21st International Pig Veterinary Society Congress

Organizing Committee

President: Ernest Sanford
Vice-President/Secretary: John Harding
Finance/Treasurer: Al Theede
Scientific Committee Co-chairs: Sylvie D’Allaire, Robert Friendship
Sponsorship Committee Co-chairs: Camille Moore, Neil Shantz
Social Committee Co-chairs: Chris Byra, Gail Cunningham, Julie Ménard
Technical Tours: Chris Byra, Rick Stanley
Accompanying Persons Tour Program: Madonna Benjamin

Scientific Committee

Co-chairs:
Sylvie D’Allaire, Faculté de médecine vétérinaire, Université de Montréal
Robert Friendship, Ontario Veterinary College, University of Guelph

Members:
Ron Ball, Faculty of Agricultural, Life and Environmental Sciences, University of Alberta
Tim Blackwell, Ontario Ministry of Agriculture, Food and Rural Affairs
Cornelius F.M. de Lange, Ontario Agricultural College, University of Guelph
Jérôme del Castillo, Faculté de médecine vétérinaire, Université de Montréal
Cate Dewey, Ontario Veterinary College, University of Guelph
Richard Drolet, Faculté de médecine vétérinaire, Université de Montréal
George Foxcroft, Faculty of Agricultural, Life and Environmental Sciences, University of Alberta
Carl A. Gagnon, Faculté de médecine vétérinaire, Université de Montréal
Harold Gonyou, Prairie Swine Center, University of Saskatchewan
Marcelo Gottschalk, Faculté de médecine vétérinaire, Université de Montréal
Carlton Gyles, Ontario Veterinary College, University of Guelph
John Harding, Western College of Veterinary Medicine, University of Saskatchewan
Dan Hurnik, Atlantic Veterinary College, University of Prince Edward Island
Roy Kirkwood, College of Veterinary Medicine, Michigan State University
Ann Letellier, Faculté de médecine vétérinaire, Université de Montréal
Guy-Pierre Martineau, École Nationale Vétérinaire de Toulouse
Scott McEwen, Ontario Veterinary College, University of Guelph
Suzanne Millman, College of Veterinary Medicine, Iowa State University
Zvonimir Poljak, Ontario Veterinary College, University of Guelph
Dongwan Yoo, College of Veterinary Medicine, University of Illinois
IPVS Board

President 2010  Dr. Ernest Sanford - Canada
Vice President 2010  Dr. John Harding - Canada
President Elect 2012  Dr. Won Hyung Lee - Korea
President 2008  Dr. Peter Evans - South Africa
President 2006  Dr. Bent Nielsen - Denmark
President 2004  Dr. Henning Bossow - Germany
President 2002  Dr. Hank Harris - USA
President 2000  Dr. Ross Cutler - Australia
IPVS General Secretary  Dr. Francois van Niekerk - South Africa
Congress Secretary 2010  Dr. Al Theede - Canada
Preface

The 21st International Pig Veterinary Society Congress is held in Vancouver, Canada, marking the first time Canadians have had the opportunity of hosting this meeting. As a tribute to one of the founders of the IPVS and one of its most influential members, the 21st Congress will begin with the Tom Alexander Memorial Lecture delivered by Dr Hank Harris. In a slight departure from the format of previous meetings there will be only two keynote speakers, both on the opening morning. To introduce major topics there will be eight lead speakers who will each present a talk at the beginning of the specific concurrent session matching their area of expertise. For the first time at an IPVS congress posters will be presented electronically. The number of abstracts for this conference exceeds that of any previous IPVS congresses and this provided the scientific chairs with a challenge in terms of organizing the submissions for oral and poster presentations.

We wish to thank the following reviewers for reading and scoring the abstracts and assisting with the organization of the program:

Glen Almond  Janet Alsop  Oystein Angen  Marie Archambault  Poul Baekbo
David Benfield  Pat Blackall  Tim Blackwell  Thomas Blaha  Patrick Boerlin
Corrie Brown  Mary Buhr  William Caine  Susy Carman  Glen Cassar
Chan Hee Chae  Jan Dahl  Peter Davies  Martin de Jong  Kees deLange
Anne Deckert  Cate Dewey  Scott Dee  John Deen  Jérôme del Castillo
Dennis DiPietre  Mariano Domingo  Trish Dowling  Richard Drolet  Gerald Duhamel
Kay Faaberg  John Fairbrother  Ying Fang  George Foxcroft  Julie Funk
Carl Gagnon  Connie Gebhart  Harold Gonyou  Marcelo Gottschalk  Marie Gramer
Roberto Guedes  Carlton Gyles  Fred Haesebrouk  Pat Halbur  Derek Haley
David Hampson  Patricia Holyoake  Scott Hurd  Dan Hurnik  André Jestin
Han Soo Joo  Sven Jorsal  Roy Kirkwood  Robert Knox  Paul Langford
Lars Larsen  Martine Laitat  Arlette Laval  Ann Letellier  Paul Luimes
Joan Lunney  Janet MacInnes  François Madec  Dominiek Maes  Guy-Pierre Martineau
Eric Mateu  Scott McEwen  Steven McOrist  B.M. Meehan  Suzanne Millman
Cora Miry  Soenke Moehn  Antonio Morilla  Bob Morrison  Herve Morvan
Michael Murtaugh  Hans Nauwynck  Eric Nelson  Jens Peter Nielsen  John Patience
Cinta Prieto  Zvonimir Poljak  John Prescott  Sylvain Quessy  Simone Oliviera
Tanja Oprisnig  Andrijana Rajic  Jim Riviere  Nicolas Rose  J. M. Sanchez-Vizcaino
Joaquim Segales  Mariela Segura  Glenn Songer  Vibeke Sørensen  Jim Squires
Tomasz Stadejek  Katharina Stärk  Eileen Thacker  Flemming Thorup  Montserrat Torremorell
J.-P. Vaillancourt  Alain Villeneuve  Amy Vincent  Per Wallgren  Scott Weese
Michael Wendt  Kyoung-Jin Yoon  Ruurd Zijlstra  Jeff Zimmerman.

The final program consists of 266 oral presentations in addition to the 2 keynote and 8 lead presentations. There are roughly 890 posters. For the convenience of delegates the proceedings are divided into two parts representing oral presentations in part 1 arranged according to session and the posters in part 2 with papers grouped based on subject. For quick overview, a table of contents for both orals and posters is included at the beginning of the proceedings as well as an overall author index at the end.

We sincerely hope all delegates will enjoy this time of coming together and sharing ideas and information and that the scientific and social programs will stimulate and encourage the advancement of knowledge and friendship.

Sylvie D’Allaire and Robert Friendship

# Table of Contents

## Invited Speakers

### Tom Alexander Memorial Lecture

- Pig health assurance - underlying principles and future direction .................................... 1
  DL Hank Harris

### Keynote Address

- Animal welfare and the veterinary profession: 50 years of change .............................. 7
  David Fraser

## Lead Speakers

- Role of nutrition and intestinal adaptation in weanling pig health ................................. 11
  Douglas Burrin
- Progress in Porcine Reproductive and Respiratory Syndrome Virus (PRRSV): What we know about PRRSV, from basic to applied science – A historical perspective ................................................................. 13
  Jane Christopher-Hennings
- Pork safety: past achievements and future challenges .................................................. 15
  Peter Davies
- Porcine circovirus type 2: success and failure ............................................................... 20
  Caroline Fossum
- Application of advanced AI technologies to improve the competitiveness of the pork industry .......................................................... 25
  George R. Foxcroft
- *Mycoplasma hyopneumoniae* infections in pigs: update on epidemiology and control ................................................................. 30
  Dominiek Maes
- Social behavior in swine and its impact on welfare ...................................................... 36
  Jeremy N. Marchant-Forde
- Dysentery and ileitis – High time to tackle the difficult science behind these diseases ................................................................. 40
  Steven McOrist

## Oral Presentations

### Monday July 19

- Practitioner Line - Skin diseases .......................................................................................... 42

**Abstract**

The work of Tom Alexander centered on controlling swine diseases to benefit the breeding stock and commercial pig producer, and his discoveries and keen insight led to the principles of health assurance used world-wide in the industry today. An overview of his contributions to pig disease research and production, beginning with his involvement as an organizer of the first IPVS Congress in 1969, and exemplified by his paper delivered at that meeting concerning the development of disease-free pigs, will be followed by a look to the future.

**Introduction**

"Important principles may, and must be inflexible"
—- Abraham Lincoln

"The principles of disease control must not be set in stone. They are really guidelines which should be under constant re-evaluation and modification. But modification of a principle or action contrary to a principle should not be taken by any department or country without good reason and only after consultation and agreement among the appropriate parties.

—- Tom Alexander, PIC Veterinary Liaison Meeting, Schlesvig, Germany 1991"

The contradiction between these two quotations, one by a great politician and one by a great contributor to swine medicine exemplify Tom's career as both an academician and as an early proponent of what we now refer to as evidenced-based medicine (1,6,52).

Let me explain by presenting an example - Tom was a student and early adopter of the Specific Pathogen-Free (SPF) program originated by George Young in the U.S. (61). In fact, Tom's paper presented at the first IPVS meeting in 1969 and co-authored by Ken Woolley (founder of Pig Improvement Company, now known as PIC) was entitled, SPF Swine Repopulation (15). By that time, Tom had designed and operated the first experimental primary SPF procurement unit in Ontario, Canada and his paper was the first introduction to the concept in Europe. It was Tom's association with Ken and PIC which caused him to realize that strict adherence to the SPF principles would not be practical for either a breeder or a commercial operation. And although SPF organizations are still in existence today in some countries such as Switzerland, Denmark and at a minor level in North America, they have had to adopt Tom's approach to flexibility in the principles of health assurance. One could further expand this example by stating that the SPF association is a political organization while practical health assurance programs are carried out under the context of a profitable business. To paraphrase Tom's philosophy, which has now been adopted by virtually all breeders and commercial operations of any size world-wide, health assurance principles must be adhered to as long as they don’t bankrupt the business.

It seems only fitting that at the first IPVS meeting to be held in Canada that we honor Tom Alexander and give him credit for establishing the first SPF units in Canada and bringing these procedures to Europe via the first IPVS meeting held in Cambridge, England.

**Tom's Major Achievements and Contributions**

I'll return to more about Tom's approach to swine evidenced-based medicine but first let us look at his educational background and his many contributions to swine medicine as an academician.

After receiving his veterinary degree at London, Tom became house surgeon at the Large Animal Clinic in Ontario Veterinary College, finished a Master of Veterinary Science degree (Toronto) and served in various academic posts in Ontario through 1966. He completed his PhD degree at Cambridge during the years of 1962-65, returning for a short time to Ontario prior to accepting a lecturer position at Cambridge in 1966 where he remained until retirement in 2004. It was while in Canada that Tom met and married his wife Lenore.

Tom's work at Ontario regarding SPF and gnotobiotic pigs (10,12,57) led to investigations into vomiting and wasting disease of pigs (3,5,11,56). He was the first to describe its viral etiology, and picornaviruses became the subject of his PhD dissertation at Cambridge (8) under the mentorship of A.O. Betts. David Taylor and Tom were the first to describe the etiologic agent of swine dysentery (SD) in 1971(58). Their work was simultaneously and independently confirmed by Bob Glock and my team at Iowa State University (ISU) (33,41). The first IPVS meeting I attended was in 1972 in Hanover, Germany where Tom's group and mine presented papers on the etiology and pathology of SD. These discoveries by our two teams led to a lasting friendship, my consultative involvement with PIC, and scientific collaboration between Tom and me (40,62). Tom subsequently made many other contributions to our knowledge of swine dysentery (4,14,44).

Tom's pioneering work in primary SPF pigs, gnotobiots and discovery of anaerobic spirochetes in the intestine of pigs led him to more sophisticated studies on the anaerobic microbiota of pigs, sheep and rabbits (9538,9556,9559). Eventually, his group at Cambridge and mine at ISU combined efforts to discern the role of 'normal' flora such as Bacteroides and Fusobacteria in the pathogenesis of SD (40,62). Tom and Dick Lysons were the first to develop gnotobiotic lambs with a defined functional rumen flora (46).

While Tom was completing his PhD work on picornaviruses, he conducted some collaborative investigations and experiments with S.D. Elliott and J.H. Thomas on streptococcal meningitis and arthritis (28). Eventually, when streptococcal meningitis re-emerged in the British pig industry and became a threat to both pigs and humans around 1975, Tom led the effort to understand...
and control the disease. This work by Tom and his student and colleague, Felicit Clifton-Hadley was his largest contribution to the scientific literature. These clinical investigations and experiments led to discoveries pertaining to pathogenesis, control measures including vaccine development, and epidemiology of the disease (19,21-26,42,43,64).

The development of Medicated Early Weaning (MEW) was one of Tom’s best known contributions to the pig industry (13). Until 1978, there were 3 methods of starting and maintaining high health status herds with new genetic material: 1) direct population from another high health status herd; 2) grafting desired genes by artificial insemination or embryo transfer or cross-fostering young piglets; and 3) population by primary SPF methods (1). In 1977, the main PIC nucleus herd (Fyfield Wicke) became infected with Mycoplasma hyopneumoniae. The herd had been established by surgical-derivation in 1962 and this was its first encounter with the organism. Ken Woolley asked Tom to try a different method other than surgical-derivation to set up a new nucleus herd free of M. hyopneumoniae. Tom proposed the hypothesis that medication of both the sow and piglets combined with early weaning would result in pigs free of the infection. He enlisted Dick Lysons (then at Compton) and some PIC folks (mainly Graham Boon and Keith Thornton) to help with the design and implementation of his hypothesis. The MEW project was a huge success and resulted in not only the elimination of M. hyopneumoniae but also Bordetella bronchiseptica and some non-pathogenic colonic treponemes (now called Brachyspira). The MEW technique was soon adopted in PIC herds in France, Brazil and the U.S. with similar results. In an attempt to decrease the cost of repopulating herds even further, PIC modified the procedures which became known by several synonyms; modified MEW (MMEW), Isowean, and Segregated Early Weaning (SEW) (27,32,36-39,45,53). MEW or MMEW are now used to eliminate a variety of infectious agents including: pseudorabies virus, Porcine Reproductive Respiratory Syndrome Virus (PRRSV), Transmissible Gastroenteritis (TGE) Virus, Leptospira, Pasteurella multocida, Actinobacillus pleuropneumoniae, Streptococcus suis type II, and Haemophilus parasuis. The modifications applied to MEW were the basis for the development of multiple site production rearing systems (37,39). Other breeding stock companies have used the techniques to eliminate various infectious agents.

In the late 90s, Tom became interested in zoonoses involved in pig to human xenotransplantation (54). One of his last presentations, at the 1998 IPVS, bore the title ‘Zoonoses’, in which he described all the pathogens of pigs of possible concern to human health. He concluded that the only pathogens of significance was Salmonella (2). His concern at the time was the possibility that transgenic pig hearts and kidneys would soon be transplanted into humans. This has not been forthcoming, unfortunately, for a variety of reasons unrelated to the risk of pig to human transmission of disease.

During the early days of his tenure as Lecturer at Cambridge University, Tom first met Ken Woolley, President of PIC. Becoming an advisor to PIC was crucial to Tom’s development as both an academician, applied scientist and leader of evidenced-based swine medicine. The most important swine diseases at the time were atrophic rhinitis and enzootic pneumonia. Professor Betts in London was an early investigator in etiologic studies on enzootic pneumonia of pigs and pig producers in England were wanting pigs free of the disease. While Peter Whittlestone and Reg Goodwin at Cambridge and Bill Switzer and John Mare in Ames were discovering the causative agent (called Mycoplasma hyopneumoniae (48) in Ames and M. suis pneumoniae (34,35) in Cambridge), Tom was busy establishing enzootic pneumonia free herds for PIC. Goodwin was a proponent of the SPF approach which he later named ‘Minimal Disease (MD) Program’. Through his experience in dealing with the practical aspects of advising a breeding stock company, Tom departed from the SPF and MD programs strict adherence to rigid rules concerning the presence/absence of specific pathogens. It was his departure from testing for the presence of specific pathogens to consideration of the practical difference between infection versus disease which set the stage for Tom’s remarkable contributions to pig production world-wide (1).

Tom relied heavily on the discoveries being made by Betts, Goodwin, Whittlestone and Switzer in his advisory capacity to PIC, as it was during this period of time when respiratory diseases such as Mycoplasma pneumonia and atrophic rhinitis were key economic factors in commercial production. Tom formulated the Veterinary Liaison Scheme for PIC and the implementation of disease control strategies in that document have now become dogma in the swine industry world-wide.

This was how they worked:

Tom was one of the first veterinarians to recognize that pig density and farm location were important for disease control for both commercial operators and breeding stock producers (reviewed by Tom in his Howard Dunne Memorial lecture at the American Association of Swine Practitioners in 1998 (16) and also published by the Pig Veterinary Society (7)).

Tom found that the SPF and MD programs were too inflexible for the development of a breeding stock organization such as PIC. His insight led to concepts which are common terms/principles in the industry today: single sourcing of breeding stock and replacements, yet to vet interactions for matching the infectious disease status between source farm and the recipient farm, laboratory tests can be useful but never do a test if you aren’t sure of how to interpret the results, a breeder cannot guarantee freedom from disease (the main downfall of the SPF/MD programs), when problems arise in a breeder herd, shipments must be put on ‘hold’ until an investigation can occur to protect downstream recipient herds, pig movement should only be one way, down a pyramid but never reversed or across a pyramid and the implementation of biosecurity measures including shower-in; shower-out. Without doubt, many breeders went out of business for failure to follow these rules. Today, most breeders follow these rules and many commercial operations who have become breeders in their own organizations should follow them more closely. There is no doubt that PIC would not enjoy its dominant position today in the breeding stock business if it had not been for Tom’s insight and creativity in these early days of PIC (personal communication, Bill Christianson, CEO, Genus Americas).

In 1989, Tom organized a meeting of all the PIC associated veterinarians from around the world in Schleswig, Germany. It was a 3 day meeting in which he led the 30 plus attendees in a discussion leading to the creation of a document entitled the Principles of Disease Control (later called The Principles which underlie the PIC Health Assurance Programme). The current version is reprinted here with the permission of PIC. One of the most entertaining aspects of the meeting was the ‘role playing’ performed by veterinarians from various countries which led to a better understanding of practical disease control approaches.
The Principles Which Underlie The PIC Health Assurance Programme

1. Genetic improvement is a long term business and therefore the over-riding approach to disease control in PIC must be long term.

2. Every PIC herd should be set up with the healthiest pigs available that are appropriate for the purpose.

3. For insurance purposes there should be a contingency plan for the supply of suitable genetics to sustain the business.

4. It is both impossible and unnecessary to try to standardise the health status of all the herds throughout a breeding organisation.

5. PIC aims to protect customer health but cannot guarantee freedom from specific infectious agents.

6. PIC should adopt a continuous policy of maintaining high health status overall by such measures as closure of herds when they become unsatisfactory, the application of total or partial repopulation and the establishment of new high health status herds.

7. PIC must monitor for evidence of virulent pathogens over a wide spectrum of diseases and anticipate that new diseases will arise.

8. When a problem is suspected in a herd, sales must be put on hold while it is investigated.

9. Location is the most important factor in preventing contamination and herd breakdowns.

10. If a herd is situated in an excellent location the most important biosecurity factor is then the introduction and removal systems.

11. All pig transport and pig movement must meet PIC specifications.

12. Pigs should move in one direction only, that is down the pyramids and not across it or up it.

13. Appropriate biosecurity measures must be taken on every farm to prevent contamination and should be proportional to the impact of a breakdown in that unit.

14. The movement of people between herds or other sources of contamination must be controlled and appropriate downtime must be laid down for each herd.

