**ABSTRACT**

We present the final results from the **XMM-Newton** validation follow-up of new **Planck** galaxy cluster candidates. We observed 15 new candidates, detected with signal-to-noise ratios between 4.0 and 6.1 in the 15.5-month nominal **Planck** survey. The candidates were selected using ancillary data flags derived from the ROSAT All Sky Survey (RASS) and Digitized Sky Survey all-sky maps, with the aim of pushing into the low SZ flux, high-z regime and testing RASS flags as indicators of candidate reliability. Fourteen new clusters were detected by **XMM-Newton**, ten single clusters and two double systems. Redshifts from X-ray spectroscopy lie in the range 0.2 to 0.9, with six clusters at z > 0.5. Estimated masses (M500) range from 2.5 \times 10^{14} to 8 \times 10^{14} M_\odot. We discuss our results in the context of the full **XMM-Newton** validation programme, in which 51 new clusters have been detected. This includes four double and two triple systems, some of which are chance projections on the sky of clusters at different redshifts. We find that association with a source from the RASS-Bright Source Catalogue is a robust indicator of the reliability of a candidate, whereas association with a source from the RASS-Faint Source Catalogue does not guarantee that the SZ candidate is a bona fide cluster. Nevertheless, most **Planck** clusters appear in RASS maps, with a significance greater than 2σ being a good indication that the candidate is a real cluster. Candidate validation from association with SDSS galaxy overdensity at z > 0.5 is also discussed. The full sample gives a **Planck** sensitivity threshold of Y_{500} \sim 4 \times 10^{-4} arcmin^2, with indication for Malmquist bias in the Y_{500} versus Y_{500} relation below this threshold. The corresponding mass threshold depends on redshift. Systems with M_{500} > 5 \times 10^{14} M_\odot at z > 0.5 are easily detectable with **Planck**. The newly-detected clusters follow the Y_{500} versus Y_{500} relation derived from X-ray selected samples. Compared to X-ray selected clusters, the new SZ clusters have a lower X-ray luminosity on average. There is no indication of departure from standard self-similar evolution in the X-ray versus SZ scaling properties. In particular, there is no significant evolution of the Y_{500}/M_{500} ratio.

**Key words.** cosmology: observations – galaxies: clusters: general – galaxies: clusters: intracluster medium – cosmic background radiation – X-rays: galaxies: clusters

1. Introduction

The Planck\(^1\) satellite has been surveying the millimetre sky since 2009. Its two instruments together cover nine frequency bands: the Low Frequency Instrument (LFI; Mandel et al. 2010; Bersanelli et al. 2010; Mennella et al. 2011) at 30, 44, and 70 GHz, and the High Frequency Instrument (HFI; Lamarre et al. 2010; Planck HFI Core Team 2011) at 100, 143, 217, 353, 545, and 857 GHz. Before the HFI coolant ran out in January 2012, Planck had successfully performed nearly 5 surveys of the entire sky.

Planck allows the detection of galaxy clusters by their imprint on the cosmic microwave background (CMB) via the Sunyaev-Zeldovich (SZ) effect, a characteristic spectral distortion of the CMB due to inverse Compton scattering of photons by hot electrons in the intra-cluster medium (Sunyaev & Zeldovich 1972). The SZ signal of galaxy clusters is expected to correlate tightly with cluster mass (e.g., da Silva et al. 2004) and its surface brightness is independent of redshift. SZ selected cluster samples are thus particularly well-suited for statistical studies of the galaxy cluster population, either as a probe of the physics of structure formation, or for cosmological studies based on cluster abundance as a function of mass and redshift. Compared to other SZ surveys, such as those with the Atacama Cosmology Telescope (ACT, Marriague et al. 2011) or the South Pole Telescope (SPT, Carlstrom et al. 2011), the Planck survey covers an exceptionally large volume; indeed, it is the first all-sky survey since the ROSAT All-Sky Survey (RASS) in the X-ray domain. Planck allows the detection of clusters below the flux limit of RASS based catalogues at redshifts typically greater than 0.3 (Planck Collaboration 2012, Fig. 9). The first Planck SZ catalogue, the Early SZ (ESZ) sample, was published in Planck Collaboration (2011a). It contains 189 clusters and was the ratio of the Hubble constant at redshift \(z\) to its present-day value. The quantities \(M_{500}\) and \(R_{500}\) are the total mass and radius corresponding to a total density contrast \(\delta = 500\), as compared to \(\rho_c(z)\), the critical density of the Universe at the cluster redshift; \(M_{500} = (4\pi/3) 500\rho_c(z) R_{500}^3\). The SZ flux is characterised by \(Y_{500}\), where \(Y_{500} D_A^2\) is the spherically integrated Compton parameter within \(R_{500}\), and \(D_A\) is the angular-diameter distance to the cluster. Thus, as defined here, \(Y_{500}\) has units of solid angle and is given in arcmin\(^2\) in Table 2.

2. Sample selection

2.1. Planck catalogue

In this paper, candidates were chosen from the catalogue derived from the first 15.5 months of data (the “nominal” mission). The processing status, calibration, and map versions were those of Planck collaboration (2011a).

Planck allows the detection of galaxy clusters by their imprint on the cosmic microwave background (CMB) via the Sunyaev-Zeldovich (SZ) effect, a characteristic spectral distortion of the CMB due to inverse Compton scattering of photons by hot electrons in the intra-cluster medium (Sunyaev & Zeldovich 1972). The SZ signal of galaxy clusters is expected to correlate tightly with cluster mass (e.g., da Silva et al. 2004) and its surface brightness is independent of redshift. SZ selected cluster samples are thus particularly well-suited for statistical studies of the galaxy cluster population, either as a probe of the physics of structure formation, or for cosmological studies based on cluster abundance as a function of mass and redshift. Compared to other SZ surveys, such as those with the Atacama Cosmology Telescope (ACT, Marriague et al. 2011) or the South Pole Telescope (SPT, Carlstrom et al. 2011), the Planck survey covers an exceptionally large volume; indeed, it is the first all-sky survey since the ROSAT All-Sky Survey (RASS) in the X-ray domain. Planck allows the detection of clusters below the flux limit of RASS based catalogues at redshifts typically greater than 0.3 (Planck Collaboration 2012, Fig. 9). The first Planck SZ catalogue, the Early SZ (ESZ) sample, was published in Planck Collaboration (2011a). It contains 189 clusters and was the ratio of the Hubble constant at redshift \(z\) to its present-day value. The quantities \(M_{500}\) and \(R_{500}\) are the total mass and radius corresponding to a total density contrast \(\delta = 500\), as compared to \(\rho_c(z)\), the critical density of the Universe at the cluster redshift; \(M_{500} = (4\pi/3) 500\rho_c(z) R_{500}^3\). The SZ flux is characterised by \(Y_{500}\), where \(Y_{500} D_A^2\) is the spherically integrated Compton parameter within \(R_{500}\), and \(D_A\) is the angular-diameter distance to the cluster. Thus, as defined here, \(Y_{500}\) has units of solid angle and is given in arcmin\(^2\) in Table 2.

2 These multiple systems, where more than one cluster contribute to the Planck signal, can be either chance association on the sky of clusters at different redshifts, or physically related objects at the same redshift. When referring to double or triple systems in the text, we do not distinguish between the two cases.

Notes. Column (1): Planck source name. Columns (2) and (3): right ascension and declination of the Planck source (2000). Columns (4) and (5): signal-to-noise ratio of the Planck candidate detection with the MMF3 algorithm in the Planck-maps, and number of methods blindly detecting the candidate. Column (6): quality grade of the SZ detection (A is best). Columns (7)–(10): XMM-Newton observation identification number, filter used, on-source exposure time with the EPN camera, and fraction of useful time after cleaning for periods of high background due to soft proton flares (EMOS and EPN camera, respectively). Column (11): category resulting from the pre-selection of the candidates. Column (12): confirmed clusters are flagged. (†) indicates double projected systems.

