In state of the art organic electronics, device performance and lifetime crucially depend on the properties of both the active materials and their interfaces. It is an unfortunate fact that the dramatic progress which has been recently achieved in materials design and manufacturing has not been matched by an equal improvement in interface engineering. Consequently, devices typically contain a large number of layers with different functions that could, ultimately, be replaced by several “smart” interfaces. Significant surface dipoles are routinely observed when a conjugated molecule is deposited in vacuum onto an atomically clean metal surface because of the direct mixing of its π-orbitals with the metallic bands upon covalent-type chemisorption. The origin of the interfacial dipole at the organic-metal interface has been investigated by following the change in the metal work function ΔWF upon adsorption of the organic monolayer.1–4

Here, we focus on a specific class of interfaces that is very common in a large range of applications, namely, weakly interacting systems of π-conjugated molecules (or polymers) on metallic contacts. Indeed, for ex situ prepared interfaces by solution processing, the direct overlap between the π-orbitals of the conjugated materials (polymer or molecule) and the metal surface is often prevented by either surface oxide and/or hydrocarbon surface contaminations. However, even for such cases significant dipoles have been observed.5–7 Upon varying the work function of the substrate, abrupt transitions are observed between a Schottky–Mott regime, in which the interface dipole is negligible, and Fermi-level pinning regimes, where the size of the dipole scales with the difference between the adiabatic (i.e., fully relaxed, electronically, and geometrically) ionization potential or electron affinity of the conjugated polymer and the work function of the substrate.6 This is explained by spontaneous charge transfer between the electrode and the conjugated polymer via tunneling (integer charge transfer), but it has been never directly observed.

In this letter, we report a joint experimental and theoretical study of the tetrakis(dimethylamino)ethylene/Au interface by photoelectron spectroscopy and quantum chemical modeling. TDAE is used as a model system that mimics the situation of an organic semiconductor, with an electron donor character, that has no direct overlap between its π-molecular orbitals and the metal bands. The TDAE molecule has a strong electron donor character due to the presence of four amine groups providing an excess of electron density on the central vinylic group (C=C bond). The electron rich C=C bond is encased by eight outer methyl groups which prevents the overlap between molecular orbitals and metal bands.

Polycrystalline gold substrates were sputter cleaned in ultrahigh vacuum (UHV) and thereafter cooled down before exposure to the vapor of TDAE. At a temperature just above the condensation temperature of TDAE (about 200 K in UHV) a stable submonolayer of TDAE is formed.8 In the following, we will simply refer to this stable coverage as a monolayer, although it should be noted that the areal density is considerably less than that of a densely packed single layer of TDAE molecules. The work function of the bare gold surface is 5.2 eV. Upon exposure to TDAE, UV photoelectron spectroscopy (UPS) reveals that the work function of the TDAE-modified gold surface decreases by 1.3 down to 3.9 eV. For the sake of comparison, the change in work function for a polycrystalline gold surface due to hydrocarbon contamination arising from air exposure is about 0.7 eV and attributed mostly to the Pauli repulsion. The magnitude of the shift resulting from TDAE absorbed on the gold thus shows that additional effects are involved. Since the molecule itself does not carry an intrinsic dipole in its neutral or charged state,9 the large work function change can only be explained by a charge transfer reaction between TDAE and Au.

In Fig. 1, the UPS (hν=21.2 eV) valence band spectra of gold (dotted line), a TDAE monolayer on gold (full line), and a TDAE multilayer (dashed line) are shown. In addition to these spectra, Fig. 1 also includes simulated spectra of different charge states of TDAE as well as a gas-phase UPS spectrum. The theoretical simulations (adapted from Ośikowicz et al.10) are based on Koopmans’ approximation; i.e., using density functional theory eigenvalues (B3LYP hy-
paring the monolayer and multilayer signals. As can be seen from the spectra of the different charged states, the calculated spectra of the TDAE monolayer on gold, are shifted to align the peaks originating from the orbitals of TDAE, to that found for the chemisorbed TDAE monolayer used as an internal reference level when comparing the monolayer and multilayer signals. As can be seen from the UPS spectrum (versus vacuum level) obtained for the TDAE multilayer in order to account for solid-state polarization effects. For more details, see Ref. 10.

The presence of TDAE on the Au surface is clearly revealed by the appearance of the two peaks located between 8 and 10 eV attributed to the \( \sigma \)-levels of the molecule (Fig. 1). Those levels are used as an internal reference when comparing the monolayer and multilayer signals. As can be seen from the calculated UPS spectra, the TDAE\(^{+}\) radical cation is characterized by the destabilization of the HOMO. The destabilization of the HOMO is due to elongation of the C–N bond upon oxidation resulting from a reduction of the antibonding character on the C–N bond. Such an effect is similar to the formation of polaron levels in the band gap of extended \( \pi \)-systems, such as conjugated polymers. The dication TDAE\(^{2+}\), obtained after removal of two electrons from the HOMO level of TDAE, does not contribute to the photoelectron signal intensity in this energy region. Hence, the modification of the HOMO of TDAE upon adsorption on gold can reveal the charge state of the molecule.