15. To prevent dissemination of disease and because PIC cannot standardise health, PIC should aim at single sourcing and minimize source changes, keeping necessary changes within pyramids.

16. Laboratory tests can be very useful, but never do a test if you cannot be sure of interpreting the results.

17. The implementation of the health assurance programme should be predominantly regional and local rather than central, and where appropriate PIC should use independent veterinarians.

18. Every new nucleus and multiplier herd should be totally populated with PIC stock and must be pre-approved by Health Assurance.

19. Because clinical signs of disease are a major component of monitoring and diagnosis, antibiotics or vaccines that mask clinical signs must not be used routinely in PIC herds.

20. Every herd that receives live animals should isolate and monitor them before introduction.

21. Boar studs should be considered equal to nucleus herds with respect to set-up, monitoring and biosecurity.

22. PIC should be open about the operation of the health assurance programme and should communicate with individual customers particularly when problems arise.

23. Welfare is a component of the health assurance programme and should be monitored regularly.

The principles must not be set in stone. They are really guidelines which should be under constant re-evaluation and modification. But modification of a principle or action contrary to a principle should not be taken by any department or country without good reason and after consultation and agreement with Health Assurance.

No matter where in the world a new infectious agent emerged or re-emerged, Tom would often play a role in discerning the economic importance of the agent in a particular region or country and then either direct or assist in developing disease control strategies. Many of these opportunities came about because of his senior advisory role to PIC but often veterinarians and geneticists from other breeding stock companies or SPF organizations would call on him for advice. There are numerous unpublished documents penned by Tom in the files of veterinarians world-wide. These deal with a variety of infectious agents from Pasteurella multocida to PRRSV and PCV-2. Many of these contributions were not necessarily credited to Tom. For example, he had a major role in the early development of procedures to control PRRSV in boar studs UK and US and in the elimination of Foot and Mouth Disease virus in a herds in China (55).

Future Direction

Advancing Pig Health

I commend the organizing and scientific committees of this meeting for choosing this theme. Since the first IPVS meeting in 1969 which Tom helped organize, this group has emphasized the importance of infectious and non-infectious diseases and their impact on pig health. As new agents emerge and old ones re-emerge, pig veterinarians and scientists must continually utilize field data, evidence-based analysis/conclusions and scientific discoveries to improve the health status of swine. Furthermore, economic constraints combined with management and structural changes such as vertical integration are continual threats to the health and well-being of swine. The scientific program committee has done an excellent job in fulfilling the theme of the congress.

Vaccines will become increasingly important for the control of infectious diseases especially when fewer and fewer pharmaceuticals are available for either growth promotion or prevention/therapy. Within the next 10 years, immunogenetics will become increasingly important not necessarily for the creation of disease resistant pigs but rather for the development of vaccine-ready pigs (47,63). Evidence already exists in both swine and cattle that multi-disciplinary approaches combining immunobiology, quantitative and molecular genetics with reverse genetics related to infectious agents will lead to more powerful and cost effective prevention of infectious diseases. If regulatory agencies do not streamline approval processes and recognize molecular based technologic advances, the consolidation of the swine industry will result in integrators preparing their own sophisticated vaccines. Both virulent and avirulent (modified live) viruses have been used extensively in swine in an attempt to control PRRSV (49-51,65). It has been clearly shown that the re-introduction of live PRRSV into swine induces new strains of the virus containing both virulent and vaccine genes.
(29,66). These newly created viruses not easily controlled with currently available vaccines. Recently, it was reported that the use of attenuated Newcastle Vaccines has created and maintained a large population of vaccine-related genotype viruses. The presence of these viruses has allowed for co-infection and recombination of vaccine and wild type strains (20).

I predict that by 2020, Porcine Reproductive Respiratory Syndrome (PRRS) virus will be eradicated from many swine rearing areas of the world. This will be due to industry recognition that live viruses (modified live or virulent) must not be used in control programs for the disease. Breeders have long since recognized the necessity of maintaining nucleus and multiplier herds free of PRRSV. In addition, it is well known and accepted that closed herds with high biosecurity measures often eliminate the virus if live viruses are not used in the herd (60). Swine influenza virus (SIV) will continue to infect and form reassortants in the adult breeding herds. The concern that these viruses pose a threat to human health will drive the industry to wean and rear pigs free of SIV. Isowean pigs can be procured free of SIV(38) and a multi-site system has successfully eliminated SIV without vaccination (59). Vaccines will be developed which override the interference of the SIV immune response due to maternal antibody.

Recombinant-based vaccines will become more commonly available for the prevention of swine diseases. At the present time, they are more costly to produce than traditional vaccines from live or inactivated viruses. It is important for the creation of stockpiles of vaccines for Foreign Animal Diseases (FAD) that recombinant based vaccines be created and approved for use in the U.S. For example, Foot and Mouth Disease vaccines are currently not produced in the U.S. due to difficulty in production of vaccines requiring growth of the virus. As the recombinant vaccines are improved and shown to provide a significant economic benefit, these vaccines will replace traditional vaccines. Some vaccines for Porcine Circovirus (PCV) are recombinant proteins (derived from baculovirus) and others are prepared from chimeric viruses (30,31). There are no recombinant vector based vaccines for swine available in the U.S. Chimeric and vector based recombinant vaccines have a distinct advantage in that they induce both humoral and cell mediated responses (17,18). Recombinant vaccines will be especially useful in the development of vaccines which differentiate infected from vaccinated animals (DIVA).

**Pig Health Assurance World-Wide**

Pigs world-wide will be reared in systems in which the newly weaned pig is placed in isolation away from the breeding and farrowing operations. This simple concept originated with Tom's concept of medicated early weaning (MEW) in 1978 (13). The modifications made to MEW eventually led to the development of three site and multi-site production systems which are utilized in every main pig rearing country in the world (37,39). Even natural and organic pig rearing systems rely on this concept of isolated weaning for disease control.

The major disadvantage of multi-site rearing systems is the evolution of lowered herd immunity due to separation of the young growing and finisher pigs (37). This will be overcome by improved vaccines. However, as consolidation continues in the swine industry, a major restructuring of wean to finish buildings will occur. This will result in more strict adherence to all-in, all-out and single sourcing principles as advocated by Tom many years ago. Furthermore, commercial operations will follow the lead of breeders and pay closer attention to the value of well isolated sites in order to minimize disease during the grower-finisher stages.

Welfare and environmental issues will continually challenge the industry but the solutions to these problems will actually improve the health and productivity of pigs. Less crowding with better housing will lead to improved pig health and financial success. Furthermore, the environment will improve as the concentration of pigs per square mile decreases. The isolation/location of pig units will benefit from a biosecurity standpoint.

In the 1960/70s, the United Kingdom led the world in innovation and efficient swine production. This was soon followed by North American producers in the adoption of new technology, expansion, improvement in pigs per sow per year and feed efficiency and vertical integration especially in the 1980/90s. For 2010 and beyond, we'll witness huge technological advance and contribution to the pig industry in China. As Tom suggested, the Principles of Health Assurance will need to be flexible to meet these changing times and situations by country.

I would like to end on a personal note.

Tom was friend, mentor, and colleague to me but most of all I was the pupil. He came into my life at a most opportune time. I am forever grateful.

*When the pupil is ready to learn, a teacher will appear.*

Introduction

About 10 years ago I received an unexpected telephone call. It was from the Burger King Corporation to say that the company wanted to create a program to assure their customers about the welfare of the animals in their supply chain, and would I serve on the advisory committee. I admit to having been a trifle skeptical. Fast food restaurants as agents of social change? – it did not quite fit the popular stereotype. But I joined the committee and was pleasantly surprised to find myself in discussions about maintaining public trust and ‘doing the right thing’ for animals. To cut a long story short, Burger King’s engagement in animal welfare led to some tangible changes. In fact Temple Grandin (2000), after years of inspecting slaughter plants with mediocre animal welfare standards, reported a dramatic improvement immediately after chain restaurants became involved.

This, of course, is just one example of the remarkable growth in attention being paid to animal welfare, in some cases by unexpected players:

• Around the same time the International Finance Corporation, the investment arm of the World Bank, called for animal welfare to be part of the business plan of the livestock companies in which they invest.

• In 2008 the FAO, the United Nations agency involved in agriculture and hunger reduction, held an international consultation on how to help countries, especially developing countries, to implement good animal welfare practices.

• And it is expected that a ‘Universal Declaration on Animal Welfare’ will soon be presented to the United Nations with the expressed support of many of the world’s countries.

Nearly 40 years ago, when I began doing research on the welfare of pigs, animal welfare was on the very fringe of science. To most people the words ‘research’ and ‘animal welfare’ did not belong in the same sentence except perhaps to criticize animal welfare standards in laboratories. So how did it happen that animal welfare moved from being a fringe issue to something that attracts the attention of Burger King, the World Bank and the United Nations?

In this presentation I would like to trace this change by looking at four topics:

• some of the reasons behind the growing focus on animal welfare
• the debate about exactly what ‘animal welfare’ means
• some of the science that has been applied to animal welfare issues
• and the role of veterinarians in this rapidly changing world.

The growing focus on animal welfare

Every culture has an ‘animal mythology’ – a set of fundamental beliefs and values regarding animals – which we can often perceive through the art and stories of the culture (material in this section is from Fraser, 2008). In the creation story of the Ojibway culture of central Canada, people had fallen from the sky onto an earth that was covered in water, and they were able to survive only because the animals took pity on them, starting with the turtle who allowed its shell to form the base of the dry land. And throughout Ojibway legends and conduct, we see this fundamental assumption – perhaps not surprising for a hunting culture living in a harsh northern climate – that people are vulnerable beings whose survival is made possible by the cooperation of animals.

In these two examples of animal mythology we see both empirical beliefs – about what animals are like and the history of our involvement with them – and evaluative or ethical beliefs about how important animals are and how they should be treated. The biblical creation story implied that people and animals are separated by a large gulf which included at least three components. One was appearance: people had been created in the ‘image’ of God, and therefore looked nothing like birds, fish or quadrupeds. Second, people had a different origin: they were created separately from the animals and for a different purpose. And third (although disagreement arose on this point) people were seen as having a unique inner, spiritual nature that animals did not share. Here, then, were three empirical beliefs – about different appearance, different origin, and different inner life – that reinforced the idea of humans as fundamentally different from animals and helped to justify the use of animals for human purposes.

But in modern culture, empirical beliefs are not fixed by the constant retelling of traditional stories, but rather are subject to change in light of scientific discoveries and other developments. And indeed over the centuries we have seen these three empirical beliefs gradually chipped away, at least partly by science.

The first scientific development came from anatomy. Beginning in Italy during medieval times, the study of anatomy became one of the frontiers of scientific research for many centuries. Moreover, this research was communicated to the public in the many ‘dissecting theatres’ that sprouted up in the major centres of learning. These theatres allowed people to witness the dis-
section of animals or even humans cut down from the gallows. And through this anatomical research and the remarkably direct form of public education, it came to be recognized that humans – organ for organ and bone for bone – are actually built on the same anatomical template as the other vertebrate animals.

This realization became common knowledge around the year 1700, and it touched off two centuries when scientists and philosophers alike struggled to understand the implications of this new knowledge. The process culminated with the evolutionary biology of the 1800s and the startling proposal that the reason why we and other species have the same anatomical structure is that we share a common evolutionary origin. Thus, by about a century ago people had lost both their unique appearance and their unique origin.

Late in the 1900s, I think the study of animal behaviour led to a further revision in our view of animals, this one centred on their mental and emotional lives. A classic example is the work of primatologist Jane Goodall who studied animals in such detail that she could describe their personalities and unique life histories. From Jane Goodall we learn about the young chimpanzee she called ‘Flint’ who, at the mature age of eight, remained so attached to his aging mother that when she died, he stayed near the place of her death until he himself died of starvation. Drawing together this and many other observations, primatologist Roger Fouts (1997) described the chimpanzee as a:

‘highly intelligent, co-operative, and violent primate who nurtures family bonds, adopts orphans, mourns the death of mothers, practises self-medication, struggles for power, and wages war.’

Thus, with some species at least, even in our mental lives the gap between humans and animals has come to seem remarkably narrow.

To sum up, the large gap between people and animals that we saw in the Biblical creation story has narrowed through scientific research, so that many people today believe that humans and animals share a common anatomical form, a common evolutionary ancestry and, with some species, a complex mental and emotional life. This altered set of empirical beliefs, about what animals are like, has stimulated a massive rethinking of our ethical beliefs, about how animals should be treated. And because science has expanded from being an element of Western culture, and has become more an element of global culture, perhaps it is not surprising that animal welfare is rapidly becoming a global issue.

**What is animal welfare?**

As the current wave of concern about animal welfare began, roughly in the 1960s, a debate emerged over what animal welfare really involves.

The first major criticism of confinement production systems came in the book *Animal Machines*, by the English animal advocate Ruth Harrison (1964). She described cages for laying hens and crates forveal calves, and she claimed that these systems are so unnatural that they cause animals to lead miserable and unhealthy lives. She went on to ask:

How far have we the right to take our domination of the animal world? Have we the right to rob them of all pleasure in life simply to make more money more quickly out of their carcasses?

Later, in *Animal Liberation*, Australian philosopher Peter Singer (1990) adopted the principle that actions should be judged right or wrong on the basis of the pain or pleasure that they cause, and he claimed:

There can be no moral justification for regarding the pain (or pleasure) that animals feel as less important than the same amount of pain (or pleasure) felt by humans.

In these and many other quotations, a key concern centres on words like “pleasure”, “pain”, “suffering”, and “happiness”. There is no simple English word to capture this class of concepts. They are sometimes called “feelings but that term seems too insubstantial for states like pain and suffering. They are sometimes called “emotions but emotions do not include states like hunger and thirst. Perhaps the most accurate, if rather technical, term is “affective states”, a term that refers to emotions and other feelings that are experienced as either pleasant or unpleasant rather than hedonically neutral.

In discussing animal welfare, however, some people put the emphasis elsewhere. A British committee that was formed to evaluate the welfare of farm animals concluded:

In principle we disapprove of a degree of confinement of an animal which necessarily frustrates most of the major activities which make up its natural behaviour. (Brambell 1965)

Astrid Lindgren, the famous author of the Pippi Longstocking stories and a driving force behind animal welfare reform in Sweden, proposed:

Let [farm animals] see the sun just once, get away from the murderous roar of the fans. Let them get to breathe fresh air for once, instead of manure gas. (Anonymous 1989)

And American philosopher Bernard Rollin (1993) insisted that we need:

… a much increased concept of welfare. Not only will welfare mean control of pain and suffering, it will also entail nurturing and fulfilment of the animals’ nature.

In these quotations, although affective states were often involved implicitly or explicitly, the central concern was for a degree of “naturalness” in the lives of animals: that animals should be able to perform their natural behaviour, that there should be natural elements in their environment, and that we should respect the “nature” of the animals themselves.

All of the above quotations reflected the views of social critics and philosophers, but when farmers and veterinarians engaged in the debate, they brought a different focus. For example, one veterinarian defended confinement systems this way:

My experience has been that ... by-and-large the standard of welfare among animals kept in the so called “intensive” systems is higher. On balance I feel that the animal is better cared for; it is certainly much freer from disease and attack by its mates; it receives much better attention from the attendants, is sure of shelter and bedding and a reasonable amount of good food and water. (Taylor 1972)

Or as the veterinary educator David Sainsbury (1986) put it:

Good health is the birthright of every animal that we rear, whether intensively or otherwise.
Here the primary emphasis is on the fairly traditional concerns of veterinarians and animal producers that animals should have freedom from disease and injury, plus food, water, shelter and other necessities of life – concerns that we might sum up as the basic health and functioning of the animals.

In these various quotations, then, we see a variety of concerns that can be grouped roughly under three broad headings: one centres on the affective states of animals, one on the ability of animals to lead reasonably natural lives, and one emphasizes basic health and functioning. These are not, of course, completely separate or mutually exclusive; in fact, they often go hand in hand. Letting a pig wallow in mud on a hot day is good for its welfare because the pig will presumably feel more comfortable (an affective state), because it can perform its natural cooling behaviour (natural living), and because it will have less disruption of its body processes caused by heat stress (basic health).

But the different criteria do not always go together. The gestation stall, where sows cannot walk or turn around for most of pregnancy, is a way of promoting healthy weight gain and avoiding injuries from aggression, but it is very unnatural and may create a life that is not very pleasurable. Feeding sows as much as they want may avoid unpleasant feelings of hunger, but can lead to unhealthy weight gain. Some outdoor systems look very natural, but involve parasitism and low piglet survival. Thus, genuine disagreements can arise when people try to create standards or practices to promote animal welfare based on any one of the three areas of concern.

Animal welfare science

As this debate unfolded in the 1960s and 1970s, people began doing scientific research on animal welfare. Partly the research was done for the practical goal of making production systems more efficient by making them better suited to the animals. And partly the research was done because people expected science to resolve the disagreements over the interpretation of animal welfare. Surely, if animal welfare standards were ‘science-based’, there could be no disagreements based on differing interpretations of animal welfare. The outcome, however, proved more interesting as the following simple examples show.

Some of the research used the basic health and functioning of animals as an indicator of animal welfare. In one elegantly simple example Ragnar Tauson and co-workers (1998) improved the design of cages for laying hens just by studying the health of birds in cages of different types. They found that the birds developed foot lesions if the slope of the floor was too steep, and neck lesions if the feed trough was too deep and installed too high for comfortable access. There was often feather damage that could be reduced by using solid side partitions, and overgrown claws that could be prevented by installing abrasive strips. By modifying cage designs accordingly, Tauson was able to make large improvements in animal welfare as well as production efficiency, and this research then formed the basis of animal welfare standards for cage design, first in Sweden and then in the European Union.

Other scientists tried to improve animal welfare by making living conditions more ‘natural’ for animals. On many commercial dairy farms, calves are separated from their mothers within the first day after birth, and are then fed milk from a bucket, usually in two fairly large meals per day. This, of course, is very unnatural. Under natural conditions, the calf would stay close to the cow for the first two weeks, and would feed many times per day in smaller meals. Leaving cows and calves together is not feasible on dairy farms, but calves can still be fed in a more natural way. First, if the calves suck from a teat rather than drink from a pail, the sucking action seems to stimulate certain digestive processes more effectively. Second, if the teat feeding system allows the calves to have many small meals per day (as they would if feeding from the cow), then they can consume a larger daily intake without developing digestive problems. As a result, such calves gain much more weight than calves fed twice a day by bucket (Appleby et al. 2001).

In other cases, research has tried to reduce unpleasant affective states in animals. Hot-iron disbudding of calves involves heating a ring-shaped iron to about 600 degrees Celcius and pressing it against the calf’s head so that it burns through the nerves and blood vessels that would allow the horn to develop. Research in New Zealand by Stafford and Mellor (2005) used changes in plasma levels of the stress-related hormone cortisol as an indirect indicator of the resulting pain. Hot-iron disbudding was followed immediately by an increase in cortisol, but that reaction was blocked if lidocaine was used to freeze the area. Even with lidocaine, however, cortisol levels showed a clear increase several hours after the disbudding, probably because the area remained inflamed and painful after the freezing had worn off. However, if an analgesic such as ketoprofen is added to the calf’s milk on the morning and evening of the dehorning, the second peak of cortisol is also eliminated. The results indicate that effective pain management requires both local freezing and a longer-acting analgesic.

In the early stages of the debate about animal welfare, some people expected that the science would eliminate any disagreement over the different elements of animal welfare by finding the one ‘scientific’ view. Instead, each of the different views of animal welfare led to research that provided different and complementary ways of improving animal welfare, and all three have led to practical improvements and science-based animal welfare standards. Thus, instead of the science resolving the different interpretations of animal welfare, the different interpretations actually came to underlie and enrich the science.