March 2011. The detection and quality assessment of the cluster candidates followed the general procedure described in Planck Collaboration (2011a). Briefly, a blind cluster search was performed with the three methods: the matched multi-frequency filter “MMF3” developed by Melin et al. (2006); an independent matched multi-frequency filter “MMF1”; and the PowellSnakes algorithm (PWS; Carvalho et al. 2009, 2012). Candidates then underwent internal SZ quality checks, removing spurious detections (e.g., association with artefacts or galactic sources), and assessment of the SZ signal detection. The signal assessment included quantitative criteria such as the signal-to-noise ratio and the number of methods blindly detecting the candidate, Ndet, as well as a qualitative assessment based on visual inspection of the frequency maps, reconstructed SZ images, and the frequency spectra for each cluster. The latter procedure is summarised in an SZ quality grade, QSZ, as described in Planck Collaboration (2012).

Previously known clusters were identified via cross-correlation with catalogues and NED/Simbad queries. Possible counterparts were searched for within a 5° radius of the Planck position, allowing us to assign two further external reliability flags:

- association of a FSC (Faint Source Catalogue) or a BSC (Bright Source Catalogue) RASS source (Voges et al. 1999, 2000) or an excess of counts (with corresponding signal-to-noise ratio) in the RASS [0.5−2] keV image;
- galaxy over-density in the Digitized Sky Survey (DSS) red plates3, from a visual check. In the Sloan Digital Sky Survey (SDSS) area4, two independent galaxy detection algorithms were applied to the DR7 galaxy catalogues (Fromenteau et al., in prep.; Li & White, in prep.). Both algorithms use photometric redshift information. Quality match criteria were assigned based on cluster richness or the over-density signal-to-noise ratio.

2.2. XMM-Newton target selection

The resulting targets are listed together with their SZ quality flags in Table 1. The range of signal-to-noise ratios, 4 < SN < 6.1, is wide, with nearly uniform coverage, so that the validation results can be useful for defining the final signal-to-noise ratio for the Planck Cluster Catalogue. We considered lower signal-to-noise ratios than the previous validation programme, with 9 targets at SN < 5 and a median SN of 4.9, as compared to 5.1 previously (for 10.5 months of survey data). A priori, this allows us to reach lower flux or higher redshift. To further push the sample towards high redshift, we discarded candidates with estimated R500 size greater than 5′. Although the large positional uncertainty of Planck candidates makes the search for a DSS counterpart non-trivial, the brightest galaxies of clusters at z < 0.5 are generally visible in DSS (e.g., Fassbender et al. 2011). We thus also used DSS images to select high-z clusters. Half the targets, labelled PHZ (potentially at high z) in Table 1, have no visible counterpart in DSS red plates. These are obviously riskier candidates, particularly those with low Ndetection / QSZ.

As previous validation observations have shown, the association of a SZ candidate with a RASS FSC or BSC source is not in itself sufficient to confirm the candidate, as chance association with a point source is always a possibility. Conversely, a candidate with no counterpart in the RASS catalogue may well be a bona fide cluster. With this campaign, in combination with the previous observations, we also aim to address the use of RASS data as an indicator of candidate reliability. In the sample of 36 candidates observed previously, thirteen candidates were associated with a BSC source and seventeen candidates with an FSC source. Only six SZ candidates had no FSC/BSC counterpart, of which the three confirmed candidates were detected in RASS at a signal to noise ratio of 1.7 < SN < 2.8. To better span the range of external RASS flags, we chose ten candidates with no FSC or BSC counterpart, six of which correspond to a RASS SN < 1.5. Of the remaining five candidates, only one is associated with a BSC source and four are associated

3 http://stsdau.stsci.edu/dss
4 http://www.sdss.org
with an FSC source. The RASS association for all XMM-Newton validation targets is summarised in Table 3.

Finally one candidate, PLCK G210.6+20.4, was specifically chosen to further test our SDSS-based confirmation of very poor SZ candidates. PLCK G210.6+20.4 is the lowest SZ signal-to-noise candidate, detected at $S/N = 4$ by one method only, with a $Q_{\text{SZ}} = C$ grade and no significant signal in RASS data. However, the galaxy-detection algorithms (Sect. 2.1) that we used indicated that the candidate is associated with an SDSS galaxy over-density at $z = 0.5$.

3. XMM-Newton observations and data analysis

Candidates were observed between 31 July 2011 and 13 October 2011. The observation identification number and observation setup are given in Table 1. Due to a slew failure in the satellite revolution 2132, the PLCK G208.6$-$74.4 observation was incomplete, with an EPN exposure time of 3.4 ks. The target was observed initially at the end of its summer visibility window, and could only be reobserved five months later. It was replaced with an additional visible candidate, PLCK G329.5$-$22.7.

Calibrated event lists were produced with v11.0 of XMM-SAS. Data that were affected by periods of high background due to soft proton flares were omitted from the analysis (Pratt et al. 2007); clean observing time after flare removal is given in Table 1. The status of each SZ candidate is also given in Table 1: 12 of the 15 candidates are confirmed to be real clusters, among which two are double systems. XMM-Newton images of unconfirmed candidates are shown in Fig. 1; confirmed candidates are shown in Fig. 2.

We derived redshifts and physical parameters of the confirmed candidates as described in Planck Collaboration (2011a); Planck Collaboration (2012). Cleaned XMM-Newton data were pattern-selected. Each photon was then assigned a weight equivalent to the ratio of the effective area at the photon energy and position to the central effective area, computed with SAS task EVGWEIGHT. Images and spectra were extracted using this weight, assuring full vignetting correction (see Arnaud et al. 2001). Bright point sources were excised from the data and the background was handled as described in Pratt et al. (2010). The particle-induced background (PB) was estimated using a stacked event list built from observations obtained with the filter wheel in closed position. The cosmic X-ray background was modeled using a PB-subtracted spectrum of an annular region external to the cluster emission.

In the spectroscopic analysis, the hydrogen column density was fixed at the 21-cm value of Kalberla et al. (2005). The redshift was estimated by fitting an absorbed redshifted thermal model to the spectrum extracted within a circular region corresponding to the maximum X-ray detection significance. The quality of the $z$ estimate was characterised by the quality flag $Q_z$ as introduced in Planck Collaboration (2011b). $Q_z$ was set to $Q_z = 0$ when the redshift could not be constrained due to the lack of line detection. $Q_z = 1$ corresponds to ambiguous $2\chi^2$ estimate, when the spectral fit as a function of $z$ exhibited several $\chi^2$ minima that could not be distinguished at the 90% confidence level. $Q_z = 2$ corresponds to a well constrained redshift (i.e., a single $\chi^2$ minimum).

Surface brightness profiles centred on the X-ray peak were extracted from 3$''$/3 bins in the [0.3–2] keV band for each instrument independently, background subtracted, co-added and rebinned to 3$''$ per bin. 3D gas density profile were obtained using the regularised non-parametric method of direct deprojection and PSF deconvolution of the surface brightness profile developed by Croston et al. (2006). Global cluster parameters are estimated self-consistently within $R_{500}$ via iteration about the $M_{500}$–$Y_X$ relation of Arnaud et al. (2010), assuming standard evolution,

$$E(z)^{2/3}M_{500} = 10^{14.567 \pm 0.010} \frac{Y_X}{2 \times 10^{14} M_\odot \text{keV}} \times 0.561 \pm 0.018 M_\odot.$$ 

The quantity $Y_X$, is defined as the product of $M_{500}$, the gas mass within $R_{500}$, and $T_X$, the spectroscopic temperature measured in the $[0.15–0.75]R_{500}$ aperture. In addition, $L_{500}$, the X-ray luminosity inside $R_{500}$, is calculated as described in Pratt et al. (2009). The SZ flux was then re-extracted, $Y_{500}$ being calculated with the X-ray position and size $R_{500}$ fixed to the refined values derived from the high-quality XMM-Newton observation. The X-ray properties of the clusters and resulting refined $Y_{500}$ values are listed in Table 2.

