Abstract— The ability to detect and track non-stellar objects by utilizing a star tracker may seem rather straight forward, as any bright object, not recognized as a star by the system is a non stellar object. However, several pitfalls and errors exist, if a reliable and robust detection is required.

To test the operation, performance and robustness of such a function, the Autonomous Vision System (AVS), a fully autonomous star tracker that has flown onboard the Teamsat was equipped with several advanced features. These features included a non-stellar object detection and tracking module and an image and science data compression module.

This paper describes the AVS, sensitivity, and possible detection ranges for various objects. The general description is followed by examples of images and tracking series obtained by the AVS on Teamsat.

1. TEAMSAT OVERVIEW

The second Ariane 5 prototype vehicle to be launched by ArianeSpace was designed to lift two test payloads Maqsat-B and Maqsat-H into Geostationary Transfer Orbit (GTO). ESTEC, a technical facility of the European Space Agency (ESA), applied for, and got approved that part of the mass of the Maqsat-H could be used for a technological demonstration sub-payload. The objectives of ESTEC were twofold. Firstly, to get practical experience with a Better-Faster-Cheaper type mission. And secondly, to provide space departments of European universities and companies with an opportunity to get advanced technologies and equipment tested in space.

The result of this effort was Teamsat. This sub-payload, weighing 350kg, was to be developed, assembled, tested and operationally verified, in precisely 1 year, all at marginal cost.

Teamsat was to be launched into a geostationary transfer orbit by the Ariane 5 vehicle. At or near apogee several geostationary satellites were expected to come within the detection range of the AVS, whence the detection and tracking of these was a major objective for the flight. Furthermore, Teamsat featured a small sub-satellite YES (Young Engineers Satellite) that was to be deployed late in the mission. Another objective was therefore to track YES during and after deployment for as long as possible.

The non-nominal operation of the first stage of the launch vehicle resulted in an apogee too low to enable the detection of geostationary satellites. However, as the launcher used all fuel to achieve the highest possible apogee, no fuel was left for attitude maneuvers during deployment let alone for the depletion burn. Hence several objects were moving around the vicinity of Teamsat throughout and provided for an excellent set of test objects for the AVS.

2. AVS AND DETECTION SENSITIVITY

The AVS differ mainly from other star trackers by being fully autonomous. Based on a powerful microprocessor, the AVS is a perfect platform for doing complex image analysis. It consists of a small camera head unit (CHU) and a data processing unit (DPU). Depending on the shielding thickness, the masses of the CHU and DPU are only 180 and 700 grams respectively.

The separation of the CHU and DPU is primarily due to three reasons. 1) Minimal disturbance, since the CHU can be placed far from the DPU. 2) Possibility of direct integration of the CHU with a science instrument in an optical bench for optimal attitude precision. 3) Flexibility in satellite bus integration due to the small size.

The star tracker function of the AVS is based on two different attitude determination algorithms.

The first is the so-called "Initial Attitude Acquisition" algorithm which solves the "Lost in Space" situation. It uses triplets of stars to perform a very fast search for matches in a special compiled star database. The output of this algorithm is the attitude with a precision of approximately 1/100 of a degree.

The second algorithm is called "A-priori Attitude Determination". It uses the previously determined attitude to determine the current attitude. This routine is always invoked first. If it fails, which will be the case if it is the first image since boot, or if the attitude drift from the previous image is too large, then the "Initial Attitude Acquisition" algorithm will be invoked followed by the "A-priori Attitude Determination" algorithm again.

Both algorithms are very fast, in the range of 50-100ms depending on which portion of the sky is imaged. This makes it possible always to perform any sequence of the two algorithms if the AVS is running at a rate of 1 – 4 Hz. If the attitude drift from the previous image is less than approximately 1 degree, which normally is the case, then only the "A-priori Attitude Determination" will be performed. Therefore it is possible to operate the AVS at higher frequencies.

The star catalogue is generated from the Hipparcos Catalogue using the proper motion for the epoch of the mission.

