(Received 15 February 1996; accepted for publication 18 May 1996)

By placing several Si δ -doped layers close to the surface of a GaAs molecular beam epitaxy-grown crystal, we achieve a compensation of the Schottky barrier and obtain a good Ohmic contact between an *in situ* deposited (without breaking the vacuum) Al metallization layer and a highly modulation doped (n^{++}) conduction layer embedded below the δ -doped layers in the GaAs crystal. When cooled to below the critical temperature (≈ 1.2 K) of Al, superconductivity is induced in the conductive layer of the semiconductor. We have studied the current voltage (I - V) characteristics in a planar geometry where the Al has been removed in a thin stripe. We find a manifestation of the superconducting energy gap and a rich fine structure at injection energies both below and above the gap. © 1996 American Institute of Physics. [S0003-6951(96)00231-8]

The study of superconductor-semiconductor (S-Sm) junctions is a field of increasing interest. For applications, the main effort has been invested in making a three-terminal device, where the field effect in the semiconductor can be used to control a supercurrent between the closely placed superconducting contacts.¹ A supercurrent can flow, if the distance between the superconductors is comparable to the coherence length ξ in the semiconductor, and if the S-Sm interfaces are highly transmissive. More fundamental aspects dealing with the basic understanding of the induction of superconductivity in mesoscopic (phase-coherent) normal conductors have also gained increased interest.^{2,3} At a normal-superconductor (N-S) interface the well known proximity effect can, thus, be explained on a microscopic level in terms of the Andreev reflection, where an electron in the normal conductor can be transmitted as a Cooper pair into the superconductor if a hole is retroreflected along the time-reversed path of the electron.

The key parameter in the description of Andreev reflections is the dimensionless parameter Z ,⁴ which enters the expression for the normal resistance of a N-S interface $R_N = R_0(1 + Z^2)$. R_0 is the barrierless resistance, whereas Z is a measure of the effective interface barrier height. In a model system with a δ -function barrier Z is given by $Z = \sqrt{Z_0 + (1-r)^2/4r}$, where $Z_0 = H/\hbar v_F^{\text{sm}}$ and $r = v_F^{\text{sm}}/v_F^{\text{sp}}$. Here H is the strength of the δ -function barrier and v_F^{sm} , v_F^{sp} are the Fermi velocities in the normal metal and the superconductor, respectively. The contributions to Z , thus, come from an interface energy barrier and a Fermi velocity mismatch between the two materials. The lower the Z the higher is the probability for Andreev reflection processes at the S-N or S-Sm interfaces. Another important quantity is the coherence length in the normal metal (or degenerated semiconductor). This length determines the length scale over which electrons and Andreev reflected holes can maintain their phase coherence. In the dirty limit where the electronic mean free path l is much shorter than the coherence length,

$\xi = \sqrt{\hbar D/2\pi k_B T}$, where $D = \frac{1}{3}v_F^{\text{sm}}l$ is the diffusion constant for diffusion in three-dimensions.

The above definitions of the important quantities draw the attention to the choice of materials. III-V semiconductors have played a key role, with highly doped InAs as the preferred material due to its ability to form very low interface barriers with most metals deposited on the surface. p -type InAs forms a two-dimensional (2D) electron gas inversion layer at the surface but, unfortunately, with a rather low mobility. More advanced materials such as InAs-AlSb quantum wells were used by Nguyen *et al.*⁵ Here a planar structure with a 2D carrier density of roughly 10^{12} cm^{-2} and mobilities of the order of $10 \text{ m}^2/\text{V s}$ (corresponding to mean free paths of $1.3 \mu\text{m}$) was successfully used to obtain S-Sm-S structures exhibiting well pronounced supercurrent. Kleinsasser *et al.*⁶ have employed backgated n -type $\text{In}_{0.47}\text{Ga}_{0.53}\text{As}$ grown on p -type InP substrates to produce three-terminal Josephson field effect transistor devices. In both these works a clear excess current was observed, indicating Z factors around 1 or below. Another approach is the use of annealed Ti/Sn contacts to a GaAs/AlGaAs heterostructure containing a 2D electron gas buried below the surface.⁷

All the above works, however, rely on rather involved processing procedures. To obtain a high interface transmissivity and a long coherence length, one needs a high doping level and a high carrier mobility in the semiconductor channel. These two demands are not easily combined, and one often has to choose a suitable compromise. In this Letter we report a new and very simple method for making planar S-Sm-S structures with very high contact transmissivities and reasonably long coherence lengths. From a technological point of view GaAs is the most studied among the III-V materials, and many experimental groups have access to molecular beam epitaxy (MBE) systems with Ga, As, Al, and Si sources.