4. XMM-Newton validation outcome

4.1. False cluster candidates

For the three candidates shown in Fig. 1, no obvious extended X-ray sources were found within 5$''$ of the Planck position. We followed the maximum likelihood procedure described by Planck Collaboration (2011a) to find all extended sources in the field detected at the $2\sigma$ level. We then assessed whether they could be the counterpart of the Planck candidate from their position and X-ray flux, using the relation between the X-ray flux.

Fig. 1. XMM-Newton [0.3–2] keV energy band images of the three unconfirmed cluster candidates centred on the SZ position (yellow cross). The red circles indicate the presence of an extended source. Green squares in the right panel are positions of galaxies in the SDSS over-density.
Fig. 2. *XMM-Newton* [0.3–2] keV energy band images of confirmed cluster candidates. North is up and East is to the left. Image sizes are $3\theta_{500}$ on a side, where $\theta_{500}$ is estimated from the $M_{500} - Y_X$ relation of Arnaud et al. (2010) assuming standard evolution. Images are corrected for surface brightness dimming with $z$, divided by the emissivity in the energy band, taking into account galactic absorption and instrument response, and scaled according to the self-similar model. The colour table is the same for all clusters, so that the images would be identical if clusters obeyed strict self-similarity. A yellow cross indicates the *Planck* position and a red/green plus sign the position of a RASS-BSC/FSC source. The clusters are sorted according their estimated redshift. For the double systems (last two rows) the middle and right panels show the two components and the left panel the wavelet-filtered overall image.

**Notes.** Columns (2) and (3): right ascension and declination of the peak of the X-ray emission (J2000). Column (4): redshift from X-ray spectral fitting. Column (5): quality flag for the X-ray redshift measurement (see Sect. 3). Column (6): total EPIC count rates in the [0.3–2] keV band, within the maximum radius of detection given in Col. (7). Columns (8)–(14): R500 is the radius corresponding to a density contrast of 500, estimated iteratively from the M500 − YX relation. YX = M500/T500 is the product of the gas mass within R500 and the spectroscopic temperature T500 and M500 is the total mass within R500. L500(0.1−2.4) is the luminosity within R500 in the [0.1−2.4] keV band. Y500 is the spherically integrated Compton parameter measured with Planck, centred on the X-ray peak, in the R500 sphere, and the X-ray observations. Other possible zhigh = 0.12, 0.40; the former solution is excluded from the X-ray versus SZ properties and the latter is unlikely (see Sect. A.1); [15] Fe = 0.26, 0.46. The [15] Fe = 0.26 is unlikely in view of the X-ray versus SZ properties (see Sect. A.1); [14] 78 = 0.40, 1.03. The given solution, [15] Fe = 0.62 is that consistent with the optical redshift zopt = 0.66 ± 0.05 (Sect. A.2). [15] Fe = 0.87 (excluded from DSS red image, see Sect. A.1) and [15] Fe = 0.10 for the A and B components, respectively.

in the [0.1–2.4] keV band, F_X, and the SZ flux Y500 established by Planck Collaboration (2012):

\[
\frac{F_{X}/10^{-12} \text{ erg s}^{-1} \text{ cm}^{-2}}{Y_{500}/10^{-2} \text{ arcmin}^2} = 4.95 E(z)^{5/3} (1+z)^{-3} K(z). \tag{1}
\]

Here \( K(z) \) is the K correction, neglecting its temperature dependence.

4.1.1. PLCK G196.4–68.3 and PLCK G310.5+27.1

PLCK G196.4–68.3 was classified as PHZ (potentially at high z). Analysis of the XMM-Newton data on PLCK G196.4–68.3 revealed two extended sources at 9.7 and 11.8 from the SZ position. Both sources correspond to a RASS-FSC source. Both sources are too far away to be the X-ray counterpart of the Planck candidate. A RASS-FSC source is located at 5.2 from the SZ position and likely contributes to the S/N = 1.7 signal derived from RASS data at the Planck source location. However, the comparison of its surface brightness profile with the XMM-Newton PSF shows that it is consistent with a point source. We thus conclude that PLCK G196.4–68.3 is a false detection.

PLCK G310.5+27.1 was also classified as PHZ. Two extended X-ray sources were detected at 10.5 and 2.5 from the SZ position, respectively. The former is too far away to be the X-ray counterpart, while the latter is very weak. Analysis of the surface brightness profile confirmed that it is extended. The detection radius is small, \( \theta_{68} = 0.044 \) and the spectrum extracted from this region is too poor to put robust constraints on the redshift or the temperature. However, using the \( F_X/\text{Y}_{500} \) relation (Eq. (1)) and the measured X-ray flux, we can put an upper limit on \( Y_{500} \) assuming a redshift as high as \( z = 2 \) and taking into account a factor of two dispersion around the relation. For a temperature of \( kT = 4 \) keV and \( z = 2 \), we derive a flux within the detection radius of \( F_X = 2.8 \times 10^{-14} \text{ erg s}^{-1} \text{ cm}^{-2} \). Assuming that this flux is close to the total, this gives an upper limit on the SZ flux of \( Y_{500} \sim 9 \times 10^{-5} \text{ arcmin}^2 \), nearly an order of magnitude smaller than the Planck value \( Y_{500} \sim 6.7 \times 10^{-4} \text{ arcmin}^2 \). Moreover, the SZ significance drops under 2\( \sigma \) when the flux is re-extracted at the X-ray position. We conclude that this candidate is also a false detection.

Both of these false candidates were detected by two methods, with a medium quality grade of \( Q_{SZ} = B \) and at \( S/N = 4.7 \) and \( S/N = 4.8 \), respectively. A \( Q_{SZ} = A \) quality grade is thus not sufficient to ensure candidate validity at these signal-to-noise ratios. On the other hand, all \( Q_{SZ} = A \) candidates down to \( S/N = 4.6 \) that have been followed up by XMM-Newton have been confirmed.

4.1.2. PLCK G210.6+20.4

PLCK G210.6+20.4 is associated with an SDSS cluster. The SDSS search algorithm identified a galaxy over-density of 77 members at a photometric redshift of \( z \sim 0.57 \), consistent with the spectroscopic redshift of the brightest cluster galaxy (BCG) at \( z = 0.52 \). The barycentre of the concentration and the BCG are located 1.5 and 5 from the Planck position (see Fig. 1), respectively. The X-ray analysis revealed the presence of an extended source, centred on the BCG, detected at 3\( \sigma \) in the [0.3−2] keV image. However, the source is very faint and more reminiscent of a group of galaxies than of a rich cluster. This is confirmed by the X-ray spectroscopic analysis. Extracting and fitting the spectrum with an absorbed thermal model at \( z = 0.52 \), we measured a temperature within the detection radius \( \theta_{det} = 0.77 \) of \( T_{R80} = 1.5 \pm 0.5 \) keV and a flux of \( F_X = 2.31 \times 10^{-14} \text{ erg s}^{-1} \text{ cm}^{-2} \). Using Eq. (1) as above, the upper limit on the corresponding SZ flux is \( Y_{500} \sim 2.6 \times 10^{-2} \text{ arcmin}^2 \), more than 10 times lower than the Planck value of \( 4.9 \pm 1.2 \times 10^{-12} \text{ arcmin}^2 \). The X-ray source is too weak to be the Planck counterpart and we conclude that the candidate is not a cluster.
In the previous XMM-Newton validation run, the two candidates potentially associated with $z > 0.5$ SDSS clusters were confirmed, including PLCK G193.3−46.1 at $z = 0.6$. This showed that SDSS can robustly confirm candidates up to such high $z$. It is instructive to compare PLCK G210.6+20.4 with PLCK G193.3−46.1. In both cases the search algorithm found a rich concentration of galaxies, as expected for Planck clusters. The masses, reconstructed from the luminosity function, are $\sim 3 \times 10^{14} M_\odot$ and $9 \times 10^{14} M_\odot$, respectively, i.e., the false candidate has a larger mass. In both cases, the galaxy distribution appears rather loose (compare Fig. 1 right panel and Planck Collaboration 2012, Fig. 5). The XMM-Newton observation revealed that PLCK G193.3−46.1 is a double peaked cluster, i.e., a dynamically perturbed cluster with an ICM distribution consistent with the galaxy morphology. In view of the XMM-Newton image, the galaxy concentration at the location of PLCK G210.6+20.4 is likely a filamentary structure where only the part around the BCG is virialised and contains gas that is hot enough to emit in X-rays. This would also explain the large offset between the BCG position and the galaxy concentration barycentre, which is much larger than in the case of PLCK G193.3−46.1. These two cases illustrate the difficulty of distinguishing between massive clusters and pre-virialised structures with rather shallow SDSS data at high $z$. Beyond luminosity and mass estimates, important diagnostics include the offset between the SZ, BCG, and barycentre, as well as the galaxy distribution morphology, if available, and other ancillary data, such as significant RASS emission. These factors must all be considered for firm confirmation of low signal-to-noise-ratio SZ detections. On the other hand, we cannot be sure that the apparent SZ signal is purely due to noise, and cannot exclude a contribution from the pre-virialised structure itself, especially if it corresponds to a warm filament along the line of sight.

