Modeling of Yb$^{3+}$-Sensitized Er$^{3+}$-Doped Silica Waveguide Amplifiers

Christian Lester, Anders Bjarklev, Thomas Rasmussen, and Palle Geltzer Dinesen

Abstract—A model for Yb$^{3+}$ sensitized Er$^{3+}$-doped silica waveguide amplifiers is described and numerically investigated for high gain erbium-doped waveguide amplifiers (EDWA’s), it is necessary to use high Er-concentrations, which involves interaction between neighboring erbium ions and result in a quenching process. The quenching process reduces the pump efficiency, and a full inversion cannot be reached [1].

I. INTRODUCTION

SHORT amplifiers are currently attracting increased interest, especially for use in integrated optics. To make short high gain erbium-doped waveguide amplifiers (EDWA’s), it is necessary to use high Er-concentrations, which involves interaction between neighboring erbium ions and result in a quenching process. The quenching process reduces the pump efficiency, and a full inversion cannot be reached [1]. To minimize quenching in the amplifier, the EDWA can be Yb$^{3+}$ sensitized. The Yb$^{3+}$ ions then absorbs most of the pump power, and cross relaxation between adjacent Er$^{3+}$ and Yb$^{3+}$ ions allows the absorbed energy to be transferred to the erbium system [2]. This will result in a higher gain because more pump power can be absorbed and an improved inversion is obtained.

The sensitization of erbium-doped fibers with ytterbium is also a well-established technique for increasing the choice of pump wavelength to range from 800 to 1100 nm [3]. We introduce a model for an Yb$^{3+}$-sensitized EDWA that includes the amplified spontaneous emission (ASE) in the ytterbium band, and also takes the dissipative ion-ion interaction into account. We show the results of an analysis of an Yb$^{3+}$-sensitized EDWA, using the general model applied in the small-signal regime (signal input power less than $-30$ dBm).

The influence of the ytterbium ASE on the small-signal gain is maximum. By doping the EDWA with ytterbium, the pump light is mainly absorbed by the Yb$^{3+}$-ions. A energy diagram of the Er-Yb-sensitized system is shown in Fig. 1. Excited Yb$^{3+}$ ions transfer energy to neighbouring Er$^{3+}$-ions, whereby the Er$^{3+}$ becomes excited, this is shown in the dashed square of Fig. 1. The decay from the metastable level in Er$^{3+}$ is much faster than the backtransfer to the Yb$^{3+}$ ground state; therefore, the backtransfer is neglected in the modeling. The equation for the inversion in the Yb$^{3+}$-system $X_{Yb}$ then becomes

$$X_{Yb} = \frac{W_{PA}}{W_{PA} + W_{PE} + 1/\tau_{Yb} + k_{tr}/N^{ER}}$$

where $N^{ER}$ is the Er-concentration in the ground state, $W_{PA}$ and $W_{PE}$ are the pump absorption and emission rates, respectively, both including the ASE. $\tau_{Yb}$ is the spontaneous emission lifetime for Yb$^{3+}$, and $k_{tr}$ is the transfer coefficient for the energy transfer from the Yb-system to the Er-system. The transfer coefficient is largely independent of the Er-concentration, however, the dependence on the Yb-concentration is more complicated [6], [7]. Furthermore, $k_{tr}$ depends on the host glass, typically values are in the range $2 \cdot 10^{-22}$ m$^3$/s to $5 \cdot 10^{-22}$ m$^3$/s [6]-[8]. For Yb-concentrations less than $1.0 \cdot 10^{27}$ m$^{-3}$, the transfer coefficient drops with the concentration, and for concentrations larger than $1.0 \cdot 10^{27}$ m$^{-3}$, $k_{tr}$ is assumed constant, until crystallization sets in at $3.0 \cdot 10^{27}$ m$^{-3}$ [6]. Because little information about the transfer coefficient between ytterbium and erbium...
is available for Er/Yb-doped glasses, $k_{Er}$ is kept constant at $5 \cdot 10^{-22} \text{ m}^3/\text{s}$ for Yb-concentrations between $1.0 \cdot 10^{27} \text{ m}^{-3}$ and $3.0 \cdot 10^{27} \text{ m}^{-3}$. For Yb-concentrations decreasing from $1.0 \cdot 10^{27} \text{ m}^{-3}$ to $1.0 \cdot 10^{25} \text{ m}^{-3}$, the transfer coefficient $k_{Er}$ is assumed to drop linearly from $5 \cdot 10^{-22} \text{ m}^3/\text{s}$ to $1 \cdot 10^{-22} \text{ m}^3/\text{s}$, as shown in the inset of Fig. 2.