Our samples consisted of 200 nm GaAs grown in a MBE chamber on an undoped GaAs substrate. The 200 nm were doped with Si to $4.4 \times 10^{18} \text{ cm}^{-3}$ and capped with 5

FIG. 1. (a) The differential resistance and the excess current for one of our samples with δ doping. At the sharp peaks in differential resistance (at ± 1.8 mV), the excess current is quenched due to self-heating. (b) The same quantities measured on a sample without δ doping. We notice a much higher resistance level and a deficit current instead of an excess current. The difference in the noise level in (a) and (b) is due to slightly different experimental setups when used recording the two traces. In these plots the etched stripe had the form of a straight line across the mesa. At the top of the figure we show the corresponding cross sections of the samples.

δ -doped layers separated by 25 Å of undoped GaAs. Each of the δ -doped layers contained 5×10^{13} cm $^{-2}$ Si atoms. These layers were inserted to decrease the Schottky barrier at the subsequent Sm–S interface formed as the structure was terminated with 200 nm of pure Al, which was deposited after the substrate temperature had fallen to about 30 °C (to prevent the formation of AlAs at the interface). As seen in Fig. 1, the insertion of the δ -doped layers had a dramatic effect on the interface resistance. The contact resistivity was lowered by three orders of magnitude from about 1×10^{-7} Ω m ^{2} to about 0.5×10^{-10} Ω m ^{2} . A 17 μ m wide mesa structure was etched in the Al and the doped GaAs layer, and Ti/Au bonding pads were deposited. A 1 μ m wide line was then etched in the Al across the mesa using conventional electron beam lithography with poly(methylmethacrylate) resist. The Al was wet-etched in H $_3$ PO $_4$:H $_2$ O (1:2) at 50 °C for about 2 min. The two-terminal resistance was dominated by the oxide barriers between the Al and the Ti/Au pads, whereas the four-terminal resistance exclusively probed the 1 μ m long Al–GaAs–Al configuration. In order to make a systematic study of the electrical properties of the S–Sm–S interface, the line across the 17 μ m wide mesa was etched in meander patterns of different total lengths as exemplified in the inset of Fig. 3. The mobility of the doped GaAs layer with the Al removed from the surface was 0.132 m ^{2} /V s and the carrier density 4.75×10^{24} m $^{-3}$. This gave a mean free path of roughly 50 nm and a 0.3 K coherence length of 250 nm. The lowest obtainable Z factor for $H=0$, i.e., assuming solely a contribution from the Fermi velocity mismatch between the

FIG. 2. (a) The resistance nonlinearity is seen to vanish as the temperature is raised to above 1.2 K, which is the critical temperature for the Al films. We see that the zero bias anomaly is quickly quenched as the temperature is increased, while the fine structure (the subharmonic energy gap structure) is more robust. The crossover voltage at which the resistance changes from R_S to R_N follows roughly the temperature dependence of $\sqrt{T_c - T}$. (b) The nonlinearity can also be quenched by applying a magnetic field. Here the normal region, where Al was removed, had the form of a meandering line as shown in the inset of Fig. 3. The total length of the line was 100 μ m.

doped GaAs layer and the Al, would be 0.39. From our experiments we deduced Z values in the range 0.7–0.9 for the δ -doped samples.

The critical temperature for our Al films was about 1.2 K, and the electrical measurements were performed in a ^{3} H cryostat with a base temperature of 0.3 K. In our experimental setup, we applied a dc voltage bias and superimposed a small sinusoidal ac modulation, that allowed us to measure the differential resistance and the I – V characteristics simultaneously. The ac bias was kept sufficiently low to ensure that the measured ac voltage remained much lower than $k_B T/e$. Above T_c the I – V characteristics were linear. Below T_c the characteristics became nonlinear. At very high biases the differential resistance reached the normal resistance level R_N . An excess current relative to the normal state characteristic was detected until a certain voltage V_c , where Joule heating caused a breakdown of superconductivity in the banks near the normal conductor. This breakdown resulted in an abrupt jump of the current from the excess current in the superconducting state to the normal state current. This jump gave rise to a sharp peak in the differential resistance. As seen in Fig. 1(b), samples cut from a wafer without δ doping exhibited a deficit current. Above V_c , irregularities or mesoscopic fingerprints were detected in the differential resistance on top of a constant level equal to the normal state resistance R_N . The peak heights at $\pm V_c$ and the mesoscopic fingerprints above V_c and below $-V_c$ were not always fully symmetric. Below V_c the differential resistance dropped to an overall level lower than R_N . This lower resistance level we denote R_S . V_c is not the gap voltage $2\Delta/e$ since it had different values for samples with different shape of the