4.2. Confirmed candidates

Twelve of the 15 candidates are confirmed as real clusters, of which two are double systems as shown in Fig. 2. Physical parameters are given in Table 2. For the two double systems, the cluster closest to the Planck position is labelled A and the other is labelled B in Table 2.

4.2.1. Single clusters

The redshifts of eight clusters are well constrained by the XMM-Newton spectrum (quality flag of $Q_z = 2$). Three of these clusters, PLCK G219.9−34.4, PLCK G011.2−40.4 and PLCK G348.4−25.5 were classified as PHZ. The first two are indeed at $z = 0.46$ and $z = 0.66$, respectively, but PLCK G348.4−25.5 is at $z = 0.25$. Knowing the precise cluster location with XMM-Newton, we re-examined the DSS image. A bright galaxy is indeed located exactly at the position of the X-ray peak; however, the field is crowded and there is no obvious galaxy concentration around that BCG. This explains our initial mis-classification.

The redshift determination for three single clusters is more uncertain. There are several $\chi^2$ minima that cannot be distinguished at the 68% confidence level ($Q_z = 1$). As proposed by Planck Collaboration (2012), we used the X-ray versus SZ properties to eliminate unphysical solutions, as well as DSS data. This is detailed in Appendix A.1. The XMM-Newton analysis gives three possible redshifts for PLCK G147.3−16.6: 0.4, 0.62, and 1.1, the last being the best-fitting value. The cluster has an interesting double-peaked morphology. It is likely an on-going merger of two nearly equal mass systems (Fig. 3). The analysis of imaging data obtained with the Telescopio Nazionale Galileo La Palma (TNG) telescope and the Nordic Optical Telescope, as well as spectroscopic data obtained at Gemini, are detailed in Appendix A.2. We confirm a redshift of $z = 0.66 \pm 0.05$.

The spectral analysis of PLCK G208.6−74.4 gives a single $\chi^2$ minimum at $z = 0.9 \pm 0.04$, in very good agreement with SZ versus X-ray properties. However we assign a quality flag of $Q_z = 1$ since the statistical quality of the spectrum is poor due to the short exposure time. Furthermore the DSS image is ambiguous: although there is no visible galaxy at the X-ray maximum, the centroid of the large scale X-ray emission is close to a bright DSS galaxy.

In summary, of the seven candidates we classified as PHZ, two are false, four are indeed at $z \geq 0.5$, and one is at a low redshift of $z = 0.25$. In addition to those clusters which were classified as PHZ, two further $Q_z = 1$ clusters, PLCK G239.9−40.0 and PLCK G208.6−74.4, are most likely at high $z$.

4.2.2. Multiple systems

In PLCK G196.7−45.5, two clusters, separated by $\sim 5.5$ arcmin, lie within the Planck position error box: PLCK G196.7−45.5A at 2′34 and PLCK G196.7−45.5B at 3′9 from the SZ position. In view of the Planck resolution, 5′ to 30′ depending on frequency (Mennella et al. 2011; Planck HFI Core Team 2011), both clusters certainly contribute to the SZ signal. It is likely a chance association, although given the uncertainty in the redshifts, a binary system cannot be ruled out (see Appendix A.1). In PLCK G329.5−22.7, the cluster PLCK G329.5−22.7A lies about 1′ from the Planck position, while the second object is about 8′ away. From the $Y_X$ values and redshift estimates, cluster B is expected to have a $Y_{500}$ flux 1.8 times smaller than that of cluster A, thus contributing 36% to the total flux. Its contribution to the blind signal may differ, as the blind signal is extracted using a single component model found roughly peaked at cluster A. Indeed comparison of such a single component extraction with that using a double component

Fig. 3. A $gri$ composite image of the central 5′5 × 3′4 of PLCK G147.3−16.6, based on imaging data from NOT/MOSCA ($g$ and $i$) and TNG/DOLORES ($r$ and $i$). Boxes: cluster galaxies spectroscopically confirmed with Gemini (excluding the two galaxies at $z = 0.68$). North is up and East to the left. The green contours show the luminosity distribution of the red sequence galaxies indicated by red symbols in Fig. A.2, smoothed with a $\sigma = 14′′$ Gaussian filter. The plotted contour levels are at (10, 20, 30) times the rms variation in the luminosity distribution.
model (with flux ratio fixed to the X-ray constraint) suggests a contamination from cluster B of about ~20%. In summary, PLCKG329.5–22.7A is the main contributor to the SZ detection, although PLCKG329.5–22.7B certainly contributes. The redshifts of the two clusters are well determined, $z = 0.24$ and $z = 0.46$, respectively, showing that they are not physically related. This double system is thus a chance association on the sky.

Overall, we have found four double systems and two triple systems among the 43 Planck candidates confirmed by XMM-Newton, i.e., 14% multiple systems. Since the XMM-Newton validation follow-up observations are neither representative nor complete, this fraction of multiple systems cannot be extrapolated to the population at large; however, it is more than five times larger than the fraction of cluster pairs separated by less than 10′ (63/1882 objects) in the whole MCXC X-ray catalogue compilation (Piffaretti et al. 2011). This is clearly a selection effect due to confusion in the large Planck beam, which it might be necessary to take into account for a precise estimate of the selection function.

4.3. Planck position reconstruction uncertainty

The Planck position reconstruction uncertainty is driven by the spatial resolution of the instruments. The positions determined by the Planck detection algorithm are compared to the precise XMM-Newton positions in Figs. 4 and 5, where we put together all validation observations of single systems. The mean offset between the Planck and the XMM-Newton position is 1.5′, with a median value of 1.3′, as expected from Planck sky simulations (Planck Collaboration 2011a, Fig. 7 left). For 70 and 86% of the clusters, this offset is less than 2′ and 2.5′, respectively. The assumed positional uncertainty of up to 5′ is certainly conservative and an offset of 5′ is actually very unlikely. This needs to be taken into account when searching for possible counterparts in ancillary data or follow-up observations.

The offsets of five sources are greater than 2.5′. Three of those objects are very diffuse, likely dynamically unrelaxed systems, at relatively low $z$, including the prominent outlier PLCKG18.7+23.6 at $z = 0.09$ (Fig. 4, purple point). As noted by Planck Collaboration (2011b) a real, physical offset between the X-ray and SZ peak may contribute to the overall offset for this type of cluster. In all cases but one, the offset remains smaller than the cluster size $R_{500}$. The notable exception is PLCKG11.2–40.4 (Fig. 4). The XMM-Newton position of this cluster is 4′2 or ~1.8 $R_{500}$ from the Planck position. The peak in the SZ reconstructed map is also ~3′ away from from the Planck position. This cluster is detected by only one method and has a low quality grade $Q_{SZ} = C$, being located in a particularly noisy region of the Planck map. This is likely to complicate the estimate of the cluster position.