Because of quenching in the waveguide, described by the ratio $W_{HF}$ in Fig. 1, the erbium inversion $X_{Er}$ can be determined from a cubic equation [1]. By modifying this equation to account also for Yb$^{3+}$-sensitized EDWA’s, the following equation is derived:

$$X^3_{Er} + \left( R_{PA} + k_{Er} N^2_{Yb} + W_{SA} + R_{PE} + W_{SE} \right) \tau_0 + 1 = 0$$

$$\times \left( \frac{Q}{\rho} \right)^2 X_{Er} - \left( R_{PA} + k_{Er} N^2_{Yb} + W_{SA} \right) \left( \frac{Q}{\rho} \right)^2 \tau_0 = 0 \quad (3)$$

where $N^2_{Yb}$ is the Yb-concentration in the excited state, $R_{PA}$ and $R_{PE}$ are the pump absorption and emission rates in erbium, respectively; $W_{SA}$ and $W_{SE}$ are the signal absorption and emission rates. $Q$ is the quenching concentration which responds to the Er-concentration where the fluorescence lifetime is $\tau_f = 0.5 \cdot \tau_0$, and $\tau_0$ is the fluorescence lifetime in the limit where the Er-concentration $\rho$ approaches zero. Emission and absorption cross sections are for Er$^{3+}$- in P-doped silica [1], and for Yb$^{3+}$ in pure silica [9] (Fig. 2 shows the spectra for Yb$^{3+}$ and Er$^{3+}$ around the pump wavelengths between 850 and 1200 nm).

The model takes into account the forward and backward ASE for both the pump and the signal. The ASE for the pump is mainly related to the ytterbium ASE, yielding two times 150 frequency slots from 850–1050 nm. The signal ASE is related to the erbium system, and is also represented by 2 times 150 frequency slots from 1400–1700 nm. The ASE, signal and pump propagation yield 602 coupled differential equations that are solved by numerical integration through the waveguide.
When changing the Yb-concentration, the gain is also changed (this is shown in Fig. 4) where the Yb-concentration is changed between no ytterbium and an Yb-concentration of 15 times the Er-concentration. The length of the waveguide is optimized with respect to gain. It is seen that the optimum Yb-concentration is changed with the pump wavelength. For pump wavelengths longer than 1.1 μm, the optimum Yb-concentration is approximately between 10 and 15 times the Er-concentration. For pump wavelengths around 980 nm and less, the optimum Yb-concentration is about the same as the Er-concentration. From Figs. 3 and 4, it is observed that the maximum gain for the Yb⁺⁺-sensitized EDWA is not achieved at the pump wavelength with the highest absorption cross section (around 975 nm in Fig. 2). At high absorption cross sections and Yb-concentrations above 10 times the Er-concentration, the Yb⁺⁺ population of the excited ions builds above the population required to obtain the full Er⁺⁺ inversion, so losing energy to Yb⁺⁺ fluorescence. When comparing the performance of the Yb⁺⁺⁻sensitized EDWA to the EDWA without Yb⁺⁺, Fig. 4 illustrates that by sensitizing the EDWA with ytterbium the gain can be increased from 9–18 dB.