The AVS uses only the lowest 8 bit of 14 bit dynamic range of the CCD. If more light reaches a pixel than corresponds to the 8 bit - P_{255} (Def.: DN = Digital Number [0:255]), the pixel value will remain P_{255} . This means it takes an

illumination resulting in a value of $64 \cdot P_{255}$ for a pixel to saturate and spill over into the CCDs anti-blooming channels. These can handle another factor of 100 before the charge starts to spill over to neighboring pixels. To avoid blooming disturbances on neighboring pixels, the illumination of a single pixel must be kept below approximately $5000 \cdot P_{255}$. Sirius at $m_v = -1.4$ is only at $150 \cdot P_{255}$, while Jupiter and Venus at $m_v = -4$ is at $1600 \cdot P_{255}$. Blooming is only a problem in the sense that it takes longer time to process the image and the attitude precision is getting reduced.

An example of this is shown in Figure 1. It shows an image of a $\frac{3}{4}$ full moon in the field of view. The image is taken during a test at the JPL facility Table Mountain Observatory north of Los Angeles, USA. The ASV does take a little longer time to process the image, but it is still quite capable to determine the attitude from the stars in the remainder of the image. The moon itself is only about $1/20^{\text{th}}$ the width of the image. The rest of the light around the moon is due to the atmosphere spreading, blooming, and the 2^{nd} order effect of the lens. The attitude is determined to be R.A. = 37.627511, Decl. = 2.902540, and Rot. = 136.736162.

The dynamic range of the CCD makes it possible to detect fainter stars than $m_v = 7$. However, a threshold is used in the centroiding algorithm so that stars fainter than $m_v = 7$ will not be included in the attitude determination. Including fainter stars in the star catalogue will not improve the precision of the attitude. On the contrary, it will only increase the number of stars substantially in the star catalogue. Also the star catalog does not include deep space objects such as galaxies and nebula, which will have to be accounted for if fainter stars were used.

Figure 1. AVS determines the attitude even though the Moon is in the fov.

Asteroids, comets, planets and satellites will also be detected if they are brighter than $m_v = 7$. Since Teamsat in GTO would be close to the GEO satellites once every orbit, one of the objectives for AVS was to detect and track these non-stellar objects.

3. TRACKING RANGE OF GEO-SATELLITES

In order to calculate the tracking range of any non-stellar object in the field of view of the AVS, an estimate of the expected illumination of the object and of the CCD must be made.

The apparent visual magnitude of the sun at the Earth is $m_{v,\text{sun}} = -26.8$ and the illumination from the Sun is $E_{\text{sun}} = 1370 \text{ W/m}^2$. A star or an object of magnitude $m_v = 7$ yields an illumination of:

$$E_{m_v=7} = E_{\text{sun}} \cdot 2.512^{-26.8-7} = 41 \text{ pW/m}^2$$

This means that an object must have an illumination at the CCD of more than 41 pW/m^2 in order to be detectable if the AVS threshold is set at $m_v=7$. The incident solar power P_{object} on a object with an area A_{object} at the distance $r_{\text{sun-object}}$ (measured in AU) from the sun can be calculated as:

$$P_{\text{object}} = E_{\text{sun}} \cdot \left(\frac{1 \text{ AU}}{r_{\text{sun-object}}} \right)^2 \cdot A_{\text{object}}$$

The illumination from the object, at the distance r_{AVS} , to the AVS lens can be estimated as:

$$E_{\text{AVS}} = \frac{\alpha \cdot v_f \cdot P_{\text{object}}}{2\pi \cdot r_{\text{AVS}}^2}$$

where α is the albedo of the object, and v_f is the fraction of the object visible from the AVS. An estimate of the detection range $r_{\text{object-AVS}}$ of objects from the AVS can then be found as:

$$r_{\text{object-AVS}} = \sqrt{\frac{\alpha \cdot v_f \cdot E_{\text{sun}} \cdot A_{\text{object}}}{2\pi \cdot E_{\text{AVS}} \cdot r_{\text{sun-object}}^2}}$$

For GEO satellites $r_{\text{sun-object}}$ is approximately 1AU and the satellite have a body area A_{object} of approximately 15 m^2 . If the illumination E_{AVS} is set equal to the illumination corresponding to a $m_v=7$ star, and using an albedo $\alpha=0.7$ and a visible fraction $v_f=0.7$, the detection range is approximately 6.300 km. For the ideal case with $\alpha=v_f=1.0$, the detection range is 8.900 km. Table 1 summarizes detection ranges for different values of the combined factor $\alpha \cdot v_f$, and the object area A_{object} .