Finally, we note that the position reconstruction uncertainty is on average smaller than for the ESZ sample that peaks at ~2′ (Planck Collaboration 2011a, Fig. 7 right). This is likely the result of the higher redshift range considered here. Indeed, at this redshift the sources are more compact and their position is easier to reconstruct. Furthermore, possible physical offsets are expected to become negligible as they become unresolved.

4.4. New clusters in the $z$–$L_X$ and $z$–$M_{500}$ plane and Planck sensitivity

The present validation sample covers a wide range of redshift, $0.2 < z < 0.9$, and SZ flux, $2.9 \times 10^{-4}$ arcmin$^2 < Y_{500} < 8.8 \times 10^{-4}$ arcmin$^2$. As expected from the lower signal-to-noise ratio considered and the deeper sky coverage (Sect. 2), the $Y_{500}$ range is lower than that of the previous validation sample, $4 \times 10^{-3}$ arcmin$^2 < Y_{500} < 1.4 \times 10^{-3}$ arcmin$^2$. Although not perfect, the strategy to preferentially select high-$z$ clusters was successful, with five clusters found at $z > 0.5$, including three PHZ candidates. The full XMM-Newton validation sample (single objects only) is shown in the $L_X$–$z$ plane in Fig. 6. We continue to populate the higher $z$ part of the $L_X$–$z$ plane and confirm Planck can detect clusters well below the X-ray flux limit of RASS-based catalogues, ten times lower than REFLEX at high $z$, and below the limit of the most sensitive RASS survey (MACS). The figure makes obvious the gain in redshift coverage as compared to the RASS-based catalogues.

Fig. 4. Distance of blind SZ position to X-ray position, $D_{SZ-X}$, as a function of $D_{SZ-X}$, normalised to the cluster size $\theta_{500}$, for single confirmed systems. The clusters are colour-coded according to redshift.

Fig. 5. Histogram of the distance between the X-ray peak determined from the XMM-Newton validation observations and the Planck SZ position for all clusters (orange filled) and those associated with a source from the RASS Faint Source Catalogue or Bright Source Catalogue (red hatched). The histogram of the distance between the X-ray peak and the RASS source position is plotted for comparison (blue hatched).
The positions of the associated FSC and BSC source are indicated in the individual XMM-Newton image of each candidate in Fig. 2, and for previous observations, in Figs. 3 and 2 published in Planck Collaboration (2011b and 2012). Comparing the positions of the SZ candidates and their FSC/BSC counterparts with the X-ray peaks determined from the XMM-Newton validation observations, we notice that the FSC/BSC position is a better estimate of the position of the cluster than the position returned by Planck alone. Most of the FSC/BSC sources are located within 1’ of the XMM-Newton position versus 2’ for the Planck–SZ position (see Fig. 5). Thus, the association with a faint or bright RASS source can be used to refine the SZ position estimate.

**5. Using RASS data in the construction of the Planck cluster catalogue**

**5.1. Position refinement**

The positions of the associated FSC and BSC source are indicated in the individual XMM-Newton image of each candidate.
5.2. X-ray flux estimate

Figure 9 summarises the comparison between RASS and XMM-Newton unabsorbed fluxes computed in the [0.1–2.4] keV band. The XMM-Newton flux is given in Table 3. Fluxes measured in an aperture of 5′ centred on the Planck candidate position from RASS images are referred to as “blind”. Here the RASS count rate is converted to flux assuming a typical redshift of $z = 0.5$, temperature of $kT = 6$ keV, and the 21–cm $N_H$ value. All other fluxes are recomputed in an aperture corresponding to $R_{500}$, centred on the X-ray peak as determined from the XMM-Newton validation observations, and using the measured temperature and redshift to convert XMM-Newton or RASS count rates to flux.

These figures indicate that the RASS blind fluxes and the RASS fluxes measured within $R_{500}$ are in relatively good agreement, with a slight underestimate at high fluxes (left panel). RASS and XMM-Newton fluxes measured within $R_{500}$ are also in relatively good agreement, although with a slight underestimate together with increased dispersion at low fluxes (middle panel). As a result, RASS blind fluxes slightly underestimate the “true” XMM-Newton flux measured within $R_{500}$, by $\sim 30\%$ at $10^{-12}$ erg s$^{-1}$ cm$^{-2}$. The underestimate increases with decreasing S/N (right panel).

In view of this agreement, we conclude that the RASS blind flux can be used to estimate the exposure time required for X-ray follow-up of a Planck candidate, once confirmed at other wavelengths. The main limitation is the statistical precision on the RASS estimate.

5.3. Candidate reliability

The association of an SZ candidate with a RASS-B/FSC source is neither a necessary nor a sufficient condition for an SZ candidate to be a bona fide cluster. Putting together the results from all XMM-Newton validation observations for a total of 51 Planck cluster candidates, we find that three of the eight false candidates are associated with an FSC source, while eleven candidates are confirmed without association with a RASS-FSC/BSC source. On the other hand, it is striking that PLCKG266.6–27.3, the most distant cluster of the sample, with a $z = 0.97$, is detected at a $S/N > 5$ in RASS, and is in fact found in the RASS Faint Source Catalogue.

5.3.1. RASS source density

It is important to underline that the RASS is not homogeneous, and that neither the BSC nor the FSC are flux-limited or complete in any way. Using the RASS-BSC and FSC, we computed the source density map of each catalogue and the associated probability that a Planck candidate will be associated with a B/FSC source within a radius of 5′. The method is described in Appendix B, and the resulting probabilities are given in Table B.1.

Figures 10 and B.1 show the RASS-FSC and BSC source density maps with all XMM-Newton validation observations overplotted. The faint source distribution directly reflects the RASS scanning strategy, as evident in Fig. 10. In this context, the probability of chance association is also an indication of how well covered the region is and thus on the depth of the X-ray observation at this position. We found a mean probability of association with an FSC source of $S(R \leq 5') \times \bar{\rho} \sim 6\%$ over the whole sky, where $S(R \leq 5')$ is the area corresponding to a circle of 5′ and $\bar{\rho}$ is the mean density at the position of the candidate, respectively. The corresponding mean probability of association with a BSC source is $\sim 1\%$. However, in the best-covered regions of the RASS the probability can reach 95% for the FSC and 9% for the BSC, while in the least-covered regions these probabilities drop to 0.4% and 0.2%, respectively.

5.3.2. BSC source association

All 12 candidates associated with a BSC source are confirmed. This is not surprising. For the BSC, the probability of chance association is relatively low, varying from less than 1% to 9%, depending on the sky region. For one cluster, PLCKG305.9–44.6, the XMM-Newton validation observation reveals that a point source is located at the position of the BSC source. However, the source is labelled as extended in the BSC, and in fact the X-ray emission likely corresponds to a blend of the point source and extended cluster emission that was not resolved with the large ROSAT PSF. This is supported by a comparison of the XMM-Newton and RASS images.

Thus we conclude that the correspondence of a Planck SZ candidate with a RASS-BSC source is a very good indication of there being a real cluster at this position.

5.3.3. FSC source association

For the FSC catalogue, on the contrary, the conclusion is more uncertain because of the larger probability of chance association. Most (18 of 21, i.e., more than 85%) of the candidates associated with a faint source are indeed confirmed. For the
Planck Collaboration: Validation of new Planck clusters with XMM-Newton

Notes. (1) Name of the candidate. (2) Signal-to-noise ratio of the RASS count rate in the [0.5−2] keV band, measured within a region of 5° radius centred on the SZ candidate position. (3) Flux in the [0.1−2.4] keV band as measured with XMM-Newton within $r_{\text{500}}$. (4) Association with a source from the RASS Faint Source Catalogue (F) or Bright Source catalogue (B) published by Voges et al. (1999, 2000). (5) Number of the XMM-Newton validation run. (6) Confirmed clusters are flagged. The FSC source is not the cluster.

