to understand how the mPBI molecules degrade in an alkaline solution.

#### 1.4 Outline of the Thesis

This thesis comprises six chapters and is organized as follows

#### • Chapter 1 - Introduction

The introduction of the fuel cell technology and two degradation issues related to the materials inside the fuel cell which is the main focus of this thesis. A brief review of the degradation of the M/N/C catalyst in an acid condition and polybenzimidazole membrane in an alkaline solution.

#### • Chapter 2 - Theoretical Framework

A brief introduction to the electronic structure problem in condensed matter physics, the DFT calculations, and an overview of exchange-correlation functionals used in this thesis.

• Chapter 3 - Effect of Local Carbon Structure on the Activity and Stability of Single-atom Electrocatalyse

An investigation of the stability and ORR activity under acidic conditions of the M/N/C catalyst with different local carbon surrounding the  $MN_y$  site and different metal atoms.

• Chapter 4 - Effect of Electrolyte Anion Adsorption on the Activity and Stability of Single Atom Electrocatalysts

A study of the effect of electrolyte anion adsorption on catalytic activity and stability of the M/N/C catalyst under two electrochemical conditions, which are the ORR and the CO<sub>2</sub> reduction reaction (CO<sub>2</sub>RR).

- Chapter 5 Degradation of Polybenzimidazole in Alkaline Solution The DFT investigation of the minimum degradation pathway of the mPBI molecule in an alkaline solution. The role of explicit water molecules and the effect of hydroxide ion concentration on the free energy barrier
- Chapter 6 Summary and Outlook Main findings and an outlook for future work.

### Chapter 2

### **Theoretical Framework**

Density functional Theory (DFT) calculations are widely used as a standard tool for materials modeling problems in physics, chemistry, and materials science. This chapter briefly introduces the basic theoretical framework, including the electronic structure problem in condensed matter physics and DFT, as used in this thesis.

#### 2.1 Electronic Structure Problem

A piece of any material consists of atoms, a set of atomic nuclei, and electrons interacting via electrostatic force. One of the fundamental ground state properties of such a system is its energy which changes when atomic positions are altered. The ground state properties can be determined by solving the time-independent Schrödinger equation.

$$\hat{H}\Psi(R,r) = \varepsilon\Psi(R,r)$$
 (2.1)

where  $\varepsilon$  is the energy eigenvalue, and  $\Psi(R, r)$  is the wavefunction of the system, depending on both the electron coordinates (r) and the nuclei coordinates (R). The Hamiltonian can be written as follows

$$\begin{split} \hat{H} &= -\sum_{I=1}^{P} \frac{\hbar^{2}}{2M_{I}} \nabla_{I}^{2} - \sum_{i=1}^{N} \frac{\hbar^{2}}{2m} \nabla_{i}^{2} \\ &+ \frac{e^{2}}{2} \sum_{I=1}^{P} \sum_{J \neq I}^{P} \frac{Z_{I}Z_{J}}{|R_{I} - R_{J}|} + \frac{e^{2}}{2} \sum_{i=1}^{N} \sum_{i \neq j}^{N} \frac{1}{|r_{i} - r_{j}|} - e^{2} \sum_{I=1}^{P} \sum_{i=1}^{N} \frac{Z_{I}}{|R_{I} - r_{j}|} \\ \hat{H} &= \hat{T}_{n} + \hat{T}_{e} + \hat{U}_{nn}(R) + \hat{U}_{ee}(r) + \hat{V}_{ne}(R, r) \end{split}$$
(2.2)

where  $R = R_I$ ; I = 1, ..., P is a set of P nuclei coordinates and  $r = r_i$ ; i = 1, ..., N is a set of N electron coordinates.  $Z_I$  and  $M_I$  are the nucleus charge and mass, respectively, while m is the electron mass.  $\hat{T}_n$  of the Hamiltonian is the kinetic energy of the nucleus.  $\hat{T}_e$  is the kinetic energy of the electrons.  $\hat{U}_{nn}(R)$  is the nucleus-nucleus interaction.  $\hat{U}_{ee}(r)$  is the electron-electron interaction.  $\hat{V}_{ne}$  is the interaction between the nucleus and electron. The final term makes the nucleus and electron parts inseparable.

The nucleus is considered to be much heavier and slower than the electrons. Therefore, the nucleus can be assumed stationary from the point of the electron. Then, the electrons are considered moving in the potential corresponding to the configuration of the nuclei and instantaneously adapting to nuclei motions [72]. This approximation is known as Born-Oppenheimer approximation [72]. For a given set of nuclei with coordinate R, the electronic part related to electron motion can be separated and solved.

$$\Psi(\mathbf{R},\mathbf{r}) = \Psi_{\mathbf{e}}(\mathbf{r};\mathbf{R})\Psi_{\mathbf{n}}(\mathbf{R}) \tag{2.3}$$

where  $\Psi_e(r; R)$  is the many-body electronic wave function and  $\Psi_n(R)$  is the nuclear wave function. The electronic Schrödinger equation can be expressed as follows

$$\hat{H}_e \Psi_e(r; R) = E(R) \Psi_e(r; R)$$
(2.4)

where E(R) are the electronic eigenvalues corresponding to the given nuclei configuration. The nuclei coordinates are only a parameter in  $\hat{H}_e$ ,  $\Psi_e(r; R)$  and E(R). The electronic Hamiltonian ( $\hat{H}_e$ ) can be written as follows

$$\hat{H}_{e} = -\sum_{i=1}^{N} \frac{\hbar^{2}}{2m} \nabla_{i}^{2} + \frac{e^{2}}{2} \sum_{i=1}^{N} \sum_{i\neq j}^{N} \frac{1}{|r_{i} - r_{j}|} - e^{2} \sum_{I=1}^{P} \sum_{i=1}^{N} \frac{Z_{I}}{|R_{I} - r_{j}|}$$

$$\hat{H}_{e} = \hat{T}_{e} + \hat{U}_{ee}(r) + \hat{V}_{ext}(r)$$

$$(2.5)$$

where  $\hat{T}_e$  is the kinetic energy of the electron.  $\hat{U}_{ee}(r)$  is the electron-electron interaction.  $\hat{V}_{ext}(r)$  is the nucleus-electron interaction, which is an interaction between electrons and the external potential generated by the given configuration of the nuclei. The electronic Schrödinger equation is still complicated to solve as the electrons interact among themselves via electrostatic forces. The presence of electrons in one region can influence the behavior of electrons in other regions. In other words, the probability of finding two electrons (two particles with the same charge) is reduced due to Coulomb repulsion, known as correlation interaction. Furthermore, the probability of finding two electrons is further depleted if they have the same spin due to Pauli's exchange principle, known as an exchange interaction. Thus, the electrons cannot be treated individually. Also, the electronic wavefunction cannot be written simply as a product of single-electron wavefunctions. As a many-body problem, the exact solution of the electronic Schrödinger equation consisting of N electrons will solve the equation in 3N degrees of freedom. Instead of doing so, the many-body wave function in the DFT is solved in terms of electronic density; n(r). Thus, it solves the equation in only the three spatial degrees of freedom.

#### 2.2 Density Functional Theory

#### Hohenberg-Kohn Theorem

DFT is based on the Hohenberg-Kohn theorem [73], proposing the formal theoretical basis for obtaining electronic energies through electronic density.

**Theorem 1** states that the external potential;  $v_{ext}(r)$ , is a unique functional of the density; n(r), apart from a trivial additive constant. Hence, the energies and other properties of the system at the ground state are determined by the ground state electronic density. Given the external potential;  $v_{ext}(r)$ , the total energy can be represented as a functional of the electronic density.

$$E[n(r)] = T[n(r)] + U_{ee}[n(r)] + \int v_{ext}(r)n(r)dr$$
(2.6)

where T[n(r)] is the kinetic energy of the electron.  $U_{ee}[n(r)]$  is the potential energy due to electron-electron interaction. These two terms depend on the electron density. The final term is the potential energy due to the interaction between electrons and the external potential from the nuclei.

**Theorem 2** states that the ground state energy can be obtained from the ground state electronic density, which minimizes the total energy. Thus, the energy functional; E[n(r)] is minimized for the ground state density;  $n_0(r)$ , whose energy is the ground state energy;  $E_0$ .

$$E_0 = \min_{n(r)} E[n(r)]$$
(2.7)

However, to get the exact ground state electron density, the exact expression of the first two terms in Equation 2.6 must be known.

#### Kohn-Sham Equations

Instead of considering a system of interacting electrons, the exact ground-state electron density is obtained from the non-interacting electron system subjected to an effective external potential;  $v_{eff}(r)$ , such that the same ground-state electron density as the interacting electron system is obtained [74]. As a result, the Hamiltonian can be written for the non-interacting electron system consisting of N electrons as follows

$$\hat{H}_{s} = \sum_{i=1}^{N} \left[ -\frac{\hbar^{2}}{2m} \nabla_{i}^{2} + v_{eff}(r_{i}) \right]$$
(2.8)

where  $v_{eff}(r)$  is the effective external potential, which ensures that the electron density of the non-interacting electron system is the same as the electron density of the interacting electron system. A many-body wavefunction of the non-interacting electron system can be expressed as a Slater determinant of a single-electron wavefunction;  $\Phi_i$  (called Kohn-Sham orbitals). The Kohn-Sham orbitals,  $\Phi_i$ , can be obtained by solving the oneelectron Schrödinger equation, the Kohn-Sham equation.

$$\hat{H}_{KS}\Phi_{i} = \left[-\frac{\hbar^{2}}{2m}\nabla_{i}^{2} + v_{eff}(r_{i})\right]\Phi_{i} = \varepsilon_{i}\Phi_{i}$$
(2.9)

The electron density of the non-interacting electron system can be written as

$$n(\mathbf{r}) = 2\sum_{i=1}^{N} |\Phi_i|^2$$
(2.10)

The total energy of the non-interacting electron system with electron density, n(r), can be written as

$$E_s = T_s[n(r)] + \int v_{eff}(r)n(r)dr \qquad (2.11)$$

where  $T_s[n(r)]$  is the kinetic energy of the electrons in the non-interacting electron system. Applying the variational principle to the total energy of the non-interaction electron system results in the following equation.

$$\frac{\delta T_{s}[n(r)]}{\delta n(r)} + v_{eff}(r) = \mu_{s}$$
(2.12)

For the interacting electron system, the total energy in Equation 2.6 can be rewritten in terms of the kinetic energy of the non-interacting electron system.

$$E[n(r)] = T_{s}[n(r)] + \frac{1}{2} \int \int \frac{n(r)n(r')}{|r-r'|} dr dr' + \int v_{ext}(r)n(r)dr + E_{xc}[n(r)]$$
(2.13)

where the second term is the Hartree energy which is the classical electrostatic energy from a charge distribution given by n(r).  $E_{xc}[n(r)]$  is the exchange and correlation energy which is a correction term, including the kinetic correlation energy and exchange-correlation energy. The kinetic correlation energy accounts for the fact that the many-body electronic wavefunction of the interacting electron system cannot be written as Slater determinants of the single-electron wavefunction. The exchange-correlation energy accounts for other missing parts, including exchange energy and correlation energy of electrons. Furthermore, the Hartree energy also includes the interaction of an electron with itself. In order to cancel out this nonphysical contribution,  $E_{xc}[n(r)]$  is expected to account for this contribution error. However, the exact mathematical expression of  $E_{xc}[n(r)]$  term is unknown.

Minimizing the total energy of the interaction electron system with respect to the density, under the constraint that this density integrates into N particles, the following equation is obtained for the ground state density.

$$\frac{\delta T_{s}[n(r)]}{\delta n(r)} + \int \frac{n(r')}{|r-r'|} dr' + v_{ext}(r) + \frac{\delta E_{xc}[n(r)]}{\delta n(r)} = \mu$$
(2.14)

Since the interacting and non-interacting electron systems have the same ground state density and ground state energy, the chemical potentials must be equal. Thus  $v_{eff}(r)$  can be expressed as the following equation.

$$v_{eff}(\mathbf{r}) = v_{ext}(\mathbf{r}) + \int \frac{\mathbf{n}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}' + \frac{\delta E_{xc}[\mathbf{n}(\mathbf{r})]}{\delta \mathbf{n}(\mathbf{r})}$$

$$= v_{ext}(\mathbf{r}) + v_{H}(\mathbf{r}) + v_{xc}[\mathbf{n}(\mathbf{r})]$$
(2.15)

As a result, the problem can be solved self-consistently. From a given external potential of the system, the initial guess of electron density is used to formulate the effective potential. Then, the Kohn-Sham equation can be solved to give a new electron density. The Kohn-Sham equation has to be solved self-consistently to ensure the input electron density equals the output electron density. The exact ground state electron density can be obtained only if the exact exchange-correlation functional is known. However, the exact exchange-correlation functional, including all the exchange and correlation contributions to the energy from the real many-body wave function, is not known. In order to make the DFT procedure practical, approximations for the exchange-correlation functional are required. Consequently, the accuracy of DFT calculations relies on accurate approximations of the exchange-correlation functional.

#### 2.3 Exchange-correlation functional

The exchange-correlation functional can be approximated in several ways. Each gives different results and uses different amounts of resources. The simplest approximation is a Local Density Approximation (LDA) where the exchange-correlation functional at each position is the exchange-correlation of the homogeneous electron gas with the same electron density [74]. In this way, the exchange-correction functional is a local functional that depends only on the electron density at the considered position. The functional may be written as follows

$$E_{xc}^{LDA}[n(r)] = \int n(r)\varepsilon_{xc}^{HEG}[n(r)]dr \qquad (2.16)$$

where  $\varepsilon_{xc}^{\text{HEG}}$  is the exchange-correlation energy density of the homogeneous electron gas with a uniform density n. As its name implies, the electron density is constant at all points in the space of the homogeneous electron gas. The LDA functional is exact for the homogeneous electron and is expected to be a good approximation for a system with a uniform electron density or where the electron density varies slowly in space, like bulk metals [75]. However, it fails for systems where the electron density changes rapidly through space, such as molecules and surfaces.

An extension of the LDA functional using information about the local electron density; n(r), and the local gradient in the electron density;  $\nabla n(r)$ , is a Generalized Gradient Approximation (GGA) [76]. There are many ways in which information from the electron density gradient can be included. Generally, the exchange-correlation functional in the GGA can be written as

$$E_{xc}^{GGA}[n(r)] = \int n(r)\varepsilon_{xc}^{HEG}[n(r)]F_{xc}[n(r), \nabla n(r)]dr$$
(2.17)

where  $F_{xc}$  is the enhancement factor that modifies the local LDA contribution to the energy. The exchange-correction functional depends on the electron density at the considered position and the nearest neighbor, containing a semi-local interaction. Two of the most widely used functionals in calculations involving solids are the Perdew-Wang functional (PW91) [77] and the Perdew-Burke-Ernzerhof functional (PBE) [76], which have proven quite successful in calculating many properties, most notably lattice constants [78].

However, the local and semi-local correction hardly captures the non-local interaction in the long-range such as van der Waals (vdW) dispersion interactions which fundamentally occur due to correlations that exist between temporary fluctuations in the electron density of one molecule and the energy of the electrons in another molecule responding to these fluctuations [75]. Including the non-local vdW interactions could have the advantage of describing the surface chemical reaction where the non-local vdW interaction plays an important role. A Bayesian Ensemble Error functional with van der Waals correlations (BEEF-vdW) [79] is another GGA functional with added vdW interaction. The general expression of the BEEF-vdW functional can be written as

$$E_{xc}^{BEEF-vdw}[n(r)] = \sum_{m=0}^{M-1} a_m E_m^{GGA-x} + \alpha_c E^{LDA-c} + (1 - \alpha_c) E^{LDA-c} + E^{nl-c}$$
(2.18)

where  $E^{nl-c}$  is the non-local correlation which is the vdW-DF2 functional [80]. The correlation contribution is a linear combination of LDA and PBE correlation functional with a mixing parameter ( $\alpha_c$ ), determining the LDA and PBE correlation functional ratio. The exchange contribution is an empirically fit functional of the GGA exchange functional. The enhancement factor ( $E_m^{GGA-x}$ ) is expanded based on M Legendre polynomial with the expansion coefficient ( $a_m$ ). The parameters of the functional  $a_m$  and  $\alpha_c$  are optimized with respect to a collection of experimental data in such a way that the uncertainty of the calculation can be quantified. Thus, the BEEF-vdw functional can further provide an uncertainty of DFT calculations.

An extension of the approach is using a mixture of the exchange-correlation density functional from LDA or GGA with the exact exchange energy calculated as in a Hartree-Fock method, the hybrid functional. In the Hartree-Fock method, the manybody wave function is approximated by a single Slater determinant, and the total electron energy can be written as follows

$$E_{HF} = T_s + E_H + E_x^{HF} + V_{ext}$$
(2.19)

where  $T_s$  is kinetic energy calculated in the same way as in Equation 2.11,  $E_H$  is the Hartree energy which is the classical electrostatic energy from the charge distribution, and  $E_x^{HF}$  is the exact exchange energy where the self-interaction is canceled out exactly. The limitation of the Hartree-Fock approximation is that the many-body wave function is not well-represented by a single Slater determine; the exact correlation term ( $E_c$ ) is still missing.

The hybrid functional can generally be expressed as follows

$$E_{xc}^{HF} = \alpha E_x^{HF} + (1 - \alpha) E_x^{LDA/GGA} + E_c^{LDA/GGA}$$
(2.20)

where the coefficient  $\alpha$  is either chosen to assume a specific value or is fitted to some properties of the molecule database. An example of this approximation is the B3LYP functional [81] which successfully predicts small molecule properties [75]. While the hybrid functional aim at reducing the self-interaction error by including the exact exchange, computing the exact exchange can be very computationally demanding.