The take-home message for the animal-based industries is that all three views of animal welfare have a scientific basis, and that the single-minded pursuit of any one criterion of animal welfare may fail to promote animal welfare as judged by the other criteria. For standards and practices to be widely accepted as improving animal welfare, they need to make a reasonable accommodation to all three.

The role of veterinarians

What is the role of veterinarians in this world of changing values and emerging science?

First, we need to recognize that animal welfare research is not a mature field of science. Much of the research is still more conceptual than strategic. Much of it is done at a research-farm scale, not a commercial scale. And much of it does not yet involve the multi-disciplinary teams that are needed to look at all the implications of new ideas. There is a great opportunity for veterinarians to work with animal welfare scientists to refine and broaden the science, and to apply it in practical ways. Here, then, is a scientific and technical role.

Second, the increased public concern about the welfare of animals has created an expectation that veterinarians will provide leadership in promoting animal welfare, not just as technical
specialists working to prevent and treat disease (important as that is), but also as champions of animal welfare in a broader sense that includes the different areas of concern. Here is a social leadership role.

I believe there is some urgency about fulfilling these roles. Some highly intensive pig production emphasizes basic health but ignores other animal welfare concerns; these systems sometimes offend against the public’s view of what constitutes decent treatment of animals. Unless scientists and veterinarians can deal with the problems, then legislators and referenda may do so instead, and the outcomes may be less than ideal for the animals and for producers. At the other extreme there is a growth in outdoor systems that tend to be seen by the public as high-welfare, more or less by definition, but may involve serious problems of basic health and functioning. There is a need for technical innovation and good standards to ensure that this well-intentioned development does lead to good welfare for the animals.

But why, in 2010, are such basic problems as these still waiting to be solved? A century ago, agricultural and veterinary students studied a subject called ‘animal husbandry’ which included the feeding, breeding, handling, management and housing of animals. Then certain branches of science became established – nutrition, physiology, genetics – and before long, animal husbandry was replaced by a handful of scientific specialties. But when that happened, some of the original components of animal husbandry – the handling and management and housing – seemed to be forgotten as areas for scientific research and training. I think animal welfare science is finally restoring these missing elements of animal husbandry, but with a scientific basis that was not available a century ago. Here we see an educational role for veterinarians: to use animal welfare science as a way of restoring animal husbandry in veterinary education.

Conclusions

What can we conclude from a presentation that has ranged from creation stories to studies of animal pain? Perhaps five things:

• First, the social concern about animal welfare that we see today has grown out of a long history of change in attitudes, driven to a large degree by scientific discoveries that narrowed the gap that we perceive between people and animals.

• Second, social concern about animal welfare includes three main elements: (1) the basic health and functioning of animals, (2) the affective states of animals, especially freedom from negative states such as pain and distress, and (3) the ability to live in a way that suits the animals’ natural behaviour and other adaptations.

• Third, each of these elements of animal welfare has a scientific basis, and all three have given rise to practical improvements and science-based standards. The science did not arbitrate among the different views of animal welfare; rather the different views of animal welfare influenced the science and contributed to the richness of its ideas and approaches.

• Fourth, the single-minded pursuit of any one element of animal welfare does not guarantee a high level of animal welfare as judged by the others. For practices and standards to be widely accepted as improving animal welfare, they need to strike a balance among all three.

• Fifth, the increased focus on animal welfare, and the emerging science of animal welfare, have created expanded opportunities for veterinarians to take on new scientific and technical roles, new social leadership roles, and new educational roles in improving the lives of animals.

Role of nutrition and intestinal adaptation in weaning pig health

Douglas Burrin

USDA-ARS, Children’s Nutrition Research Center, Houston, TX, USA

Summary

The growth rate of the pig is most rapid during the neonatal and weaning periods. Nutrition and gastrointestinal function play a critical role in the survival, health and growth of the young pig during this transition from suckling to weaning. The high metabolic rate and cellular turnover of gut tissues result in substantial first-pass utilization of dietary nutrients, especially amino acids, to maintain gut function. The changes in the diet composition and gut microbiota after weaning are associated with increased gut growth and metabolism, which may limit the systemic availability of dietary nutrients. Strategies aimed at optimizing gut metabolism and supplementing key gut-nutrients in support of gut function may improve growth.

Early gut development and nutrition

The neonatal and weaning phases occupy critical periods of postnatal growth and development in commercially reared pigs. The relative rates of growth are higher during the neonatal period than at any time during postnatal life. More importantly, however, is that during the neonatal and weaning phases, the survival, health and subsequent growth rate of young pigs depends on their ability to adapt physiologically to significant changes in nutrition and the environment. Critically to this adaptation process is the development of the gastrointestinal tract, particularly digestive, absorptive and immune function. Nutrition is a key determinant in the functional development and growth of the gastrointestinal tract.

The gastrointestinal tract of the piglet increases nearly threefold between birth and two weeks after weaning, increasing from 2% to 6% body weight. A major stimulus for gut growth at birth is the initiation of suckling or enteral nutrition. Enteral nutrients have a major anabolic effect on the neonatal gut, but growth factors present in sow’s colostrum and milk may also have trophic effects. Weaning is the second major milestone in gastrointestinal growth in the developing piglet. Nutrition plays a central role during weaning, first by limiting gut growth due to increased dry matter intake and changes in diet composition. The weaning transition is marked by reduced villus height, increased crypt cell hyperplasia and expansion of the lamina propria cell population. The weight of the colon is increased approximately threefold within seven days after weaning, mainly due to increased fermentation of undigested dietary carbohydrates and fiber. The hyperplasia in the crypt epithelium and lamina propria is thought to be linked to gut hypersensitivity reactions associated with plant proteins in the weaning diet, such as soy glycins and lectins.

The weanling pig is especially vulnerable to pathogenic infection because of the withdrawal of sow’s milk and the increased colonization of commensal gut microorganisms. Pathogenic infection results in an activation of the mucosal immune system and release of proinflammatory cytokines (e.g. tumor necrosis factor “ and interleukins) that have been shown to increase crypt cell proliferation, villus enterocyte apoptosis, and intestinal acute phase protein synthesis.

The concept of gut nutrient requirements

Most swine nutritionists have an extensive knowledge of the nutrition requirements for the pig growth. However, in recent years, the concept of nutrient requirements has evolved to include the needs specifically for the gut. Technical advances have enabled direct estimates of gut nutrient utilization and their impact on the whole animal nutrient metabolism in vivo studies in pigs using isotopic tracers and measurements of trans-organ balance of substrates. These and other studies with cultured porcine intestinal epithelial cells have revealed important qualitative characteristics of the metabolic fate of key substrates and the underlying cellular basis for intestinal nutrient utilization.

Studies with pigs have shown that the neonatal intestine plays a key role in the metabolism of amino acids involved in the urea cycle, particularly arginine, proline, and ornithine. There is extensive interconversion between these amino acids and the intestine represents an important site of net arginine synthesis in neonatal pigs. Studies in pigs have also demonstrated the extensive metabolism of other essential amino acids, including threonine, lysine, phenylalanine, branched-chain amino acids, and methionine. It is generally considered that the primary metabolic fate of essential amino acids taken up by the gut is incorporation into tissue proteins. However, studies show that extensive irreversible catabolism and oxidation of amino acids occurs in the gut. Moreover, many of these essential amino acids are metabolized to other intermediates involved in intestinal function. For example, threonine is believed to be channeled into mucin synthesis and secreted by goblet cells, because mucin peptides are rich in threonine. Methionine may be converted to cysteine or s-adenosyl-methionine used in polyamine synthesis. Cysteine is used as a precursor for glutathione synthesis and maintenance of mucosal anti-oxidant status. The oxidation of some essential amino acids, such as the branched-chains and lysine, in the gut may be nutritionally significant. The high essential amino acid utilization rate by gut tissues can have a significant impact on the systemic availability for lean tissue growth. Historically, weanling pig diets have been formulated largely to overcome the limitations or immaturity in digestive function in

11
order to maximize growth of the whole animal. However, with a new understanding of intestinal nutrient utilization, it is possible to now formulate weanling pig diets with the specific goal of optimizing the growth, function and health of the gut. From the foregoing discussion of intestinal nutrient utilization some of the most promising candidates are glutamine, glutamate and threonine.

**Nutrition and enteric health and function**

A critical factor influencing the growth of weanling pigs is the degree of colonization with commensal and pathogenic microbes. Exposure to these microbes and their toxins can adversely affect intestinal structure and function. The pro-inflammatory stimulus induced by bacteria, endotoxin and cytokines significantly increases the intestinal protein synthesis rate. Studies in sheep show that parasitic infection increases the rate of leucine utilization and oxidation by PDV tissues, thereby reducing the systemic availability of dietary amino acids by 20-30%. Thus, it is likely that the degree of commensal and pathogenic microbial load directly affects the intestinal nutrient requirements, which in turn may consume dietary nutrients and limit growth of weanling pig.

Antimicrobial compounds are fed to weanling pigs in order to suppress the activity of the gut microflora and enhance growth. Antimicrobials are thought to act via four possible mechanisms, a) prevention of infection, b) reduced microbial nutrient use, c) enhanced nutrient absorption, and d) reduced growth-depressing microbial metabolite load. It is generally held that one or a combination of these mechanisms act to diminish the thickness and mass of the intestinal mucosa and associated lymphoid tissue. A critical mechanistic question regarding the site of dietary amino acid utilization in the gastrointestinal tract is whether this activity is associated with the luminal microbes or the cell populations of the mucosa.

Alternative nutritional strategies are being used to manipulate the gut microflora including probiotics, prebiotics, organic acids, spray-dried plasma, and high concentrations of copper and zinc. These approaches have become an increasingly important consideration in swine nutrition, given the evidence of their benefits in animals and humans coupled with the growing concern of antimicrobial resistance. Probiotics and prebiotics are used to induce the colonization of bacteria (e.g. lactobacillus and bifidobacteria) considered to be beneficial for the host. The consequences of these alternative nutritional strategies on gut metabolism and nutrient utilization are poorly understood and warrant further study.

It is an absolute honor to be asked to give the opening talk at the PRRSV session at the 21st International Pig Veterinary Society Congress in Vancouver. After looking through the list of subsequent speakers, I recognize the great expertise and innovative thinking that is present and want to recognize those that have contributed to our knowledge about PRRSV. Hopefully this will be an encouraging presentation by demonstrating how we have collaborated and innovated in the past and how we can continue the momentum in trying to prevent this disease.

This talk will show a historical and comparative viewpoint in the discovery of PRRSV and subsequent development of reagents and diagnostic applications. I think we should take some encouragement in knowing that PRRSV is still a relatively “young” pathogen in the swine population compared to others such as transmissible gastroenteritis virus (TGEV) which was described in the US in 1946; pseudorabies virus (PRV), first found to be filterable in 1813 in cattle, but recovered from swine in 1909; and foot and mouth disease virus (FMDV) which was identified as a filterable agent in 1897 [1]. In addition, PRRSV is not “latent” like PRV where there is a constant risk of previously infected animals transmitting the virus; PRRSV is very susceptible to disinfectants, heat and drying (compared to porcine circovirus 2 (PCV2) and some other viruses which are not as readily inactivated); it is not transmissible to or from people like swine influenza virus (SIV) and we also have new technologies to rapidly identify the virus which were not previously available for other disease eradication programs. In addition, we currently have a voluntary, coordinated, funded and focused effort in the United States (http://www.prrs.org http://www.prrssymposium.org), Canada and other countries, to understand, control and eliminate PRRSV transmission.

PRRSV was first identified as the cause of “Mystery Swine Disease,” “Blue-eared” Pig Disease or “Swine Infertility and Respiratory Syndrome” (SIRS), now known as “PRRSV” in 1991 in Europe and subsequently in the US. Even though PRRSV is not eradicated, it should be noted that the causative agent of PRRSV was first identified only about 20 years ago. By comparison, PRV was first reported in swine in 1909 with much of the eradication completed in 2005; classical swine fever virus (CSF/Hog cholera) was first reported in 1810 with much of the eradication completed in the US between 1962 and 1976 and Brucellosis was identified in 1897 and nearly eradicated at this time. In these cases, between 100-200 years passed before eradication or near eradication was completed after identification of these swine pathogens.

Persistence of PRRSV was initially described, but PRRSV is not “latent” whereby viral replication can be re-activated and shedding of the virus can recur. With PRRSV, transmission of virus from pigs infected in utero can be documented up to 112 days of age [2]. However, duration of shedding may be somewhat age dependent with 4 month old gilts not demonstrating viral shedding between 90-180 days post inoculation [3], whereas 90-100% of PRRSV infected 3 week old pigs were still infected at 63-100 days [4]. Therefore, recommendations have been made to close herds for 200 days post clinical signs to prevent shedding to newly introduced pigs. These findings demonstrate that there is a finite time period of viral shedding, unless a new viral strain or PRRSV naïve pigs are introduced.

Since PRRSV is an enveloped virus (unlike PCV2), it is susceptible to heat, drying and disinfectants which allows for more efficient removal of the virus from the environment. In 1992, the characteristics of this virus were described in cell culture whereby virus infectivity was completely inactivated after 45 minutes at 56 C, but more stable after 1 month incubation at 4 C or 4 months at -70 C [5]. This susceptibility to higher temperatures and stability at lower temperatures was further confirmed for a range of PRRSV strains [6]. This information is also useful for effective biosecurity protocols [7].

Transmission of PRRSV through other animal vectors or people has not been confirmed, although mechanical transmission could occur through insects and fomites [8, 9]. This differs from SIV whereby pigs are susceptible to influenza that could be transmitted through people [10], making biosecurity more difficult.

Newer diagnostics such as rapid molecular tests (real-time, quantitative or isothermal PCR) were discovered and utilized after 1983 [11] for “same day” results. These tests were not previously available for other swine pathogen elimination programs, but should be an advantage for PRRSV elimination protocols.

More convenient surveillance methods are also available to obtain and test samples economically and with the welfare of the animal in mind. These include pooling of samples, obtaining oral fluids [12] or blood swabs [13] and using newer technologies to multiplex for identification of various swine disease antigens, antibodies or immune parameters simultaneously [14].

Coordinated efforts to control or eliminate PRRSV are becoming more prevalent worldwide. In the US, the PRRSV Coordinated Agriculture Program (CAP1 and CAP2) started by the USDA in 2004 are designed to enable “the collective talents of the stakeholder community of scientists, veterinarians, pork producers, and allied industry researchers to develop innovative strategies to lessen the impact of PRRS and lead to the eventual elimination of the virus.” Research on vaccines that are effective against the collective of PRRSV strains and that can be differentiated from field strains should continue. With these resources and findings, we should be further along on PRRSV elimination than historically has been the case with other swine pathogen elimination programs.

Pork safety: past achievements and future challenges

Peter Davies
University of Minnesota, St Paul, MN, USA

Introduction

Ever since the dawn of phagocytosis, eating has been a risky endeavor. Because internalizing portions of our external environment can never be entirely risk free, food safety is a relative concept. However, eating entails less risk than not eating, and the availability and cost of food influence the levels of protection or assurance that consumers demand for their food supply. Hunger and undernutrition are responsible for about 35% of child deaths and 11% of the total global disease burden. At the other extreme, the World Health Organization projects that by 2015 more than 700 million adults will be obese, and 2.3 billion overweight. Overnutrition is imposing increasing burdens on health costs in many countries, with a recent estimate of $147 billion annually for the USA. Paradoxically, obesity is also positively associated with poverty as energy dense foods of low nutritional value tend to be cheap. Like malnutrition and obesity, food safety presents another manifestation of global inequity linked to poverty and food security.

Pork has long been the most consumed meat globally, and projections of future global pork demand remain robust, largely driven by anticipated growth in developing economies. The fact that per capita meat consumption increases as wealth increases reflects that animal proteins are preferred protein sources across the majority of cultures. However, contemporary discussions of projected world population growth, its implications for land use, and the environmental impact of food production raise complex questions about the future of meat consumption. McMichael et al (2007) calculated that global average meat consumption was 100 grams per person per day, but varied ten-fold between high-consuming and low-consuming populations. They proposed 90 g per day as a “working global target” but advocated more even distribution and that not more than 50 g per day should be from ruminants. Although some grass roots groups and celebrities have promoted campaigns to reduce meat consumption (e.g. meat-free Monday), it is unrealistic to expect material change will arise from ‘enlightened’ consumer behavior. Policy options that could influence meat consumption patterns are yet to be clearly articulated. Similar to the situation with greenhouse gas emissions, increasing tensions are likely as the force of growing demand for animal protein in the developing world strains against calls for restraint from the relatively well fed western world. Priority issues in food safety also vary geographically, and some foodborne hazards that remain major public health issues in developing countries have been reduced to insignificance in developed countries. However, in most countries biological hazards greatly outweigh physical and chemical hazards in terms of public health impact and consumer concern, and therefore will be the focus of this paper.

How safe is pork today?

It depends - whose pork and compared to what? Unlike crossing a road, where the hazards can be directly perceived, foodborne hazards are mostly invisible to consumers. Food safety is termed a ‘credence attribute’. Opinions are forged from both personal experience and external information, and perceptions of safety are influenced by social processes, including the media and government agencies. Food is such an intimate element of the human experience that there are all manner of passionate opinions about what we should eat, and how it should be produced, procured and prepared. Engaging authors such as Michael Pollan and Eric Schlosser, and films like Food Inc., have inspired a mass of neoromantic ‘locavores’ who disparage almost every facet of the mainstream commercial food industry. Critics of ‘industrialized production’ and ‘factory farming’ habitually confute diverse issues (social justice, environmentalism, animal welfare…), and food safety is usually prominent in the mix. Mostly, however, they tend to be vague about which hazards are of particular concern, and why those specific hazards present greater risk in modern systems of animal production. Ironically, the consumer pressures that propelled revision of Federal regulations of meat inspection in the USA in the 1990s, may have also contributed to integration in the pork industry. Market demands for assurance of safety and quality (including traceability) motivate stronger packer-producer alliances, vertical integration, and marketing of branded products.

In the USA, the ritually cited estimate of the annual burden of foodborne illness is 76 million cases per year, 325,000 hospitalizations, and 5000 deaths (based on the 1997 population). Certainly disturbing numbers, but denominators matter and those numbers translate to approximately one foodborne illness per 4200 meals; one hospitalization for every 1 million meals; and one death for every 65 million meals. Food is consumed without any harm more than 3,999 times out of 4,000 meals, demonstrating that the US food supply is relatively safe. However, the considerable burden of foodborne disease reflects the huge impact of low risk events that are spread across entire populations, and guarantees that food safety will remain a pivotal issue across all sectors of the food industry and in international trade. Export markets will remain exquisitely sensitive to real or perceived concerns with pork safety.

Pork safety - contemporary vs. historic risks

Swine production in developed countries has evolved rapidly, and shifts towards larger farms and more ‘industrial’ pork production practices are also evident in some developing countries. I will avoid the perilous turf of contemporary international comparisons, but pork safety in the USA today is demonstrably safer that at any time in the past. The aspirations driving most innovation in pork production [e.g., all-in/all-out (AIAO) management; multiple site production] have been improved animal health, productivity and profitability. Factors likely to influence pathogen transmission include herd size, population structure and dynamics; sources and health status of incoming stock; area density of pigs and other species; biosecurity practices; group sizes and animal density; replacement practices in breeding herds; pig flow (e.g., AIAO vs. continuous flow); housing systems;
ventilation systems and air quality; sources, quality and delivery systems of feed and water; hygiene and effluent management; nutritional programs; weaning age; and specific health interventions (e.g., vaccines). Although designed to control pathogens of swine, the collective modifications implemented in modern pig production logically will have had collateral impact on the risks of introduction and transmission foodborne pathogens. Available evidence indicates that foodborne risks to US pork consumers have declined markedly in recent decades.