Consistent with the mean probability of chance association of 6% computed above; however, the association with an FSC source is still an indicator of reliability even in the regions of high probability of chance association. For instance, the two highest-redshift clusters ($z \approx 0.9$) are correctly associated with a faint source, despite both being in the ecliptic pole region where the probability of false association is high. The scanning strategies of Planck and RASS are very similar in that both surveys are deeper in the same regions. In well-covered regions, the association with the faint source catalogue allows us to probe less massive or higher redshift potential clusters. A possible indicator of false association might be the distance between the FSC source and the SZ position, although no strict criterion can be applied. Seventy-five per cent of the false associations correspond to a distance greater than 3°, compared to 2 out of 16 (13%) for true associations.

5.3.4. No association

Sixteen candidates are not associated with a B/FSC source. Five of these candidates are false and eleven candidates are true sources with no B/FSC source association. As mentioned above, the association with a B/FSC is not necessary for anSZ candidate to be a bona fide cluster. However, we note that the median probability of FSC chance association, a measure of survey depth as discussed Sect. 5.3.1, is 2.1% for clusters without association, to be compared to 6.7% for associated clusters (see also Fig. 10). These true clusters with no B/FSC counterpart are located in the shallower part of the RASS survey, which likely explains why they are not associated.

5.3.5. RASS flux and signal-to-noise limit for candidate validation

Unassociated and associated candidates follow the same general correlation between the RASS blind flux, $F_X$, and the SZ flux, $Y_{500}$ (Fig. 11). This correlation presents some dispersion, with deviations from the mean as large as a factor of three. This is expected from the large statistical errors, as well as from the intrinsic dispersion and $z$ dependence of the $F_X/Y_{500}$ ratio (Planck Collaboration 2012) and the difference between the blind and true X-ray fluxes (Sec. 5.2).

Because of this large dispersion, it is not possible to determine a strict RASS limit (or signal-to-noise ratio) limit below which a candidate should be discarded. However, we note that all new clusters have an X-ray flux greater than $\sim 2 \times 10^{-13}$ erg s$^{-1}$ cm$^{-2}$ (grey area in Fig. 11). This flux is consistent with the $Y_{500}$ threshold $Y_{500,\text{thresh}} \approx 2-5 \times 10^{-4}$ arcmin$^2$, as defined from the region affected by the Malmquist bias (see Fig. 7). This RASS flux limit is more than 10 times lower than the REFLEX flux limit of $\sim 2 \times 10^{-13}$ erg s$^{-1}$ cm$^{-2}$, but still detectable with RASS. For the confirmed candidates, the minimum signal-to-noise ratio computed from RASS data is $\sim 0.70$. Below that limit, all the candidates were false. All candidates with RASS $S/N > 3$ are confirmed, and only one false candidate is found for RASS $S/N > 2$. The latter is an SZ candidate detected at low Planck $S/N = 4$. Such clusters, however, could not be identified from RASS data alone. They cannot be identified as clusters on the basis of source extent because of the low statistical quality of the signal. Confirmation and identification follow-up is unmanageable in view of the number of sources at such low flux, the vast majority of which are unidentified AGN or noise fluctuations.
Fig. 10. Density map of the RASS-Faint Source Catalogue (FSC) with XMM-Newton validation results overplotted. The source density map has been normalised by the median of the pixel density distribution. The source density directly reflects the RASS scanning strategy, with the largest exposure and source density at the Ecliptic poles. Cyan pluses (+): confirmed candidates associated with a BSC source. Other confirmed candidates are plotted in green, and false candidates are plotted in red. Pluses (+): good association with a FSC source. Crosses (×): mis-association with an FSC source. Circles (○): no association with a FSC/BSC source. Confirmed candidates with no association are mostly located in low density regions corresponding to the shallower part of the RASS survey.

Fig. 11. Relation between RASS blind fluxes and SZ fluxes, $Y_{500}$, for single systems confirmed with XMM-Newton (all validation observations). The RASS flux is the unabsorbed flux computed in the [0.1–2.4] keV band and measured in a 5′ aperture centred on the Planck position. The points are colour-coded as a function of redshift. Squares are candidates associated with a FSC source while diamonds are candidates associated with a BSC source.

5.3.6. RASS reliability flag

In view of the above results, we conclude the following regarding the most relevant RASS reliability flags:

- positional association of a Planck SZ candidate with a RASS-FSC source at S/N > 2 is a good indication of a real cluster;
- an SZ candidate with no signal at all in RASS is false at very high confidence. Obviously, candidates with low signal-to-noise ratio in a well-covered region are particularly likely to be false.

6. A preview of cluster evolution

With this new XMM-Newton validation campaign, we have now assembled a sample of 37 new single Planck clusters covering a redshift range 0.09 < $z$ < 0.97. With only snapshot XMM-Newton observations, the global properties and density profile of each object are measured accurately enough to allow a first assessment of evolution with redshift. The structural and scaling properties of the sample are illustrated in Fig. 12. We considered three redshift bins, $z$ < 0.3 (10 clusters), 0.3 < $z$ < 0.5 (19 clusters) and $z$ > 0.5 (8 clusters). We confirm our previous finding regarding the scaling properties of these new Planck selected clusters, and do not find any evidence of departure from standard self-similar evolution.

The average scaled density profile (top left panel of Fig. 12) is similar for each $z$ bin and is flatter than that of REXCESS, a representative sample of X-ray selected clusters (Arnaud et al. 2010). Once scaled as expected from standard evolution, the new clusters in each redshift bin follow the same trends in scaling properties (Fig. 12): they are on average less luminous at a given $Y_{500}$, or more massive at a given luminosity, than X-ray selected clusters. On the other hand, they follow the $Y_{500}$–$Y_X$ relation predicted from REXCESS data (Eq. (2)).

To study possible evolution with $z$, we plot in Fig. 13 the $D_A^2 Y_{500}/C_{XSZ} Y_X$ ratio as function of $z$, including the 62 clusters of the Planck-ESZ sample with XMM-Newton archival data.
Planck Collaboration: Validation of new Planck clusters with XMM-Newton

**Fig. 12.** Scaling properties of Planck clusters, colour-coded as a function of redshift. In all figures, $R_{500}$ and $M_{500}$ are estimated from the $M_{500}$–$Y_X$ relation of Arnaud et al. (2010). Top left panel: the scaled density profiles of the new clusters confirmed with XMM-Newton observations. The radii are scaled to $R_{500}$. The density is scaled to the mean density within $R_{500}$. The thick lines denote the mean scaled profile for each sub-sample. The black line is the mean profile of the REXCESS sample (Arnaud et al. 2010). Other panels: scaling relations. Squares show the new clusters confirmed with XMM-Newton observations. Points show clusters in the Planck-ESZ sample with XMM-Newton archival data as presented in Planck Collaboration (2011c). Relations are plotted between the intrinsic Compton parameter, $D^2 A Y$, and the mass $M_{500}$ (top right panel), between the X-ray luminosity and $Y_{500}$ (bottom left panel) and between mass and luminosity (bottom right panel). Each quantity is scaled with redshift, as expected from standard self-similar evolution. The lines in the left and middle panel denotes the predicted $Y_{500}$ scaling relations from the REXCESS X-ray observations (Arnaud et al. 2010). The line in the right panel is the Malmquist bias corrected $M$–$L$ relation from the REXCESS sample (Pratt et al. 2009; Arnaud et al. 2010). The new clusters are on average less luminous at a given $Y_{500}$, or more massive at a given luminosity, than X-ray selected clusters. There is no evidence of non-standard evolution.

7. Conclusions

We have presented results on the final 15 Planck galaxy cluster candidates observed as part of a 500 ks validation programme undertaken in XMM-Newton Director’s Discretionary Time. The sample was derived from blind detections in the full 15.5-month nominal Planck survey, and includes candidates detected at $4.0 < S/N < 6.1$. External flags including RASS and DSS detection were used to push the sampling strategy into the low-flux, high-redshift regime and to better assess the use of RASS data for candidate validation. This last phase of the follow-up programme yielded 14 clusters from 12 Planck candidate detections (two candidates are double systems) with redshifts between 0.2 and 0.9, with six clusters at $z > 0.5$. Their masses, estimated using the $M_{500}$–$Y_X$ relation, range from $2.5 \times 10^{14}$ to $8.0 \times 10^{14} M_\odot$. We found an interesting double peaked cluster, PLCK G147.3−16.6, that is likely an ongoing major merger of two systems of equal mass. Optical observations with NOT, TNG, and Gemini confirmed a redshift of 0.65.