### Chapter 3

# Effect of Local Carbon Structure on the Activity and Stability of Single-atom Electrocatalyse

This chapter is based on the work presented in Paper I as given in Appendix D, covering the main points and results.

#### 3.1 Introduction

A single metal atom supported on nitrogen-doped carbon (M/N/C) has gained much attention as a low-cost ORR catalyst due to its high initial activity, especially Fe/N/C catalysts [82–84]. The FeN<sub>4</sub> site has been proposed as the active site for the Fe/N/C catalysts [9, 31, 85]. Depending on the synthesis approach, which involves pyrolysis at a high temperature of iron, nitrogen, and carbon precursor [14, 86], various local carbon structures around the FeN<sub>4</sub> site. For instance, FeN<sub>4</sub>C<sub>8</sub> [31, 32], FeN<sub>4</sub>C<sub>10</sub> [18, 33], FeN<sub>4</sub>C<sub>12</sub> [9, 18, 33], edge-hosted FeN<sub>4</sub> sites [34] have been proposed as the active site for the ORR. The local carbon structures are also important in the ORR activity [18, 30, 33, 42, 87].

On top of the ORR activity, one issue facing the Fe/N/C catalysts is insufficient stability. The Fe/N/C catalysts tend to degrade quickly under acidic environments [88]. While the degradation mechanism remains elusive. Many possible degradation processes have been proposed, such as carbon surface oxidation [17, 39], demetallation [13, 89], and carbon corrosion [16, 20]. The stability is also affected by the synthesis process [14]. A previous study has shown a higher ORR activity in alkaline media of the Fe/N/C catalysts prepared via the pyrolysis in NH<sub>3</sub> atmosphere than those prepared in inert gas [14]. At the same time, the Fe leaching rate in acid media has also been enhanced for the NH<sub>3</sub> pyrolyzed Fe/N/C catalysts [14]. It has been suggested that the pyrolysis in the flowing of NH<sub>3</sub> promotes basicity and porosity in the Fe/N/C catalysts [14, 29], resulting in enhanced ORR activity [18, 90]. While the demetalla-

tion of the FeN<sub>4</sub> motifs near the micropores could cause the initial activity to lose [29]. Using operando x-ray absorption spectroscopy to study the Fe/N/C catalysts, Li *et al.* [18] have reported two FeN<sub>4</sub> motifs in the Fe/N/C catalysts which are a low spin site; FeN<sub>4</sub>C<sub>10</sub> site and a high spin site; FeN<sub>4</sub>C<sub>12</sub> site. They have found that both sites initially contribute to the ORR activity, but only the FeN<sub>4</sub>C<sub>10</sub> site is durable in acid conditions [18], suggesting a significant role of the local carbon structure on the stability. Besides the Fe/N/C catalyst, the pyrolyzed M/N/C catalysts with M = Mn, Co, and Ru have resulted in a substantial active site for the ORR under acid conditions [12, 19, 91, 92]. Understanding how the local carbon structures and the nature of metal center atoms affect the catalytic activity and stability are thus beneficial for designing active and durable M/N/C catalysts.

While the materials screening for the ORR catalyst have focused on the catalytic activity [93–95], stability under working conditions is also an important criterion [96–99]. The demetallation of the metal atom due to protons attack has been used to determine the stability of the M/N/C catalyst under acid conditions [100–102]. The embedding energy, indicating the bonding strength between the embedded metal atom with the N-doped carbon structure against the cohesion energy of the bulk metal, is often used to represent thermodynamic stability for the M/N/C catalysts [94, 102, 103]. Previous work on the thermodynamic dissolution of the FeN<sub>4</sub> structures on two different local carbon structures toward aqueous Fe<sup>2+</sup> has been studied by Glibin *et al.* [104], suggesting acid stability of the FeN<sub>4</sub> sites. In contrast, Holby *et al.* [27] have indicated the acid instability and likelihood of the dissolution of the FeN<sub>4</sub> site. Also, they have suggested that the FeN<sub>4</sub> site is stable only when OH is adsorbed on the FeN<sub>4</sub> motif. The absolute thermodynamic stability of FeN<sub>4</sub> sites remains controversial [27, 104].

This chapter studies the stability under acid ORR conditions of the  $MN_y$  motif with different local carbon surroundings and metal atoms. The stability is considered based on the tendency of the metal atom to dissolve from the carbon structure. The acid stability descriptor is then determined and used along with the ORR activity descriptor to suggest promising acid-stable and active M/N/C catalysts.

#### 3.2 Structural Models

The model structures of the M/N/C catalyst considered in this chapter are shown in Figure 3.1. The  $MN_4C_{10}$  structure is the  $MN_4$  motif embedded on the bulk graphene. Ten carbon atoms in this structure surround the  $MN_4$  site. The  $MN_4C_Z$  and  $MN_4C_A$  structure are the  $MN_4$  motifs at the zigzag and armchair edge, respectively. The  $MN_4C_{12}$  structure is the  $MN_4$  motif near the micropores with a porphyrin-like structure where twelve carbon atoms surround the  $MN_4$  site. The  $MN_4C_8$  structure is the  $MN_4$  motif bridging between two armchair edges, and eight carbon atoms surround the  $MN_4$  site.

The FeN<sub>4</sub>C<sub>12</sub> structure has been identified by X-ray absorption spectroscopy and proposed as the active site toward the ORR by Zitolo *et al.* [9]. The FeN<sub>4</sub>C<sub>8</sub> site has been proposed as the ORR active site in the Fe/N/C catalyst by several experimental studies [31, 34, 85]. Li *et al.* [18] and Mineva *et al.* [33] have identified both of the FeN<sub>4</sub>C<sub>10</sub> and

 $FeN_4C_{12}$  structure in the Fe/N/C catalysts.

Furthermore, defining a single metal atom coordinated with four neighbor atoms is saturated; two unsaturated sites, which are the  $MN_3C_Z$  and  $MN_3C_A$  site, are included. According to Cheng *et al.* [105], these unsaturated motifs at the graphene edge are thermodynamically favorable under the synthesis environments. The  $MN_3C_{10}$  motifs where the single metal atom coordinated with three nitrogen atoms and one carbon atom embedded on the bulk graphene are also included. The metal atom considered in this chapter is Cr, Mn, Fe, Co, Ni, and Ru. These transition metal elements were considered because of either relatively cheap and abundant 3d transition metals or already being synthesized and showing promising ORR activity in the experiments [12, 19, 91, 92]. For all considered structural models, the unit cell dimensions in the structure plane are 16.9 x 9.8 Å, with variations due to different metal atoms. The vacuum layer added perpendicular to the structure plane is about 15 Å.

**Figure 3.1:** Structural models of the M/N/C catalysts: (a)  $MN_4C_{10}$ , (b)  $MN_4C_{12}$ , (c)  $MN_4C_8$ , (d)  $MN_4C_Z$ , (e)  $MN_4C_A$ , (f)  $MN_3C_{10}$ , (g)  $MN_3C_Z$ , (h)  $MN_3C_A$ . (C = gray, N = blue, H = white, M = orange).

#### 3.3 Computational Details

The calculations in this chapter were performed using spin-polarized density functional theory (DFT) calculations as implemented in the Vienna ab initio simulation package (VASP) [106]. The projector augmented wave (PAW) [107] is used to describe the core electron. A plane-wave basis function with a kinetic energy cutoff of 600 eV defines the valence electron. A Fermi smearing is used with a width of 0.1 eV. The exchange and correlation energy are described using the BEEF-vdW functional [79]. The self-consistent electron density loop is converged to  $10^{-5}$  eV. The structures are prepared using the atomic simulation environments (ASE) package [108]. The lattice relaxation of the single metal atom embedded on the carbon surface is relaxed in a vacuum until all forces are below 0.025 eV/Å. For binding energy calculations, the solvent effect is included during the relaxation. The implicit solvation implemented in VASPsol [109, 110] with a dielectric constant of 80 representing the water medium is used. A dipole correction is used perpendicular to the catalyst surface to decouple the electrostatic

potentials on the two sides of the catalyst. The Brillouin zone is sampled with a  $3 \times 3 \times 1$  Monkhorst Pack k-point mesh [111] for all structural models in Figure 3.1. The calculations are submitted, managed, and received using the MyQueue [112] workflow tool, a python front-end to the job scheduler, in combination with ASE.

It is assumed that the adsorbate on a catalyst surface has only a vibration degree of freedom and only this vibration contributes to its free energy. The free energies (G) of the adsorbate on the catalyst surface are the calculated DFT energy ( $E_{DFT}$ ), including zero point energy (ZPE), vibrational internal energy ( $U_{vib}$ ), and vibrational entropy ( $S_{vib}$ ) of the adsorbate.

$$\begin{split} & G = E_{DFT} + ZPE + U_{vib} - TS_{vib} \\ & ZPE = \sum_{i} \frac{hv_i}{2} \\ & U_{vib} = \sum_{i} \frac{hv_i}{exp(\frac{hv_i}{k_BT}) - 1} \\ & S_{vib} = k_B \sum_{i} \left( \frac{hv_i}{k_BT(exp(\frac{hv_i}{k_BT}) - 1)} - ln\left(1 - exp(-\frac{hv_i}{k_BT})\right) \right) \end{split}$$

where  $v_i$  is the vibration frequencies of the adsorbate approximated as a quantum harmonic oscillation and calculated using a thermochemistry class in the ASE package [108].  $k_B$  is the Boltzmann constant and T is temperature (K). The calculations are considered at T = 298.15 K.

For the gas molecule, the free energy is also considered at T = 298.15 K and pressure = 1 bar. The free energies of the gas molecule is the calculated DFT energy ( $E_{DFT}$ ) corrected by including ZPE, enthalpy (H), and entropy (S): G =  $E_{DFT}$  + ZPE + H – TS. These values (ZPE, H, S) for the gas molecules are taken from the thermochemical database [113]. For O<sub>2</sub> gas molecule, the DFT calculations poorly describe its energy in the gas phase (in the GGA levels) [79]. Thus, the free energy of O<sub>2</sub> gas molecule is calculated in the way to reproduce the experimental free formation energy of liquid water:  $2H_2 + O_2 \rightarrow 2H_2O$  where  $\Delta G_{H_2O} = -4.92$  eV at T = 298.15 K and  $p_{H_2} = p_{O_2} = 1$  bar [114].

According to Christensen's scheme, the energies of  $H_2$ ,  $H_2O$  gas molecule, and binding energy of \*OOH are corrected by 0.09 eV, -0.03 eV, and 0.20 eV, respectively, due to the error in the energy levels of the ORR intermediates specific to the BEEF-vdW functional [115, 116].

The change in free reaction energy with potential ( $U_{SHE}$ ) and pH was calculated using the computational hydrogen electrode (CHE) [117]. By definition of the standard hydrogen electrode (SHE) at 0 V<sub>SHE</sub>, there is an equilibrium between hydrogen molecules in the gas phase with solvated protons and electrons.

$$\mathrm{H^{+}} + \mathrm{e^{-}} \rightleftharpoons \frac{1}{2}\mathrm{H_{2}}$$

The free reaction energy of hydrogen adsorption on the catalyst surface at any

considered potential (U<sub>SHE</sub>) and pH can, for example, be written as

$$\mathrm{H}^{+} + \mathrm{e}^{-} +^{*} \rightarrow^{*} \mathrm{H}$$

$$\Delta G_{*H}(U_{SHE}, pH) = G(^{*}H) - G(^{*}) - \frac{1}{2}G(H_2) + eU_{SHE} + k_B T p H \ln(10)$$
(3.1)

$$=G(^{*}H) - G(^{*}) - \frac{1}{2}G(H_{2}) - \Delta G_{e} - \Delta G_{H}$$
(3.2)

$$=\Delta G_{*H} - \Delta G_e - \Delta G_H \tag{3.3}$$

where \* denotes the adsorbed site on the catalyst surface. G(\*) and G(\*H) are the total free energy of the catalyst surface and the catalyst surface with \*H, respectively.  $\Delta G_H = -k_B TpH \ln(10)$  and  $\Delta G_e = -eU_{SHE}$  where e is the numerical charge of an electron.  $\Delta G_{*H}$  is the free adsorption energy of hydrogen at pH = 0 and U = 0 V<sub>SHE</sub> which can be expressed as follows

$$\Delta G_{*H} = G(*H) - G(*) - \frac{1}{2}G(H_2)$$
(3.4)

#### 3.4 Stability Diagram and Relative Stability

The stability under electrochemical environments is evaluated by considering the likelihood of the metal center atom dissolving from the M/N/C structures. It should be noted that other degradation reactions have also been suggested to cause the instability of the Fe/N/C catalysts, especially in acidic conditions. For instance, the carbon surface oxidation by  $H_2O_2$ -derived radicals. The carbon surface oxidation could lead to an inactive FeN<sub>4</sub> site toward the ORR [17] or the dissolution of the Fe atom [18, 26]. The carbon corrosion has been observed at high potential and can lead to the destruction of the FeN<sub>4</sub> motif [16, 20]. The demetallation has also been proposed to cause a fast activity decay of the Fe/N/C catalyst under acid conditions [29]. These possible degradation reactions could coincide and be interrelated [18]. The ambiguous interaction between each possible degradation reaction makes it difficult to explore them simultaneously. We believe that the relation between the local carbon structure and the metal center atom with the demetallation could provide a better understanding of the degradation of the M/N/C catalysts.

According to a theoretical study on the dissolution reaction of the FeN<sub>4</sub>C<sub>10</sub> site on a bilayer-graphene structure by Holby *et al.* [27], the metal atom (M) leaves the MN<sub>y</sub>C structure, resulting in an aqueous metal ion with a charge x ( $M^{x+}$ ), and the dissolvedmetal carbon cavity (N<sub>y</sub>C). Different degrees of protonation at the N-dangle bonds of the dissolved-metal carbon cavity is possible under acid conditions, resulting in the N<sub>y</sub>CH<sub>n</sub> structure.

$$MN_yC + nH^+ \to M^{x+} + N_yCH_n + (x-n)e^-$$
 (3.5)

The reaction free energy for dissolving the metal atom from the graphene host structure at the potential  $U_{SHE}$  and pH can be expressed as follows [27].

$$\Delta G_{diss} = G(M^{x+}) + G(N_y C H_n) + (x - n)\Delta G_e - G(M N_y C) - n\Delta G_H - \frac{n}{2}G(H_2)$$
(3.6)

where  $G(M^{x+})$  is the free energy of the dissolved metal ion, and it is approximated as

$$G(M^{x+}) = E_M(bulk) + \Delta G_x$$
(3.7)

where  $E_{DFT}$ (bulk) is the total energy per atom of the metal in the bulk structure obtained from the DFT calculations.  $\Delta G_x$  is reaction free energy for the dissolution of the bulk metal, taken from the literature [114, 118, 119] and given in Table A.1. The  $\Delta G_x$  depends on the dissolved metal concentration, and so does the  $\Delta G_{diss}(U_{SHE}, pH)$ . This chapter considers the dissolved metal ion concentration of  $10^{-6}$  M. The dissolved metal ions considered in this chapter are  $Cr^{2+}$ ,  $Cr^{3+}$ ,  $CrOH^{2+}$  for Cr;  $Mn^{2+}$ ,  $Mn^{3+}$  for Mn; Fe<sup>2+</sup>, Fe<sup>3+</sup>, FeOH<sup>2+</sup> for Fe; Co<sup>2+</sup>, Co<sup>3+</sup> for Co; Ni<sup>2+</sup>, Ni<sup>3+</sup> for Ni; and Ru<sup>2+</sup>, Ru<sup>3+</sup> for Ru. The dissolution of the M/N/C catalyst is considered at T = 298.15 K. The N<sub>y</sub>CH<sub>n</sub> structure is the dissolved-metal carbon cavity with n H atoms bonded at the carbon cavity where n = 0 - 4 is considered for the structural model (a)-(f) in Figure 3.1 and n = 0 - 3 is considered for the structural model (g)-(h) in Figure 3.1. The minimum energy structures of the dissolved-metal N<sub>y</sub>C<sub>10</sub>H<sub>n</sub> carbon cavity structure can be found in Figure 3.2 and for other local carbon structures are given in Figure A.1 of Appendix A.

Furthermore, it is assumed that the catalyst surface is in equilibrium with protons, electrons, and liquid water, so oxygen and hydroxyl may be exchanged between the catalyst surface and a reference electrolyte [96].

$$^{*} + H_{2}O \rightleftharpoons^{*} OH + H^{+} + e^{-}$$
(3.8)

$$^{*} + H_{2}O \rightleftharpoons^{*} O + 2H^{+} + 2e^{-}$$
(3.9)

The change in free energy for the forward reactions in Equation 3.8 and 3.9 at the potential  $U_{SHE}$  and pH can be expressed as follows

$$\Delta G_{*OH}(U_{SHE}, pH) = G(^{*}OH) + \frac{1}{2}G(H_2) + \Delta G_H + \Delta G_e - G(^{*}) - G(H_2O)$$
(3.10)

$$\Delta G_{*O}(U_{SHE}, pH) = G(^{*}O) + G(H_2) + 2\Delta G_H + 2\Delta G_e - G(^{*}) - G(H_2O)$$
(3.11)

After all, the dissolution reaction of the M/N/C catalyst in an aqueous environment can generally be expressed as follows

$$^{*}O_{a}H_{b}MN_{y}C + (2a - b + n)H^{+} \rightarrow aH_{2}O + M^{x+} + N_{y}CH_{n} + (x - n - 2a + b)e^{-}$$
 (3.12)

where a, b, n, and x are an integer. Additionally, the relative stability denoted as  $\Delta G_R$  is calculated to represent a thermodynamic driving force toward the dissolution of the catalyst surface [120]. The  $\Delta G_R$  is defined as the free energy difference between the catalyst surface (either with or without the adsorbate) and the most stable dissolved species at each condition. The more positive the relative stability, the less stable the catalyze surface is against the dissolution.