Parasitic hazards – achievements to celebrate

A telling feature at last year’s 8th International Symposium on Parasitic hazards in pork. Primarily a gathering of scientists from developed countries, there was not one paper on Taenia solium, the most injurious porkborne pathogen in the world. Estimated to infect 50 million people worldwide and cause up to 50,000 deaths per year, it is also largely responsible for the fourfold higher rates of epilepsy in developing versus developed countries. This parasite thrives wherever sanitation is poor and traditional, free-range/scavenging pig production is practiced, and has a tragic impact on the poorer populations of many developing countries. In the United States, a growing number of infected pork have resulted from commercial pork production in developed countries. At Safepork, only two papers addressed pork’s most infamous hazard, Trichinella spiralis, with one of these papers documenting the extremely low seroprevalence of T. spiralis in commercial pigs in the USA. The virtual elimination of T. spiralis from modern commercial swine production has relegated the once perennial ‘poster child’ of porkborne disease to little more than an historical footnote in the annals of US public health and the commercial swine industry.

Toxoplasma gondii is one of three pathogens responsible for three-quarters of fatal foodborne infections in the United States. Congenital T. gondii infection occurs in 500 to 5000 of the 4.2 million US newborns annually and about 1.2 million Americans are affected by ocular toxoplasmosis. The societal cost of congenital toxoplasmosis alone was estimated in 1990 to be up to $8.8 billion annually, and it has been inferred that about 50% of cases in the USA are foodborne. Less than 30 years ago, T. gondii infection occurred in 40% of US sows and 20% of market hogs, and undercooked pork was considered an important risk for human infection. Subsequent studies of national scope indicate that T. gondii seroprevalence has been reduced by some 90% (Figure 1). Because Toxoplasma seroprevalence in the past was much higher in pigs than in other food animals in the USA, pork was conventionally viewed to be the highest risk meat. Whether true or not in the past, recent case-control studies in the USA and Serbia suggest that this is not the case.

The parasitic triad of Taenia, Trichinella and Toxoplasma has arguably been responsible for the lion’s share of the burden of porkborne illness throughout the history of mankind, and they remain obdurate problems in many developing countries. The reduction of these agents to a state of relative inconsequence in modern pork production in developed countries is a substantial, yet largely unheralded, public health accomplishment. Even for the more epidemiologically complex T. gondii, the virtual elimination of Toxoplasma risk from pork is a feasible goal in modern confinement systems. The inherent trade off between parasite risk and the desired attributes of non-confinement livestock systems is captured in the following quotation about the potential for producing Toxoplasma-free meat: “Modern production technologies have shown that this is feasible and have led to a marked decrease of T. gondii infections in meat producing animals such as pigs. Conversely, demand for animal friendly production systems may however lead to a re-emergence of T. gondii in pork and poultry”. The first step towards effective management of T. gondii in less intensive pork production systems will be recognition of the inherently greater risk of exposure.

Enteric foodborne pathogens – a challenge for the 21st century?

In contrast to the heady progress in preharvest control of parasitic agents, experiences with bacterial foodborne pathogens have been humbling. The bacterial pathogens of most concern to pork safety (Salmonella, Campylobacter, Listeria, and Yersinia enterocolitica) have their primary ecological niche in the intestinal tracts of healthy birds and mammals. Their presence on meat stems from contamination events that can occur anytime during harvest and processing until meat is served to the end consumer. Contamination risk during harvest and processing is clearly a function of both on-farm exposure and slaughter hygiene, therefore both preharvest and postharvest arenas are logical targets for interventions. Salmonella, remains the preeminent bacterial hazard in most pork industries and was the subject of some 40% of papers at Safepork in 2009. Apart from the northern Nordic countries (Sweden, Finland and Norway), where uncommonly low Salmonella prevalence supports the possibility of excluding Salmonella from pig populations, most countries identify reduction rather than elimination of Salmonella to be a more attainable goal in pork production.

The body of epidemiologic knowledge and experience with preharvest control of Salmonella dwarfs those of other enteric bacterial pathogens. Even so, there remains a dearth of validated, evidence-based interventions for preharvest Salmonella control. Despite the appealing logic for preharvest control of foodborne pathogens, the task has proven daunting and opinions remain divided on the feasibility and cost-effectiveness of preharvest control programs for Salmonella in pigs. Investment in preharvest surveillance and control has been widespread in western Europe, but much less in North America where substantial reduction of Salmonella contamination of hog carcasses has been achieved by improvements in the post harvest sector (Figure 2). Over some 15 years, the wealth of data generated by the Danish National Salmonella control program has provided much insight into the challenge of preharvest control. The most recent analysis from this program indicated that benefits from preharvest control were most likely to accrue in low prevalence regions and small processing plants. It was concluded that in medium to high prevalence scenarios, even drastic reductions at herd level may yield only limited benefits in reducing the prevalence of positive carcasses. These findings reinforce the importance of ‘downstream’ exposure to Salmonella during transport and lairage which has been extensively documented but remains difficult to resolve. While advances in process control and new interventions during slaughter and processing have yielded measurable improvements in meat hygiene, considerable investments in preharvest control of Salmonella appear to have yielded only modest benefits. Epidemiologic knowledge about Campylobacter, Listeria, and Yersinia in swine production remains insufficient to adequately inform specific preharvest control measures for these pathogens.
The most vocal proponents of preharvest control of foodborne enteric bacteria have combined a degree of epidemiological naiveté with a belief (regardless of the vacuum of supporting data) that the 'problem' was attributable to modern farming methods, and specifically confinement production. In my opinion, the least equivocal outcome from fifteen to twenty years of preharvest research is that elimination of organisms that are normal flora (Campylobacter coli), or common commensals (Salmonella, Listeria, Yersinia) of the swine intestinal tract will not be achieved by facile interventions in farm management. The complexity of the epidemiology of Salmonella and other enteric organisms is difficult to overstate, but dominated by the fact that these organisms are commonly carried by, and shed in the feces of, healthy animals. In a review of preharvest food safety, Oliver et al (2009) conveyed the likely magnitude of the challenge of control of foodborne bacteria by forecasting 'there is little doubt that solutions to these and many other complex issues will be delineated through science-based research that will be conducted during the next century.' Development of valid and reliable preharvest interventions to control bacterial foodborne pathogens remains the preeminent challenge for researchers in pork safety, and one that may indeed endure for several decades even for the most researched pathogens. In contrast post harvest interventions, and most notably food irradiation, present proven, safe and relatively low cost options for risk reduction for multiple hazards which should be pursued for higher risk items such as ready-to-eat and comminuted meat products.

However, implementation of food irradiation in the meat industry remains enmeshed in ideological opposition. Those who might oppose irradiation of higher risk meat products of on the grounds that producers must take more responsibility for food safety must be more motivated to constrain industry than to protect consumers from foodborne illness.

Into the future and the wild card of emerging pathogens

Just a few decades back, several of today’s headlining foodborne pathogens were either unknown (E. coli O157:H7) or not known to be transmitted in food (e.g. Listeria, Campylobacter). We can anticipate that both true emergence and apparent emergence (discovery of pre-existing agents through new diagnostic approaches) of pathogens will present new challenges to pork safety and risk communication for the swine industry. Currently topical examples are methicillin resistant Staphylococcus aureus and Clostridium difficile. These are major emerging pathogens in human medicine, and the presence of strains of these organisms in animal reservoirs, including pigs, is a valid cause for consternation. There is a need for much better understanding of the ecology and epidemiology of these organisms both in swine production and post harvest. Similarly ongoing discoveries of multihost viral agents in pigs (e.g., Hepatitis E and B viruses, caliciviruses and noroviruses) prompt questions about their zoonotic and foodborne disease potential. For all multihost microbial species, both emerging and familiar, more profound understanding of host adaptation and host specificity is necessary and requires greater research investment. For newly recognized organisms, understanding the biological and epidemiological determinants of possible risk to human or animal health is not a trivial task. The likely complexity is exemplified by Hepatitis E viruses which are widespread in swine throughout the world, but vary in genotype geographically, by host species, and in zoonotic risk. In some countries swine reservoirs have been shown to make negligible contributions to the human disease, demonstrating the principle that prevalence of an agent alone is a highly inadequate measure of zoonotic or foodborne risk. Advances in sequencing, subtyping, and other tools for ‘molecular epidemiology’ are bringing new opportunities to explore host adaptation of potential porkborne pathogens, with the power to greatly enhance both our biological insight and the acuity of risk analysis and communication efforts. Unfortunately, the increasingly adversarial climate in the USA promises rapid (and therefore not necessarily well founded) accusations of industry culpability whenever any potential zoonotic or foodborne issue comes to light.

Looking forward, the international marketplace for pork will require incrementally more demanding standards for pork safety. In order to remain competitive in premium markets, exporters must achieve and assure very low risks for chemical, physical and microbial hazards, and any failures have the potential to incite crippling consequences for market access. Quality assurance programs implemented on farms should be adequate to manage the majority of physical and chemical hazards, as well as parasitic foodborne hazards. Unless major research breakthroughs occur in preharvest control of enteric bacteria, improved meat hygiene and slaughter processing will continue to be the mainstay for microbiological safety. As always, the emergence of new or previously unrecognized foodborne hazards (both real and perceived) remains the most unpredictable and potentially devastating food safety issue.

Porcine circovirus type 2: success and failure

Caroline Fossum
Section of Immunology, Department of Biomedicine and Veterinary Public Health, SLU, Uppsala, Sweden

Introduction
Vaccination against porcine circovirus type 2 (PCV2) reduces the incidence and severity of porcine circoviral disease (PCVD), in particular the postweaning multisystemic wasting syndrome (PMWS). This confirms that PCV2 is the essential infectious agent in this disease syndrome, but attempts to elucidate why PMWS became an emerging disease have failed. Much still remain to be clarified regarding the epidemiology of PCV2, its interaction with the host and the role of other infections in the development of PCVD. The current views on these issues are summarized below.

Porcine circovirus
Porcine circovirus (PCV) are small (approximately 1760 nt), single-stranded (ss) DNA virus that belong to the family Circoviridae. Two genotypes of PCV (PCV type 1 and PCV type 2) with similar genomic organisation and an approximate 80% homology at their nucleotide sequences are described (Meehan et al., 1998). PCV1 is regarded apathogenic whereas PCV2 has been associated with a number of disease syndromes of which PMWS is the best characterized. In 1999, an experimental model that evoked PMWS in colostrum-deprived piglets at co-inoculation of porcine parvovirus (PPV) and PCV2 was established (Allan et al., 1999).

The circular genome of PCV encodes a structural protein, the capsid (cap) protein, and a replicase protein with two splice variants (Rep and Rep’). Both Rep and Rep’ are necessary for initiating the rolling-circle amplification used by PCV. In addition, a third open reading frame (ORF3) exists in PCV that is transcribed counter clockwise to ORF1 (rep, rep’) and ORF2 (cap). The proposed apoptotic role of the gene product from ORF3 (Liu et al., 2005) or its importance for viral pathogenesis is not fully clarified but it is noteworthy that the greatest genomic differences between PCV1 and PCV2 are found within ORF3. Our current knowledge about the genomic organisation of PCV, their replication and interaction with host proteins are detailed in a recent review by Finsterbusch and Mankertz (2009).

Porcine circovirus type 2 (PCV2) and diseases related to PCV2
Despite many similarities between PCV1 and PCV2, only PCV2 has been associated with disease. Today, PCV2 is confirmed to be a necessary infectious agent for development of PMWS and demonstration of moderate to massive quantities of PCV2 within histopathological lesions in lymphoid tissues (lymphocyte depletion together with histiocytic infiltration and/or inclusion bodies and/or giant cells) is a major diagnostic criterium. Clinical signs of PMWS include progressive weight loss (wasting), enlarged inguinal lymph nodes, and in some cases jaundice, dyspnoea and/or diarrhoea. As reviewed (Ramamoorthy and Meng, 2009; Gillespie et al., 2009; Grau-Roma et al., 2010), PCV2 is also involved in a number of other syndromes including “respiratory”, “reproductive” and “enteric” disorders as well as porcine dermatitis and nephropathy syndrome (PDNS).

PCV2 isolated from pigs with various clinical conditions showed different replication kinetics when studied in vitro (Meerts et al., 2005), perhaps suggesting a variation in their virulence. Due to a high similarity between sequences from various PCV2 isolates (approximately 95% at the amino acid level) such a link is not very likely, but cannot be ruled out. Phylogenetic analysis performed in several countries however revealed a clustering of PCV2 into “genotypes / genogroups” with clade formations that could be related to “year of isolate” (Olvera et al., 2007). Analyses of these clades shows a relation between patterns in the PCV2 ORF2 sequence and cases of PMWS. Such a connection is further supported during an outbreak of PCVD in Canada in late 2004 - 2006 with more severe lesions and increased mortalities and the emergence of a new PCV2 variant, referred to as “RFLP type 321” (Gagnon et al., 2007; Carman et al., 2008). Indeed, reports from several countries describing a shift in genotype/genogroup of PCV2 accompanied by increased incidences of PMWS are accumulating as summarized in a recent review (Grau-Roma et al., 2010). To ease further comparative analyses a common nomenclature has been proposed with two main genotypes (PCV2a and PCV2b) and a very rare genotype, recovered from pigs in Denmark, designated PCV2c (Segalés et al., 2008). In general, it appears from the epidemiological evidence that PCV2b is the genotype associated with outbreaks of severe PMWS post 2003.

The importance of PCV2 genotype for the pathogenicity of the virus is however still puzzling and results from experimental infections are not conclusive (Lager et al., 2007; Opiensnig et al., 2008; Saha et al., 2010). It appears that PCV2a and PCV2b on their own do not differ in virulence but a recent study highlights the importance of order of infection (Harding et al., 2010). In that experimental model, infection of gnotobiotic pigs with PCV2b seven days after a PCV2a infection, but not vice versa, caused PMWS. A similar approach but using eleven week old SPF-pigs that were repeatedly infected with infectious clones of heterologous PCV2a or with PCV2a followed by PCV2b did not induce any signs of clinical disease (Opiensnig et al., 2010a). Neither were any macroscopic lesions observed in the pigs although all seroconverted to PCV2 and PCV2 could be demonstrated at microscopic lesions in some samples. Both PCV2a and PCV2b DNA sequences were present in samples obtained from some of these dually infected pigs.

The simultaneous presence of PCV2a and PCV2b has been reported in field samples and also chimeric virus composed of an ORF1 region from PCV2a and an ORF2 region from PCV2b is described (Hesse et al., 2008). Even more interesting is the demonstration of naturally occurring chimeric PCV2 genomes that are recombinant within the ORF2 region (Cheung, 2009). Modifications within this region that encodes the cap gene can affect the structural capsid protein and thereby modify B-cell epitopes of the virus. Antigenic differences between PCV2 isolates have been demonstrated using monoclonal antibodies to the capsid
Porcine circovirus type 2 (PCV2) and other viral infections in PMWS

It is generally accepted that herd management has a predominant impact on the incidence of PMWS. In particular animal hygiene and other general disease-preventing measures are important factors to reduce porcine circoviral disease (Madec et al., 2008). In a field study conducted in one Norwegian and two Swedish finishing farms the role of management became evident (Brunborg et al., 2010). One of the Swedish farms changed its recruitment routines and finishing pigs were disturbed during a period obtained from the open market and the time between batches was reduced to less than 24 hours. This shift coincided in time with an increased frequency of runts, wasting pigs and a subsequent diagnose with PMWS whereas pigs in the other Swedish farm and in the Norwegian farm performed normal.

Serological analyses revealed prominent differences in the levels of antibodies to PCV2 and number of PCV2 DNA copies in samples collected sequentially during the first five weeks of the finishing period in the three farms. The amount of PCV2 DNA copies was similar in samples obtained from pigs at arrival to the two Swedish finishing farms but was hardly detectable in samples collected in the Norwegian farm. The initial level of antibodies to PCV2 was comparatively low and increased with time in the PMWS affected farm but remained at a steady high level in samples collected from pigs in the healthy Swedish farm. The majority of the Norwegian pigs remained seronegative to PCV2 during the first five weeks but an extended sampling revealed that these pigs had seroconverted after 9 weeks in the finishing herd and that the pigs then displayed a low number of PCV2 DNA copies in blood. This study was conducted when Norway was still free from PMWS and it is notable that the genotype of PCV2 determined for the Norwegian samples was PCV2a whereas pigs in the Swedish farms harboured PCV2b, respectively they originated from the healthy farm or from that affected by PMWS. Indeed, a high similarity within PCV2b genotype was determined in samples obtained from the two Swedish farms (full genome sequence 99.7% at the nucleotide level) regardless they were affected by PMWS or not.

Longitudinal case-control studies, analysing time for seroconversion and PCV2 DNA load, performed in Danish and Spanish herds showed that the PCV2 load increased with decreasing maternal immunity (Grau-Roma et al., 2009). PMWS developed when the PCV2 DNA load was at its highest which in Spain occurred at the beginning of the fattening period but in Denmark took place in the nursery phase. In another Danish study weaned pigs, aged 8–14 weeks, from PMWS affected herds were mingled with 4 – 6 weeks old PCV2 positive pigs from PMWS unaffected herds (Kristensen et al., 2009). Three to four weeks later PMWS developed in pigs from the unaffected herds both in those that were mingled in the same pen and in those housed in pens adjacent to pigs from the PMWS-affected herds. Thus, PMWS can be induced in pigs from PMWS free herd following contact to pigs from farms with clinical PMWS.

In both studies referred to above other pathogens than PCV2 were present on the farms. In the Spanish/Danish study the presence of Mycoplasma hyopneumoniae, Actinobacillus pleuropneumoniae, Pasteurella multocida, Lawsonia intracellularis, Salmonella spp. PPV, porcine reproductive and respiratory virus (PRRSV), swine influenza virus and Aujeszky’s disease virus (AD) was confirmed and in the latter Danish study the PMWS-affected herds were seropositive for M. hyopneumoniae and PRRSV. Therefore an attempt was made to isolate virus from organ material collected from the PMWS-affected pigs using a large panel of different cell-types (Lohse et al., 2008). However, no viral cofactor could be linked to the development of PMWS. Instead, a difference in nucleotide sequence was found for PCV2 obtained from PMWS-affected and from non-affected herds. It is thus demonstrated that PMWS can be transmitted from affected to non-affected animals but we have failed to identify the “agent” that spreads the disease and to understand the disease process.

An earlier field study in Spain has indicated that another circular single-stranded DNA virus, the Torque teno virus (TTV) belonging to the genus Anellovirus, family Circoviridae, and in particular genogroup 2 (g2) of porcine TTV is more frequent in PMWS-affected pigs (Kekarinen et al., 2006). An experimental co-infection with g1-TTV and PCV2 in gnotobiotic pigs supports the theory that TTV can act as a co-factor in the development of PMWS. Instead, a difference in nucleotide sequence was found for PCV2 obtained from PMWS-affected and from non-affected herds. It is thus demonstrated that PMWS can be transmitted from affected to non-affected animals but we have failed to identify the “agent” that spreads the disease and to understand the disease process.

Human Boca-virus was discovered in 2005 and was given its name due to sequence homologies with bovine parvovirus and canine minute virus. This parvovirus is widespread in the human population and has been associated with respiratory tract diseases and gastrointestinal infection (Allander, 2008). Thus the finding of a porcine boca-like virus together with TTV and PCV2 in lymph nodes from clinical cases of PMWS was exiting. For a further study of the distribution of these viruses an archived material was used. The archived material consisted of lymph nodes collected during a phylogenetic study of PCV2 carried out in Sweden before and after the enzootic outbreak of PMWS in 2004 (Timmusk et al., 2008) and was supplement with more
recently collected samples, including some from piglets with congenital tremor. In total, samples from 58 pigs, 34 with PMWS and 24 without PMWS, were analysed by PCR or qPCR for the presence of PCV2a, PCV2b, g1-TTV, g2-TTV and the porcine boca-like virus.