It can be seen that the detection range varies from approximately 5-10.000 km depending on the size of the satellite, its orientation and its surface properties. It was therefore planned to have the AVS detect and track the GEO satellites and any other non-stellar object while Teamsat approached apogee in the orbit.

Table 1. Detection range of GEO satellites.

$\alpha \cdot v_f$	A_{object}	$r_{\text{object-AVS}}$
0.5	10	5.135 km
0.7	10	6.080 km
1.0	10	7.265 km
0.5	15	6.290 km
0.7	15	7.445 km
1.0	15	8.900 km
0.5	20	7.265 km
0.7	20	8.595 km
1.0	20	10.275 km

4. ACHIEVED ORBIT

Due to the anomaly in the first stage of the launcher, the actual orbit achieved by Teamsat was quite different from what was planned. The nominal and achieved orbit parameters are shown in Table 2.

Table 2. Orbit parameters.

	Nominal	Achieved
Semimajor axis (km)	24628	19962
Eccentricity	0.717	0.654
Inclination	7.75°	7.77°
R.A. of Sac. Node	58°	58°
Arg. of Perigee	178°	178°
1 st Apogee Altitude (km)	35919	26639
Perigee Altitude (km)	580.9	528.7

The separation of Teamsat from the launcher also left Teamsat in a very flat spin. The AVS, pointing aft on Teamsat, made the attitude measurements based on onboard star tracking. The measurements were obtained while passing from looking at the earth to the sun. Figure 2 summarizes the Teamsat attitude as determined by the AVS measurements. L is the angular momentum of Teamsat, x is the Teamsat symmetry axis, R.A. and DEC are the right ascension and declination to which L points at the specified time.

Since the apogee of the orbit was about 9.280km short of the GEO, it can be seen from Table 1, that only in the case of total reflection from a large satellite would the AVS be able to detect any GEO satellites. Further, the non-nominal spinning of Teamsat caused the AVS to point at the Earth and the Sun for large portions of the time. Due to the design of Teamsat, the AVS was only allowed to be mounted with a very short 5 cm baffle. Even though the AVS was looking directly in to the Sun for large portions of the time, as soon as it came out of the

Figure 2. Teamsat attitude as determined by the AVS.

Sun, it just performed an "Initial Attitude Acquisition" and was back on track again. No damage were expected to the CCD by looking at the Sun and none was observed.

5. TRACKED OBJECTS

The AVS is equipped with a non-stellar object detector which have been assessed in real-sky tests using earth-orbiting satellites as objects. A typical pointing accuracy of 3" was found with a 25" noise per star at a detection limit of $m_v = 9$. The non-stellar object function may be enabled by command, and the number of objects tracked (up to 200) is user selectable.

As stated earlier, asteroids, comets, planets and satellites will also be detected by the AVS if they are brighter than $m_v = 7$. The same goes for radiation spots on the CCD. All of these will be detected as outliers since they are not in the star catalogue and therefore rejected during the attitude determination process. Even though the AVS is capable of detecting faint $m_v = 9$ objects, the compiled star catalogue on board Teamsat only contained stars down to $m_v = 7$. The AVS do have the capability to inflight upload all software anew including a new star catalogue, so as to handle the increased detection distance to the GEO satellites. Due to the restricted TC bandwidth it was however not possible to do this on Teamsat.

The radiation spots are concentrated on a single or double pixel, and will be located in the same pixel positions in sequences of images, while non-stellar objects will move relative to the stars as well as the pixel position when the

Figure 3. The Ariane 502 launch configuration and the position of Teamsat.

AVS is spinning. Any object detected, not recognized as "stars" or radiation spots, can then be used as a target to the detection and tracking of non-stellar objects in the field of view of the AVS in sequences of images.