**Figure 3.2:** The minimum energy structures of the dissolved-metal  $N_yC_{10}H_n$  carbon cavity with n = 0 - 4 (a - e): top view (top) and side view (bottom). (C = gray, N = blue, H = white, M = orange).

#### 3.4.1 Stability of the Fe/N/C catalyst

The stability of the Fe/N/C catalysts under electrochemical environments is firstly discussed. Figure 3.3 shows the stability diagram of considered Fe/N/C structures. Only the most stable phase at each condition is shown in the stability diagrams. The stability diagram is divided into different areas with different colors based on the most stable dissolved metal ion and the most stable adsorbate on the metal site. For instance, all  $Fe^{2+} + N_4C_{10}H_n$  phases (where n = 0 - 4) are represented with the same color in the stability diagram. Under the acidic ORR-related condition ( $U \approx 0.6 - 0.8 V_{SHE}$  and pH = 0), the most stable phase is the dissolved Fe ion, suggesting that all considered Fe/N/C structures are prone to leach under the acidic ORR-related condition. At the same potential range in alkaline conditions (pH = 14), either \*OH or \*O adsorbats on the Fe atom. Then, the adsorbate stabilizing the Fe atom becomes the most stable phase for the FeN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>12</sub>, FeN<sub>4</sub>C<sub>A</sub>, FeN<sub>4</sub>C<sub>Z</sub>, and FeN<sub>3</sub>C<sub>10</sub> structure. However, the FeN<sub>4</sub>C<sub>8</sub>, FeN<sub>3</sub>C<sub>Z</sub>, and FeN<sub>3</sub>C<sub>A</sub> structures are still prone to the dissolution under the alkaline conditions.

In Figure 3.3, the  $\Delta G_R$  at pH = 0 of the Fe/N/C structure is plotted as a function of potential. The most stable dissolved species used as the reference for  $\Delta G_R$  are superimposed as horizontal bars at the bottom. For the bare Fe/N/C structure at U = 0.8 V<sub>SHE</sub> and pH = 0, the following order of  $\Delta G_R$  is found: FeN<sub>4</sub>C<sub>A</sub> < FeN<sub>4</sub>C<sub>Z</sub> < FeN<sub>4</sub>C<sub>10</sub> < FeN<sub>3</sub>C<sub>10</sub> < FeN<sub>4</sub>C<sub>12</sub> < FeN<sub>3</sub>C<sub>Z</sub> < FeN<sub>4</sub>C<sub>8</sub> < FeN<sub>3</sub>C<sub>A</sub>, suggesting that the stability against the dissolution decreases from the FeN<sub>4</sub>C<sub>A</sub> to FeN<sub>3</sub>C<sub>A</sub>. The formation of \*OH and \*O on the Fe/N/C structure reduces the thermodynamic driving force toward the dissolution. Considering the most stable surface at U = 0.8 V<sub>SHE</sub> and pH = 0, the following order of  $\Delta G_R$  is found: \*O-FeN<sub>4</sub>C<sub>A</sub> < \*O-FeN<sub>4</sub>C<sub>Z</sub> < \*O-FeN<sub>4</sub>C<sub>10</sub> < \*OH-FeN<sub>3</sub>C<sub>10</sub> < \*O-FeN<sub>4</sub>C<sub>2</sub> < \*O-FeN<sub>4</sub>C<sub>8</sub>.

At 0.2 - 0.9 V<sub>SHE</sub> and pH = 0; the thermodynamic driving force toward the dissolution of the FeN<sub>4</sub>C<sub>12</sub> site is about 0.70 eV greater than that of the FeN<sub>4</sub>C<sub>10</sub> site, suggesting that the FeN<sub>4</sub>C<sub>10</sub> site is more stable than FeN<sub>4</sub>C<sub>12</sub> site under acid condition, in line with the experiments by Li *et al.* [18]. The horizontal bars in Figure 3.3 indicate

the most stable dissolved species at each condition. The dissolution reactions change with the working condition (U<sub>SHE</sub> and pH) and the local carbon structures. For the FeN<sub>4</sub>C<sub>8</sub>, FeN<sub>3</sub>C<sub>A</sub>, and FeN<sub>3</sub>C<sub>Z</sub> structure, the dissolution reaction results in 0-1 proton transferred to the carbon cavity, while 1 - 3 protons are transferred to the carbon cavity of the other structures. The protonation reaction at the carbon cavity is thermodynamically favorable for the N<sub>4</sub>C<sub>12</sub>, N<sub>3</sub>C<sub>10</sub>, N<sub>4</sub>C<sub>Z</sub>, N<sub>4</sub>C<sub>A</sub>, N<sub>4</sub>C<sub>10</sub>, and N<sub>3</sub>C<sub>Z</sub> dissolved-metal carbon cavity, but it is thermodynamically unfavorable for the N<sub>3</sub>C<sub>A</sub> and N<sub>4</sub>C<sub>8</sub> structure, see Figure A.2 in Appendix A.

**Figure 3.3:** (top) Stability diagram and (bottom)  $\Delta G_R$  at pH = 0 of the considered Fe/N/C structures without and with the adsorbate (Fe, \*OH-Fe, and \*O-Fe): (a) FeN<sub>4</sub>C<sub>10</sub>, (b) FeN<sub>4</sub>C<sub>12</sub>, (c) FeN<sub>4</sub>C<sub>8</sub>, (d) FeN<sub>4</sub>C<sub>2</sub>, (e) FeN<sub>4</sub>C<sub>A</sub>, (f) FeN<sub>3</sub>C<sub>10</sub>, (g) FeN<sub>3</sub>C<sub>Z</sub>, and (h) FeN<sub>3</sub>C<sub>A</sub>.

**Figure 3.4:** (a) Scheme illustration of a possible dissolution mechanism of FeN<sub>4</sub>C<sub>10</sub> structure. (C = gray, N = blue, H = white, M = orange), (b) Free energy diagram corresponding to the possible dissolution mechanisms of FeN<sub>4</sub>C<sub>10</sub> structure with up to 3H<sup>+</sup> at U = 0.8 V<sub>SHE</sub> and pH = 0, (c)  $\Delta$ G<sub>protonate</sub> at the atoms surrounding the Fe atom in considered Fe/N/C structures as a function of number of H<sup>+</sup> at pH = 0 and U = 0.8 V<sub>SHE</sub>, (d)  $\Delta$ G<sub>dem</sub> for the Fe atom from the considered Fe/N/C structures to dissolved Fe<sup>3+</sup> ion as a function of number of H<sup>+</sup> at pH = 0 and U = 0.8 V<sub>SHE</sub>. Figure (c-d) uses the same markers and colors.

From a thermodynamic perspective, whether the protonation occurs before or after the demetallation leads to the same overall dissolution reaction and relative stability as shown in Figure 3.4 (a-b). However, the proton transfers might not necessarily affect the kinetic dissolution rate if they occur late in the exothermic process. Therefore, the protonation reaction occurring at the atoms surrounding the Fe atom, followed by the demetallation, is considered. The reaction free energies for the protonation at the atoms coordinated with the Fe atom ( $\Delta G_{\text{protonate}}$ ) and the followed demetallation of the Fe atom to dissolved Fe ion ( $G_{\text{dem}}$ ) are calculated as the following equations and shown in Figure 3.4 (c-d).

$$\begin{split} \mathrm{FeN}_y\mathrm{C} + \mathrm{n}(\mathrm{H}^+ + \mathrm{e}^-) &\to \mathrm{FeN}_y\mathrm{CH}_n\\ & \mathrm{FeN}_y\mathrm{CH}_n \to \mathrm{Fe}^{\mathrm{X}+} + \mathrm{N}_y\mathrm{CH}_n + \mathrm{Xe}^- \end{split}$$

$$\Delta G_{\text{protonate}}(U_{\text{SHE}}, pH) = G(FeN_vCH_n) - G(FeN_vC) - n\Delta G_H - n\Delta G_e$$
(3.13)

$$\Delta G_{dem}(U_{SHE}) = G(N_V CH_n) + G(Fe^{+x}) + x\Delta G_e - G(FeN_V CH_n)$$
(3.14)

where G(FeN<sub>y</sub>CH<sub>n</sub>) is the total free energy of the FeN<sub>y</sub>C with n H atoms at the atoms coordinated with the Fe atom. The protonation at the atoms coordinated with the Fe atom is an endothermic process and becomes more thermodynamically unfavorable as the potential increases or more protons are added. On the other hand, the demetallation becomes more favorable after the atoms coordinated with the Fe atom are protonated and become more thermodynamically favorable as the potential increases or more protons are added. At the potential U = 0.8 V<sub>SHE</sub> and pH = 0, the reaction free energy for the protonation at the atoms surrounding the Fe atom is likely to increase from the FeN<sub>4</sub>C<sub>Z</sub> < FeN<sub>4</sub>C<sub>12</sub>  $\approx$  FeN<sub>3</sub>C<sub>10</sub>  $\approx$  FeN<sub>3</sub>C<sub>A</sub> < FeN<sub>3</sub>C<sub>Z</sub>  $\approx$  FeN<sub>4</sub>C<sub>A</sub> < FeN<sub>4</sub>C<sub>10</sub> < FeN<sub>4</sub>C<sub>8</sub>. After the protonation, the reaction free energy for the demetallation is likely to increase from the FeN<sub>4</sub>C<sub>8</sub>  $\approx$  FeN<sub>3</sub>C<sub>A</sub> < FeN<sub>3</sub>C<sub>Z</sub> < FeN<sub>4</sub>C<sub>10</sub> < FeN<sub>4</sub>C<sub>A</sub>  $\approx$  FeN<sub>3</sub>C<sub>10</sub>  $\approx$  FeN<sub>3</sub>C<sub>2</sub> < FeN<sub>4</sub>C<sub>10</sub> < FeN<sub></sub>

It is found that the Fe atom in the FeN<sub>4</sub>C<sub>8</sub>, FeN<sub>3</sub>C<sub>Z</sub>, and FeN<sub>3</sub>C<sub>A</sub> structure bond weakly with the carbon structure, compared to the others. As a result, the Fe atom in these structures can easily leave the carbon structure, even without the protonation at the atoms around the Fe atom. A previous DFT study by Tan *et al.* [26] also reported the weak bonding between the single Fe atom with the carbon structure in the FeN<sub>4</sub>C<sub>8</sub> structure and suggested the thermodynamic instability of FeN<sub>4</sub>C<sub>8</sub> structure.

The protonation at the atoms surrounding the Fe atom in the considered Fe/N/C structures weakens the bond between the Fe atom and the carbon host structure, making the followed demetallation more facile. Thus, the basicity of neighboring atoms and the bonding strength between the single Fe atom and the carbon host structure contribute to the stability of the Fe/N/C catalyst under acidic conditions. The FeN<sub>4</sub>C<sub>12</sub> has a strong bonding between the Fe atom and the carbon host structure, but the nitrogen atoms around the Fe metal site are vulnerable to proton. While the nitrogen ligand in the FeN<sub>4</sub>C<sub>8</sub> structure can resist the action of protons in an acid solution but the bonding between the Fe atom and the FeN<sub>4</sub>C<sub>10</sub> structure under the same acid conditions. It should be noted that the stability calculation is here analyzed from thermodynamic trends, whereas the kinetic activation energy determines the rate of metal leaching. Therefore, a complete stability descriptor would require kinetic analysis of the dissolution mechanism.

According to the previous study on the dissolution of the FeN<sub>4</sub>C<sub>10</sub> motif on the bilayer-graphene by Holby *et al.* [27], the unit cell size and the graphene underlayer can influence the calculated stability. In order to assess the sensitivity to these choices, the FeN<sub>4</sub>C structures with a bigger unit cell are given in Figure A.3 of Appendix A. It can be seen that there is an influence of the size of the unit cell on the calculated stability. The change in the unit cell size leads to the variation in the dissolution potential toward the dissolved Fe<sup>2+</sup> ion (n = a = b = 0 and x = 2 in Equation 3.12) about 0.08 V<sub>SHE</sub>. However, the same trend in the dissolution potential order is obtained from both of the unit cell size which is FeN<sub>4</sub>C<sub>8</sub> (-1.09, -0.98) < FeN<sub>4</sub>C<sub>10</sub> (0.35, 0.27) < FeN<sub>4</sub>C<sub>A</sub> (0.65, 0.52)

< FeN<sub>4</sub>C<sub>12</sub> (0.79, 0.73) < FeN<sub>4</sub>C<sub>Z</sub> (0.94, 0.97). The numbers in the parentheses are the dissolution potential to Fe<sup>+2</sup> in V<sub>RHE</sub> unit obtained from the unite cells in Figure 3.1 and bigger unit cells, respectively. The dissolution potential order here agrees with the trend reported by Tan *et al.* [26]. The variation in adsorption free energy of \*O and \*OH on the Fe atom due to the change in the unit cell size is about 0.08 and 0.07 eV, respectively. The  $\Delta G_R$  trend at U = 0.8 V<sub>SHE</sub> and pH = 0 obtained from the bigger unit cell is \*O–FeN<sub>4</sub>C<sub>A</sub> < \*O – FeN<sub>4</sub>C<sub>10</sub> < \*O – FeN<sub>4</sub>C<sub>Z</sub> < \*O – FeN<sub>4</sub>C<sub>12</sub> < \*OH – FeN<sub>4</sub>C<sub>8</sub>, largely agree with results obtained from the unit cells in Figure 3.1. The effect of graphene underlayer on the dissolution potential has been reported by Holby *et al.* [27], causing a higher dissolution potential (about 0.08 V<sub>RHE</sub>) compared to that on the graphene monolayer. The difference in local atomic structures around the FeN<sub>4</sub> motif; however, cause the variation in the dissolution potential to about 0.30 - 1.43 V<sub>RHE</sub>, greater than the effect of the graphene underlayer. Thus, the FeN<sub>4</sub> motif embedded on the graphene monolayer is expected to be able to capture the effect of the local carbon structure on the stability.

Up to this point, the calculations use the implicit solvent. The explicit solvent effects on the catalyst surface and adsorbates are investigated in the following section. A single water layer containing 16 H<sub>2</sub>O molecules is applied for the catalyst surface without any adsorbate, and a single water layer containing 15 H<sub>2</sub>O molecules surrounding the intermediate \*O, \*OH, or \*OOH) is applied for the catalyst surface with the adsorbate. The explicit water layer is applied on only one side of the catalyst surface, the same side as the adsorbate. According to a previous DFT study by Svane *et al.* [121], there is no further stabilization effect when adding explicit water layers on both sides of the CoN<sub>4</sub>C<sub>12</sub> structure compared to the explicit water layer on only one side [121].

In order to find the minimum energy structure of the explicit water layer, the minima hopping algorithm implemented in the ASE package [122–124] is used. The explicit water layer, either with or without adsorbate, is placed on the FeN<sub>4</sub>C<sub>10</sub> structure. The minima hopping algorithm is performed to find at least 30 local minima with the maximum force on each atom less than 0.05 eV/Å. Then, the lowest energy structure and the structures within 0.1 eV of the lowest structure are relaxed further until the maximum force on each atom less than 0.025 eV/Å. The minimum energy structure is then used for the binding energy and stability calculations. The minimum energy structures of the explicit water layer on the FeN<sub>4</sub>C<sub>10</sub> structure without and with intermediate obtained from the minima hopping algorithm are shown in Figure 3.5.

The adsorption energy of the ORR intermediates in the explicit solvation is calculated by replacing one water molecule from the explicit water layer with the adsorbate [125]. This way, the total number of adsorbate and water molecules is kept constant for all situations. The energy of one water molecule in the explicit water layer is assumed to be the average energy of water molecules in the explicit water layer and can be calculated as follows

$$E^{WL}(H_2O) = \frac{1}{16} \left( E(*16H_2O) - E(*) \right)$$
(3.15)

where  $E(*16H_2O)$  and E(\*) are the total energy of the catalyst surface with and without the explicit water layer, respectively. The adsorption energy of \*O on the metal site
with the explicit water layer (at  $U_{SHE} = 0$  and pH = 0) can, for the example given by

$${}^{*}16H_{2}O + H_{2}O \rightarrow {}^{*}O | {}^{*}15H_{2}O + H_{2}$$
  
$$\Delta G_{*O}^{WL} = G({}^{*}O | {}^{*}15H_{2}O) + G(H_{2}) - G({}^{*}15H_{2}O) - G(H_{2}O)$$
(3.16)

where  $G(*O|*15H_2O)$  is the total free energy of the catalyst surface with the \*O adsorbate on the metal site and 15 explicit water molecules around the \*O adsorbate. One water molecule in the single water layer is removed to be placed by the \*O adsorbate, so  $G(*15H_2O)$  is calculated as

$$E(*15H_2O) = E(*16H_2O) - E^{WL}(H_2O)$$
(3.17)

It should be noted that only the vibration of the reaction intermediate X is considered and contributes to the  $G(*X|*15H_2O)$ , where X = O, OH, and OOH.

**Figure 3.5:** The minimum energy structures of the explicit water layer on the  $\text{FeN}_4C_{10}$  structure obtained from the minimahopping algorithm: (a) \*16H<sub>2</sub>O, (b) \*O|\*15H<sub>2</sub>O, (c) \*OH|\*15H<sub>2</sub>O, (d) \*OOH|\*15H<sub>2</sub>O. (C = gray, N = blue, H = white, O = red, M = orange).