The full XMM-Newton validation follow-up programme detailed in this paper and in Planck Collaboration (2011b); Planck Collaboration (2012) comprises 51 observations of Planck...
clustering candidates. The efficiency of validation with XMM-
Newton stems both from its high sensitivity, allowing easy de-
tection of clusters in the Planck mass and redshift range, and from
the tight relation between X-ray and SZ properties, which probe
the same medium. The search for extended XMM-Newton emis-
sion and a consistency check between the X-ray and SZ flux is
then sufficient for unambiguous discrimination between clusters
and false candidates. We have confirmed the relation between
the X-ray flux and the SZ flux, as a function of redshift, and esti-
mat ed its typical scatter. This relation is used in the validation
procedure. By contrast, optical validation is hampered by the
relatively large XMM-Newton source position uncertainty and the large
scatter between the optical observables (such as galaxy number)
and the mass (or SZ signal), both of which increase the chance
of false associations.

The programme yielded 51 bona fide newly-discovered clus-
ters, including four double systems and two triple systems. There
are eight false candidates. Thirty-two of the 51 individual clus-
ters, including four double systems and two triple systems. There
are eight false candidates. Thirty-two of the 51 individual clus-
ters, including four double systems and two triple systems. There

ters, including four double systems and two triple systems. There
are eight false candidates.

– The newly-detected clusters follow the \( Y_X - Y_{500} \) relation
derived from X-ray selected samples. This is consistent with the
prediction that both quantities are tightly related to the cluster
mass.

– New SZ selected clusters are X-ray underluminous on av-
average compared to X-ray selected clusters, and more mor-
phologically disturbed. The dispersion around the \( M - L_X \)
relation may be larger than previously thought and dy-
namically perturbed (merging) clusters might be under-
represented in X-ray surveys. This has implications for

statistical studies of X-ray selected samples, either to con-
strain cosmological models from cluster number counts or to
probe the physics of structure formation from the cluster
scaling properties. As discussed in detail by Angulo et al.
(2012), precise knowledge of the actual scatter between the
mass and the observable used in the detection is critical in
both applications.

– We found no indication of departure from standard self-
similar evolution in the X-ray versus SZ scaling prop-
erties. In particular, there is no significant evolution of the
\( Y_X / Y_{500} \) ratio. Beyond new cluster confirmation and characterisation, we
checked the pertinence of the validation process based on Planck
internal quality assessments and cross-correlation with ancilliary
data. There are eight false candidates in total, all of which were
found at \( S/N < 5 \). These failures underline the importance of
the number of methods detecting the clusters and were used to
refine our internal quality flag definitions. All candidates with
\( Q_{SZ} = A \) are confirmed. Galaxy overdensity in SDSS data can
confirm candidates up to \( z \sim 0.6 \), although it remains difficult
to distinguish between massive clusters and pre-virialised struc-
tures at high \( z \). The quality of the SZ detection, ancillary data
such as significant RASS emission, and the offsets between SZ,
BCG, and other positions, must all be considered for firm con-
firma tion. Using the full sample of 51 observations, we inves-
tigated the use of RASS-based catalogues and maps for Planck
catalogue construction, finding that:

– Planck clusters appear almost always to be detectable in
RASS maps, although there is not a one-to-one correspon-
dence between a RASS-BSC or FSC source and the presence
of a cluster.

– Association of a cluster candidate with a RASS-BSC source
is a very strong indication that it is a real cluster.

– Whether or not there is a RASS-BSC or FSC source, \( S/N > 2 \)
in the RASS maps is a good indication of a true candidate, while
\( S/N < 0 \) is a good indication of a false candidate.

– The association with a faint or bright RASS source can be
used to refine the SZ position estimate. The RASS blind flux

\[ Y_{X,500} > 5.10^{-4}\text{arcmin}^{-2} \]
can be used to estimate the exposure time required for X-ray follow-up of a Planck candidate, once confirmed at other wavelengths. The main limitation is the statistical precision on the RASS estimate.

The XMM-Newton validation observations could also be used for the verification of Planck performances, showing that:

- The mean offset between the Planck position and the cluster position is 1.5′, as expected from Planck sky simulations, and this offset is less than 2.5′ for 86% of the clusters.

- Planck can detect clusters well below the X-ray flux limit of RASS based catalogues, ten times lower than REFLEX at high $z$, and below the limit of the most sensitive RASS survey (MACS).

- The Planck sensitivity threshold for the nominal survey is $Y_{500} \sim 4 \times 10^{-4}$ arcmin$^2$, with an indication of Malmquist bias in the $Y_{500}$ vs $Y_{500}$ relation below this threshold. The corresponding mass threshold depends on redshift, but Planck can detect systems with $M_{500} > 5 \times 10^{14} M_\odot$ at $z > 0.5$.

- Overall, there is a high fraction of double/triple systems in the XMM-Newton validation follow-up sample, illustrating the problems of confusion in the Planck beam.

These results illustrate the potential of the all-sky Planck survey to detect the most massive clusters in the Universe. Their characterisation, and the determination of their detailed physical properties, depends on a vigorous follow-up programme, which we are currently undertaking.

Acknowledgements. The Planck Collaboration thanks Norbert Schartel for his support of the validation process and for granting discretionary time for the observation of Planck cluster candidates. The present work is based on observations obtained with XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA Member States and the USA (NASA). Fig. A.1. EPIC spectra (data points with errors) of PLCK G147.3−16.6. Only data points above 2 keV are shown for clarity, but data down to 0.3 keV are used in the spectral fitting. The redshift estimate is ambiguous, with the $\chi^2$ distribution showing three minima. Left panel: the best-fitting thermal model (solid lines) at $z = 1.03$ with the position of the redshifted Fe K line marked. Right panel: same for the second best solution at $z = 0.62$, consistent with the optical redshift.

Appendix A: Redshift estimates of confirmed candidates

A.1. Refinement of the XMM-Newton redshift estimate for $Q_z = 1$ cases

The redshift determination from XMM-Newton spectral analysis is uncertain for five clusters. There are several $\chi^2$ minima that cannot be distinguished at the 90% confidence level ($Q_z = 1$). As proposed by Planck Collaboration (2012), we estimated the $Y_X/Y_{500}$ and $F_X/Y_{500}$ ratios as a function of $z$ and compared them to expected values, to eliminate unphysical solutions.

Three possible redshifts were found for PLCK G352.1−24.0, 0.12, 0.4, and 0.77. The $Y_X/Y_{500}$ ratio method enables us to exclude the low redshift $z = 0.12$ solution. The $z = 0.4$ solution yields a $Y_X/Y_{500}$ ratio twice higher than expected, at the limit of the observed dispersion. Furthermore, we confirmed that there is no evidence of galaxy concentrations in the DSS red image at the precise XMM-Newton cluster location. We thus adopt the highest $z$ value, $z = 0.77$, confirming the cluster to be at high $z$.

The best fitting redshift for PLCK G239.9−40.0, $z = 0.74$, yields the $Y_X/Y_{500}$ ratio closest to expectation and is adopted in the further analysis. The lowest $z = 0.26$ solution is very unlikely, yielding a $Y_X/Y_{500}$ ratio twice as high as expected. The other possible solution is $z = 0.46$: there are some very faint objects in the DSS images at the XMM-Newton position, although whether those are galaxies is unclear.

