Comment on “Macroscopic Resonant Tunneling of Magnetization in Ferritin”

In the recent Letter [1], Tejada et al. presented experimental results of zero-field cooled (ZFC) magnetization $M_{ZFC}$ and hysteresis of ferritin. The authors concluded that their data showed strong departure from conventional behavior of thermally blocked particles and suggested quantum tunneling as an alternative explanation. One of their arguments is that they observed that for applied fields up to about 0.4 T, the temperature $T_B$ at the maximum of $M_{ZFC}$ increases with field, a feature which the authors claimed to be contrary to the case for simple superparamagnetic blocking. A similar increase of $T_B$ with the applied magnetic field has earlier been observed for ferrofluids containing Fe$_3$O$_4$ [2] and Fe$_{l-h}$C$_x$ [3,4] particles with negligible interparticle interactions. We have shown [3] that the effect can be explained by superparamagnetic relaxation in a simple model where the non-linear relation between the magnetization and the field is taken into account according to the Langevin function. We have applied this model to a system of particles with the properties of the ferritin particles in the paper by Tejada et al. We have used the values of the anisotropy constant $K = 2.6 \times 10^5$ J m$^{-3}$, the spontaneous magnetization $M_s = 4.7$ kA m$^{-1}$, and the average magnetic moment $m = 8.2 \times 10^{-22}$ A m$^2$ deduced from Tejada et al. [1], and an intrinsic relaxation time $\tau_0 = 10^{-12}$ s from Ref. [5]. In the calculations we included the effect of the anisotropy on the magnetization [6] and the effect of the field on the energy barrier $E$ for magnetization reversal. We applied the relation $E = KV(1 - B/B_0)^a$ for particles with a random orientation of easy axes, using the average switching field $B_0 = 0.958K/M_s = 5.3$ T [7], and $a = 1.5$ [8]. $V$ is the particle volume. By use of this model we found that the increase of $T_B$ with the field, observed by Tejada et al., may be reproduced if we assume that the magnetic moments of the ferritin particles are log normally distributed with a geometrical standard deviation, $\sigma = 1.4$. This distribution reflects the distribution of magnetic moments within the range of particle sizes 3.5 to 7.5 nm given by Tejada et al., as well as the particle size distribution for ferritin in Ref. [9]. The values of $T_B$ calculated for fields up to 0.6 T are shown in Fig. 1, together with the experimental data obtained by Tejada et al. As can be seen, the observed increase of $T_B$ with the applied field may well be described with our simple model for superparamagnetic particles and thermal blocking. The observed decrease of $T_B$ in fields above 0.4 T may be explained by other effects coming into play, because the Zeeman energy becomes comparable to the anisotropy energy. From these considerations we conclude that with respect to the field dependence of $T_B$, up to 0.4 T the experimental results of Tejada et al. are fully compatible with the behavior expected for particles that undergo simple superparamagnetic blocking and therefore give no evidence for macroscopic tunneling of the magnetization.