For simplicity, the same single water layer obtained with the FeN<sub>4</sub>C<sub>10</sub> structure is also used for other considered Fe/N/C structures. The explicit solvation effect is investigated on the FeN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>12</sub>, FeN<sub>4</sub>C<sub>8</sub> and FeN<sub>4</sub>C<sub>Z</sub> structure as shown in Figure A.4 of Appendix A. The water-to-adsorbate ratios are the same for all considered Fe/N/C structures. However, it should be noted that the explicit water molecules configuration on other considered Fe/N/C structures can be different from that of the FeN<sub>4</sub>C<sub>10</sub> structure, especially for the edged hosted FeN<sub>4</sub> structures. In order to get a more accurate explicit solvation model, the minimahopping algorithm or the ab initio molecular dynamics simulation might be needed for each specific Fe/N/C structure. The trend in the dissolution potential order is likely to be FeN<sub>4</sub>C<sub>8</sub> (-1.09, -1.02, -0.93) < FeN<sub>4</sub>C<sub>10</sub> (0.35, 0.47, 0.46) < FeN<sub>4</sub>C<sub>12</sub> (0.79, 1.08, 0.95) < FeN<sub>4</sub>C<sub>Z</sub> (0.94, 1.04, 0.84). The numbers in the parentheses are the dissolution potential to Fe<sup>+2</sup> in V<sub>RHE</sub> unit obtained from each structure with implicit, vacuum, and explicit solvation, respectively. The dissolution potentials toward Fe<sup>2+</sup> with the implicit solvation are about 0.14 V<sub>RHE</sub>, lower than those in a vacuum. With explicit solvation, the dissolution potential is close to those in a vacuum, with a variation of about 0.06  $V_{RHE}$ . The except is for the FeN<sub>4</sub>C<sub>Z</sub> structure. There is about 0.20  $V_{RHE}$  difference in the dissolution potential obtained in a vacuum and explicit solvation. The difference here could be due to the distortion of the structure. With the explicit water layer, the nitrogen atoms of the N<sub>4</sub>C<sub>Z</sub>H<sub>0</sub> structure are distorted out of the plane, see Figure A.4 (d) in Appendix A. While these nitrogen atoms are still on the plane for the other solvations.

With the explicit solvation,  $\Delta G(*O)$  and  $\Delta G(*OH)$  on the Fe atom is stabilized (relative to vacuum) about 0.41 eV and 0.22 eV, respectively. With the implicit solvation, a similar magnitude of the stabilization energy (relative to vacuum) is found, which is 0.30 eV and 0.22 eV for  $\Delta G(*O)$  and  $\Delta G(*OH)$ , respectively. For the the considered FeN<sub>4</sub>C structures with the explicit solvation, the trend of  $\Delta G_R$  at U = 0.8 V<sub>SHE</sub> and pH = 0 is found to be  $*O-FeN_4C_Z < *O-FeN_4C_{10} < *O-FeN_4C_{12} < *O-FeN_4C_8$ . Meanwhile, it is found to be  $*OH-FeN_4C_Z < *OH-FeN_4C_{10} < *OH-FeN_4C_{12} < *OH-FeN_4C_8$  in vacuum. The difference in  $\Delta G_R$  is mainly due to the different stabilization on the adsorbate via the different solvations. It is seen that there is an influence of solvation on the stability calculations. The implicit solvation, which stabilizes about the same as the explicit solvation, is used in the further calculations to avoid structural distortion.

#### 3.4.2 Stability of the M/N/C catalyst

The thermodynamic stability analysis is extended to other transition metal elements (M = Cr, Mn, Co, Ni, and Ru). The stability diagrams of these M/N/C structures are given in Figure A.5 - A.9. Under the ORR-related condition (U  $\approx$  0.6 - 0.8 V<sub>SHE</sub> and pH = 0), all considered M/N/C structures are likely to dissolve, so the considered M/N/C structures are unstable under the acidic ORR condition. Figure 3.6 (a) shows  $\Delta G_R$  of the bare M/N/C structures at U = 0.8 V<sub>SHE</sub> and pH = 0. Regardless of the metal atom, the MN<sub>4</sub>C<sub>8</sub>, MN<sub>3</sub>C<sub>2</sub>, and MN<sub>3</sub>C<sub>A</sub> structures are less stable than the others. On the other hand, the MN<sub>4</sub>C<sub>A</sub> structure is likely to be the most stable structure against dissolution. The general trend in the thermodynamic driving force toward the dissolution of the bare M/N/C structure at U = 0.8 V<sub>SHE</sub> and pH = 0 is Cr > Mn > Ru > Fe > Co > Ni. In order to understand the stability trend among different metal elements, the dissolution reaction of the bare M/N/C surfaces without the protonation at the carbon cavity is considered.

The energy of the metal atom in the M/N/C structure against forming a bulk metal is investigated as follows

$$\Delta E_{\text{bulk}} = E_{\text{DFT}}(\text{bulk}) + E(N_{\text{v}}\text{CH}_{0}) - E(\text{FeN}_{\text{v}}\text{C})$$
(3.18)

Figure 3.6 (c) shows  $\Delta E_{bulk}$  for considered metal atom on different considered local carbon structures. Among considered structures, the metal atom in the MN<sub>4</sub>C<sub>8</sub>, MN<sub>3</sub>C<sub>Z</sub>, and MN<sub>3</sub>C<sub>A</sub> structure is unstable, preferring the bulk metal over the M/N/C structure. Furthermore, the following equation considers the energy for oxidizing the

metal atom at a working potential ( $U = 0.8 V_{SHE}$ ).

$$\Delta E_{\text{oxidize}} = G(M^{X+}) - x\Delta G_e - E_{\text{DFT}}(\text{bulk})$$
(3.19)

where  $G(M^{x+})$  is considered to be the free energy of the most stable dissolved metal ion at U = 0.8 V<sub>SHE</sub> for each metal elements, thus x = 2 for Co, Ni; x = 3 for Cr, Mn, Fe, and Ru. Figure 3.6 (d) shows  $\Delta E_{oxidize}$  for considered metal elements. The oxidization energy increases from Cr < Mn < Fe < Co < Ni. For the 3d metals, the metal oxidation energy plays an important role in the dissolution reaction, causing a significant difference in the acid stability among the 3d elements. The stability of the bare M/N/C structures toward the dissolution increases from Cr < Mn < Fe < Co < Ni, following the oxidation trend. For Ru (4d element), the bond strength between the single Ru atom and the carbon structure is weaker than other metal elements in the same carbon structure. However, the Ru atom is more difficult to oxidize. Overall, the stability of the bare Ru/N/C structure is likely to be between the Mn/N/C and Fe/N/C structures.

**Figure 3.6:**  $\Delta G_R$  at U = 0.8 V<sub>SHE</sub> and pH = 0 of (a) the bare M/N/C structures and (b) the most stable phase (at U = 0.8 V<sub>SHE</sub> and pH = 0) of the M/N/C structures. The marker for the surface: M = circle, \*OH-M = square, \*O-M = triangle. (c)  $\Delta E_{bulk}$  of M/N/C structures. (d)  $\Delta E_{oxidized}$  for metal elements at U = 0.8 V<sub>SHE</sub>

The formation of \*O and \*OH is thermodynamically favorable on the Cr, Mn, Ru, and Fe atoms on most considered structures at U = 0.8 V<sub>SHE</sub> and pH = 0 and results in increased stability against the dissolution. Under the same conditions, the bare metal site is the most stable phase of the considered Co/N/C and Ni/N/C structures. Figure 3.6 (b) shows  $\Delta G_R$  for the most stable phase of considered M/N/C structures at pH = 0 and U = 0.8 V<sub>SHE</sub>. In general, the MN<sub>4</sub>C<sub>10</sub> or MN<sub>3</sub>C<sub>10</sub> sites, embedding on the bulk graphene, and the MN<sub>4</sub> site on the graphene edge (MN<sub>4</sub>C<sub>2</sub>, MN<sub>4</sub>C<sub>8</sub>) and the unsaturated MN<sub>3</sub> site at the graphene edge (MN<sub>3</sub>C<sub>Z</sub>, MN<sub>3</sub>C<sub>A</sub>). Still, the stability of the most stable phase of the M/N/C structure toward the dissolution is likely to increase from Cr < Mn < Fe < Ru < Co < Ni.

A previous study by Singh *et al.* [120] has suggested that the materials with relative stability up to 0.5 eV/atom can persist in electrochemical environments due to insufficient energy gained via dissociation to the Pourbaix stable domains to overcome the energy barrier for the dissociation reaction. Thus, according to our study, the Fe, Co, Ru, and Ni atom in the  $MN_4C_{10}$ ,  $MN_4C_Z$  and  $MN_4C_A$  structure can well be kinetically stable under acid conditions. The Ru atom in the  $MN_4C_Z$  and  $MN_4C_A$  structure, and the Ni atom in the  $MN_4C_A$  structure are the most promising stable structure under the acid conditions as the thermodynamic driving force toward the dissolution is less than about 0.2 eV. These results align with the experiment by Cao *et al.*, which found that the dissolution rate of the Ru atom was less than 5% when the Ru/N/C catalyst was operated in the acid solution for 30 hours at the applied potential of 1.5 V<sub>RHE</sub> [40].

Meanwhile, the Cr and Mn atoms in most considered M/N/C structures have a considerable driving force toward dissolution (> 0.5 eV), so these catalysts are likely to be unstable in the acid condition. According to the experimental study by Sahraie *et al.* [126], the Mn/N/C catalysts lose the ORR activity more than the Fe/N/C catalyst during the stability test (0.5 - 1.3 V<sub>RHE</sub>) in both acid and alkaline electrolyte.

Additionally, the previous experimental study by Xie et al. [19] has reported that in the acid conditions where the potential is cycled between  $0.5 - 1.0 V_{RHE}$ , the Co/N/C catalyst has significantly lower metal leaching compared to the Fe/N/C catalyst, especially when purged with O2. According to our calculations, the thermodynamic driving force toward the dissolution of the bare Fe/N/C structures is about 0.56 eV higher than that of the Co/N/C structures under acid conditions. When either the \*OH or \*O adsorbs on the metal site, the relative stability of the most stable phase of both metal atoms is comparable. The experimental study by Xie *et al.* has also reported lower carbon oxidation on the Co/N/C catalyze surface than on the Fe/N/C catalyst surface [19]. While the carbon surface oxidation has been proposed to be able to inactivate the M/N/C catalyst toward the ORR [17] and trigger the demetallation [26]. Thus, Xie et al. have suggested the reasons for the enhanced durability of the Co/N/C catalyst under the acid conditions compared to the Fe/N/C catalyst are because the degradation via the chemical oxidation on the catalyst surface and the active site demetallation is alleviated [19]. The effect of carbon surface oxidation on the stability of the M/N/C catalysts would undoubtedly be interesting to study.

The formation of \*O and \*OH on carbon atoms adjacent to the FeN<sub>4</sub> center in the FeN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>12</sub> and FeN<sub>4</sub>C<sub>Z</sub> structure is investigated. The catalyst surface is assumed to be in equilibrium with protons, electrons, and liquid water. As given in Figure A.10 of Appendix A, the formation of \*O or \*OH on the adjacent carbons is not thermodynamically favored at pH = 0 in the potential range of 0 - 1.2 V<sub>SHE</sub>. In previous studies by Zhang *et al.* [91] and Jung *et al.* [127], the formation energies of \*O from water on various carbon atoms near the CoN<sub>4</sub>C<sub>10</sub> structure is higher than 2.8 eV, also suggesting thermodynamically unfavorable to form \*O on the adjacent carbon atoms. However, the carbon surface oxidation could occur via other reactions such as the dissociation of H<sub>2</sub>O<sub>2</sub> [17] or \*OOH [26].

Furthermore, the effect of the nearby \*O and \*OH on the dissolution reaction of the  $FeN_4C_{10}$  structure is investigated as given in Figure A.11 (a-c). The Fe-N bonding in the FeN<sub>4</sub>C<sub>10</sub> structure and the H-N bonding in the N<sub>4</sub>C<sub>10</sub> structure is strengthened (about 0.49 eV, and 0.86 eV, respectively) by a nearby \*OH. Thus, breaking the Fe-N bonds requires more energy. However, the H binding with the carbon cavity is also more energetically favorable. The dissolution reaction of the bare FeN<sub>4</sub>C<sub>10</sub> structure with nearby \*OH at U = 0.8 V<sub>SHE</sub> and pH = 0 occurs via the n = 1 reaction and  $\Delta G_R$  is about 0.37 eV higher than that of the clean surface. With the nearby \*O on the FeN<sub>4</sub>C<sub>10</sub> structure, the Fe-N and H-N bindings become weaker compared to the clean surface (about 0.78 eV and 0.39 eV, respectively). The dissolution reaction of the bare  $FeN_4C_{10}$ structure with nearby \*O at U =  $0.8 V_{SHE}$ , pH = 0 occurs occur via the n = 0 reaction and  $\Delta G_R$  is about 0.66 eV higher than that of the clean surface. It can be seen that the oxygen functional groups near the Fe site can affect the stability. While, the formation of these oxygen functional groups (\*O, \*OH) could depend on the carbon structures [18, 26]. Also, the nature of the metal atom is important to be considered in the formation of oxygen functional groups via the dissociation of  $H_2O_2$  [17] or \*OOH[19, 92]. Such an investigation would certainly be interesting but it is beyond the scope of the present study.

In addition to the oxygen functional groups on the carbon surface, the carbon surface could contain additional N heteroatoms. The graphitic N atoms surrounding the FeN<sub>4</sub> site have been reported to improve ORR activity in alkaline, and acidic electrolytes [128]. The stability diagrams of the FeN<sub>4</sub>C<sub>10</sub> with two graphitic N atoms are given in Figure A.11 (d-e). It can be seen that the graphitic N atoms near the FeN<sub>4</sub> center also affect the stability. The thermodynamic driving force toward the dissolution of the bare Fe site in both considered Fe/N/C structures with additional graphitic N atoms at pH = 0, U = 0.8 V<sub>SHE</sub> is increased compared to the clean surfaces. However, only some specific configurations of the graphitic N atoms are considered here. Different configurations could affect stability so does the activity [128]. The effect of N atoms or other hetero atoms on the carbon surface on the stability and activity of the Fe/N/C catalyst would certainly be interesting but is out of the scope of this present study.

Additionally, the anion-selective adsorption on the active site on the M/N/C catalyst can occur. It has been reported that various anions from the electrolytes are competitive with the adsorption of water on the  $MN_4C_{12}$  structure (M = Fe, Cr, Mn, and Co) and can promote the ORR activity [93, 129, 130]. The effect of the electrolyte anion adsorption on the stability of the single atom catalyst will be discussed in Chapter 4.

#### 3.5 ORR Activity

The ORR is considered to proceed through a four-electron associative pathway, and the metal site is considered the active site. A previous theoretical study by Liu *et al.* [30] has reported that the activation energy for the direct  $O_2$  dissociation reaction is higher for the OOH dissociation reaction on the FeN<sub>4</sub>C<sub>10</sub>, FeN<sub>4</sub>C<sub>12</sub>, and FeN<sub>4</sub>C<sub>8</sub> structure; thus, the OOH dissociation path is kinetically more feasible than the  $O_2$  dissociation pathway. It is assumed that the ORR will proceed without hindrance if the reaction free energy of all elementary steps is negative, assuming no kinetic barrier for each step. The four elementary steps can be expressed as

$$O_2 + H^+ + e^- + * \rightarrow * OOH$$
  
\*OOH + H<sup>+</sup> + e<sup>-</sup>  $\rightarrow * O + H_2O$   
\*O + H<sup>+</sup> + e<sup>-</sup>  $\rightarrow * OH$   
\*OH + H<sup>+</sup> + e<sup>-</sup>  $\rightarrow * + H_2O$ 

At pH = 0 and U = 0  $V_{SHE}$ , the reaction free energy of the consecutive step along the ORR can be expressed as follows

$$\Delta G_1 = \Delta G_{*OOH} + \Delta G_{H_2O} \tag{3.20}$$

$$\Delta G_2 = \Delta G_{*O} - \Delta G_{*OOH} \tag{3.21}$$

$$\Delta G_3 = \Delta G_{*OH} - \Delta G_{*O} \tag{3.22}$$

$$\Delta G_4 = -\Delta G_{*OH} \tag{3.23}$$

where  $\Delta G_{*OOH}$ ,  $\Delta G_{*O}$  and  $\Delta G_{*OH}$  are the adsorption free energy of \*OOH, \*O and \*OH on the metal site at pH = 0 and U = 0 V<sub>SHE</sub>, which are defined relative to water.

$$\Delta G_{*OOH} = G(^*OOH) + \frac{3}{2}G(H_2) - G(^*) - 2G(H_2O)$$
(3.24)

$$\Delta G_{*O} = G(*O) + G(H_2) - G(*) - G(H_2O)$$
(3.25)

$$\Delta G_{*OH} = G(^{*}OH) + \frac{1}{2}G(H_2) - G(^{*}) - G(H_2O)$$
(3.26)

At any considered pH and  $U_{SHE}$ , the reaction free energy of the consecutive step along the ORR can be expressed as follows

$$\Delta G_{i}(U_{SHE}, pH) = \Delta G_{i} - \Delta G_{H} - \Delta G_{e}$$
(3.27)

where  $\Delta G_i$  (i = 1 - 4) is the reaction free energy of the consecutive step along the ORR at pH = 0 and U = 0 V<sub>SHE</sub>. An initial chemical step of O<sub>2</sub> adsorption is not explicitly considered. A previous theoretical study by Svane *et al.* [93] has reported that the

 $O_2$  adsorption on the bare metal sites in the MN<sub>4</sub>C<sub>12</sub> structure is exothermic ( $\Delta H < 0$  eV), ranging from -0.57 eV on the CrN<sub>4</sub>C<sub>12</sub> to 0.03 eV on the FeN<sub>4</sub>C<sub>12</sub>. Furthermore, a previous theoretical study by Liu *et al.* [30] has predicted that the adsorption energy for  $O_2$  is -0.63 eV on the FeN<sub>4</sub>C<sub>12</sub> structure, -0.95 eV on the FeN<sub>4</sub>C<sub>10</sub> structure and -1.67 eV on the FeN<sub>4</sub>C<sub>8</sub> structure. These suggest that the O<sub>2</sub> adsorption has surmountable barriers at room temperature.