Besides detecting and tracking GEO satellites, the AVS was to track any other object in the vicinity of Teamsat. The launch configuration of the Ariane 502 is shown in Figure 3. The short fairing is ejected at burnout of the first stage and is not expected to be visible for the AVS when it is first turned on. Maqsat-H was scheduled to separate from the speltra with the Maqsat-B test satellite inside 48° after burnout of the second stage (i.e. perigee). The Maqsat-H and the speltra was supposed to be oriented in the velocity direction at the time of separation. The AVS would then have been able to continuously track the speltra as it would drift away. Due to the nonnominal launch insertion into the orbit, the satellites were spinning and were oriented almost perpendicular to the velocity vector at the time of separation. This situation is depicted in Figure 4. The figure also shows the resulting approximate orbits of the separated objects. The two objects will drift apart for almost half an orbit and then start to approach each other again. Therefore the object should continue to be in the vicinity of Teamsat throughout the mission. Indeed we continued to see the object from time to time depending on the distance and the attitude in the 20 orbits. The expected separation velocity was 1ms^{-1} , which would give a maximum separation of approximately $0.5 \cdot T_{\text{orbit}} \cdot v_{\text{separation}} \approx 15\text{ km}$.

The first image acquired by the AVS after launch is shown in Figure 5. Part of the light from the Earth can be seen in the upper right corner, and the glare from it is effecting almost half of the image. The stars can be seen as small

almost vertical lines due to the high rotation of Teamsat. Radiation spots are seen as small bright dots on a single or double pixel. To the left under the TM dropout can be seen a non-stellar object.

This object is much larger than the stars and the line it draws during the integration time is in a slightly different direction than the stars. The "two parts" of the objects is due to the interlace mode operation of the CCD camera. The object is most probably the speltra with the Maqsat-B. The AVS detected the object and outputted the attitude of the object as seen from the AVS. Assuming the object is the speltra, the distance to it can be estimated to be approximately 1000-1500m.

Another instrument aboard the Teamsat was the Young Engineers Satellite (YES), which was a small micro-satellite tethered system. It was originally planned to have deployed a 35 km long tether, after which it should have been ejected from the bottom of Teamsat to re-enter and burn up in the atmosphere. The International Steering Committee for Space Debris gave it a no-go due to risk considerations, which resulted in YES being ejected without the tether. If Teamsat had been launched into nominal attitude in the orbit, YES should have been in the field of view of the AVS, and it should therefore have been detected and tracked by the AVS in a sequence of images.

However, due to the spinning of the Teamsat at ejection time, YES was also not ejected along the orbit direction, causing it too to reappear from time to time in the field of view of the AVS. Figure 6 shows one of the last images taken by the AVS. It shows what is believed to be YES as well as the speltra.

Figure 4. Orbit of Teamsat and Maqsat B after separation.

Figure 5. First image acquired by the AVS. The gray band across the image is due to a telemetry dropout between the Teamsat OBDH and the ground EGSE.

Figure 6. One of the last images acquired by the AVS.

Note also the increased number of radiation spots in the image in Figure 5 compared to the image in Figure 6. On Teamsat, the thickness of the Camera Head Unit was deliberately made thin, so as to receive a life time radiation dose during the approximately 20 orbits each passing the Van Allen proton belts twice. This was one of the other main goals of the AVS onboard Teamsat so as to get real data for the radiation sensitivity of the CCD chip and camera design.

6. CONCLUSION

The Teamsat was only equipped with NiCd batteries and no solar cells so the mission duration was limited to approximately 4 days. During this period, the different instruments on the AVS were switched on and off periodically in order to distribute the power equally. This and the fact that the Teamsat satellite was ejected spinning into a non-nominal orbit looking at the Sun for large portions of the time resulted in a non-optimal test sequence for the AVS with respect to accuracy and detection possibilities, but nice testobjects were imaged.

However, the AVS functioned flawlessly. It determined the attitude and attitude dynamics of the Teamsat after the non-nominal orbit insertion. It did not receive any damage, except for the expected radiation effects on the CCD, and kept functioning even though it was pointing at the sun for large portions of the time. It also received the planned life time dose of radiation in order to study the effects hereof.

The AVS was not able to detect the GEO satellites due to the non-nominal orbit, but it reliably detected the objects in the vicinity of Teamsat throughout the mission.

Though the Ariane 502 launch itself was not a perfect mission, for the AVS onboard the Teamsat it proved to operate quite successfully under difficult circumstances.