A discriminative qPCR confirmed earlier sequencing data (Timmusk et al., 2008) showing that PCV2b was present at high DNA copy numbers (≥108 per 100 ng DNA) in samples obtained from PMWS-affected pigs. In two of these pigs PCV2a was also detected but at a lower DNA copy number. PCV2b was also detected in samples from pigs not affected by PMWS but then always at DNA copy numbers below 106 per 100 ng DNA. Regardless of health status TTV-1, TTV-2 and pBo-likeV were present in 70-90% of the samples, and PCV2 was demonstrated in the majority of samples although at higher levels in samples collected from pigs affected with PMWS than from the others. The most pronounced difference was that pBo-likeV was detected in more samples from PMWS affected pigs and the simultaneous detection of TTV-1, TTV-2 and pBo-likeV was more frequent in samples from PMWS-affected pigs (Table 1).

**Table 1. Percentage of samples positive for PCV2a, PCV2b, g1-TTV, g2-TTV-2 or pBo-likeV as determined by qPCR or PCR among pigs affected with PMWS (PMWS+) or not (PMWS-).** Also the percentage of samples simultaneously positive for g1-1TTV, g2-1TTV-2 and pBo-likeV is given.

A similar distribution of g1-1TTV, g2-1TTV-2 and pBo-likeV in pigs with and without PMWS has been described for samples collected in UK (Gordon Allan and Michael McMenamy, Dept of Veterinary Science, Queen’s University Belfast, Belfast, Northern Ireland, personal communication). Thus, it is possible from these studies to determine the role of TTV and the porcine Boca-like virus in the aetiology of PMWS. However, in a Chinese study PCV2, PRRS, CSFV and TTV2 were more frequent in samples collected from pigs that also were positive for pBo-likeV than among those negative for the bocavirus (Zhai et al., 2010) suggesting that pBo-likeV could act in synergy with other virus or predispose for other viral infections.

Interestingly, in vitro studies using DNA from human TTV genogroup 4 demonstrated that DNA of this TTV can induce murine immune cells to produce and secrete cytokines such as interferon-γ (IFN-γ), interleukin-6 (IL-6), and IL-12 (Rocchi et al., 2009). Indeed, linearized DNA from porcine g1-1TTV and g2-1TTV could in vitro interfere with IFN-α production by porcine plasmacytoid dendritic cells (Martinez-Guinó et al., 2009).

**PCV2 and the immune response**

The possibility that small circular DNA virus could harbour immunomodulatory sequences, i.e., CpG-motifs, was first suggested for PCV2 (Hasslunger et al., 2003). It was shown that the DNA genome of PCV2 contains sequences that in synthetic form (oligodeoxyribonucleotides; ODNs) could act immunomodulatory on porcine peripheral blood mononuclear cells (porPBMC) in vitro and e.g. inhibit the IFN-α response to other DNA but not RNA-virus (Wikström et al., 2007). Further analyses of the PCV2 genome for presence of CpG motifs identified additional 18 motifs that could induce IFN-α production and three inhibitory motifs (Kekarainen et al., 2008a). Indeed, PCV2 propagated in PK-15 cells, but not PCV1, could act immunomodulatory and reduce the IFN-γ and IFN-α responses to recall antigen stimulation (Kekarainen et al., 2008b). In addition, PCV2 and UV-inactivated PCV2 induce IL-10 and thereby down-regulates the production of IFN-γ and IL-12. Thus, a reduced production of IFN-α in combination with IL-10 production is likely to suppress a Th-1 type of immune response and thereby promote virus persistence.

One of the most important factors in the defence against viral infections is IFN-α. This cytokine can be produced in low amounts by monocytes / macrophages and myeloid dendritic cells and in particular by plasmacytoid dendritic cells (PDC) that respond with high production of IFN-α to certain stimuli. Inhibition of IFN-α is important during the early defence against viral infections because it can induce an antiviral state in neighbouring non-infected cells and it activates the killing activity by Natural killer (NK) cells. Furthermore, IFN-α together with IL-12 promotes the development of a T helper cell (Th) type 1 immune response that is important in the defence against viral infections. The IFN-α response is thus a strategic point for a virus to modify and demonstration of non-replicating PCV2 in cells of the myeloid lineage (monocytes, macrophages and dendritic cells) in infected pigs is therefore remarkable. Series of elegant studies performed at the Institute of Virology and Immunophrophylaxis, Mittelhäusern, Switzerland have outlined the interaction of PCV2 and/or the viral DNA with porcine dendritic cells and effects on their function that are summarized in a recent review (Kekarainen et al., 2010).

Against this background it is plausible that the replication of PCV2 in vitro is enhanced by addition of IFN-α or IFN-γ (Meerts et al., 2005). Indeed an interferon-stimulated response element (ISRE) is present in the PCV2 genome within the promoter region of the rep gene that seems to play a role in the response of PCV2 to IFNs (Rammamoorthy et al., 2009) but the underlying mechanisms are far from outlined.

Using the PCV2/PPV co-infection experimental model a weak T lymphocyte response, measured as PCV2-specific IFN-γ secreting cells at in vitro re-stimulation was evidenced (Steiner et al., 2009). This response coincided with viremia, approximately 8 days post infection whereas the specific antibody response was delayed until four weeks post infection. Indeed, a transient correlation exists between viremia and IL-10 expression in pigs subclinically infected with PCV2 (Darwich et al., 2008). Studies that further support these findings include the increased expression of IL-10 mRNA levels observed in PBMC obtained form pigs experimentally co-infected with PRRSV and PCV2 (Shi et al., 2010) and examination of IL-10 producing splenocytes obtained from naturally cases of PMWS (Crisci et al., 2010).

An important role of IL-10 is the regulation of B cell isotype switch. A number of field studies have documented the importance of neutralizing antibodies against PCV2 for protection against PMWS (for review see Kekarainen et al., 2010). As initially demonstrated by Meerts et al. (2006) protection is correlated to isotype switching and animals that remain IgM positive are those that are most likely to develop PMWS.

Taken together, the studies of PCV2 and its interaction with the porcine immune system has been a partial success and the knowledge that pigs can mount an immune response to the cap protein of PCV2 that protects against PCVD has been utilized in the vaccine development.
Vaccination against PCV2

Vaccine development has so far focused on induction of immunity against the structural cap protein of PCV2. For instance, a chimeric viral particle composed of ORF1 from PCV1 and ORF2 from PCV2 is the source of antigen in the inactivated vaccine Suavaxyn® PCV2 from Fort Dodge. Also Ingelvac® CircoFLEX (Boehringer Ingelheim) and Porcillis® PCV (Intervet/Schering-Plough) contain at killed baculovirus vector carrying ORF2 whereas killed PCV2 is included in Circovac® (Merial). The latter vaccine is intended for vaccination of sows two weeks before farrowing. The immune sow will transfer a passive immunity to the piglet that is expected be protective during the subsequently development of an active immunity at exposure to PCV2 in the environment. The other three commercial vaccines are used for vaccination of pigs, approximately 3 weeks old. Despite differences in the source of antigen, adjuvant formulation and administration regime all these commercial vaccines have proven to protect efficiently against PMWS during field conditions. In addition, the sow vaccine improves farrowing rates and infertility problems (reviewed in Kekarainen et al., 2010).

A concern has been that PCV2a is the antigen source in the commercial vaccines listed above. Theoretically, amino acid changes in the cap protein of PCV2b could reduce the protective effect of an immune response elicited by PCV2a. Results obtained at experimental challenge of PCV2a-vaccinated pigs with PCV2b however imply a good “cross-protection” (Fort et al., 2009; Opriessnig et al., 2010b). Thus, development of vaccine against PCV2d has been an outstanding success. Also immunologists are likely to benefit from these achievements. By scrutinizing the protective immune response elicited at vaccination against PCV2d insight will be gained about immune mechanisms necessary for induction of protection against porcine circovirus.

PCV as a contaminant in vaccines

Lately attention has been drawn to PCV as contaminants in vaccines for human use. Two licensed rotavirus vaccines, aimed to protect against enteric disease in infants, were found contaminated with PCV1 alone or in combination with PCV2, (http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm211101.htm). In particular the PCV2 contamination urges for continual studies that increase our understanding of this virus, including its potential to replicate in human cells and the eventual immune modulating capacity of PCV2 DNA on human cells.

Introduction

The use of artificial insemination (AI) in the pig has had a major impact on genetic improvement in the swine industry over the last 40 years. However, the overall production efficiency of the breeding herd is highly dependent on the reproductive capacity (fertility) of the boars used for breeding and the genetic merit of the boars for the performance of terminal line offspring. Given the polygamous structure of swine production, poor quality boars will affect the reproductive outcome of numerous females. In the case of AI this could be thousands of females. Although ejaculates collected for use in AI are subjected to standard semen analysis in commercial boar studs, the effectiveness of these evaluations is low compared to other food-animal species.

The following discussion of the need to use more advanced AI technologies to improve the impact of genetically elite boars is based on three assumptions:

1. Employing the use sub-fertile boars and low quality ejaculates reduces production efficiency.
2. The use of pooled semen from poorly defined males breaks the link between known genetic value of individual boars and the paternity of progeny produced.
3. The excessive number of sperm used per litter born (probably over 9 billion sperm using current practices), and hence the high numbers of boars needed for semen production, reduces the genetic impact of the best boars.

Collectively, these inefficiencies in AI use in the pork industry represent a major disadvantage to pork producers in a global food-animal marketplace. Given the recent advances in genomics technologies, our ability to identify boars with even greater potential EBVs will increase and the potential to optimize the use of these boars in efficient pork production systems will increase. Available estimates suggests that advanced AI technologies can increase the genetic value of every pig produced by as much as $1.00.

Strategic advantages resulting from improved evaluation of boar fertility.

The ultimate measures of boar reproductive performance are pregnancy rate and litter size born. However, these are retrospective measures of boar fertility and can be highly influenced by breeding management and the quality of the gilts and sows bred (Colenbrander et al., 2003). A combination of a thorough physical examinations of the boar and conventional semen evaluation (concentration, morphology, motility) can provide an alternative to actual fertility data (Gibson, 1989). While these evaluations can establish that an animal is either sub-fertile or infertile, they fail to identify the relative fertility of boars that meet accepted industry standards for sperm and ejaculate quality (Ruiz-Sanchez, 2006). In general, the predictors of fertility currently applied in most commercial AI centers provide a very conservative estimate of the relative fertility of individual boars. Furthermore, the relatively high sperm numbers used in commercial AI practice (usually more than 3 billion total sperm per dose of extended semen), and the pooling of semen from multiple ejaculates, masks the limited fertility of some of these boars. Differences in fertility are more evident when lower numbers of sperm are used for AI and boars are evaluated on an individual basis.

As discussed by other reviewers, if the full economic impact of the highest genetically indexed boars is to be realized at commercial production level, the number of gilts and sows bred per boar must be maximized (Gerrits et al., 2005). A number of innovations in insemination technology, including post-cervical (Watson and Behan, 2002) and deep-uterine (Vazquez et al., 2005) insemination are conducive to the use of lower sperm numbers per insemination. The further possibility of using controlled ovulation techniques to achieve single fixed-time insemination protocols (Baer and Bilkei, 2004; Cassar et al., 2005) would also substantially increase the utilization of genetically superior boars. The combined application of post-cervical and fixed-time insemination (Pelland et al. 2008) could further promote dissemination of the most superior genetics.

Effective prediction of relative boar fertility is essential and will allow for the removal of less productive boars from commercial studs. This in turn will optimize the use of proven, high fertility, and genetically high indexed boars at lower sperm numbers per AI dose. At the nucleus level this will allow for increased selection pressure by increasing the number of offspring bred per collection from high ranking boars. At the level of terminal line production, this would allow for considerable improvements in production efficiency to be realized, by capitalizing on boars with a high index for traits such as growth rate, feed conversion efficiency and the carcass characteristics of their progeny. Even if the same costs were paid in genetic royalties, by purchasing fewer total doses of semen from genetically superior boars, the cost benefits realized by producers in grow-finish performance of the progeny and the value of the carcass sold appear to be substantial.

If these changes in production strategy are to be realized, it is critical to identify boars of relatively low fertility that will not perform well when used in the more challenging situations of reduced sperm numbers per AI dose or single fixed-time insemination. The very definition of ‘useable semen’ changes in this more demanding context. Existing information, and recent research directed to achieving these more demanding criteria of useable semen, is presented below. This review will consider preliminary data that reinforces the need to identify substantial differences in boar fertility, and the “averaging effect” that results from the use of pooled semen doses from several boars. Finally, recent data supporting the case for a move towards single fixed-time AI and possibly post-cervical insemination as the critical “next steps” in applying our best pig genetics to more competitive pork production systems will be presented.
Approaches to boar semen evaluation

There is a long history behind the search to find a single or combination of tests that can accurately predict male fertility from a semen sample (Amann, 1989). Unfortunately, there appears to be no simple answer to this very complex question (Rodriguez-Martinez, 2003). Laboratory assays often examine all of the sperm present in a sample for fertility, yet only one to 30 or so sperm are necessary to fertilize all available oocytes. Braundmeier and Miller (2001) suggested that the sperm that fertilize the oocytes in vivo may be a small (even a single), highly selected, sub-population that is not representative of the average sperm evaluated in the sample. They also suggest that, because sperm must meet many requirements for successful fertilization, testing a single attribute is unlikely to be a true measure of ultimate fertility. Using similar reasoning, Rodriguez-Martinez (2003) suggested that to accurately predict semen quality it is necessary to test all key sperm attributes within large heterogeneous sperm populations that potentially affect fertilization and embryonic development. Nevertheless, the markers of relative fertility finally selected must ultimately predict the relative fertility of boars when using low sperm doses of extended semen for AI (Rodriguez-Martinez et al., 2009).

Braundmeier and Miller (2001) reviewed a number of functional and molecular tests used to assess male fertility. In this review they described two different sperm traits that affect fertility.

- **Compensable traits** are those that can be overcome by introducing large numbers of sperm during insemination. Problems with motility and morphology will reduce the number of sperm that are able to reach the oocyte, but by introducing large numbers of sperm the reduction in fertility can be minimized.

- **Uncompensable traits** are those that cannot be overcome by introducing larger numbers of sperm. These defects affect fertilization and embryo development and include nuclear vacuoles, sperm chromatin structure issues and morphologic problems that do not inhibit fertilization.

**To effectively predict fertility, it is essential to discriminate between compensable and uncompensable traits in an ejaculate.** Evaluation of relative boar fertility in vivo using high sperm numbers per dose (e.g. 3 billion sperm) will mask differences in compensable traits and will not allow the industry to identify boars that will perform well in more demanding applications of AI.

Conventional semen evaluation generally includes a measure of seminal volume, sperm concentration, and the percentage progressively motile and morphologically normal sperm (Amann et al., 1995). Although some of these parameters are correlated with fertility in the boar (Flowers, 1997; Xu et al., 1998), several authors suggest that this information, while important, does not accurately predict whether a male is truly fertile (Brahmkshtri et al., 1999; Correa et al., 1997; Rawls et al., 1998). As shown in Table 1, existing analyses are also usually inadequate for predicting relative fertility in healthy boars with ejaculate quality that meets normal industry standards (>70 % motility and <30% abnormal sperm) (Flowers, 1997; Alm et al., 2006), even though the reproductive efficacy of these boars may still be substantially different (Flowers, 1997; Tardif et al., 1999; Popwell and Flowers, 2004; Ruiz-Sanchez, 2006). As illustrated in Table 2, differences in relative fertility become increasingly evident when low sperm doses (<2.0 billion sperm) are used for AI (Tardif et al., 1999; Watson and Behan, 2002; Ardon et al., 2003; Ruiz-Sanchez, 2006). This approach likely averts the compensatory effect of using excessive sperm numbers per AI dose (Saacke et al., 2000; Alm et al., 2006), thereby revealing important fertility differences among boars.

Although numerous other potential markers of semen quality and boar fertility have been investigated (see reviews of Foxcroft et al., 2008), and might eventually simplify the evaluation process, sufficient information already exists on which to base dramatic improvements in AI technology in the pork industry.
Evidence for differences in relative boar fertility in commercial studs

The almost universal use of pooled semen doses in commercial boar studs severely limits the collection of data on relative boar fertility at production level. However, the limited data available continues to suggest a substantial range of fertility exists in contemporary populations of boars. Indeed, in the absence of routine procedures for identifying relative boar fertility, and hence an ability to effectively select stud boars for relative fertility at genetic nucleus level, a normal distribution of fertility traits should be expected. In recent discussions of overall breeding herd performance (Billy Flowers – personal communication) the point has also been made that limitations in AI technology should be expected. In recent discussions of overall breeding herd performance (Billy Flowers – personal communication) the point has also been made that limitations in AI technology may lead the industry to continually underestimate the existing productivity of contemporary commercial dam-lines. All these points are evident in recent data obtained from single-sire matings at the multiplication level (Figure 1).

Figure 1. Data on litter size born in sows bred to commercial Landrace boars using single-sire matings with 3 billion sperm per AI dose. (Tony Chandaruk - Personal communication)

These results indicate that the productivity of the top two thirds of these boars is very high, and at an average of over 13 pigs total born, would allow ambitious targets for breeding herd performance to be achieved. However, when the productivity of the lower one third of these boars is included, overall productivity falls by over one pig born. This relatively inferior performance of 20 to 30% of boars evaluated is consistent with the more extensive data presented in Tables 1 and 2. With current AI practices, these substantial differences in boar productivity, and the link to known progeny produced by individual boars, are confounded by 1) the use of pooled semen and 2) high sperm numbers per AI dose.

The problem of pooling semen when trying to optimize production efficiency.

In one recent preliminary study, we evaluated the performance of two boars which routinely met normal criteria for acceptable semen quality (better than 80% motility and <15% abnormal sperm) and had a history of good fertility when used in experiments requiring adequate numbers of pooled semen doses to normalize any confounding “boar effect” on the fertility of gilts and sows allocated to different experimental treatments. Before using these boars for homospermic (single sire) inseminations in gilts and sows in an experiment, we evaluated the performance of the two boars (Blue and Red) using both pooled (heterospermic) and single-sire (homospermic) AI protocols. In all cases, a total of 2 billion sperm per AI dose were used. As shown in Table 3, both boars were very productive with single-sire inseminations and still performed acceptably in AI with pooled semen. There was, nevertheless, a difference of 2.5 total embryos at day 30 of gestation between these boars, due to a 15% difference in either the fertilization rate and/or embryonic survival to this stage of pregnancy. Notably, the outstanding performance of the most fertile (Blue) boar was masked by using pooled semen and adoption of a single sire (homospermic) AI strategy would improve the total numbers of pigs born, by allowing the Blue boar to express his true reproductive potential. It seems reasonable to assume that a similar “averaging effect” results from the pooling of semen from the best boars shown in Figure 1 with less productive boars in this population.

Table 3 Results from two fertile boars when used in homospermic or heterospermic AI protocols with 2 billion sperm per AI dose. (SRTC – unpublished data, 2009)

Data from another recent study, comparing seminal plasma protein profiles from two boars with dramatically different fertility (Novak et al., 2008), highlights the problem of linking the progeny born to boars used for AI when using pooled semen doses for commercial production. The fertilizing capacity the two boars studied (Boar A and B, Table 4), which had similar and traditionally acceptable semen parameters at collection, was initially tested with homospermic matings (i.e. single-sire AI). Based on approximately 30 mating records per boar, major differences between these boars in recorded farrowing rate and litter size born were evident. The semen from these boars was then pooled with 3 other boars with similar semen parameters and used for insemination (i.e. heterospermic semen from 5 boars in total, with equal numbers of sperm from each boar within the pooled AI dose). These pooled inseminations resulted in a 90% farrowing rate (9 pregnancies from 10 inseminations made) and 104 piglets were born these 9 litters. Paternity testing of the resulting piglets, using a panel of up to 84 single nucleotide polymorphism markers, identified Boar B as the sire of 29.8% (31/104) of the piglets, while Boar A was identified as the sire for only a single piglet.