FIG. 3. The I - V characteristic (thin solid line) for the same sample as shown in Fig. 2. The thick line is the differential conductance with indications of a subharmonic energy gap-structure. The dashed line indicates the I - V curve corresponding to the normal resistance R_N . The inset shows the sample geometry, with a meandering line etched in the Al on top of the sample.

etched stripe. This is clearly seen by comparison of Figs. 1 and 2. Superimposed on R_S was a fine structure that was symmetric around zero bias voltage. The precise shape of this fine structure was sample dependent. Around zero dc bias either a bare peak or a peak with a small dip inside it was observed. As seen in Fig. 2, the fine structure below V_c disappeared gradually as the temperature or the magnetic field approached its critical value. The peak around zero bias is most strongly affected by the temperature and by magnetic fields. The temperature dependence of V_c is roughly $\sqrt{T_c - T}$, corresponding to an energy balance where the dissipated power $P = V_{\text{appl}}^2 / R \propto (T_c - T)$.

The I - V characteristics can be understood if one takes into account the distribution of current (and voltage drop) away from the etched stripe, the Blonder, Tinkham, Klapwijk theory, and simple heating effects. From the excess current and the zero bias resistance level we were able to deduce Z values in the range 0.7–0.9. In a planar geometry the current density $J(x)$ through each S–Sm interface will be a function of the distance from the edge. Given an applied potential V_{appl} between the two Al banks, it can easily be shown, that the distributed voltage drop is given by

$$\frac{d^2 V}{dx^2} = -\frac{\rho_{\text{sm}}}{d} J(x), \quad (1)$$

where ρ_{sm} is the resistivity of the semiconductor and d is the thickness of the conducting semiconductor layer. The total current is given by

$$I = w \int_0^\infty J(x) dx, \quad (2)$$

where w is the width of the S–Sm interface. If the two equations above are solved in the normal state with suitable boundary conditions and $J(V(x)) = V / \rho_N$ one gets for the normal resistance

$$R_N \equiv V_{\text{appl}} / I = 2 \frac{\rho_N}{l_N w} + R_{\text{sm}}, \quad (3)$$

where $R_{\text{sm}} = \rho_{\text{sm}} L / dw$ is the resistance of the piece of semiconductor of length L between the superconducting banks, while ρ_N is the normal state contact resistivity with dimension $[\Omega \text{ m}^2]$. $l_N = \sqrt{\rho_N d / \rho_{\text{sm}}}$ is the decay length for $V(x)$ across each of the S–Sm interfaces away from the etched stripe. For samples cut from the δ -doped wafer l_N was of the order of $0.5 \mu\text{m}$, while for solely modulation doped samples it was roughly $60 \mu\text{m}$. In the superconducting state, the energy gap will, thus, appear at voltages $V_{\text{appl}} = 2\Delta/e + R_{\text{sm}} I$.

In Fig. 3 we show the dI/dV - V and I - V curves for a typical sample. In Fig. 3 we have indicated the positions of $\pm 2\Delta/e$, $\pm \Delta/e$, and $\pm 2\Delta/3e$. We interpret the observed structure as subharmonic energy gap structure originating from multiple Andreev scattering across the S–Sm–S junction.^{8,9} This structure can persist even to $T=0$ with unaltered amplitude. The value of Δ is, however, subject to a voltage dependence due to the self-heating effect. The dip at zero bias was not present in all our samples and is, presumably, a precursor to a supercurrent, or the so-called zero bias excess conductance observed by many workers.¹⁰

In conclusion, we have demonstrated a new and very simple technique to make S–Sm–S structures with high interface transmissivities. In our samples we have observed high bias excess current and subharmonic energy gap structure. Finally, we have demonstrated how to interpret data taken in a planar geometry.