The thermodynamic limiting potential  $(U_L)$  is defined as the highest potential at which all elementary steps are downhill in free energy. The elementary step with the most positive free energy at U = 0 V<sub>SHE</sub> is the potential determining step which firstly becomes uphill in free energy when the potential increases. The U<sub>L</sub> and overpotential can be calculated as follows

$$U_{L} = -\max\{\Delta G_{1}, \Delta G_{2}, \Delta G_{3}, \Delta G_{4}\}/e$$
(3.28)

overpotential = 
$$U_{eq} - U_L$$
 (3.29)

The equilibrium potential of the ORR is  $U_{eq} = 1.23$  V, corresponding to the situation where the reaction has the maximum potential allowed by thermodynamics. Therefore,  $U_L = U_{eq}$  for the ideal catalyst. However, the  $U_L$  is generally lower than  $U_{eq}$ , and the overpotential represents the additional potential needed to proceed with the ORR. The larger the overpotential, the lower activity of the catalyst.

Depending on the local carbon structures and the metal atom, the formation of \*OH and \*O on the metal site can be thermodynamically favorable. The \*OH or \*O binds strongly on the metal site in the  $MN_4C_8$ ,  $MN_3C_Z$ , and  $MN_3C_A$  structures compared to the others. The metal site in these structures is likely to be occupied by \*OH or \*O under the ORR-related condition. Due to the metal site embedded on the two-dimensional nitrogen-doped carbon surface, two sides of the metal atom can expose to the electrolyte. The metal site already occupied by one \*OH or \*O would still have the other side available for the ORR to proceed. The adsorbate ligand can modify the electronic states of the metal site, affecting the binding of the second adsorbate on the other side [10, 93, 121, 131, 132]. The ORR activity of the M/N/C structures, including the adsorbate ligand (OH or O), is considered in the following section. The adsorbate ligand is the most stable adsorbate on the metal site at U = 0.8 V<sub>SHE</sub> and pH = 0, a representative condition at which the PEMFC would be operated.

There is a scaling relation between  $\Delta G(^{*}OH)$  and  $\Delta G(^{*}OOH)$  on considered structures including ligand on the back side of the metal atom (with the mean absolute erre (MEA) of 0.11 eV). This scaling relation is known for metal and oxide surfaces [133].

$$\Delta G(^{*}OOH) = \Delta G(^{*}OH) + 3.23$$
 (3.30)

A similar scaling relation obtained from the  $MN_4C_{12}$  structures has been previously reported by Svane et al. [93]. This scaling relationship implies that the best liming potential is 0.83 V<sub>SHE</sub>, resulting in the minimum overpotential of 0.4 V<sub>SHE</sub>. The limiting potential as a function of  $\Delta G(*OH)$  for each metal atom in considered M/N/C structures is shown in Figure 3.7. The ORR activity of the Fe/N/C structures is firstly discussed. The adsorption of the \*OH on the bare Fe site is strong. Thus the ORR is limited by the reduction of \*OH to H<sub>2</sub>O. The order of the overpotential on the bare Fe site is found to be: FeN<sub>4</sub>C<sub>12</sub> (0.60 V<sub>SHE</sub>) < FeN<sub>4</sub>C<sub>A</sub> (0.77 V<sub>SHE</sub>) < FeN<sub>4</sub>C<sub>10</sub> (0.83 V<sub>SHE</sub>) < FeN<sub>4</sub>C<sub>Z</sub> (0.95 V<sub>SHE</sub>) < FeN<sub>3</sub>C<sub>10</sub> (1.18 V<sub>SHE</sub>) < FeN<sub>4</sub>C<sub>8</sub> (1.65 V<sub>SHE</sub>) < FeN<sub>3</sub>C<sub>Z</sub> (1.79 V<sub>SHE</sub>) < FeN<sub>3</sub>C<sub>A</sub> (2.13), agreeing with a previous theoretical study by Yang *et al.* [134]. At U = 0.8 V<sub>SHE</sub> and pH = 0, the either \*OH or \*O can be formed on the metal site, depending of the local carbon structures. The presence of OH and O ligands weakens the binding strengths of the ORR intermediates on the Fe site compared to the bare Fe site. Considering the ORR activity on the Fe/N/C structures with the most stable adsorbate at U = 0.8 V<sub>SHE</sub> and pH = 0 as a ligand on the back side, the following order of the overpotential is found: \*OH-FeN<sub>4</sub>C<sub>8</sub> (0.43 V<sub>SHE</sub>) < \*O-FeN<sub>3</sub>C<sub>Z</sub> (0.54 V<sub>SHE</sub>)  $\approx$  \*OH-FeN<sub>3</sub>C<sub>10</sub> (0.54 V<sub>SHE</sub>) < \*O-FeN<sub>3</sub>C<sub>A</sub> (0.56 V<sub>SHE</sub>) < \*O-FeN<sub>4</sub>C<sub>10</sub> (0.63 V<sub>SHE</sub>) < \*O-FeN<sub>4</sub>C<sub>12</sub> (0.80 V<sub>SHE</sub>) < \*O-FeN<sub>4</sub>C<sub>A</sub> (0.81 V<sub>SHE</sub>) < \*O-FeN<sub>4</sub>C<sub>Z</sub> (1.06 V<sub>SHE</sub>).

For other considered metal elements, the ORR intermediates bind strongly on the bare Cr, Mn, and Ru sits, especially in the  $MN_4C_8$ ,  $MN_3C_7$ , and  $MN_3C_A$  structures. The ORR activity is located on the left leg of the volcano plot, restricted by the reduction of \*OH to H<sub>2</sub>O. The OH and O ligands, which are also expected on these metal atoms under the ORR-related condition, can weaken the binding strengths of the ORR intermediates on the metal site. Thus, the OH and O ligand can enhance the ORR activity. Especially on the unsaturated  $MN_3C_7$ , and  $MN_3C_A$  structures, it is found that the OH and O ligand results in higher ORR activity than the bare metal site in the same local carbon structure.

The binding strengths of the ORR intermediates on the bare Co site are weaker than the previously discussed metal elements. Still, the ORR intermediates are found to strongly bind on the bare Co site, especially on the MN<sub>4</sub>C<sub>8</sub>, MN<sub>3</sub>C<sub>Z</sub>, and MN<sub>3</sub>C<sub>A</sub> structures. The ORR activities of the considered Co/N/C structures are also on the left leg of the volcano but located nearer to the top than previously discussed metal elements. Except for the bare CoN<sub>4</sub>C<sub>12</sub> site, the ORR is limited by the reduction of \*OH to H<sub>2</sub>O. The OH and O ligands weaken the ORR intermediates' binding strengths on the Co site. Unlike previously discussed metal atoms, the ligand negatively affects the ORR activity on the CoN<sub>4</sub>C<sub>12</sub>, CoN<sub>4</sub>C<sub>Z</sub>, and CoN<sub>4</sub>C<sub>A</sub> structure. This is becuase the activity of these structures without the ligand is already near the top of the volcano. However, under the ORR-related condition (U = -0.8 V<sub>SHE</sub>, pH = 0), the ligand is expected only on the CoN<sub>3</sub>C<sub>10</sub>, CoN<sub>3</sub>C<sub>Z</sub>, and CoN<sub>3</sub>C<sub>A</sub> structure which can substantially enhance the ORR activity, compared to the bare Co site with the same local carbon structures.

For the Ni/N/C structures, the ORR intermediates bond weakly with the bare Ni site, and the adsorption of O and OH ligands are not thermodynamically favorable under the considered condition, except on the NiN<sub>3</sub>C<sub>A</sub> and NiN<sub>3</sub>C<sub>Z</sub> structure. The ORR activity on considered Ni/N/C structures under the ORR-related condition is limited by the formation of \*OOH, and is lower than other metal elements.

**Figure 3.7:** U<sub>L</sub> as a function of  $\Delta G(^{*}OH)$ : (a) Cr/N/C, (b) Mn/N/C, (c) Fe/N/C, (d) Co/N/C, (e) Ni/N/C, (f) Ru/N/C structure. The U<sub>L</sub> of the most stable phase (at pH = 0 and U = 0.8 V<sub>SHE</sub>) are marked with filled color. The marker for the surface: M = circle, \*O-M = square, \*OH-M = triangle.

In general, the adsorption free energy of the ORR intermediate on the bare metal site embedded in the same local carbon structures is likely to increase from: Cr < Mn < Ru < Fe < Co < Ni. Under the ORR-related condition, the ligand atom is likely to occur on the Cr, Mn, Fe, and Ru atoms. The presence of O or OH ligand weakens the binding strength of the ORR intermediate, leading to a modified ORR activity. Among the different local carbon structures, the binding strength of the ORR intermediate on the bare metal site in the  $MN_4C_8$ ,  $MN_3C_Z$ ,  $MN_3C_A$  structure is stronger than the others. Under the ORR-related condition, the ORR on these structures always proceeds with the ligand on the back side, also leading to a substantial change in the ORR activity compared to the bare metal site with these local carbon structures.

With the presence of one adsorbate on MN<sub>4</sub>C<sub>8</sub> structure, it is found that the metal

atom is likely to lay above the basal plane, forming a distorted square-pyramidal geometry instead of a square-pyramidal geometry. The metal site then prefers a higher magnetization state (the number of spin up - the number of spin down) and stronger binding with the adsorbate compared to the square-pyramidal geometry.

Considering the FeN<sub>4</sub>C<sub>12</sub>, FeN<sub>4</sub>C<sub>10</sub>, and FeN<sub>4</sub>C<sub>8</sub> structures as an example in Figure 3.8. The pristine structures of the  $FeN_4C_{12}$ ,  $FeN_4C_{10}$ , and  $FeN_4C_8$  structure are in a square planar geometry. The d-orbitals splitting of the metal center is based on the crystal field theory. The oxidation station on the metal center in the pristine  $FeN_4$ structure is considered to be 2+, and the electronic configuration in the d-orbitals of the metal center is considered based on the converged magnetization projected on the metal atom. In this way, the Fe<sup>+2</sup> in the square planar geometry has two unpaired electrons in the d-orbitals. When \*OH bonds with the Fe center, one d-electron is transferred to the \*OH. The \*OH-FeN<sub>4</sub>C<sub>12</sub> and \*OH-FeN<sub>4</sub>C<sub>10</sub> structure are in the square pyramidal geometry where the Fe<sup>3+</sup> has only one unpaired electron in their d-orbitals. For the \*OH-FeN<sub>4</sub>C<sub>8</sub> structure, the \*OH adsorption causes the elevation of the Fe atom about 0.80 Åabove the catalyst plane. The distortion could lead to a different orbital configuration, as suggested by Jurca et al. [135]. The possible electron configuration in the d-orbital splitting associated with the distortion is shown in Figure 3.8 (b). Three unpaired electrons remain in the d-orbital, resulting in a higher magnetization state. This electron configuration could have lower energy than those in the square-pyramidal geometry or allow the d-electron donated from the metal atom to be more facile. As a results, the \*OH adsorption on the FeN<sub>4</sub>C<sub>8</sub> structure is more energetically favorable than on the  $\text{FeN}_4\text{C}_{12}$  and  $\text{FeN}_4\text{C}_{10}$  structure.

It should be noted that the pristine structure of the edge-hosted  $MN_4C_Z$  and  $MN_4C_A$  site is also in a square planar geometry and have a similar converged magnetic moment on the metal atom as the bulk-hosted  $MN_4C_{10}$  structure either with and without one \*OH. Thus, we expect a similar d-electronic configuration for both edge-hosted and bulk-hosted  $MN_4$  sites. Additionally, the d-band center change due to the structure change from the bulk-hosted  $MN_4$  site to the edge-hosted  $MN_4$  site varies with the metal center atom, and there is no correlation between the d-band center and the adsorption energy strength of the reaction intermediate.

According to Figure A.12, the distorted square-pyramidal geometry upon the intermediate adsorption resulting in a high magnetization is seen in the \*OH-MN<sub>4</sub>C<sub>8</sub> structure with M = Mn, Ru and Co, compared to those on \*OH-MN<sub>4</sub>C<sub>x=10,12</sub> structure. Although the magnetization of the metal atom in the \*OH-MN<sub>4</sub>C<sub>8</sub> structure with M = Cr and Ni are not different from other \*OH-MN<sub>4</sub>C<sub>x=10,12</sub> structures, the elevation of the metal atom and the adsorption strength is relatively higher than the other \*OH-MN<sub>4</sub>C<sub>x=10,12</sub> structure.

**Figure 3.8:** The d-orbital splitting and electronic configuration in d-orbitals for Fe atom in (a) FeN<sub>4</sub>C<sub>12</sub>, FeN<sub>4</sub>C<sub>10</sub>, and FeN<sub>4</sub>C<sub>8</sub> structure in a square-planar geometry. (b) \*OH-FeN<sub>4</sub>C<sub>12</sub>, \*OH-FeN<sub>4</sub>C<sub>10</sub> structure in a square pyramidal geometry and \*OH-FeN<sub>4</sub>C<sub>8</sub> structure in a distorted square pyramidal geometry. The electron donated to the adsorbate is red, and the remaining electrons in the d-orbitals are black. The relative position of the energy level is qualitative only. Magmom is the converged magnetization (number of spin-up + spin-down) projected on the Fe atom. The insets show the structures with the height of the Fe atom above the N<sub>4</sub> plane. (C = grey, N = blue, H = white, Fe = orange, O = red). The oxidation of the Fe atom in the pristine FeN<sub>4</sub>C structure is 2+, and it is 3+ with \*OH.

Furthermore, the  $MN_3C_Z$  and  $MN_3C_A$  structures also bond with the adsorbate strongly, regardless of the metal atom. The possible explanation is that the metal atom in these two unsaturated structures has an oxidation state of 1+. Therefore, the metal atom prefers at least one bonding with the adsorbate to change the oxidation from 1+

to 2+ (or 3+), which is generally favorable for transition metal elements.

Let us consider the Ni/N/C system as an example. It is found that the Ni atom in the NiN<sub>3</sub>C<sub>A</sub> and NiN<sub>3</sub>C<sub>Z</sub> structure has the magnetization of 0.96, 0.80, respectively. If the oxidation state is 2+ (Ni<sup>2+</sup>), there are eight d-electrons arranged in five d-orbitals. Then, a possible magnetization is 0 or 2. If the oxidation state is 1+ (Ni<sup>1+</sup>), there are nine d-electrons arranged in five d-orbitals. Thus, a possible magnetization is 1, which is found in our calculation results. Furthermore, with the \*O or \*OH adsorption, the magnetization projected on the Ni atom in these two unsaturated structures is found to be 0. This magnetization value is the same as the Ni atom in the pristine NiN<sub>4</sub>C structures with the oxidation state of 2+. Also, the bonding strength with the second adsorbate becomes comparable to that of other pristine NiN<sub>4</sub>C structures.

#### 3.6 Stability vs Activity

Combining the stability and activity descriptors,  $\Delta G_R$  of the most stable surface at U = 0.8 V<sub>SHE</sub>, pH = 0 is plotted against the overpotential (see Figure 3.9). It can be seen that the FeN<sub>4</sub>, CoN<sub>4</sub>, and RuN<sub>4</sub> sites mainly on the bulk graphene (MN<sub>4</sub>C<sub>10</sub>, MN<sub>3</sub>C<sub>10</sub>) and the graphene edges (MN<sub>4</sub>C<sub>A</sub>, MN<sub>4</sub>C<sub>Z</sub>) are a promising candidates with  $\Delta G_R < 1.0 \text{ eV}$  and the overpotential < 1.0 V<sub>SHE</sub>. These promising candidates are already well-known M/N/C catalysts and have been experimentally tested as ORR catalysts in acid conditions [12, 19, 90, 91, 95, 128, 136]. The MN<sub>y</sub>C structures with M = Cr, Mn are predicted to be unstable under the considered condition as the thermodynamic driving force toward the dissolution is greater than 1 eV. Also, the unsaturated MN<sub>3</sub>C<sub>A</sub>, and MN<sub>3</sub>C<sub>Z</sub> structures that exhibit high catalytic activity are not in Figure 3.9 as they are also not stable under the acidic ORR conditions.

It can be seen that Ru/N/C structures are active and stable under the ORR-related condition. Furthermore, the Ru atom has either OH or O ligand on the back side at the considered condition. These results are in line with the experiments by Xiao *et al.* [137], which have reported a higher activity and stability of the Ru/N/C catalyst than the Fe/N/C catalyst in 0.1 M HClO<sub>4</sub>. Also, they have suggested that the \*OH-RuN<sub>4</sub> site is the active and durable site for the Ru/N/C catalyst under acid conditions. In addition, a previous experimental study by Cao *et al.* [40], and Zhang *et al.* [90] have suggested the RuN<sub>4</sub> site with O or OH ligand as the active and durable site of the Ru/N/C catalyst in acid solution.

The experimental study by Zitolo *et al.* [12] has found that the Fe-based moieties experience a structural change and an electronic-state change, implying the formation of O and OH ligand on the Fe site under the operating condition. At the same time, they have found no structural and electronic change for the Co-based moieties. In our study, most considered Fe/N/C structures can have either O or OH ligand on the Fe atom at pH = 0 and U = 0.8 V<sub>SHE</sub>. While at the same condition, only some of the considered Co/N/C structures have the OH ligand.