In Fig. 1, all spectra except those of Au and the TDAE monolayer on Au, are shifted to align the peaks originating from the \( \sigma \)-orbitals of TDAE, to that found for the chemisorbed TDAE monolayer used as an internal reference level when comparing the spectra of the multilayer and that of the TDAE monolayer reveals a clear destabilization of the low binding energy peak associated with the HOMO from 1.8 to 1.2 eV. This 0.6 eV shift toward high binding energy indicates the presence of singly charged molecular radical cation TDAE\(^{+}\) on gold in agreement with the theoretical simulations. This not only proves that positively charged species are formed, but also indicates that the amount of charge transfer must be nearly integer. In contrast, partial charge transfer accompanied by hybridization with the Au bands would lead to a wide distribution of states, and not a resolvable singly occupied molecular orbital (SOMO).

FIG. 1. (Color online) The UPS spectra of the clean gold surface (dotted line), the TDAE monolayer on gold (full line), and a multilayer of TDAE (dashed-dotted line), together with an enlargement of the lowest part of the valence band, are displayed in the upper part of the figure. Below, the calculated spectra of the different charged states are plotted together with a gas-phase measurement of TDAE. The binding energies are vs the gold Fermi level.

In addition to the experimental results, first principles calculations are performed on models for the TDAE/Au interface. The gold (111) surface is modeled in the calculations by a Au\(_{16}\) cluster with a top layer with 13 atoms, the minimal number of atoms required to fit the entire molecule on top of the surface. A second layer, which has been shown to be important for the electronic structure of thiolates on gold, contains six atoms and a third layer, a single atom, introduced to get an even number of gold atoms in total which yields a closed shell system. All Au–Au bond distances are set to 2.88 Å. TDAE is positioned in such a way that the axis through the C–C bond is parallel to the surface and the midpoint of the C–C bond is above the center gold atom in the cluster. This distance is called \( r \) in the inset of Fig. 2. The calculations were carried out using the GAUSSIAN 03 (Ref. 12) program, with the B3LYP hybrid exchange-correlation functional. Hence, in the calculation of TDAE on gold, we used the 6-31G and cc-pVDZ basis sets for the light elements (H, C, and N) and the relativistic corrected basis set LanL2DZ with effective core potentials for gold.

FIG. 2. (Color online) Chemisorption energy as a function of \( r \) for the Au\(_{16}\)–TDAE complex. Different geometries of the molecule have been used. Neutral molecule (circles), singly charged molecules (diamonds), and relaxed molecular geometry (squares). The inset shows the geometry of the complex.

of the molecule. The chemisorption energy is found for the neutral and singly charged molecule at about \(r=5.0\ \text{Å}\), while the calculation yields positive val-
ues of chemisorption energy using the geometry of the dou-
ly charged molecule. In agreement with experimental obser-
vations, two-electron transfer from TDAE to the gold surface is not taking place since the adsorption of TDAE\(^{2+}\) is not stable. To further improve the accuracy of the result we let the internal structure of the singly charged molecule relax on the surface when calculating \(E_{\text{TDAE/Au}}\) (squares in Fig. 2).

To reduce the computational time, these calculations are only performed for a few values of \(r\) around the energy minimum obtained above. The chemisorption is further stabilized \((\Delta E=−0.73 \text{ eV})\) compared to the unrelaxed system \((\Delta E=−0.66 \text{ eV})\) but the position of the energy minimum is unchanged. Note that for \(r\) larger than 7.0 Å the complex with the neutral gas-phase geometry has higher chemisorption energy than the complex for which the geometry of the singly charged molecule is used. This is expected since the charge transfer from the molecule to the cluster decreases when \(r\) is increased, and the molecule becomes more stable for the neutral structure above a certain value of \(r\).

The analysis of the charge distribution, following Mul-
lkin’s scheme, for the relaxed system shows an almost com-
plete charge transfer from the TDAE to the gold cluster \((\Delta q_{\text{TDAE}}/e=0.91\) for the relaxed system, \(\Delta q_{\text{TDAE}}/e=0.93\) for the unrelaxed system), in agreement with the experimental observations. Most of the excess positive charge (72%) on TDAE is located on the carbon atoms of the central vinylic group. In the TDAE/Au\(_{20}\) complex, this orbital is partially depopulated as a result of the charge transfer with the gold surface. The bond length of the C=\(\text{C}\) (N–\(\text{C}\)) bond is 1.41 Å (1.39 Å) in the TDAE/Au\(_{20}\) complex. Those bond lengths are similar to those obtained for an isolated singly charged TDAE. However, the dihedral angle around the central \(\text{C}–\text{C}\) bond in the chemisorbed TDAE is 28°, which is considerably smaller than for the singly charged molecule in the gas phase. This is attributed to the electrostatic contribution in the chemisorption energy that forces the cationic TDAE\(^{+}\) to come close to the gold surface and partially overcomes the rotation barrier around the central \(\text{C}–\text{C}\) bond.

In summary, we present experimental and theoretical evidence that the interface energetics for weakly interacting systems of \(\pi\)-conjugated molecules (or polymers) on metal contacts are governed by the exchange of an integer amount of electrons, as opposed to partial charge transfer in hybridized systems.

UPS measurements reveal a destabilization of the SOMO level of the adsorbate by about 0.6 eV versus the HOMO of the neutral molecule and a significant work function decrease of about 1.3 eV upon monolayer adsorption resulting from the strong electric dipoles formed upon electron transfer from TDAE to Au. Robust quantum chemical models indicate that TDAE is strongly chemisorbed on the model gold surface and carries a unitary positive charge. The negative charge at the metal surface and the positive charge carried by the molecular adsorbate protected with its methyl groups make the electrostatic contribution important to the chemisorption energy. This type of interaction can be described as a molecular ionic chemisorption.