(Simply from the perspective of optimizing breeding herd productivity, a move to single-sire Al programs seems to be justified. The very best boars will express their real potential, and overall herd productivity appears to increase. Furthermore, the small percentage of very inferior boars will quickly be identified and can be removed from commercial production. In time, it is realistic to suggest that both phenotypic and genomic markers will be developed that can be used prospectively to remove inferior boars before they are extensively used for commercial Al. However, the data presented above suggest that this can be made by adopting single-sire mating strategies and evaluating boars on the basis of routine production criteria. Economically, there appears to be little down-side risk in adopting this strategy and considerable possibilities of positive benefits. Even these preliminary data demonstrate the critical problems related to using heterospermic matings (pooled semen) in commercial practice:

1. As is evident from the results shown in Table 2 and Figure 1 above, even when semen appears to meet standard criteria for motility and morphology at collection, homospermic matings still identify some important differences among particular boars.

2. If inferior boars like Boar A in Table 4 are included in pooled semen doses, they produce very few of the terminal line progeny. Therefore, in practice, very high EBV boars may not pass on genetic potential in terms of pigs entering grow-finish production if they are used in a “competitive” pooled semen Al protocol.

3. The disproportionate contribution of each boar to the litter progeny essentially means that the boars that do sire progeny are actually being required to do so at much lower than the total number of sperm originally included in the AI dose (say 1 to 2 billion, rather than 3 billion sperm).

Application of advance Al technologies to optimize genetic transfer.

Taking all of the above information into consideration, the logical conclusion regarding future developments in AI technology would be a move to single-sire inseminations with the lowest possible doses of semen using ejaculates from boars with high genetic value and proven fertility in a “low semen dose” environment. As in other domestic species, the logical way to achieve this outcome is with the introduction of single fixed-time Al programs and possibly linking this to post-cervical Al techniques. The substantial body of data describing the development of hormone treatment protocols for induced ovulation in the pig was extensively reviewed by Brüssow et al. (2009). Linked to this discussion is the interesting conclusion that contemporary commercial sows in well managed breeding herds show increasingly less variation in the weaning-to-estrus interval and may not even show a clear response to equine Chorionic Gonadotropin (eCG) treatment at weaning (Patterson et al., 2009). As a result, there are already reports of acceptable outcomes when exogenous hormones are used to induce ovulation in sows at a fixed time after weaning.

A recent study by Johnston et al. (2009), using a Gonadotropin Releasing Hormone (GnRH) agonist which was applied to sows 4 days post-weaning and followed by a single insemination 24 hours later, resulted in farrowing rates and litter sizes comparable to sows receiving multiple inseminations during estrus (Table 5). It also resulted in a major improvement in the number of pigs born per insemination dose used and demonstrates the potential to maximize the use of a smaller number of high index boars.

Furthermore, Zak et al. (2009) have demonstrated that administration of porcine Luteinizing Hormone (pLH) at the onset of behavioural estrus to control ovulation not only facilitated fixed-time insemination, but also resulted in reduced semen usage, less labour devoted to estrus detection, as well as improved sow productivity (see Table 6). These data demonstrate that administration of pLH at the time of estrus detection would allow for the application of a single fixed-time administration 24-30 hours after pLH treatment.

In situations in which the synchrony of estrus after weaning may not allow the effective application of either pLH or GnRH at a fixed time after weaning, the alternative strategy of using ovulation-induction after an initial treatment at weaning with eCG continues to be explored with acceptable results (Cassar et al., 2005). The eCG/pLH protocol has been successfully applied in combination with post-cervical Al with reduced sperm numbers per AI dose, without adversely affecting sow fertility (Table 7).
The results of these studies has prompted work to evaluate the application of pLH at the onset of estrus followed by a single, low semen dose, 24-30 hours later using post-cervical AI (studies on-going). These and other results suggest that the implementation of single fixed-time AI programs in well managed sow herd can be a reality. Linked to the use of proven superior sires, post-cervical insemination catheters and lower doses of semen, this fixed-time insemination will allow the pork production industry to apply the genetic value of elite boars to breeding programs that are competitive with other livestock species.

Conclusions

The evaluation of relative fertility amongst commercial AI boars and a move to single-boar AI programs holds the potential for significant economic benefit to the swine industry. Information provided by this approach would also be rapidly available so that elimination of less fertile boars could be achieved at an early stage. The characterization of AI boars that maintain high productivity at lower numbers of sperm per AI dose will also allow the industry to capitalize on established and emerging AI technologies like post-cervical insemination and single, fixed-time insemination. Moreover, all these changes can be made without any loss in productivity as measured in terms of pigs born per sow per year. The higher genetic merit of boars that could be used across a greater number of gilts and sows bred would provide substantial benefits to the producer in terms of the performance of terminal line progeny. These changes can be made without affecting, or perhaps even increasing, the total genetic royalties paid to breeding companies and commercial boar studs that are willing to facilitate these improvements in the efficiency and financial performance of the pork industry.

**Mycoplasma hyopneumoniae infections in pigs: update on epidemiology and control**

Dominiek Maes

Faculty of Veterinary Medicine, Ghent University, Belgium, Merelbeke, Belgium

---

**Introduction**

*Mycoplasma hyopneumoniae* (*M. hyopneumoniae*) is the primary pathogen of enzootic pneumonia (EP), a chronic respiratory disease in pigs resulting from combined infections with *M. hyopneumoniae* and one or more secondary bacterial pathogens (Thacker, 2006). *M. hyopneumoniae* is also one of the primary agents involved in the porcine respiratory disease complex (PRDC). This respiratory complex includes both bacterial (Actinobacillus pleuropneumoniae, Pasteurella multocida, streptococci) and viral (porcine reproductive and respiratory syndrome virus (PRRSV), porcine circovirus type 2 (PCV2), Aujeszky’s disease virus, swine influenza viruses (SIV) and porcine respiratory coronavirus) agents (Sibila et al., 2009). Both disease conditions cause major economic losses to the swine industry mainly due to reduced growth rate, poor feed conversion ratio, increased medication costs and increased mortality (Maes et al., 1996). Since elimination of *M. hyopneumoniae* from infected herds is difficult to achieve and also to maintain, most efforts are currently directed towards control of the disease. In the present paper, first some aspects of the epidemiology of *M. hyopneumoniae* infections will be reviewed, next interactions with other respiratory pathogens will be discussed, and finally an update will be given on control strategies.

**Transmission of M. hyopneumoniae**

Within a herd, *M. hyopneumoniae* is normally transmitted to susceptible pigs by direct contact with infected pigs or by sharing the same air-space with infected pigs. Piglets can become infected already in the farrowing unit by the sow either by direct nose-to-nose contact or by aerosols (vertical transmission). The chance of transmission from sow to offspring is higher in gilts and low parity sows (Fano et al., 2006), but also older sows up to the 7th parity may transmit the pathogen to the piglets (Calsamiglia and Pijoan, 2000). This is not surprising as infected animals are not able to efficiently and quickly clear the *M. hyopneumoniae* organisms from the respiratory tract. A recent study (Pieters et al., 2009) showed that pigs can remain infectious for at least 200 days post infection. The percentage of sows testing positive by nPCR varies depending on the study. Calsamiglia and Pijoan (2000) reported that between 24 and 56% of the sows were positive for *M. hyopneumoniae* in a multiple site system. Sibila et al. (2007) found lower prevalences namely between 0 and 11%. The latter authors did not find any prevalence differences between sows from multiple site (MS) or farrow-to-finish (FTF) pig herds. Beilage et al. (2009) found that 65% of the sows were seropositive in 67 German pig herds, and that different management practices such as all-in all-out production in the farrowing units and acclimatization for replacement boars were associated with lower seroprevalences.

Also the percentage of infected pigs at weaning varies between studies. In most reports, approximately 5-20% of the piglets are positive at or shortly after weaning using nested PCR on nasal swabs (Sibila et al., 2008; Villarreal et al., 2010b), both in farrow-to-finish and multi-site systems.

Differing infection and disease patterns have been reported in farrow-to-finish and multi-site systems (Sibila et al., 2004). In farrow-to-finish operations, infection of piglets at the nursery stage tends to be higher and the percentage of infected pigs increases progressively with advancing age. In multi-site systems, infections in nursery and growing pigs are less important than in single-site herds, and then may increase abruptly in the fattening unit (Sibila et al., 2004). In case of PRDC, clinical symptoms typically occur at 14 to 20 weeks of age (Dee, 1996).

Transmission does not only depend on the infectivity of infectious animals, but also on the susceptibility of not yet infected animals. In an experimental study aiming to quantify the spread of *M. hyopneumoniae* using reproduction ratios (Meyns et al., 2004), it was shown that during the nursery period, one infected pig will infect at least one penmate (Table 1). In the same study, it was also shown that the transmission rate tended to be higher with a highly virulent *M. hyopneumoniae* isolate than with a low virulent isolate (Vicca et al., 2003), but the difference was not statistically different. Villarreal et al. (2010a) found slightly lower transmission rates in pigs during the same period under field conditions. Morris et al. (1995) showed that pigs being in direct contact with other infected pigs are 7 times more likely to seroconvert than those having indirect contact.

**Table 1. Results of transmission experiments of M. hyopneumoniae in nursery pigs (4-10 weeks old). Two out of 8 piglets were experimentally infected at the start of the experiment and the number of infected pigs was investigated 6 weeks later. Transmission rates are expressed using adjusted reproduction ratios (Rₚ values) (Meyns et al., 2004)**

The transmission of *M. hyopneumoniae* between herds can take place either by trade of (subclinically) infected pigs or by airborne transmission. The importance of airborne transmission has been illustrated in many field studies. Goodwin (1985) concluded that EP-free herds could be reinfected by airborne transmission of *M. hyopneumoniae* over a distance of 3.2 km. Dee et al. (2009) have recently shown that airborne transport of *M. hyopneumoniae* organisms occurred out to a distance of 4.7 km. Apart from direct contact and airborne transmission, indirect transmission of infection through fomites is not considered to be important.

**Interactions of M. hyopneumoniae with other pathogens**

The interaction of *M. hyopneumoniae* with other pathogens has received much attention. In the past, studies mainly focussed on
the interaction with parasitic and bacterial infections, whereas recently, the emphasis has been shifted towards the interactions with viral infections.

**Parasitic pathogens**

Lesions typical for EP are more severe in *M. hyopneumoniae* infected pigs that are concurrently infected with parasites such as *Metastrongylus elongatus* or *Ascaris suum*. *Flejsa and Ulvesaeter (1980)* reported that the extent of pneumonia was associated with the presence of liver lesions due to migrating *A. suum* larvae. Other studies reported that the prevalence of pneumonia in a herd was positively associated with the prevalence of liver lesions in the herd. *Steenhard et al. (2009)* showed that experimental infections with *A. suum* may significantly compromise the immune response following *M. hyopneumoniae* vaccination.

**Bacterial pathogens**

*M. hyopneumoniae* predisposes pigs to infections with secondary bacteria. Different mechanisms may be involved in this phenomenon: damage of the epithelium, induction of cuffing lesions (massive infiltration of lymphohistiocytic cells), induction of thick, viscous mucus, and modulation of the immune system. Combined experimental infections with *M. hyopneumoniae* and either *Pasteurella multocida* (Sørensen et al., 1997) or *Actinobacillus pleuropneumoniae* (Marois et al., 2009) result in more severe lesions compared to the single infections. Co- or subsequent infections with *P. multocida* and *A. pleuropneumoniae*, and with other bacteria such as *Bordetella bronchiseptica*, *Haemophilus parasuis*, *Arcanobacterium pyogenes*, streptococci or staphylococci are commonly found in field outbreaks of EP. Different studies are inconsistent as to whether there is an association between turbinate atrophy and pneumonia.

**Viral pathogens**

Initial studies focussing on the interaction between *M. hyopneumoniae* and PRRSV could not demonstrate a potentiating effect of both pathogens (Van Alstine et al., 1996). Some years later however, it was shown under experimental conditions that *M. hyopneumoniae* significantly prolonged and increased the severity of PRRSV-induced pneumonia (Thacker et al., 1999).

Dual infection studies with *M. hyopneumoniae* and SIV could not show the potentiating effects of both pathogens as observed with PRRSV. The effect was less pronounced and only transitory. *Opriessnig et al. (2004)* indicated using an experimental study that *M. hyopneumoniae* infection potentiates the severity of PCV2-associated lung and lymphoid lesions, increases the amount and prolongs the presence of PCV2-antigen, and increases the incidence of PMWS in pigs. On the contrary, the different experiments using dual infections with *M. hyopneumoniae* plus either PRRSV, SIV or PCV2 could not demonstrate a virus-dependent enhancement of mycoplasmal pneumonia. Combined infections under standardised experimental conditions may provide very useful information on the interactions of pathogens, but they only partially reflect the complexity of PRDC as occurring under field conditions. Many different pathogens may be involved under field circumstances, and environmental conditions such as management, breed and immunity of the animals, housing and air quality may largely influence the infection and disease course.

**Control of *M. hyopneumoniae* infections**

**Optimization of management practices and housing conditions**

Optimizing management and housing conditions is primordial in the control of *M. hyopneumoniae* infections and should be the first to be accomplished. Instituting management changes that reduce the possibilities of spreading *M. hyopneumoniae* or result in decreased lung damage by other pathogens may significantly improve the control of enzootic pneumonia. Additional factors different from housing and management conditions, such as strain differences, may determine the infection pattern and clinical course of the disease (Vicca et al., 2002). An overview of control measures for *M. hyopneumoniae* infections related to environmental and management factors has been published by Maes et al. (2008).

**Antimicrobial medication**

To control and treat respiratory disease including *M. hyopneumoniae* infections in pigs, tetracyclines and macrolides are most frequently used. Also, other potentially active antimicrobials against *M. hyopneumoniae* include lincosamides, pleuromutilins, fluoroquinolones, florfenicol, aminoglycosides and aminocyclitols. Fluoroquinolones and aminoglycosides have mycoplasmalcidal effects. Since the organism lacks a cell wall, it is insensitive to β-lactam antibiotics such as penicillins and cephalosporins. Although acquired antimicrobial resistance of *M. hyopneumoniae* has been reported to tetracyclines (Inamoto et al., 1994), and recently also to macrolides, lincosamides and fluoroquinolones (Vicca et al., 2004), it does not seem to constitute a major problem for treatment of *M. hyopneumoniae* infections to date.

An overview of peer reviewed studies assessing the efficacy of various antimicrobials used against *M. hyopneumoniae* infections under experimental as well as under field conditions is given by Vicca (2005). It can be concluded that for most antimicrobials tested, performance parameters were improved and lung lesions as well as clinical signs were decreased in treated animals. Treatment and control of enzootic pneumonia outbreaks may be disappointing because the symptoms may reappear after cessation of the therapy. Pulse medication in which medication is provided intermittently during critical production stages of the pigs, can also be used (Le Grand and Kobish, 1996). Pulse medication during extended periods of time as well as continuous medication during one or more production stages should be discouraged because of both the increased risk of spread of antimicrobial resistance and the possible risk for antimicrobial residues in the pig carcasses at slaughter.

In endemically infected farms, strategic medication of the reproductive herd is sometimes practiced as an attempt to decrease the bacterial shedding from sows to the newly introduced gilts. Antimicrobial medication of recently weaned pigs has been shown to reduce the number of *M. hyopneumoniae* organisms in the respiratory tract (Vicca et al., 2005; Thacker et al., 2006), but further research is necessary to quantify the shedding of *M. hyopneumoniae* organisms in sows receiving antimicrobial medication.

**Vaccination**

**Commercial vaccines**

Commercial vaccines, consisting of inactivated, adjuvanted whole-cell preparations, are widely applied worldwide. The major advantages of vaccination include improvement of daily
weight gain (2-8%), feed conversion ratio (2-5%) and sometimes mortality rate. Additionally, shorter time to reach slaughter weight, reduced clinical signs, lung lesions and lower treatment costs are observed (Maes et al., 1998, 1999). Although protection against clinical pneumonia is often incomplete and vaccines do not prevent colonization, some studies indicate that the currently used vaccines may reduce the number of organisms in the respiratory tract (Meyns et al., 2006) and may decrease the infection level in a herd (Sibila et al., 2007). Transmission studies under experimental (Meyns et al., 2006) and field (Villarreal et al., 2010a) conditions showed that vaccination against \textit{M. hyopneumoniae} with commercial vaccines induced only a limited and non-significant reduction in the spread of \textit{M. hyopneumoniae}. Consequently, vaccination alone with the current vaccines will not be sufficient to eliminate \textit{M. hyopneumoniae} from infected pig herds.

**Vaccination strategies**

Different vaccination strategies have been adopted, depending on the type of herd, the production system and management practices, the infection pattern and the preferences of the pig producer. Moreover, under field conditions, optimal vaccination strategies must balance the advantage of delayed vaccination with the need to induce immunity before exposure to pathogens. Since infections with \textit{M. hyopneumoniae} may already occur during the first weeks of life, vaccination of piglets is most commonly used. Its efficacy has been demonstrated by means of numerous studies under experimental as well as field conditions (Jensen et al., 2002). Vaccination of suckling piglets (early vaccination; < 4 weeks of age) is more common in single-site herds, whereas vaccination of nursery/early fattening pigs (late vaccination; between 4 and 10 weeks) is more often practiced in three-site systems where late infections are more common.

Traditionally, double vaccination was the most frequent practice. During the last years, one-shot vaccines have been shown to confer similar benefits as two-shot vaccines and are more often used now (Baccaro et al., 2006). One-shot vaccination is especially popular because it requires less labor and it can be implemented more easily in routine management practices on the farm.

Vaccination of suckling piglets has the advantage that immunity can be induced before pigs become infected, and that less pathogens are present that can interfere with immune response. Possible disadvantages of vaccinating piglets before weaning include the presence of maternal antibodies and an increased risk for more severe PCV2 infections after weaning.

Vaccination of nursery pigs has no or less interference with possible maternally derived antibodies. However, nursery pigs may already be infected with \textit{M. hyopneumoniae}. In addition, the age of infection or the age-window in which the piglets become infected may vary between successive groups within a herd (Sibila et al., 2004). Finally, many infections such as PRRSV or PCV2 phases may be warranted.

Vaccination of gilts is recommended in endemically infected herds to avoid destabilization of breeding stock immunity (Bargen et al., 2004). This is particularly the case when gilts are purchased from herds that are free from \textit{M. hyopneumoniae} or from herds with a low infection level of \textit{M. hyopneumoniae}

Although vaccination confers beneficial effects in most infected herds, the effects are variable between herds. The variable results may be due to different factors such as improper vaccine storage conditions and injection technique, antigenic differences between field strains and vaccine strains, presence of disease at the time of vaccination, and interference of vaccine induced immune responses by maternally derived antibodies.

**Experimental vaccines**

Investigation of new vaccines is actively occurring, including the use of aerosol and feed-based vaccines as well as subunit and DNA vaccines (Fagan et al., 2001; Lin et al., 2003; Murphy et al., 1993). Intradermal vaccination with a commercial bacterin has been shown to be efficacious (Jones et al., 2004). If \textit{M. hyopneumoniae} vaccines could be delivered to the animals via aerosols or via the feed, this would provide an easy means for mass vaccination since it would substantially reduce labor costs and it would also be better for the welfare of the pigs as well as for stimulating a mucosal immune response at the respiratory tract. However, aerosol vaccination given 3 times with 2 weeks interval provided insufficient protection, in contrast with the intramuscular application of the same commercial vaccine which was efficacious (Murphy et al., 1993). On the other hand, Lin et al. (2003) showed that an oral micro-spheres experimental vaccine based on the PRIT-5 \textit{M. hyopneumoniae} strain and prepared by a co-spray drying method significantly reduced pneumonia lesions following challenge infection with \textit{M. hyopneumoniae} in pigs.