It is seen that the stable Co/N/C structures in Figure 3.9 are more active than the stable Fe/N/C structures. The experimental study by Martinez *et al.* [10] reported the

**Figure 3.9:**  $\Delta G_R$  of the most stable phase at U = 0.8 V<sub>SHE</sub> and pH = 0 vs ORR overpotential with nonadsorbing electrolyte ions. The catalysts close to the bottom left corner are expected to be active toward ORR and stable in acid conditions

ORR activity in 0.5  $H_2SO_4$  in the order of Fe > Co > Mn, suggesting that the Fe/N/C catalyst is more active than the Co/N/C catalyst. Their DFT calculations have suggested the OH ligand on the zigzag-edge host MN<sub>4</sub> as the active site [10]. A previous computational study by Svane et al. [93] has identified the ligand on the  $FeN_4C_{12}$  and  $MnN_4C_{12}$  site in 0.5 M H<sub>2</sub>SO<sub>4</sub> solution is HSO<sub>4</sub> and H<sub>2</sub>O for CoN<sub>4</sub>C<sub>12</sub> structure, giving the ORR limiting potential order (Fe > Co > Mn) in agreement with the experiments by Martinez et al. [10]. The interaction between the M/N/C catalysts with relevant species present in the electrolyte would be interesting to consider and may give a better model that can accurately describe the catalytic activity under experimental conditions. Another possible explanation could be highly selective for the two-electron ORR pathway, potentially lowering catalytic activity for the four-electron ORR pathway. According to the experimental study by Martinez et al. [10], the Fe/N/C catalyst has a half-wave potential of 0.80 V<sub>RHE</sub> and selectivity for the four-electron pathway is more than 95% while the Co/N/C catalyst has a lower half-wave potential of  $0.77 V_{RHE}$  and a lower selectivity for the four-electron path of 90%. Gao et al. [138] have also reported high onset potential at around 0.7  $V_{RHE}$  for the Co/N/C and Fe/N/C catalyst, but the Co/N/C catalyst is more selective for the two-electron pathway than the Fe/N/C catalyst.

Additionally, some of the promising stable and active structures in acid conditions are the  $FeN_3C_{10}$ ,  $CoN_3C_{10}$ , and  $NiN_3C_{10}$  structures, suggesting that the nearest neighbor interaction can tune the catalytic activity of the M/N/C catalyst on the graphene plane. Therefore, carefully manipulating the heteroatoms around the active site can further improve the catalytic activity while maintaining acid stability. Additionally,

for the design strategies to achieve both an active site and stable M/N/C catalyst, the synthesis should aim to increase the site density of  $MN_4$  bulk-hosted structures or the  $MN_4$  on the edge-hosted graphene structure. Avoiding the formation of unsaturated  $MN_3C_Z$  or  $MN_3C_A$  structure as well as the  $MN_4C_8$  site will increase the stability of the M/N/C catalyst under acid conditions. Further stability improvement for the active M/N/C structures like  $MN_4C_{12}$ ,  $MN_4C_8$  and the unsaturated structure ( $MN_3C_Z$ ,  $MN_3C_A$ ) might be achieved by forming these active structures over another graphitic layer [27]. The metal choice also significantly affects stability and activity, so it should be considered when designing the catalyst. Integrating Fe, Co, and Ru metal elements into graphitic carbon supports like the  $MN_4C_{10}$ ,  $MN_4C_Z$  and  $MN_4C_A$  structure would be a promising catalyst for the ORR in acid conditions.

#### 3.7 Conclusions

The systematic investigation of the stability and the ORR catalytic activity of the M/N/Cstructure with different local carbon structures around the MN<sub>v</sub> motif under acid conditions was carried out in this chapter. The stability was considered from the tendency of the metal atom to dissolve into the electrolyte. The results revealed that the local carbon structures play a crucial role in the stability and ORR catalytic activity. All considered M/N/C structures with M = Cr, Mn, Fe, Co, Ni, and Ru are thermodynamically unstable in acidic ORR conditions. The thermodynamic driving forces toward the dissolution suggest that the  $MN_4$  site on the bulk graphene and graphene edge ( $MN_4C_{10}$ ,  $MN_4C_A$ ,  $MN_4C_7$ ) are more stable against the dissolution than that hosted by the microporous ( $MN_4C_{12}$ ,  $MN_4C_8$ ) or in the unsaturated structure ( $MN_3C_{Z'}$ ,  $MN_3C_A$ ). The stability also depends on the choice of a metal atom. The M/N/C structures with Fe, Co, Ni, and Ru are more stable under acid conditions than those with Mn and Cr metal atoms. Under the ORR-related conditions, we predicted the most stable phase of the active site in which O or OH ligands can occur on the back side and become a part of the active center. The ORR activity also depends on the choice of the metal atom and the local atomic structure. Combining both stability and activity descriptors, we suggested that the Fe, Co, and Ru atom mostly on the  $MN_4C_{10}$ ,  $MN_4C_Z$ ,  $MN_4C_A$ , and  $MN_3C_{10}$ structure are the promising acid-stable and active ORR catalyst. Rational modification of the carbon matrix and appropriate selection of metal atoms could be carefully used to optimize the activity and stability of the M/N/C catalysts.

## Chapter 4

# Effect of Electrolyte Anion Adsorption on the Activity and Stability of Single Atom Electrocatalysts

This chapter is based on the work presented in Paper II as given in Appendix D. The stability and activity of the M/N/C catalysts are further studied, including the effect of the electrolyte anion adsorption. This chapter covers the main points and results.

### 4.1 Introduction

The single metal atom coordinated N-doped carbon (M/N/C) has been recognized as an efficient electrocatalyst. In many experimental and theoretical studies, the Fe/N/C and Co/N/C materials have been identified as active ORR catalysts in acid electrolytes [9, 12, 31, 90, 136]. More recent studies have evidence that the M/N/C catalyst can also be an efficient catalyst for the CO<sub>2</sub>RR [139–141]. In the previous Chapter 3, we found that the local coordination plays an important role in catalytic activity and stability of the M/N/C catalyst [18, 30, 35].

Furthermore, since the M/N/C catalysts possess two-dimensional properties, it is distinct from bulk materials, where only one exposed side is responsible for their catalytic activity. Ideally, both sides of the M/N/C catalyst are exposed to electrolytes so they can interact with an adsorbate. It is, therefore, possible that an electrolyte anion or a gas molecule from the environment adsorbs on one side of the M/N/C structure while the other side is still available for the reaction to proceed [129, 130]. The presence of the adsorbate on one side of the single metal atom will modify its electronic states, affecting the binding of the second adsorbate on the other side [93, 142, 143]. Experimental and theoretical studies have considered the effect of anions from the electrolyte or a gas molecule impurity on ORR activity. For instance, Holst-Olesen *et al.* have found

that the anions from H<sub>3</sub>PO<sub>4</sub>- and CH<sub>3</sub>COOH-containing electrolytes are beneficial for the ORR activity on the Fe/N/C catalysts [129, 130]. Various combinations of the electrolyte anion ligand and the single metal center in the  $MN_4C_{12}$  structures (M = Cr, Mn, Fe, and Co) for improving the ORR activity have studied in a previous theoretical study by Svane *et al.* [93]. Recently, many studies have also reported that the introduction of axial oxygen [13, 144] and halogen atom [90] on the MN<sub>4</sub> site can achieve an efficient catalyst for the CO<sub>2</sub>RR.

The stability of the MN<sub>4</sub> site with the presence of a fifth ligand was recently discussed. Glibin et al. have previously studied the dissolution reaction of two different FeN<sub>4</sub> sites with the \*F ligand. Based on a thermodynamic model, the fluorination on the FeN<sub>4</sub> site can increase the resistance of the single metal site against acid dissolution [104]. The DFT calculations have been used to study the dissolution reaction of the FeN<sub>4</sub> site embedded on a bilayer-graphene by Holby *et al.* [27]. The presence of  $^{*}OH$ ligand on the  $FeN_4C_{10}$  site has been found to prevent the single Fe site from dissolution [27]. By using in situ Raman spectroscopy to study the Fe phthalocyanine (FePc) molecules and pyrolyzed Fe/N/C catalysts, Wei et al. have reported the structural dynamics of the FeN<sub>4</sub> active site in 0.1 M HClO<sub>4</sub> solution [145]. At a high potential of about 1.0 V<sub>RHE</sub>, a non-planar structure is induced by the presence of an adsorbate on the FeN<sub>4</sub> site, preventing FeN<sub>4</sub> site from the dissolution. At a lower potential of about  $0.05 V_{RHE}$ , they have found the irreversible attenuation of the planar Fe-N vibration, which is the evidence for dissolution of the bare Fe center [145]. Using DFT simulations with <sup>57</sup>Fe Mössbaur spectroscopy data, Nematollahi et al. have compared the DFT calculated and experimental quadrupole splitting energy of doublets ( $\Delta E_{OS}$ ) for different FeN<sub>4</sub> structures (FeN<sub>4</sub> $C_{10}$ , FeN<sub>4</sub> $C_{12}$ , FeN<sub>4</sub> $C_8$ ) both with and without ligands [36]. They have suggested that the  $FeN_4C_8$  structure with a fifth ligand such as  $OH^$ and  $NH^{2-}$  could be an active and durable site under the acidic ORR conditions [36].

In this chapter, the systematic exploration of the electrolyte anion adsorption effect on the stability and activity of a single metal atom incorporated with N atoms doped into a bulk graphene terrace ( $MN_4C_{10}$ ) and a graphene edge ( $MN_4C_A$ ) with M = 3d, 4d, 5d, or p-block (Sn, Sb, and Bi) metal atoms. The interaction between the single metal site and the electrolyte anion is evaluated to understand how the electrolyte anion adsorption thermodynamically influences the dissolution of the single metal site under electrochemical conditions relevant to the ORR and the  $CO_2RR$ . In addition, the catalytic activity with the presence of an electrolyte anion ligand for the ORR and  $CO_2RR$  is also studied. Finally, the results are used to suggest combinations of metal atom center, local carbon structure, and electrolyte for active and stable catalysts under working conditions.

#### 4.2 Computational Details

The structural models based on the  $MN_4C_{10}$  and  $MN_4C_A$  sites, as shown in Figure 3.1(a) and (e) are used to investigate the effect of electrolyte anion adsorption in this chapter. These graphene sites are selected because they are among the most stable type of sites, as previously found in Chapter 3. The DFT calculation details are the same as described in Section 3.3. Except that the thermal corrections for the adsorbates (ZPE +  $U_{vib}$  -  $TS_{vib}$ ) at T = 298.15 K are calculated from the adsorbates on the FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> sites and applied to other metal sites with the same local carbon structure. The thermal corrections for the adsorbates are given in Table B.1 of Appendix B.

#### 4.3 Formation Energy

The formation free energy of the single metal atom doped into the bulk graphene and the graphene edge is calculated as follows

$$\Delta G_{f} = E(MN_{4}C) - E(C) + 6\mu_{C} - \mu_{M} - 4\mu_{N}$$
(4.1)

where  $E(MN_4C)$  is the total energy of the single metal atom doped into graphene. E(C) is the total energy of a pristine graphene sheet or pristine graphene nanoribbon.  $\mu_C$  is the total energy of the pristine graphene sheet per carbon atom.  $\mu_M$  is the total energy of metal in its bulk structure per metal atom. The nitrogen chemical potential ( $\mu_N$ ) is treated as a parameter for using different nitrogen precursors in experiments [14, 33, 140, 141, 146, 147].  $\mu_N$  is referenced to NH<sub>3</sub>, N<sub>2</sub>, and H<sub>2</sub> gas molecule at 1 bar.

$$\mu_{\rm N}(n) = n[G({\rm NH}_3) - \frac{3}{2}G({\rm H}_2)] + \frac{1}{2}(1-n)G({\rm N}_2) \tag{4.2}$$

where G(NH<sub>3</sub>), G(H<sub>2</sub>), and G(N<sub>2</sub>) are the free energy of NH<sub>3</sub>, H<sub>2</sub>, and N<sub>2</sub> gas molecule at 1 bar, respectively and n is an integer. When n = 0, the nitrogen reference source is the N<sub>2</sub> gas molecule, and when n = 1, the nitrogen reference source is the NH<sub>3</sub> gas molecule. It is assumed that the nitrogen chemical potential can vary as a function of NH<sub>3</sub>, H<sub>2</sub>, and N<sub>2</sub> content during the synthesis. The n < 0 situation corresponds to the synthesis under the high content of (N<sub>2</sub> + H<sub>2</sub>) condition and the n > 1 situation corresponds to the synthesis to the synthesis under the high content of NH<sub>3</sub> condition.

Figure 4.1 (a) shows the  $\Delta G_f$  for  $MN_4C_{10}$  and  $MN_4C_A$  sites at two different  $\mu_N(n)$  with n = 1, 3. When n is more than 1, this can correspond to increasing NH<sub>3</sub> partial pressure during the synthesis. The temperature is considered at T = 1100 °C, a typical temperature in the M/N/C synthesis [12, 14, 139]. Regardless of the metal atom and  $\mu_N(n)$ , the single atom site is thermodynamically preferred to form at the graphene edge over the bulk graphene. A pyridine vacancy (PorN<sub>4</sub>) is slightly more stable on the graphene edge than the bulk graphene, and it is likely to be further stabilized if the bulk metal atom is supplied, forming the MN<sub>4</sub> site. Most 3d elements are thermodynamically more favorable to dope into the pyridine vacancy than the 4d-5d elements

and p-elements. The formation at T = 1100  $^{\circ}$ C, becomes thermodynamic favourable when n increases from 1 to 3 (e.g., under the elevated NH<sub>3</sub> partial pressure).

As shown in Figure 4.1 (b), the nitrogen chemical potential changes with the temperature. Thus, the formation free energy depends on the temperature and the nitrogen chemical potential. Considering the formation energy of the  $CoN_4C_{10}$  site in Figure 4.1 (c) as an example, with increasing temperature, the formation energy becomes more favorable when n > 1. In other words, the synthesis under the high NH<sub>3</sub> partial pressure and high temperature (T > 500 °C) is favorable for the single atom formation. At low temperatures (T < 100 °C), the formation energy become thermodynamic favourable when n < 0 (e.g., under high (N<sub>2</sub> + H<sub>2</sub>) content). The formation energies of other structures as a function of the nitrogen chemical potential at T = 25 and 1100 °C are given in Figure B.2 of Appendix B, where similar results are found. The results suggest that considered single metal sites doped into graphene can be synthesized in a controlled experiment.

**Figure 4.1:** (a)  $\Delta G_f$  for MN<sub>4</sub>C<sub>10</sub> and MN<sub>4</sub>C<sub>A</sub> sites at T = 1100 °C. (b)  $\mu_N(n)$  and (c)  $\Delta G_f$  of the CoN<sub>4</sub>C<sub>10</sub> site as a function of n at different temperatures.

#### 4.4 Stability Diagram and Relative Stability

Under an electrochemical environment, the single metal atom in the M/N/C structures can interact with anions from the electrolyte. We consider the anions from commonly used electrolytes for the ORR [148, 149] and the  $CO_2RR$  [150], e.g.,  $H_2PO_4^-$ ,  $HPO_4^{2-}$ ,  $PO_4^{3-}$ in  $H_3PO_4$  solution;  $HSO_4^-$ ,  $SO_4^{2-}$  in  $H_2SO_4$  solution;  $Cl^-$  in HCl solution;  $ClO_4^-$  in  $HClO_4$ solution;  $NO_3^-$  in  $HNO_3^-$  solution;  $HCO_3^-$  and  $CO_3^{2-}$  in  $H_2CO_3$  solution. Additionally, NO and CO gas molecules and CN<sup>-</sup> in HCN solution are included as they have been found to affect the catalytic activity [65, 151, 152]. The complete list of electrolyte anions and poisoning gas molecules considered here is given in Table B.2 and Table B.3 of the Appendix B. It should be noted that the adsorption of CO and NO on the metal site considered in this study does not depend on the pH and applied potential. The adsorption of the anion from the electrolyte on the single metal atom can compete with the water molecule. Thus, in each solution, the adsorption of anion or gas molecules on the metal site competes with the formation of  $*H_2O$ , \*OH, \*O from the water oxidation or reduction. Also, it is assumed that the catalyst surface is in equilibrium with protons, electrons, and liquid water [96]. Thus, the hydrogen adsorption on the metal site (\*H) is also included.

**Figure 4.2:** Thermodynamic cycle for the calculation of the free adsorption energy of the electrolyte anion in added 0.1 M electrolyte:  $\Delta G(*A^{n-})$  [93, 129].

The adsorption free energy of electrolyte anions is calculated using the thermodynamic cycle [93, 129] as shown in Figure 4.2. The adsorption free energy of the electrolyte anion in added 0.1 M electrolyte at T = 298.15 K can be expressed as follows

$$\Delta G(^*A^{n-}) = \Delta_{CHE}G(^*A) - \Delta G_{sol}(H_nA) - \Delta G_{dilute}(A^{n-})$$
(4.3)

 $\Delta_{CHE}G(*A)$  is calculated according to the computational hydrogen electrode (CHE) [117] and can be written as follows

$$\Delta_{\text{CHE}}G(^*A) = G(^*A) + \frac{n}{2}G(H_2) + n\Delta G_e + n\Delta G_H - G(^*) - G(H_nA_{(\text{gas})})$$
(4.4)

 $\Delta G_{sol}(H_nA)$  is the free energy for dissolving gaseous  $H_nA$  (at 1 bar) in water to form anion and proton at the standard state where  $[A_{(aq)}^{n-}] = [H_{(aq)}^+] = 1$  M.

$$\Delta G_{sol}(H_n A) = G(A_{(aq,1M)}^{n-}) + \frac{n}{2}G(H_2) - G(HA_{(gas)})$$
  
=  $\Delta G_f(A_{(aq,1M)}^{n-}) - \Delta G_f(HA_{(gas)})$  (4.5)

where  $\Delta G_f(A_{(aq,1M)}^{n-})$  and  $\Delta G_f(HA_{(gas)})$  are the formation energy of  $A^{n-}$  in solution phase (1 M) and  $H_nA$  in gas phase (1 bar), respectively.