In [10], a measured gain of 7.8 dB for an EDWA, with the same parameters as used in Fig. 4, is reported. However, the length has not been optimized with respect to the gain. Besides the increasing gain, the Yb⁺⁺⁻sensitized EDWA enhances the choice of pump wavelength. By optimizing the Yb-concentration according to the pump wavelength, in the range from 910–1040 nm, the gain can be kept between 15 and 18 dB. Furthermore, the Yb⁺⁺⁻sensitized EDWA optimized according to the Yb-concentration and the length with respect to the gain, has a noise figure of approximately 4 dB, when the gain exceeds approximately 18 dB. For the optimized EDWA shown in Fig. 4, the minimum noise figure is 5.7 dB. The low noise figure for the Yb⁺⁺⁻sensitized EDWA, results from the very high Er⁺⁺ inversion at the input end of the waveguide.

IV. CONCLUSION

A comprehensive model for an Yb⁺⁺⁻sensitized erbium-doped waveguide amplifier is presented. The amplified spontaneous emission in the pump band is seen to reduce the amplifier gain, when the pump wavelength is between 860 and

III. RESULTS

The buried waveguide has a core of 8 - 7 μm² and the Er-concentration is 48.8 - 10²⁴ m⁻³ as for the EDWA that was experimentally examined in [10]. The refractive index difference is 1.2%, the lifetime of the upper laser level in erbium τₑ and ytterbium τᵧ is 13.7 and 1.5 ns, respectively, the signal wavelength is 1535 nm, and the quenching concentration is 17.0 - 10²¹ m⁻³ [1]. We assume that the amplifier is pumped from the same end at which the signal enters the waveguide. The absorption and emission cross section at the signal wavelength for erbium is 5.1 - 10⁻²⁵ m² and 5.6 - 10⁻²⁵ m², respectively. The background loss, which depends on the Er-concentration, is calculated to be 0.16 dB/cm for the signal and 0.2 dB/cm for the pump [1], [10]. The signal power is −40 dBm and the pump power is fixed at 100 mW.

The influence of the ASE in the ytterbium-band on the net gain and the optimum length of the waveguide is examined in Fig. 3 as a function of the pump wavelength. The Yb-concentration is either the same as the Er-concentration or 10 times the concentration. When this ratio is substantially less, the optimum Yb-concentration is about the same as the Er-concentration. From Figs. 3 and 4, it is observed that the maximum gain for the Yb⁺⁺⁻sensitized EDWA is not achieved at the pump wavelength with the highest absorption cross section (around 975 nm in Fig. 2). At high absorption cross sections and Yb-concentrations above 10 times the Er-concentration, the Yb⁺⁺ population of the excited ions builds above the population required to obtain the full Er⁺⁺ inversion, so losing energy to Yb⁺⁺ fluorescence. When comparing the performance of the Yb⁺⁺⁻sensitized EDWA to the EDWA without Yb⁺⁺, Fig. 4 illustrates that by sensitizing the EDWA with ytterbium the gain can be increased from 9–18 dB.

In [10], a measured gain of 7.8 dB for an EDWA, with the same parameters as used in Fig. 4, is reported. However, the length has not been optimized with respect to the gain. Besides the increasing gain, the Yb⁺⁺⁻sensitized EDWA enhances the choice of pump wavelength. By optimizing the Yb-concentration according to the pump wavelength, in the range from 910–1040 nm, the gain can be kept between 15 and 18 dB. Furthermore, the Yb⁺⁺⁻sensitized EDWA optimized according to the Yb-concentration and the length with respect to the gain, has a noise figure of approximately 4 dB, when the gain exceeds approximately 18 dB. For the optimized EDWA shown in Fig. 4, the minimum noise figure is 5.7 dB. The low noise figure for the Yb⁺⁺⁻sensitized EDWA, results from the very high Er⁺⁺ inversion at the input end of the waveguide.
995 nm. Calculation based on actual erbium-doped waveguide parameters shows an increase in the gain of approximately 9 dB, when Yb$^{3+}$-sensitizing the Er$^{3+}$-doped waveguide. Furthermore, the dependence between the Yb-concentration and the choice of pump wavelength has been characterized.