In the case of PLCK G147.3−16.6, all three redshift solutions, 0.4, 0.62, and 1.03, yield a $Y_X/Y_{500}$ ratio within the observed dispersion. The best fitting value, $z = 1.03$, and the best second solution, $z = 0.62$, are consistent at the 90% confidence level, with $\chi^2$ values of 125.9 and 128.7 for 132 degree of freedom, respectively. The two models are shown in Fig. A.1. The optical measurement is described below (Sect. A.2).

The redshifts of the two components in PLCK G196.7−45.5 are uncertain. The $Y_X/Y_{500}$ and $F_X/Y_{500}$ ratio methods cannot be used for such double systems, since the individual SZ components are unresolved by Planck. Of the two solutions, $z = 0.57$ and $z = 0.87$ for PLCK G196.7−45.5A, the latter can be excluded: a clear concentration galaxies at the XMM-Newton location is visible in the DSS images, which thus cannot be at such high $z$ (see Sect. 2.2). For PLCK G196.7−45.5B we adopted the best fitting value, $z = 0.42$.

A.2. Optical redshift estimate of PLCK G147.3–16.6

The optical data for PLCK G147.3–16.6 were taken using Director’s Discretionary Time with DOLORES (Device Optimized for the LOW RESolution), a low resolution spectrograph and imager permanently installed at the TNG telescope (Telescopio Nazionale Galileo La Palma). The camera is equipped with a 2048 × 2048 pixel CCD covering a field of view of 8′.6 × 8′.6 (pixel scale of 0″.252 per pixel). Exposure times of 3000 s in the r and i bands were split into 10 single exposures of 300 s each. Exposure times of 4000 s in the z band were split into eight separate exposures. Taking advantage of the dither-offssets between single exposures, no separate sky images were required. The images were bias and flat field corrected using IRAF. For astrometric calibration we used astrometry.net. The average seeing derived from the final images is 0″.84, 0″.85, and 0″.84 in the r, i, and z-bands, respectively. In the final images, we reach signal-to-noise ratios (over the PSF area) of 11, 20, and 8 for unresolved sources of 24th magnitude. The colour composite image allows us to pre-identify the cluster members.

The cluster was also observed using the 2.56-m Nordic Optical Telescope with the MOSCA camera, a 2 × 2 mosaic of 2048 × 2048 pixel CCDs. This camera covers a total field of 7′.7 × 7′.7, and was used in 2 × 2 binned mode. This gives a pixel scale of 0″.217 per binned pixel. Total exposure times of 900 s were split into 3 dithered exposures of 300 s in each of the SDSS g- and i-bands in photometric conditions. The telescope was pointed such that the two peaks of the X-ray emission from the cluster would fall in the centreof the mosaic CCD chip that has the best cosmetic quality (named “CCD7”). After standard basic reduction and image registration, the combined images had FWHM of 0″.79 and 0″.65 in the g and i bands, respectively. Photometric calibration was based on an ensemble of stars in a field located inside the SDSS footprint, observed at similar airmass immediately following the observations of PLCK G147.3–16.6. Stellar objects were removed from the object catalogues based on their location in a size-magnitude diagram. A strong clustering of galaxies with red $g - i$ colours was immediately detected around the position of the X-ray peaks. The colour-magnitude diagram in Fig. A.2 illustrates the red sequence formed by early-type galaxies at $g - i \approx 3.15$ in this cluster. Predicted $g - i$ colours of early-type galaxies as a function of redshift were calculated by convolving the EO template galaxy spectrum of Coleman et al. (1980) with the response curves of the SDSS g and i bandpasses. From this, a photometric redshift estimate of $z_{\text{phot}} = 0.64 \pm 0.03$ was derived.

The calibrated $g$- and i-band photometry from NOT was used to select suitable spectroscopic targets for Gemini North Telescope by choosing galaxies at $g - i \approx 3.15$. The observations (Program GN-2011B-Q-41) were made with GMOS-N, with two exposures of 1800 s each. The program was in Band 2 service mode, with relaxed observing conditions: the seeing was 1″/7 the first night and 0″/8 the second night, with cirrus both nights. The observations were reduced with the standard Gemini IRAF package. We obtained redshift measurements for 13 objects. Among those, 10 have redshifts between 0.64 and 0.68, for a cluster redshift measurement of $0.66 \pm 0.05$. If we exclude two objects at $z = 0.68$, we obtain $z = 0.645 \pm 0.005$.

Appendix B: Density maps of RASS bright and faint sources

In this appendix we describe the procedure used to calculate the density maps of RASS-BSC and FSC sources, and the associated probability of false association with a Planck cluster candidate. We use the catalogues downloaded from Vizier.

B.1. Source density maps

To compute the source density maps, we use HEALPix with a resolution of $N_{\text{side}} = 64$ (each pixel is 0.8 deg$^2$). The HEALPix function ANG2PIX_RING was used to compute the pixel number corresponding to the coordinates of the FSC/BSC sources.

At each pixel, we compute the source density by summing the number of sources in the pixels inside a disc of increasing radius until a threshold number of 10 sources is reached. The source density is then the number of sources found, $N_{\text{src}}$, divided by the number of pixels, $N_{\text{pix}}$, normalised by the area covered by one pixel:

$$\rho = \frac{N_{\text{src}}}{N_{\text{pix}}} \times (49 \, 152/4\pi) \times (\pi/180)^2,$$

where $49 \, 152$ is the total number of sky pixels for this resolution and $4\pi(180/\pi)^2 \approx 41,000$ deg$^2$ is the total area of the sky. This gives the mean number of sources per square degree in each pixel.

The resulting source density maps are plotted in Figs. 10 and B.1. For the FSC density map, the mean source density per square degree ranges from 0.16 to 42.89. There is a clear correspondence between the source density and the depth of the RASS exposure, with regions of maximum source density lying in the regions of maximum RASS exposure at the ecliptic poles (Fig. 10). For the BSC density map, the mean source density per square degree ranges from 0.08 to 4.05, with a much less marked correspondence with the RASS exposure map (Fig. 10).

Figure B.2 shows the histogram of the number of pixels as a function of mean source density per square degree. We overplot on these histograms the mean ($\bar{\rho}$) and the median ($\rho_{1/2}$) value of the number of sources per square degree. We find $\bar{\rho} \approx \rho_{1/2} \sim 2$ sources deg$^{-2}$ for the FSC and $\bar{\rho} \approx \rho_{1/2} \sim 0.5$ sources deg$^{-2}$ for the BSC.

Planck Collaboration: Validation of new Planck clusters with XMM-Newton

**Fig. B.1.** XMM-Newton validation results overplotted on density map of the RASS-Bright Source Catalogue (BSC). The source density map has been normalised by the median of the pixel density distribution. Confirmed candidates are plotted in green and false candidates are plotted in red. Pluses (+): good association with a BSC source. Circles (○): no association with a BSC source.

**Fig. B.2.** Histogram of the source density map of the RASS-BSC (left panel), and RASS-FSC (right panel), per square degree. The mean and median source density of each map are plotted in blue dot-dot-dot-dash and in red dashed lines, respectively. The upper x-axis shows the associated probability of association within 5′ (see text). The sources are drawn from the whole sky so the solid angle is 4π steradian.

### B.2. Probability of association within search radius \( R \)

We can convert the local FSC/BSC source densities into probabilities of chance association of an SZ candidate with a FSC/BSC source. The probability of finding a cataloged FSC/BSC source within a search radius \( R \) of a Planck cluster candidate is the product of the FSC/BSC source density at the candidate location by the search area, \( S(R) \). This yields a mean probability of association of an SZ candidate with a B/FSC over the full sky of \( S(R \leq 5′) \times \bar{\rho} \sim 5\% \) for the FSC and 1% for the BSC. However, there is considerable variation depending on how well a given sky region is covered. In the most covered regions, the probability reaches nearly 95% of having an association within 5′ for the FSC and 9% for the BSC, while it decreases to 0.4% and 0.2% for the less covered regions for the FSC and BSC catalogues, respectively. We summarise these numbers in Table B.1.

**Table B.1.** Summary of the probability of chance association within 5′ for the RASS-FSC and the BSC.