 $\Delta G_{\text{dilute}}(A^{n-})$  in Figure 4.2 is the free energy accounting for the concentration difference from the standard state and can be expressed as follows

$$\Delta G_{\text{dilute}}(A^{n-}) = \operatorname{RT}\ln((a_{H^+})^n \gamma[A^{n-}])$$
(4.6)

where  $a_{H^+}$  and  $a_{A^{n-}}$  are the activity of  $H^+$  and  $A^{n-}$ , respectively.  $\gamma$  is an activity coefficient of  $A^{n-}$ , and  $[A^{n-}]$  is the concentration of the electrolyte anion. The electrolyte concentration is 0.1 M, and the pressure of the poisoning gas molecule is 1 bar. At different pH, it is assumed that pH is adjusted by adding non-adsorbing acid and  $a_{H^+}$  is calculated from:  $pH = -\log(a_{H^+})$ . The concentration of electrolyte anion species ( $[A^{n-}]$ ) in the 0.1 M solutions at each pH is calculated based on its pK<sub>a</sub> value. The value of  $\gamma$ ,  $\Delta G_f$  and pK<sub>a</sub> are taken from literature [93, 113, 114, 153, 154] and listed in Table B.3 of Appendix B.

Along with the adsorption of the adsorbate, the dissolution of the single metal atom from the graphene host into the electrolyte can occur and result in the dissolved metal ion with charge +x ( $M^{x+}$ ) and the graphene host cavity ( $N_4CH_n$ ) as described in Section 3.4. A completed list of  $E_M(bulk)$  and  $\Delta G_x$  for all metal elements considered in this chapter are given in Table B.4 of Appendix B.  $\Delta G_x$  is taken from literature [113, 118, 119]. The concentration of the dissolved metal ion in the calculations is  $10^{-6}$  M. Furthermore, the stability calculations are considered at T = 298.15 K.

As an example, Figure 4.3 (a) and Figure B.3 (a) show the stability diagram of the CoN<sub>4</sub>C<sub>10</sub> and CoN<sub>4</sub>C<sub>A</sub> sites in 0.1 M solutions, respectively. Only the most stable phase at each condition is shown in the stability diagram. The stability diagram is divided into different areas with different colors based on the most stable dissolved metal ion and the most stable adsorbate on the metal site, the same way as in the previous chapter. It is seen that the electrolyte anion can compete with water adsorption and become the most favorable adsorbate on a single Co atom. Like the previous chapter, we also consider the relative stability ( $\Delta G_R$ ), which is the free energy difference between the M/N/C catalyst surface (either with or without the adsorbate) and the most stable dissolved species (the dissolved metal ion and carbon host cavity). The  $\Delta G_R$  indicates the thermodynamic driving force for the dissolution of the metal atom. The more positive the relative stability, the less stable the single metal atom is against the dissolution. As shown in Figure 4.3 (b) and Figure B.3 (b),  $\Delta G_R$  of the CoN<sub>4</sub> sites is plotted as a function of applied potential at a specific pH (pH = 1 for H<sub>3</sub>PO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>, and HClO<sub>4</sub> solution and pH = 7 for H<sub>2</sub>CO<sub>3</sub> + CO solution). The most stable dissolved species for each potential used as a reference for  $\Delta G_R$  are superimposed as horizontal bars at the bottom in Figure 4.3 (b) and Figure B.3 (b). At potentials above 0.6 V<sub>SHE</sub> and pH = 1, in 0.1 M H<sub>3</sub>PO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>, and HClO<sub>4</sub> solution, it is seen that \*H<sub>2</sub>PO4, \*SO<sub>4</sub>, and \*ClO<sub>4</sub> are thermodynamically preferred on the single Co atom and further reduce the thermodynamic driving force toward dissolution compared to \*OH on the single Co atom in H<sub>2</sub>O.

**Figure 4.3:** (a) Stability diagrams for the  $CoN_4C_{10}$  site in 0.1 M solutions. (b)  $\Delta G_R$  for the sites at specific pH, and (c) stability diagrams for the  $CoN_4C_{10}$  site showing the most stable surface, and the background color corresponds to the value of  $\Delta G_R$ .

The stability and relative stability plots of the FeN<sub>4</sub> site on both bulk graphene and the graphene edge are given in Figure B.4 and B.5 of Appendix B. We find a similar trend where the electrolyte anion is thermodynamically stable on the single metal site at high potential, and the corresponding thermodynamic driving force is lower than the same single metal site in H<sub>2</sub>O. Furthermore, the thermodynamic driving force toward the dissolution decreases as the potential increases, suggesting that the demetallation could be dominant at the low potential in the acid condition. These results are in line with the experiments by Choi *et al.* where the Fe demetallation from the Fe/N/C catalyst in 0.1 M HClO<sub>4</sub> was observed at potentials below 0.7  $V_{RHE}$  [20].

Under a neutral condition (pH = 7) in 0.1 M H<sub>2</sub>CO<sub>3</sub> solution with CO, at U < -0.4 V<sub>SHE</sub>, it is seen that \*H is thermodynamically favorable on the single Co atom over the electrolyte anions. When the potential increases, the anions become the most stable adsorbate on the Co atom. \*HCO<sub>3</sub> is at potential around -0.6 to 0.4 V<sub>SHE</sub> and \*CO<sub>3</sub> is at potential above 0.4 V<sub>SHE</sub>. The thermodynamic driving force toward dissolution is lowered by about 0.46 and 2.18 eV when the \*HCO<sub>3</sub> and \*CO<sub>3</sub> are stabilized on the Co atom, compared to the \*CO-CoN<sub>4</sub>C<sub>10</sub> site in H<sub>2</sub>O + CO solution, respectively.

#### 4.5 Stability under the ORR-related Condition

The  $\Delta G_R$  of the most stable surface in 0.1 M electrolytes at pH = 1, and U = 0.80 V<sub>SHE</sub> for other MN<sub>4</sub> sites is shown in Figure 4.4. Except for PtN<sub>4</sub>C<sub>x=10,A</sub>, PdN<sub>4</sub>C<sub>x=10,A</sub>, and AuN<sub>4</sub>C<sub>x=10,A</sub> sites, the other MN<sub>4</sub> sites are likely to be stabilized by the adsorbate. Therefore the thermodynamic driving force toward dissolution is reduced compared to the bare metal site. The PtN<sub>4</sub>C<sub>x=10,A</sub>, PdN<sub>4</sub>C<sub>x=10,A</sub>, and AuN<sub>4</sub>C<sub>x=10,A</sub> sites weakly interact with both electrolyte anions and water molecules, but they are stable against the dissolutions in a wide range of pH and potentials, even without any adsorbate. For the PtN<sub>4</sub> site, our calculation results are in line with a previous experimental study by Li *et al.* [92]. They have found a minor change in the current density of a Pt/N/C catalyst under the accelerated durability tests in 0.5 M H<sub>2</sub>SO<sub>4</sub>. The relative stability of IrN<sub>4</sub>C<sub>x=10,A</sub> is below zero in the considered electrolytes, so it is stable under the considered ORR-related condition, in agreement with the experiment by Liu *et al.* [155]. During the durability test of the Ir/N/C catalyst in 0.1 M HClO<sub>4</sub>, they found about 97% current density retention of the Ir/N/C catalyst [155].

For  $CrN_4C_{x=10,A}$ ,  $MoN_4C_{x=10,A}$ ,  $RuN_4C_{x=10,A}$ ,  $ReN_4C_{x=10,A}$ , and  $OsN_4C_{x=10,A}$ sites, the binding strength of the electrolyte anion is weaker than \*O in most considered electrolytes. Thus, these metal sites are covered by \*O. For the Ru/N/C catalyst, the experimental studies by Zhang *et al.* [91] and Xiao *et al.* [137] have tested its ORR performance in 0.1 M HClO<sub>4</sub> and suggested that the active center is the RuN<sub>4</sub> site bonds with axial \*O or \*OH, agreeing with our calculations.

A previous experimental study has shown a higher activity loss of the Mn/N/C catalyst than the Fe/N/C catalyst in 0.1 M HClO<sub>4</sub> under an accelerated stress test where the potential was cycled between 0.5 and 1.3 V<sub>RHE</sub> [126]. In agreement with this experiment, in 0.1 M HClO<sub>4</sub> at U = 0.5 - 1.3 V<sub>RHE</sub>, the thermodynamic driving force toward the dissolution of the MnN<sub>4</sub>C<sub>10</sub> site is about 0.78 eV higher than that of the FeN<sub>4</sub>C<sub>10</sub> site. For the MnN<sub>4</sub>C<sub>A</sub> site, it is about 0.57 eV higher than that of the FeN<sub>4</sub>C<sub>A</sub> site.

**Figure 4.4:**  $\Delta G_R$  of the most stable adsorbate on MN<sub>4</sub> site in 0.1 M electrolytes at pH = 1, U = 0.80 V<sub>SHE</sub>: (a) MN<sub>4</sub>C<sub>10</sub>, (b) MN<sub>4</sub>C<sub>A</sub>. The inserted text indicates the most stable adsorbate on the metal site and its corresponding  $\Delta G_R$  in eV. The background color corresponds to the  $\Delta G_R$  value. The brighter the background color, the more stable it is against the dissolution.

In 0.1 M HClO<sub>4</sub> at U = 0.5 - 1.0 V<sub>RHE</sub>, both the MnN<sub>4</sub> and FeN<sub>4</sub> sites are stabilized by \*ClO<sub>4</sub>. Comparing these metal sites in H<sub>2</sub>O where the metal sites are covered by \*O,  $\Delta G_R$  for FeN<sub>4</sub> site in 0.1 M HClO<sub>4</sub> is about 0.18 eV lower than in H<sub>2</sub>O and it is about 0.13 eV lower than in H<sub>2</sub>O for MnN<sub>4</sub> site in 0.1 M HClO<sub>4</sub>. However, in both H<sub>2</sub>O and 0.1 M HClO<sub>4</sub>, the MnN<sub>4</sub> sites are found to be less stable than the FeN<sub>4</sub> sites.

Another experimental study by Xie *et al.* [19] has determined the amount of metal leaching out from the Fe/N/C and Co/N/C catalyst when the potential was cycled

between 0.6 - 1.0 V<sub>RHE</sub> in 0.5 M H<sub>2</sub>SO<sub>4</sub>. They have found a lower metal leaching from the Co/N/C catalyst than the Fe/N/C catalyst [19]. At this potential range, we find that the FeN<sub>4</sub> and CoN<sub>4</sub> sites on both bulk graphene and the graphene edge in 0.1 M H<sub>2</sub>SO<sub>4</sub> are occupied by \*SO<sub>4</sub>. The thermodynamic driving force toward the dissolution of the \*SO<sub>4</sub>-CoN<sub>4</sub> sites are about 0.14 eV lower than the \*SO<sub>4</sub>-FeN<sub>4</sub> sites, agreeing with the experiment. In the previous chapter, where the electrolyte anion adsorption has not been included, we find that the thermodynamic driving force of the most stable phase of the FeN<sub>4</sub>C<sub>x=10,A</sub> sites in H<sub>2</sub>O is about 0.02 eV higher than those of the CoN<sub>4</sub> sites. It is seen that the stability calculations, including the electrolyte anion adsorption, compare well with the experimental results for M/N/C catalysts.

For CO adsorption, the CO chemisorption experiment on the M/N/C catalyst (M = Fe and Mn) has suggested a stronger CO binding on the Fe-containing site over the Mn-containing site [126]. In agreement with the experiment, we find a stronger CO adsorption on the FeN<sub>4</sub> sites than on the MnN<sub>4</sub> sites on both bulk graphene and graphene edge. Similar results have been reported by Svane *et al.* [93] where the M/N/C catalysts are modeled based on the MN<sub>4</sub>C<sub>12</sub> structures.

Besides the nature of the metal atom center, the stability against dissolution depends on the local carbon structure around the  $MN_4$  motif. The  $MN_4$  site on the graphene edge is more stable than that on the bulk graphene. The thermodynamic driving force toward the dissolution at U = 0.80 V<sub>SHE</sub> and pH = 1 of the most stable phase of the  $MN_4C_A$  structures is about 0.52 eV lower than those of  $MN_4C_{10}$  structures.

#### 4.6 ORR Activity

Considering the  $MN_4$  site embedded in a two-dimensional carbon sheet, the adsorbates could interact with the metal atom from both sides. The electrolyte anion can strongly adsorb on both sides, blocking the metal site from the reaction intermediates. Alternatively, the electrolyte anion adsorbs only on one side, allowing the intermediate adsorbates to interact from the other side. In this chapter, the ORR is also considered to proceed through the four-electron associative pathway, and the metal site is considered as the active site. If the electrolyte anion is found to interact with  $MN_4$  site under the ORR-related condition, the ORR activity of the  $MN_4$  site is considered as the following mechanism [129].

$$^{*}A/^{*}A + ne^{-} \rightarrow^{*}/^{*}A + A^{n-}$$
O<sub>2</sub> + H<sup>+</sup> + e<sup>-</sup> +\* /\*A →\* OOH/\*A  
\*OOH/\*A + H<sup>+</sup> + e<sup>-</sup> →\* O/\*A + H<sub>2</sub>O  
\*O/\*A + H<sup>+</sup> + e<sup>-</sup> →\* OH/\*A  
\*OH/\*A + H<sup>+</sup> + e<sup>-</sup> →\* /\*A + H<sub>2</sub>O

where \*A/\*A stands for the electrolyte anions on both sides of the metal site. \*X/\*A stands for the electrolyte anion on one side and the reaction intermediate on the other side (X = O, OH, and OOH). At any considered pH and  $U_{SHE}$ , the reaction free energy

of the consecutive step along the ORR can be expressed as follows

$$\Delta G_0(U_{\text{SHE}}, \text{pH}) = \Delta G(^* A^{n-} / ^* A)$$
(4.7)

$$\Delta G_1(U_{\text{SHE}}, pH) = \Delta G_{*\text{OOH}/*A} + \Delta G_{H_2O} - \Delta G_e - \Delta G_H$$
(4.8)

$$\Delta G_2(U_{SHE}, pH) = \Delta G_{*O/*A} - \Delta G_{*OOH/*A} - \Delta G_e - \Delta G_H$$
(4.9)

$$\Delta G_3(U_{SHE}, pH) = \Delta G_{*OH/*A} - \Delta G_{*O/*A} - \Delta G_e - \Delta G_H$$
(4.10)

$$\Delta G_4(U_{SHE}, pH) = -\Delta G_{*OH/*A} - \Delta G_e - \Delta G_H$$
(4.11)

where  $\Delta G_{*X/*A}$  is the adsorption free energy of reaction intermediate X (X = O, OH and OOH) on the metal site with the electrolyte anion on the back side of the metal atom at pH = 0 and U = 0 V<sub>SHE</sub>.  $\Delta G_{*OOH/*A}$  and  $\Delta G_{*O/*A}$  are obtained from a scaling relation established between  $\Delta G_{*O}$  vs.  $\Delta G_{*OH}$  and  $\Delta G_{*OOH}$  vs.  $\Delta G_{*OH}$  on the bare metal site, given in Equation 4.12 - 4.15 (Figure B.1 in Appendix B). Note that MEA is a mean absolute error. Only  $\Delta G_{*OH/*A}$  is explicitly calculated in this chapter. A previous study by Svan *et al.* [93] has also reported a similar scaling relation between  $\Delta G_{*OH}$  and  $\Delta G_{*OOH}$  ( $\Delta G_{*OOH} = \Delta G_{*OH} + 3.24$ ) obtained from the MN<sub>4</sub>C<sub>12</sub> structures, including the adsorption free energy with the electrolyte anion on the back side of the metal atom.

For MN<sub>4</sub>C<sub>10</sub>: 
$$\Delta G_{*OOH/*A} = \Delta G_{*OH/*A} + 3.22$$
; MAE = 0.15 eV (4.12)

$$\Delta G_{*O/*A} = 2\Delta G_{*OH/*A} + 0.65 ; MAE = 0.59 \text{ eV}$$
(4.13)

For 
$$MN_4C_A$$
:  $\Delta G_{*OOH/*A} = \Delta G_{*OH/*A} + 3.16$ ; MAE = 0.14 eV (4.14)

$$\Delta G_{*O/*A} = 2\Delta G_{*OH/*A} + 0.44 ; MAE = 0.39 \text{ eV}$$
(4.15)

where 
$$\Delta G_{*OH/*A} = G(^{*OH}/^{*A}) + \frac{1}{2}G(H_2) - G(^{*}/^{*A}) - G(H_2O)$$
 (4.16)

 $\Delta G(*A^{n-}/*A)$  in Equation 4.7 is the free adsorption energy of the second electrolyte anion on the metal atom. It can be calculated using the thermodynamic cycle in Figure 4.2 and can be written as follows

$$\Delta G(^*A^{n-}/^*A) = \Delta_{CHE}G(^*A/^*A) - \Delta G_{sol}(H_nA) - \Delta G_{dilute}(A^{n-})$$
(4.17)

where  $\Delta_{CHE}G(^*A/^*A)$  is calculated according to the computational hydrogen electrode (CHE) [117] and can be written as follows

$$\Delta_{\text{CHE}}G(^*A) = G(^*A/^*A) + \frac{n}{2}G(H_2) + n\Delta G_e + n\Delta G_H - G(^*A) - G(H_nA_{(\text{gas})})$$
(4.18)

The possible electrolyte anion participating in the ORR is the most stable adsorbate at pH = 1, U = 0.80 V<sub>SHE</sub>. The corresponding ORR activity is also considered at this condition by calculating the thermodynamic barrier of the limiting step ( $\Delta G_{max}$ ). The thermodynamic barrier of the limiting step at specific U<sub>SHE</sub> and pH indicates the minimum energy required to run the reaction at that specific condition, assuming no kinetic barrier between each elementary step. The limiting potential (U<sub>L</sub>) is also calculated if all of the elementary steps along the ORR path are electrochemical reactions.