King et al. (1996) found only minimal and non-significant protection in a pig challenge infection model using a recombinant subunit vaccine based on the P97 adhesin of \textit{M. hyopneumoniae}. Intranasal immunization of pigs with the attenuated \textit{Erysipelothrix rhusiopathiae} YS-19 strain expressing a recombinant protein of \textit{M. hyopneumoniae} P97 adhesin significantly reduced the severity of pneumonic lung lesions following challenge infection (Shimoji et al., 2003). However, apparently significant immune responses were not observed in the immunized pigs. Oral administration of the same recombinant protein in another live strain of \textit{E. rhusiopathiae} (Ogawa et al., 2009) significantly reduced the severity of pneumonic lung lesions. Okamba et al. (2007) showed that a replication-defective adenovirus expressing the C-terminal portion of \textit{M. hyopneumoniae}-P97 adhesin applied intranasally and intramuscularly in BALB/c mice, induced
significant immune responses. Also several experimental DNA-vaccines have been developed and tested for immune responses in mice or pigs. Significant immune responses with DNA-vaccines were elicited in mice, based on the expression of a heat shock protein gene P42 (Chen et al., 2003), a ribonucleotide reductase R2 subunit gene fragment of *M. hyopneumoniae* (Chen et al., 2006), or the expression of different genes coding for several potential protective antigens (P36, P46, NrdF, P97, P97R1) (Chen et al., 2008). The studies suggest that these vaccines may represent new strategies for controlling *M. hyopneumoniae* infections in pigs, but they need to be validated in pigs under experimental and practical circumstances. Villarreal et al. (2009) showed that pigs inoculated with low virulent isolates of *M. hyopneumoniae* are not protected against a subsequent infection with a highly virulent *M. hyopneumoniae* isolate 4 weeks later and may even develop more severe disease signs. This may indicate that subsequent infections with different *M. hyopneumoniae* isolates may lead to more severe clinical disease in a pig herd.

Further studies are necessary for improving vaccines and vaccination strategies. From an immunological point of view, challenges include induction of immunity at the mucosal level. For rational design of vaccines, a comprehensive understanding of the pathobiology of *M. hyopneumoniae* infections and the molecular basis of pathogenicity of this micro-organism is required. Bacterial genes and antigens involved in survival of the bacterium in the host or that render the bacterium harmful to the host need to be identified. This may be facilitated by the fact that the genome of 3 different *M. hyopneumoniae* isolates has been sequenced (Minion et al., 2004; Vasconcelos et al., 2005).

**Preventive medication versus vaccination**

The use and efficacy of either vaccination or preventive (strategic) medication has been frequently discussed and the question arises whether medication and/or vaccination should be used. Advantages and disadvantages of both strategies are given in Table 2. Antimicrobials can be used in a flexible way, they are often effective against several (respiratory) pathogens and their administration is less labor-intensive since in-feed or in-water medication is mostly used. Vaccination, on the other hand, does not select for antimicrobial resistance in pathogenic bacteria and in bacteria belonging to the microbiota of the animal. It also avoids risks for antimicrobial residues in the pig carcasses at slaughter. While an immediate effect can be expected for antimicrobial treatment, the effect of vaccination of young piglets will only be evident at herd level if it is practiced for at least several months. Although vaccines are directed towards control of *M. hyopneumoniae* infections, also other secondary bacterial infections (Pasteurella multocida, Actinobacillus pleuropneumoniae) or lung lesions caused by these pathogens less frequently occur after vaccination (Maes et al., 1998; 1999; Meyns et al., 2006). In addition, it is very likely that combined vaccines will be used more frequently in the future. In this way, vaccination against different respiratory pathogens will be possible using one single application.

Neither vaccination nor preventive medication can prevent infection and adherence of *M. hyopneumoniae* to the ciliated cells of the respiratory tract (Le Grand and Kobisch 1996). Finally, in case of high infection levels and/or in herds with poor management and housing conditions, the use of antimicrobials may remain necessary or may confer additional clinical and performance benefits in vaccinated herds (Mateusen et al., 2002).

**Conclusions**

*M. hyopneumoniae* infections occur worldwide and may affect pigs in various types of pig herds. The infection pattern, clinical course, the lung lesions and ultimately the financial losses vary largely depending on the herd, the management practices, the housing conditions, and also on the interactions between different respiratory pathogens. Control measures include optimizing management practices and housing conditions, the use of medication and vaccination. These measures can decrease the infection level in a herd and the number of organisms in the lungs, and improve health conditions of the animals but they do not guarantee the absence of *M. hyopneumoniae*. Further efforts are needed for development of more effective vaccines and vaccination strategies.

Social behavior in swine and its impact on welfare

Jeremy N. Marchant-Forde
USDA-ARS, Livestock Behavior Research Unit, Purdue University, West Lafayette, IN, USA

Introduction
Pigs are social animals. From an evolutionary perspective, being social conveys a number of benefits, but potentially some disadvantages, especially for certain individuals within the group. Living in a social group can reduce predation, improve successful foraging, improve rearing of offspring, increase chances of mating and help thermoregulation. On the flip side, a group can be more conspicuous to a predator, competition within the group can reduce access to resources for some individuals, and may increase the risk of disease (1).

By definition, “social behavior is comprised of those patterns of behavior that involve two or more members of a species” (2). Thus, social behavior includes sexual behavior and parental behavior. However, the emphasis of this manuscript will be on those behaviors that relate to formation and maintenance of social organization in swine, namely those centered on aggression and social dominance, as these are the aspects of social behavior in swine that have garnered most attention in relation to the animal’s welfare. The animal’s welfare can be defined as its state as regards its attempts to cope with its environment (3).

Natural social organization
In order to better understand the consequences of the systems in which we place pigs during commercial production, it is crucial to acknowledge the pig’s origins and social behavior in a natural setting. The domestic pig is descended from the wild boar, but although they have changed greatly in terms of phenotype, their behavior, when given the opportunity, is extremely similar to their wild ancestors. The data from which we can conclude this comes from three main sources: 1) studies of wild boar in their natural habitat, 2) studies of feral populations of domestic pigs, and 3) studies of domestic pigs released into naturalistic enclosures.

The natural social organization of pigs centers on a core group or ‘sounder’ of 2-4 related sows plus their associated offspring of different sizes and ages (4,5,6). Sows in the group are likely to be sisters or mother and daughters. Group size will be influenced by habitat and resource availability (especially food), as will the size of the home range, but can be as large as 6000 hectares (7). Home ranges may overlap with other sounders, but even when sharing home ranges, sounders will tend to actively avoid open confrontation with each other (6). As the offspring mature, the females split off to form their own sounders and the males split off to form adolescent bachelor groups, becoming solitary as mature boars. During the breeding season, mature boars may associate with sounders, becoming dominant to all sounder members. Within sounders, aggression is very rare. The group usually maintains a simple, linear social hierarchy, which is relatively stable over time. Position within the hierarchy is mostly determined by size and age, with large, mature, physically-strong sows being dominant over smaller sub-adults and juveniles (4). Aggression does occur during competition for resources, especially food, but most often, subordinate animals actively avoid conflict with dominant animals (8). Food will be scattered but available ad libitum in their complex environment, as long as the pigs forage. This social organization is such that pigs are not exposed to unrelated, unfamiliar pigs. New litters are integrated into the group early in life (7-14 days of age) when the sow returns to the group with her litter after isolation at farrowing, but no aggression has been observed during these interactions (9, 10).

In contrast, pigs housed in commercial systems may be housed individually (but in close proximity to others) or in groups ranging from small (4-5) to large (200+). Regardless of group size, there will be relatively limited space and a relatively simple environment and they may encounter frequent remixing. Access to food may be ad libitum or restricted. Unsurprisingly, aggression will be much more prevalent under commercial conditions than under natural conditions. How prevalent will be largely influenced by: 1) the degree of mixing/remixing, 2) the method of feeding, and 3) the amount and quality of space.

Aggression and mixing
When unacquainted pigs are mixed together, they often fight. The fight does not often break out immediately but can be a complex and gradual event as the pigs investigate each other using a series of specific and often reciprocal behaviors, characterized by nosing, sniffing and gentle nudging (11). This may then escalate into more vigorous pushing and pressing, bites, head-knocks and mounting, which continues until one pig withdraws, with or without being pursued. Most fighting takes place within 2 h of mixing and by 24-48 h post-mixing, the level of aggressive interactions should be basal, and a hierarchy established. The hierarchy is then maintained by threats, avoidance and withdrawal, or short-lived aggressive interactions.

A fight can result in injury to one or both parties and thus the potential cost of fighting can be high, particularly for the loser, both in terms of welfare of the pig but also economically for the producer. For the individual pig, the choice to engage in fight or not in the first place, or to know when to stop calls for the pig to be able to assess its fighting ability relative to the fighting ability of its opponent (12). If pigs were unable to carry out assessment of relative fighting ability, then we may expect that every pig would have to fight with every pig with which it is mixed in order for social order to be established. We know, however, that this is not the case in some instances. For example, a study examined mixing 4 pigs from one litter with 4 pigs from another litter, meaning that there were a total of 16 possible unacquainted pairs in each of 11 pens (12). The actual number of pairs which fought ranged from only 2 to 10 (median 6). The most supported explanation as to why this happens is that within each litter, the pigs had a clear idea of their own position within the hierarchy. Seeing the outcome of an interaction between a pen-mate and an unacquainted pig thus yields useful information about your own likelihood of success in a fight. In
fact the study demonstrated a litter effect, with in each case, a ‘dominant’ litter moving freely around the pen, with a ‘subordinate’ litter huddling in one corner (12). In production, this is the most usual scenario – i.e. when pigs are mixed into a pen, there will already be existing pair-wise relationships between some members, which can help individual pigs gather information. We have examined close one-on-one encounters and looked at the sequences of behaviors that occur before a fight breaks out. We have found that escalation is more often preceded by the receiving pig ignoring the attention of the investigating pig. If the receiving pig turns to maintain nose-to-nose contact, then the chance of subsequent escalation is reduced (13).

Not surprisingly, there has been a great deal of research carried out into methods to reduce aggression at mixing (14). Many have little or no effect but there are some which clearly have an effect over the short or long term. Elements of pen design, such as a solid barrier in the center of the pen (15, 16) or the division of the lying area into distinct sub-areas can reduce aggression over the long term (17). Mixing at sunset (18, 19) and the use of drugs such as amperozide (19) and azaperone (20) can have short-term effects, but only so long as it remains dark or the drugs wear off. Mixing in the presence of a super-dominant animal – i.e. a boar – can reduce number of aggressive interactions, skin damage and flight distance (21). Other longer-term solutions include early social experience, repeated mixing, pre-mixing and use of pre-exposure pens. Allowing piglets to mix before weaning can benefit their social development and enable them to form stable social hierarchies quicker (22, 23). Repeated mixing during growth may help replacement pigs acquire social skills that serve them better later in life (24). Pre-mixing of sows into groups at weaning can help them when they are subsequently mixed into a larger group post-service (25). Finally, placing pigs into adjacent pens or a small pen within a pen, so that they can have contact without the ability to fight, prior to mixing together can greatly reduce aggression (26).

What is clear is that any method that might facilitate communication, be it olfactory, vocal or, to a degree, physical will help the pig’s ability to assess its chances better and thereby avoid fighting or at least avoid prolonged contests.

**Aggression and feeding**

Naturally, pigs tend to synchronize feeding and actively forage for relatively low quality food for many hours during the day, with peaks in activity around dawn and dusk. Again, this is potentially very different from the commercial situation. In production, pigs will have access to high quality feed, which can meet their nutritional requirements quickly and it may only be available for an extremely limited period of time each day. Whereas the grow/finish herd may have ad libitum access, but with restricted number of feeding spaces, the breeding herd usually has access to a single food drop a day, with food present for about 15-20 minutes every 24 h. In many ‘intensive’ production systems, pigs do not have access to any alternative foraging substrate, such as straw, and thus, access to food becomes an important resource and one that may play a major role in determining the amount of aggression being displayed within a system. For sows, feeding systems that promote competition for access, such as floor feeding, can have relatively high levels of aggression. Feeding systems that reduce competition by enclosing sows in stalls or being available ad libitum, can have relatively low aggression.

Floor feeding may be cheap and ‘low tech’ in terms of equipment, but it is highly competitive (27) with dominant sows able to monopolize the feed if it is not widely distributed (28). The aggression elicited by floor feeding, and its production consequences, can be manipulated by ensuring that the feeding area is as widespread as possible and that group size is kept small and stable, with animals of similar body condition and nutritional needs (29). Trough feeding is another method of feeding a group simultaneously, but without any partitions, dominant animals can again monopolize large lengths of trough space, displacing subordinate sows, especially if food distribution along the trough is uneven. Aggression can be reduced by using wet feed (30), which flows better along the trough, and by using dividers to separate the trough into individual feeding spaces. Use of trickle feeders for delivery can also help to keep sows ‘tied’ to a single feeding space and reduce displacements (29).

Other feeding options for sows include individual feeding stalls into which the sows can be shut either manually or under their own control (free-access stalls) and thereby eat at their own rate without threat of displacement. Electronic Sow Feeder (ESF) systems have the big advantage of allowing each sow to eat an individual, stockperson-controlled allowance without fear of displacement, but sows have to feed sequentially. With a single feeder per 40-60 sows, the feeder station may be occupied for much of the day with sows queuing outside. Usually a fairly stable feeding order develops, with dominant sows accessing the feeder soon after the daily cycle begins and the more subordinate sows waiting to feeding towards the end of the cycle. However, the entrance to the feeder can become a focal point of activity for large parts of the day and hence, a focal point for aggression (31).

For the growing/finishing pig, feed is usually available ad libitum. Although feeding behavior and actual feed intake is stimulated by allowing pigs to feed simultaneously, there is still the need to have allocated individual feeding spaces incorporated into the feeder design to keep aggression as low as possible (32). There is also the question of how many feeding spaces are made available for the number of pigs in the pen, whether these should be in the form of one ‘multi-space’ feeder or several ‘single-space’ feeders and where the feeder or feeders should be placed in the pen (33, 34). The term ‘social workload’ has been used to describe the effort required and aggression encountered in negotiating a route through pen-mates to a feeder and displacing pigs which are either feeding or obstructing the feeder (35). Ad libitum feeding has also been investigated for sows using high fiber diets which have increased bulk and low energy. In general, increasing fiber doubles the amount of time that sows spend eating and reduces stereotypic behavior, restlessness and aggression (36).

**Aggression and space**

The amount of space that pigs have, and the quality of that space, can have a large impact on their behavioral repertoire, including agonistic social behavior. With sows, the minimum amount of space given to sows in current commercial systems is that encompassed by a gestation crate, which at about 1.25m2 encloses the sow’s static space requirement (37). The sow enclosed within this space has no pen-mates and thus, it is commonly assumed that she is free from the aggression attributed to group housing systems. In reality, this is not true. She may be free from the physical effects of aggression – i.e. the skin lesions and other injuries that group-housed sows may show – but
several studies have shown that aggression between neighbors in crates can be high. Initial attack is more often followed by retaliation in crates, resulting in escalation in the intensity of aggression rather than the withdrawal and cessation of interaction most often seen in group housing systems (38, 39, 40).

In pen systems, the amount of space given per animal will impact aggression. In general, as space allowance decreases, the total number of aggressive interactions increases (41). However, few studies have investigated the effects of space allowance as a single factor. In many comparative studies, when space allowance has varied, so have other aspects of the pen design or the group size, making drawing conclusion about space per se difficult. In some instances, space allowance may not show a linear relationship with aggression. For example, a study examining the effects of communal area space behind free-access sow stalls shows that decreasing communal space allowance may show in inverted U-shape relationship with aggression. At high space allowance, sows using the communal area can avoid each other and at low space allowance, they utilize the free-access stalls more, also reducing aggression. When the space allowance is intermediate, the sows are motivated to use the space, but are unable to avoid agonistic interactions so easily and thus, this treatment shows most aggression.

The other important aspect of space is its quality. Much of the current research in to group housing in North America involves the changing of stall systems to pen systems within similar types of building – i.e. into fully-slatted or part-slatted, non-bedded group housing. Usually, space is still fairly restricted and the environment offers no real ‘enrichment’ apart from pen-mates with which to interact. In these systems, there may be increases in skin lesions and aggression-associated lameness compared with sows in crates. However, if other enrichment is included, such as a foraging substrate and bedding, then aggression is often reduced compared with sows in non-enriched pens (42).

**Welfare impact of aggression**

The most obvious physical impact of aggression can be injury. This can take the form of lameness, skin lesions - which are often seen on the shoulders, flanks, hindquarters and ears - or vulva biting, seen in sows in particular. If occurring near slaughter, severe physical damage may lead to condemnation of parts of the carcass, thereby financially impacting the producer. Another economic impact can be decreased growth. If individuals are unable to access enough food to meet their requirements, then growth can be reduced. This can increase the weight variability within the pen and can become self-reinforcing, with the smaller pigs getting smaller and smaller relative to their pen-mates. Within the breeding herd, the timing of group formation and any post-service mixing can be critical. It is widely acknowledged that mixing around the time of implantation should be avoided and thus mixing at weaning and/or 5-6 weeks post-service are recommended to maximize farrowing rate (43).

In terms of internal physiology, we also know that aggression activates both the sympathetic-adrenal-medullary axis and the hypothalamic-pituitary-adrenal axis, resulting in increased heart rate (31), increased plasma cortisol concentrations, increased plasma epinephrine and norepinephrine levels. For the breeding sow, this can explain the potential impact of stress due to aggression on fertility. For the slaughter pig, this can also help explain the effects of aggression on growth. With activation of the stress axes also comes a negative impact on immunity and thus disease incidence and rate of healing of any injury may be impacted. Finally, there is recent evidence that for the breeding sow, the stress due to aggression that she encounters during gestation can impact both the behavior and stress-reactivity of her offspring (44).

Dysentery and ileitis – High time to tackle the difficult science behind these diseases

Steven McOrist
University of Nottingham, Sutton Bonington, UK

Swine dysentery
Clinical features of swine dysentery (SD) have been well described in the pig industry since the 1920’s. There is a severe inflammation of the large intestine with bloody mucous diarrhoea. On affected farms, disease is usually common in fattening pigs from 12 to 75 kg, but cases also occur regularly in gilts and sows. Spread of the disease through the herd is slow, building up in numbers as the dose rate of the agent builds up in the environment. The incubation period in field cases is normally 7 to 14 days. Pigs that recover only develop a mild immunity, but rarely suffer from the full disease again. The high economic cost of disease is associated with pig mortality, high morbidity, marked depression of growth and feed conversion efficiency, and the costs of continual in-feed medication. It is an oppressive disease for pig farmers, who rarely feel able to maintain a functional pig farm while a clinical presence continues.

Swine dysentery remains a major pig health issue in Europe and Asia-Pacific regions and is increasing in the USA, as carbadox usage declines. No useful vaccine or blood test is available and ongoing medication is problematic for endemic SD – a major issue in central European pig farming is the high prevalence of tiamulin-resistant and pathogenic Strains. The actions of regulatory authorities have removed many useful and effective anti-SD drugs (quinoloxalins, metronidazoles, ionophores) across the pig raising world.