This situation includes when two NO and CO gas molecules are not thermodynamically stable on both sides of the metal atom. The  $U_L$  is the highest potential where all of the elementary steps are still downhill in free energy. The  $U_L$  and overpotential are considered at pH = 1 and can be calculated as follows

$$U_{L} = -\max\{\frac{\Delta G_{0}}{n}, \Delta G_{1}, \Delta G_{2}, \Delta G_{3}, \Delta G_{4}\}/e$$
(4.19)

overpotential = 
$$U_{eq} - U_L$$
 (4.20)

where  $\Delta G_i$  (i = 0 - 4) is the reaction free energy of the consecutive step along the ORR path in Equation 4.7 - 4.11, at pH = 1 and U = 0 V<sub>SHE</sub>. n is the number of electrons transferred during the adsorption/desorption of the second electrolyte anion on the metal site (n = 0 for the neutral gas molecule, such as CO and NO).

The ORR activity of the FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> sites in 0.1 M H<sub>3</sub>PO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>, HClO<sub>4</sub>, and HCl is firstly discussed. At U = 0.8 V<sub>SHE</sub> and pH = 1, the electrolyte anion (\*HPO<sub>4</sub>, \*SO<sub>4</sub>, \*ClO<sub>4</sub>, and \*Cl) bonds to the FeN<sub>4</sub> sites stronger than the water. Thus, these electrolyte anions can affect the ORR. Free energy diagrams of the ORR on the FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> site in these solutions at U = 0.80 V<sub>SHE</sub> and pH = 1 are given in Figure 4.5.

The ORR on the FeN<sub>4</sub>C<sub>10</sub> site in 0.1 M HClO<sub>4</sub>, and HCl is thermodynamically limited by the anion removal step, which is the change from the reaction state 0 to 1 in Figure 4.5 (a). In 0.1 M H<sub>3</sub>PO<sub>4</sub>, the thermodynamic barrier of the limiting step is the energy to remove one anion plus the energy to form \*OOH, which is the relative energy between the reaction state 0 and 2 in Figure 4.5 (a). While in 0.1 M H<sub>2</sub>SO<sub>4</sub>, the limiting step is the reduction of \*OH to H<sub>2</sub>O, which is the change from the reaction state 4 to 5 in Figure 4.5 (a). The  $\Delta$ G<sub>max</sub> at U = 0.80 V<sub>SHE</sub>, pH = 1 for the FeN<sub>4</sub>C<sub>10</sub> site in these considered electrolytes is H<sub>2</sub>SO<sub>4</sub> (0.02 eV) < HClO<sub>4</sub> (0.13 eV) < H<sub>3</sub>PO<sub>4</sub> (0.26 eV) < HCl (0.56 eV). The U<sub>L</sub> at pH = 1 with the most stable adsorbate at U = 0.80 V<sub>SHE</sub> and pH = 1 as the ligand on the back side of the metal atom is H<sub>2</sub>SO<sub>4</sub> (0.78 V<sub>SHE</sub>) > HClO<sub>4</sub> (0.67 V<sub>SHE</sub>) > H<sub>3</sub>PO<sub>4</sub> (0.60 V<sub>SHE</sub>) > HCl (0.24 V<sub>SHE</sub>). These results suggest that the ORR activity of the FeN<sub>4</sub>C<sub>10</sub> site in theses considered solutions is H<sub>2</sub>SO<sub>4</sub> > HClO<sub>4</sub> > H<sub>3</sub>PO<sub>4</sub> > HCl.

For the FeN<sub>4</sub>C<sub>A</sub> site in 0.1 M H<sub>3</sub>PO<sub>4</sub> and HCl, the ORR is thermodynamically limited by the anion removal step. In 0.1 M H<sub>2</sub>SO<sub>4</sub>, the thermodynamic barrier of the limiting step is the energy to remove one anion plus the energy to form \*OOH. The ORR is limited by the reduction of \*OH to H<sub>2</sub>O for the FeN<sub>4</sub>C<sub>A</sub> site in 0.1 M HClO<sub>4</sub>. The  $\Delta G_{max}$  at U = 0.80 V<sub>SHE</sub> and pH = 1 for the FeN<sub>4</sub>C<sub>A</sub> site in these electrolytes is H<sub>3</sub>PO<sub>4</sub> (0.01 eV) < H<sub>2</sub>SO<sub>4</sub> (0.08 eV) < HClO<sub>4</sub> (0.13 eV) < HCl (0.54 eV). The U<sub>L</sub> (at pH = 1) is in the following order: H<sub>3</sub>PO<sub>4</sub> (0.79 V<sub>SHE</sub>) > H<sub>2</sub>SO<sub>4</sub> (0.76 V<sub>SHE</sub>) > HClO<sub>4</sub> (0.67 V<sub>SHE</sub>) > HCl (0.26 V<sub>SHE</sub>). These results suggest that the ORR activity of the FeN<sub>4</sub>C<sub>A</sub> site in these considered solutions is H<sub>3</sub>PO<sub>4</sub> > H<sub>2</sub>SO<sub>4</sub> > HClO<sub>4</sub> > HClO<sub>4</sub> > HCl. It is seen that the ORR activity obtained from FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> site is different, implying a significant role of the local carbon structure around the FeN<sub>4</sub> site in the catalytic activity.

Previous experimental results by Holst-Olesen *et al.* [129], and Hu *et al.* [156] have reported that the ORR activity of the Fe/N/C catalyst in  $H_3PO_4$  are higher than

**Figure 4.5:** Free energy diagram of the ORR at pH = 1,  $U = 0.80 V_{SHE}$  on: (a)  $FeN_4C_{10}$ , (b)  $FeN_4C_A$  in  $H_2O$ , 0.1 M  $H_3PO_4$ , 0.1 M  $HClO_4$ , 0.1 M  $H_2SO_4$  and 0.1 M HCl. In each solution, the ligand on the back side of the Fe atom is the most stable adsorb at pH = 1,  $U = 0.80 V_{SHE}$ . The insets show the side view of the  $*OH/*ClO_4$  and  $*ClO_4/*ClO_4$  on the FeN<sub>4</sub> site. (C = gray, N = blue, H = white, O = red, Fe = orange, Cl = lime green).

in the other electrolytes. Holst-Olesen *et al.* [129] have reported the ORR activity in the following order for the Fe/N/C catalysts in 0.5 M electrolyte:  $H_3PO_4 > HClO_4 \approx H_2SO_4 > HCl$ . At 0.8  $V_{RHE}$ , Hu *et al.* [156] have reported the ORR activity of the Fe/N/C catalyst as the following order:  $H_3PO_4 > H_2SO_4 > HClO_4 > HCl$ . Modeling the Fe/N/C catalyst by the FeN<sub>4</sub>C<sub>12</sub> structure, Holst-Olesen *et al.* [129] have reported a good agreement between the theoretical and experimental ORR activity trends. Our calculation results obtained from the FeN<sub>4</sub>C<sub>A</sub> structure agree with the experiments by Hu *et al.* and Holst-Olesen *et al.*. While the results obtained from FeN<sub>4</sub>C<sub>10</sub> sites disagree with the experiments. Both experimental studies by Holst-Olesen *et al.* [129] and Hu *et al.* [156] have suggested a strong poison effect on the Fe/N/C catalyst by Cl<sup>-</sup> in HCl. In our calculations, the thermodynamic barrier of the limiting step in 0.1 M HCl is also higher than in other solutions. Additionally, Hu *et al.* have suggested that the catalytic activity of the Fe/N/C catalyst can be poisoned by ClO<sub>4</sub><sup>-</sup> in HClO<sub>4</sub> solution, implying the interaction between the FeN<sub>4</sub> sites and ClO<sub>4</sub><sup>-</sup> in HClO<sub>4</sub> solution [156]. In our calculation results, the \*ClO<sub>4</sub> can be adsorbed on the FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> sites at U =

0.80 V<sub>SHE</sub> and pH = 1. Furthermore, we find that the  $*ClO_4/*ClO_4$  can thermodynamically block the FeN<sub>4</sub>C<sub>10</sub> site at this condition. These results disagree with a previous study by Holst-Olesen *et al.* [129] where the  $*ClO_4$  has been found not to adsorb on the FeN<sub>4</sub>C<sub>12</sub> site at U = 0.75 V<sub>RHE</sub> in 0.5 M HClO<sub>4</sub>. The discrepancy could be due to the different local carbon structures around the FeN<sub>4</sub> site, which could also be different in each experiment, depending on the synthesis process.

The  $\Delta G_{max}$  at pH = 1 and U = 0.80 V<sub>SHE</sub> is considered as the ORR activity descriptor and is given in Figure B.6. The  $U_{I}$  at pH = 1 is also given in Figure B.7 of Appendix B. Evaluating the ORR catalytic activity in 0.5 M H<sub>2</sub>SO<sub>4</sub>, Martinez *et al.* [10] have reported the following order of the onset potential for the M/N/C catalysts: Mn < Co < Fe. Their theoretical study using the MN<sub>4</sub> at the zigzag edge of the graphene has suggested the \*OH ligand as a part of the active site. The theoretical study by Svane *et al.* [93] has reported the same order of  $U_{L}$  calculated from the MN<sub>4</sub>C<sub>12</sub> structure in 0.5 M H<sub>2</sub>SO<sub>4</sub>. According to our calculation results, the U<sub>L</sub> at pH = 1 on these metal atoms in the  $MN_4C_{10}$  structure in 0.1 M  $H_2SO_4$  differs by 0.01  $V_{SHE}$  and the order is Mn (0.77  $V_{SHE}$ ) < Fe (0.78  $V_{SHE}$ ) < Co (0.79  $V_{SHE}$ ). While, the U<sub>L</sub> calculated from the MN<sub>4</sub>C<sub>A</sub> structure is in the following order: Mn (0.70 V<sub>SHE</sub>) < Co (0.71 V<sub>SHE</sub>) < Fe (0.76 V<sub>SHE</sub>), agreeing with the onset potential order from the experiments by Martinez *et al.* Another experimental study testing the ORR performance of the Co/N/Cand Mn/N/C catalyst in 0.1 M HClO<sub>4</sub> solution has reported the onset potential of the Co/N/C and Mn/N/C catalyst in the order of Mn < Co [157]. For both  $MN_4C_{10}$  and  $MN_4C_A$  structures in 0.1 M HClO<sub>4</sub>, we find the \*ClO<sub>4</sub>-MN<sub>4</sub> site as the active center for MnN<sub>4</sub> and CoN<sub>4</sub> structures on bulk graphene and graphene edge. The order of  $U_{L}$  is found to be Co < Mn. Based on the  $MN_4C_{12}$  structure, Svane et al. [93] have found the \*OH-MnN<sub>4</sub>C<sub>12</sub> and \*H<sub>2</sub>O-CoN<sub>4</sub>C<sub>12</sub> sites as the active center in 0.5 M HClO<sub>4</sub>. Their calculated  $U_L$  is in the order of Mn < Co [93], which is in agreement with the experiment [157]. Previous experimental results have shown that the Fe/N/C catalysts can be poisoned by CN<sup>-</sup> under the acid condition[158]. In our calculation results, we also find that at U > 0 V<sub>SHE</sub> and pH = 1, the FeN<sub>4</sub>C<sub>10</sub> and FeN<sub>4</sub>C<sub>A</sub> sites are thermodynamically blocked by two \*CN. As a result, the ORR proceeds by at least a thermodynamic barrier for removing one \*CN from FeN<sub>4</sub> sites. Previous theoretical study by Svane *et al.* [93] have also reported a similar results for the  $FeN_4C_{12}$  structure. Furthermore, we find that other  $MN_4$  sites with M = Mn, Co, Ru, Rh, Os, and Ir can be blocked by two \*CN at pH = 1 and U > 0 V<sub>SHE</sub>. Additionally, it is found that two NO gas molecules can be adsorbed on both sides of  $IrN_4C_{10}$  and  $IrN_4C_A$  structures. At U = 0 - 0.8 V<sub>SHE</sub> and pH = 1, the ORR proceeds with at least the thermodynamic hindrance to remove one \*NO from the IrN<sub>4</sub> site. Furthermore, two \*CO or \*NO adsorbates are thermodynamically stable on the RuN<sub>4</sub>C<sub>A</sub> and OsN<sub>4</sub>C<sub>A</sub> structure at U = 0.80 V<sub>SHE</sub>, pH = 1. However, as a second adsorbate, the binding of \*OH on the metal site is stronger than the \*CO and \*NO. Thus, the ORR on these metal sites is limited by the reduction of \*OH to  $H_2O$ .

Comparing our calculation results with previous studies [93, 129], it is seen that the nature of the metal atom and the local carbon structure play a crucial role in determining the electrolyte adsorption and its corresponding catalytic activity.

#### 4.7 Stability under the CO<sub>2</sub>RR-related condition

Figure 4.6 shows  $\Delta G_R$  of the most stable adsorbate on the MN<sub>4</sub>C<sub>10</sub> and MN<sub>4</sub>C<sub>A</sub> site in 0.1 M electrolytes at pH = 7, and U = -0.8 V<sub>SHE</sub>. The 0.1 M H<sub>2</sub>CO<sub>3</sub> solution is included as the electrolyte used in the experiments [139, 141, 150]. In contrast to the ORR conditions, the anion from most of the considered electrolytes does not bind with the single metal site, except from the 0.1 M H<sub>2</sub>CO<sub>3</sub>. Thus, most considered electrolytes possibly have little impact on catalytic activity and stability of the MN<sub>4</sub> site under the CO<sub>2</sub>RR-related condition. Except for the 0.1 M H<sub>2</sub>CO<sub>3</sub>, we refer to the stability and catalytic activity under the CO<sub>2</sub>RR-related condition in the considered electrolytes as same as in H<sub>2</sub>O.

In H<sub>2</sub>O, we find that \*H can occupy on the CoN<sub>4</sub>, RuN<sub>4</sub>, RhN<sub>4</sub>, OsN<sub>4</sub>, and IrN<sub>4</sub> sites on both bulk graphene and graphene edge. While the MoN<sub>4</sub>C<sub>x=10,A</sub>, WN<sub>4</sub>C<sub>x=10,A</sub>, and ReN<sub>4</sub>C<sub>10</sub> sites are occupied by \*O, same as in the ORR-related condition, but with a lower thermodynamic driving force toward the dissolution. It is also seen that \*CO (in H<sub>2</sub>O + CO solution) and \*NO (in H<sub>2</sub>O + CO + NO solution) can be thermodynamically stable on many metal sites both on bulk graphene and the graphene edge. It is found that \*NO is likely to bind stronger than \*CO to the metal site. Thus, it is possible that the \*NO can block the metal site or participate in the reaction. Although \*CN can adsorb on the metal atom at pH = 7 and U = -0.8 V<sub>SHE</sub>, the binding strength of \*CN with the metal atom is weaker than that of \*CO. Thus, \*CN does not block the metal site or participate in the reaction.

In 0.1 M H<sub>2</sub>CO<sub>3</sub>, the MoN<sub>4</sub>C<sub>x=10,A</sub>, WN<sub>4</sub>C<sub>x=10,A</sub>, and ReN<sub>4</sub>C<sub>10</sub> sites bind with \*CO<sub>3</sub> via two oxygen atoms. we find that \*HCO<sub>3</sub> is stable on CrN<sub>4</sub>C<sub>x=10,A</sub>, MnN<sub>4</sub>C<sub>x=10,A</sub>, FeN<sub>4</sub>C<sub>10</sub>, ZnN<sub>4</sub>C<sub>10</sub>, SbN<sub>4</sub>C<sub>x=10,A</sub>, and BiN<sub>4</sub>C<sub>x=10,A</sub> sites. In 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO solution, CO gas molecule can compete with electrolyte anions (HCO<sub>3</sub><sup>-</sup>, CO<sub>3</sub><sup>2-</sup>) and bind to the metal sites. The most stable adsorbate on both MN<sub>4</sub>C<sub>10</sub> and MN<sub>4</sub>C<sub>A</sub> sites in H<sub>2</sub>O + CO solution and 0.1 M H<sub>2</sub>CO<sub>3</sub> + CO solution is slightly different. Similar to what is under the ORR condition, the NiN<sub>4</sub>, CuN<sub>4</sub>, PdN<sub>4</sub>, PtN<sub>4</sub>, AuN<sub>4</sub>, and SnN<sub>4</sub> sites on both bulk graphene and the graphene edge are likely to be unoccupied.

Recently, a kinetic model fitted by the experimental data by Zeng *et al.* [159] has demonstrated the role of the bicarbonate buffer on the CO<sub>2</sub>RR catalyzed by cobalt phthalocyanine (CoPC). They have suggested that the active site can be poisoned by  $HCO_3^-$  via the electrosorption at low overpotential, and the bicarbonate acts as a proton donor at a higher overpotential. Defining the onset potential for CO production to be the applied electrode potential at which the TOF of the CO formation exceeds 0.2 mmol/(h m<sup>2</sup><sub>active</sub>), the experiments have found that the Co/N/C catalyst starts producing CO at U = -0.36 V<sub>RHE</sub> [139]. Around this potential (U = -0.77 V<sub>SHE</sub> at pH = 7), it is seen from our calculations in Figure 4.3 and Figure B.3 that \*H, \*CO, and \*HCO<sub>3</sub> could thermodynamically be absorbed on the CoN<sub>4</sub> site on both bulk graphene and the graphene edge. At more positive potential, the \*HCO<sub>3</sub> becomes the most stable adsorbate on the CoN<sub>4</sub> site. while the \*H becomes more stable than \*CO and \*HCO<sub>3</sub> at more negative potential (higher overpotential).

| Bare -                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             | *