This major enteric disease is caused by the snake-like spirochaete bacterium, now called Brachyspira hyodysenteriae. This organism was first cultured and used to verify Koch’s postulates by the groups of David J. Taylor in Cambridge and Hank Harris in Iowa in 1970. They published a wide set of studies exploring the spirochaetal invasion of colonic epithelial cells and other key pathogenesis features of the early lesions (see Taylor and Blakemore 1971).

Microbiological diagnosis is critical because of the serious nature of SD, for example, a key issue surrounding the purchase of new breeding stock is whether any SD-free reassurance provided by a breeding company supplier is accurate. Diagnosis is therefore based on the history, the clinical picture, post-mortem examinations and laboratory tests involving both anaerobic isolation and PCR identification of haemolytic B hyodysenteriae.

The key scientific questions regarding Brachyspira hyodysenteriae and SD are i/ those surrounding the pathogenesis of SD – how does this organism cause the lesions? and ii/ those of immunity – why is the immune and blood reaction so weak? The failure of the veterinary science community to answer these critical questions since 1970 has been regularly noted (see ter Huurne and Gaaster 1995) and I wish to note it again here. The genome has finally been elucidated (see Bellgard et al 2009) and it points to the existence of 6 likely haemolysins and 15 proteases. However, the few mechanistic studies on pathogenesis factors of motility, LP5 outer coats and putative haemolysins do not amount to a real challenge-exposure based explanation about how this bacterium produces such an impressive yet immunologically silent lesion and illness. The desired outcomes of vaccines and blood tests and new drugs for SD, which all became viable targets in 1971, will presumably wait many further years until these basic microbiology challenge-exposure studies come about.

Part of this failure must lie with the lack of funding for basic studies of pig enteric diseases. Much of the previous funding in livestock microbiology research has ended up with the chicken and cattle sectors and focused largely on zoonotic/food industry issues such as Salmonella. Any left-over for pig studies have previously ended up in these food industry issues or studies in respiratory diseases such as PRRS.

Ileitis – proliferative enteropathy
Clinical features of proliferative enteropathy (PE, ileitis) have been well described in the pig industry since the 1930’s. In growing pigs with uncomplicated proliferation of the mucosa, the condition is a chronic proliferative enteropathy, also known as porcine intestinal adenomatosis (PIA). Case lesions and clinical signs can vary from mild and sub-clinical, through to clinical diarrhoea and weight loss; or in more severe cases additional changes can be superimposed on this basic lesion, including necrotic enteritis, or an acute proliferative haemorrhagic enteropathy. All these forms of PE remain common and important enteric diseases. Estimates across the global swine industry show that around 96 percent of farm sites are infected, wherein around 30 percent of weaner-to-finisher pigs often have detectable lesions at some point, causing clear economic losses (see McOrist et al 2003).

The nature of PE was not clear until 1973, when lesions were examined ultrastructurally and small, curved intracellular vibrioid bacteria were consistently present only within the abnormal proliferating cells of the affected mucosa (see Rowland and Lawson 1974). The identity of these PE bacteria and their true aetiologic role were finally resolved in 1993 with successful co-culture of the intracellular organism and the reproduction of the disease in pigs using a pure culture of this agent (see Lawson et al. 1993 and McOrist et al. 1993). The name Lawsonia intracellularis was chosen to reflect the key role and persistence of the Scottish veterinarian, Gordon Lawson in its discovery. The unique feature of PE pathogenesis is therefore the clear causation of a monotypic epithelial cell proliferation by an infectious bacterium. To my knowledge, only two other bacteria (unrelated species of Bartonella and Citrobacter) have some parallels in this proliferative pathogenesis and the exact mechanism also remains unknown for them.

Lawsonia research has largely focused on issues important to the pig farming industry, such as the susceptibility of Lawsonia to various antibiotics, its epidemiology within and between pig farms and methods of diagnosis in live pigs and related topics (see Stege et al 2004). Lawsonia has a small, single circular genome and 3 mega-plasmids which are features commonly seen in...
other obligate and symbiont intracellular bacteria (see Gebhart and Kapur 2007 and Schmitz-Esser et al 2008). A vaccine for ileitis was first registered in 2001 (Enterisol Ileitis, Boehringer Ingelheim) and is now widely registered and used around the world (see Guedes and Gebhart 2003 and Kroll et al 2004). Presumably, the choice of vaccine format (live attenuated oral delivery) is well-suited to this type of intracellular gut mucosal agent. This rapid ileitis vaccine development is in contrast to the slow pace of development for vaccines for other key enteric diseases of pigs, such as swine dysentery and post-weaning colibacillosis.

However, despite the interesting and unique nature of the proliferative nature of PE, with perhaps insights to be gained into human colon cancer and the gut flora, no real progress has been made on the key scientific question regarding Lawsonia – how does this bacterial organism cause the monotypic proliferative lesions in the gut epithelium? The intriguing mechanism whereby the bacteria cause infected epithelial cells to fail to mature, but continue to undergo mitosis, and form the hyperplastic to adenomatous crypts is not yet understood fully. This adenomatous effect probably reflects a Lawsonia-specific inhibition of the normal crypt cell differentiation process, as regulated locally at the crypt neck (see McOrist et al 2006 and Oh et al 2010). *L. intracellularis*-infected intestinal crypts can become enormously elongated and often branched. Loss of body protein and amino acids into the intestinal lumen and the reduced nutrient absorption by the intestinal mucosa lacking mature enterocytes are the likely causes of the reduction in weight gain and feed conversion efficiency seen in pigs affected with chronic uncomplicated PE lesions (see Rowan and Lawrence 1982 and Gogolewski et al 1991). So far, further examination of the Lawsonia genome has proved of limited insight into exactly which genes cause this cell cycle/differentiation effect, with many unknown genes evident.

We therefore note again the failure of the veterinary science community to answer this critical question with basic studies in pig enteric disease. Presumably the reasons for this failure lie again in the lack of funding for basic studies of pig enteric diseases as part of the pots allocated for livestock microbiology research.

So what will all be saying at IPVS 2020 ...... So, Grandpa Ernie, what did all the old pig scientists find out about SD and PE ???.

Lack of curiosity will kill the pig ......???

Exudative epidermitis is difficult to treat because of widespread antimicrobial resistant *Staphylococcus hyicus*

Jeonghwa Park; Robert Friendship; Cate Dewey; Scott Weese; Zvonimir Poljak
University of Guelph, Guelph, ON, Canada

**Introduction**

Exudative epidermitis (EE) or greasy pig disease is caused by *Staphylococcus hyicus*. Certain strains of *S. hyicus* produce heat-labile exfoliative toxins that are important in the pathogenesis of the disease. Infection of skin wounds during the early suckling period is the typical presentation. Recently many herds have moved away from clipping needle teeth at birth. There may be a resultant, an increase in prevalence of EE. Traditionally, an injection of penicillin has been the treatment of choice but antimicrobial resistance to penicillin has been noted (1).

There are several studies determining the occurrence of different genes encoding antimicrobial resistance in *S. hyicus* (2) but there is limited information about the distribution of the mecA gene which encodes the low affinity penicillin-binding protein PBP 2A. The objectives of this study were to evaluate the extent of antimicrobial resistance of *S. hyicus* and to determine whether the mecA gene is present in *S. hyicus* in Ontario, Canada.

**Materials and Methods**

In a survey, farmers (n=49) were asked how they treated EE and whether the treatment worked. In addition herds (n=17) with EE problems were visited and skin swabs and scrapings were obtained from pigs with clinical signs of EE (generally 6 pigs per farm). Bacterial culture was performed on the samples with *S. hyicus* and *S. aureus* recovered from 77.3% (85/110) and 45.9% (50/109) of the samples respectively. Susceptibility to penicillin (pen), ampicillin (amp), ceftiofur (cef), spectinomycin (spec), sulphonamides (sul), tetracycline (tet), tiamulin (tia) and trimethoprim/sulfa (tri/sul) was determined by the agar diffusion method defined by the Clinical and Laboratory Standards Institute (CLSI).

In addition, molecular studies were conducted on isolates to determine the presence of the mecA gene using PCR and Pulsed-field gel electrophoresis (PFGE) analysis (3).

**Results**

Based on the survey, 69.4% (34/49) of farmers used topical treatments routinely to treat EE, including mixtures of topical antibiotics, antiseptics and mineral oil. In addition, 57% of respondents said that they used injectable antibiotics and 82% indicated injectable penicillin as the treatment of choice. Many of the respondents expressed concern that treatment was of little value and that response was poor.

Antimicrobial resistance testing revealed that all isolates of *S. hyicus* and almost all isolates of *S. aureus* were resistant to penicillin and ampicillin and the majority were also resistant to ceftiofur (Figure 1).

**Figure 1. Percent of isolates resistant to antimicrobials**

The percentage of isolates of *S. hyicus* and *S. aureus* from which the mecA gene was demonstrated was 2.73% (3/110), and 5.45% (6/110), respectively. The mecA gene was present in 12.96% (14/108) of the *S. aureus* isolated from nasal swabs from these same pigs.

**Discussion**

Penicillin was identified as the most common treatment choice by pig farmers and yet all isolates from cases of EE were shown to be resistant to not only penicillin but in most cases resistant to the entire family of beta-lactam antibiotics. These results explain why farmers reported a poor response to treatment of EE. Previous researchers have noted that penicillin-resistant isolates of *S. hyicus* containing the blaZ gene were relatively common in the pig population, affecting 50 to 75% of isolates (2). Methicillin-resistant *S. aureus* has been shown to be widespread in Ontario pig farms (4) and therefore it is not surprising that the mecA gene was isolated from *S. aureus* in these pigs. The relationship between *S. aureus* and *S. hyicus* and the possibility of gene transfer between these bacteria needs to be investigated further.

Etiology of the ear necrosis syndrome – investigation of infectious agents

Christiane Lang¹ Thomas Voglmayr² Franz Waxenecker³ Ursula Hofstetter³ Herbert Weissenböck⁴ Mario Ogris⁵ Georg Bruns⁶ Mathias Ritzmann¹

Introduction
During the summer months lesions of the so-called ear necrosis syndrome can be observed frequently in weaners during the raising period. The stages range from mild epidermal changes to severe ulcers and necrosis (1). In the past, various pathogens have been discussed to be responsible for the development of ear necrosis, but the exact etiology of this disease could not be determined. Aim of this study was the evaluation of different infectious agents in pigs with ear necrosis syndrome.

Materials and Methods
A total of 96 piglets (age 6 to 10 weeks) were included in the study. Piglets in 9 of the 15 farms were sampled twice in the interval of a year; in the other 6 farms piglets were only sampled once. All piglets showed clinical signs of the ear necrosis syndrome in an initial stage. The total of piglets with ear necrosis on the respective farms ranged from 10 to 100 %. Collected samples and methods are summarized in table 1.

</tbody>
</table>

Results
The pathohistological findings included epidermal necrosis, epidermal hyperplasia, bacterial growth in superficial cell debris and intimal proliferation with consecutive vascular occlusion. In situ hybridization for PCV-2 was negative in all cases. In 61 of the swabs streptococci could be found, in 48 of the swabs staphylococci were determined. 8 piglets were PRRSV positive, none of them was positive for PCV2. Only one piglet showed a positive result for Mycoplasma suis. 3 piglets showed antibodies against Sarcoptes suis. The measured endotoxin concentration ranged between 0.10 and 1.13 U/ml. Calcium levels were increased in 20, decreased in 6 piglets, phosphorous concentrations were increased in 57 and decreased in 1 of the piglets.

Discussion
The pathohistological findings proved that ear necrosis did not only develop because of external inflicted injuries and ear biting. A multifactorial disease seemed more likely. The various infectious agents seemed to play a minor role, PCV2 could be completely excluded. Streptococci and staphylococci could be determined frequently in the swabs as well as pathohistologically, but it was unclear if they act in a sense of a primary or secondary infection. The endotoxin concentrations were in a non-critical range, but participation earlier in the course of infection can not be ruled out. Finally, the development of ear necrosis is caused by an interaction of several factors and infectious agents are definitely able to contribute to this disease pattern.

The association between tail lesions and abscesses recorded at slaughter

Marie Erika Busch; Niels Peter Baadsgaard

Pig Research Centre, Danish Agriculture & Food Council, Copenhagen, Denmark

Introduction

The presence of tail lesions in slaughter pigs has been shown to be correlated to the risk of abscesses, including osteomyelitis (1, 2, 3). However, the location of abscesses associated with tail lesions has been described in only one published paper (4), which describes significant correlations between tail lesions and abscesses in the spine, peritoneum, pelvis, legs, ribs and lungs. Abscesses are costly to the pig producer because of partial or total condemnations at slaughter. In addition, it is most likely that the disease process leading to abscesses causes reduced pig welfare and productivity, increased mortality and higher expenses for medical treatment (5, 6). The aim of the present study was to investigate the degree to which abscesses, including embolic pneumonia and osteomyelitis, could be attributed to tail lesions and to investigate the location of the abscesses associated with tail lesions. This would help the pig producer assess whether different kinds of abscesses recorded at slaughter are likely to be caused by tail lesions or whether other causes are more likely.

Materials and Methods

Data from the meat inspection was used for the analysis. The data set comprised records from 732,282 slaughter pigs (castrates and females) from 2,027 herds slaughtered at the largest Danish abattoir in Jan-Feb 2008. The meat inspection records the presence/absence of tail lesion for each individual pig as standard procedure. Similarly, the presence/absence of abscesses at different locations on the pig is recorded (see locations in Table 1). In the case of osteomyelitis, the location is not recorded. Each pig can have abscesses at several locations.

Statistical analysis: For each type of abscess, we calculated the relative risk (RR) of having an abscess when having a tail lesion compared to not having a tail lesion. The statistical significance of the interrelationships was tested by chi-square tests. In addition, the following were calculated:

- AF (attributable fraction): the proportion of abscesses in pigs with tail lesion attributable to tail lesions
- PAF (population attributable fraction): the proportion of abscesses in the population attributable to tail lesions

Results

The overall prevalence of tail lesions was 0.85 %. Table 1 shows an overview of the results.

Discussion

The associations between tail lesion and all types of abscesses, except abscess in the head, were statistically significant. The highest RR, AF and PAF were found for osteomyelitis and embolic pneumonia. Osteomyelitis was found 57 times more often in pigs with tail lesion than in pigs without tail lesion, and 32 % of the osteomyelitis cases could be attributed to tail lesions. However, these numbers are probably underestimated, since many cases of healed tail lesions are probably not recorded by the meat inspection. The risks of abscesses in the abdomen, neck/breast and limbs/toes were also correlated with the presence of tail lesion (RR 3.9-4.7). However, as seen by the low PAFs (2.4-3.0), in most cases the causes of these abscesses should be found elsewhere. For example, they could be caused by unhygienic injection practice, hernias, foot injuries or other injuries serving as an entrance for bacteria. The potential associations among diseases recorded at slaughter may direct attention to preventive measures and hence help reduce costs of partial or total condemnation of the carcass for the producer.

The development and consequences of ear necrosis in a weaner herd and two growing-finishing herds

Marie Erika Busch¹ Inger M. Jensen² Jakob Korsgaard³

1. Pig Research Centre, Danish Agriculture & Food Council, Copenhagen, Denmark; 2. Dyrlægecentralen Sydvest A/S, Loegumkloster, Denmark; 3. Oe-Vet, Naestved, Denmark

Introduction

In Danish herds, ear necrosis (EN) in weaners and older pigs is mainly located along the ventral edge of the ear. Biting by other pigs and infections (possibly as a sequel to trauma) have been suggested as causes of EN (1, 2). The aim of this investigation was to explore 1) the development and healing of EN, 2) factors within the herd associated with EN and 3) the effect of EN on the health and growth of the pigs.

Materials and Methods

Three herds with high prevalences of EN were chosen for two studies. All study pigs were females or castrates. Study 1: Study 1 was carried out in a sow/weaner herd. A total of 136 randomly selected pigs from two batches were examined 2-3 times a week for 7 weeks beginning two days before weaning (day -2). EN was scored on a scale of 0-4 representing increasing severity (0: no EN; 4: loss of ear tissue and/or EN on > 20 % of the ear). The average daily gain (ADG) of each pig during the observation period was measured. The study pigs were housed in 11 weaner pens with slatted floors and tube feeders (25 pigs/pen). The effects of weight at weaning, ear scratches on day 4, gender and sow parity on the binary ‘EN score 2-4 on day 46’ were analyzed in a logistic regression model. Study 2: Study 2 was carried out in two growing-finishing herds receiving pigs from the same sow herd (not the herd in study 1). The study comprised 218 pigs from one batch: 109 pigs without EN (controls) and 109 with EN (matched on pen, gender and weight). Pigs were examined once a week for 12 weeks from a weight of approx. 45 kg. EN was scored on a scale of 0-4 (0: no EN; 4: bloody lesion with loss of ear tissue). ADG of each pig during the observation period was measured. Pens housed 11-22 pigs and had varying flooring and feeding systems. Meat inspection data for all pigs were collected. The effects of EN, herd, gender, weight at entrance and at slaughter on ADG were analyzed in a linear mixed model.

Results

Study 1: The prevalence of severe EN was highest at the end of the observation period (Figure 1). Weight at weaning, ear scratches on day 4, gender and sow parity were not found to have any effect on the risk of having EN on day 46. Pigs with and without EN had the same ADG (250 g/day). EN was not found to have any effect on signs of disease. Study 2: No effect of EN on ADG, lean mean percentage or mortality was found (overall mortality 2.8 %). Five pigs in the EN group and one control pig became unthrifty or lame, but the difference was not statistically significant (P=0.1). At slaughter, abscesses were found in only two pigs, both from the EN group (corresponding to 1.8 % of the EN pigs).

Discussion

There were no signs that small or weak pigs were predisposed to EN. EN was not found to have any effect on growth. Despite severe lesions, EN did not result in the amount of abscesses that are common in pigs with tail lesions (3). In growing-finishing pigs, more disease was found in pigs with EN, but a larger investigation would be necessary to determine whether the difference is statistically significant. The healing of EN seen in the growing-finishing pigs could be caused by immunological or behavioral changes in the pigs.

Idiopathic Vesicular Disease (IVD): a case report in the centre of Italy

Marco Sensi1, Antonella Catalano2, Miriam Tinaro1, Caterina Mariotti1, Carmen Panzieri1, Silvia Marchi1, Silva Costarelli1
1. Istituto Zooprofilattico Sperimentale dell’Umbria e delle Marche, Perugia, Italy; 2. Azienda Sanitaria Locale 2, Perugia, Italy

Introduction
Several Swine Vesicular Disease (SVD) outbreaks were registered in central Italy (Umbria and Marche regions) during October 2008. In the same time vesicular lesions were observed in an high percentage of animals of a fattening unit (approx. 2000 fattening pigs), located the surveillance area.

The aim of this work is to describe the episode and explain the differential diagnostic pathway to rule out SVD and suspect Idiopathic Vesicular Disease (IVD)

Materials and Methods
A state veterinarian noted vesicular lesions on snout of several hogs during an inspective visit in a fattening farm, before their transport to slaughter house. The farm was immediately quarantined.

A trace back and trace forward investigation was performed by our Institute (Istituto Zooprofilattico Sperimentale dell’Umbria e delle Marche). Blood and fecal samples were collected from pigs with lesions and not and checked for exotic diseases (SVD and Foot and Mouth Disease – FMD) and for parvovirus.

Blood samples were investigated for blood count parameters.

Feed samples were collected from the hoppers and from the silo bean and tested for mycotoxines (Aflatoxines, Deoxynivalenol, Zearalenone, T2 toxin, Fumonisine).

Results and discussion
Snout erosions were observed on 20 % of the pig farm population. Few animals showed gingival and oral lesions, too. Coronary band was not interested.

Lesions were of 3-4 mm of diameter and circular or “V” shaped. (Fig. 1 and 2).

Rectal temperatures ranged from 38.5 to 39.3 °C ruling out an infectious aetiology.

Feed was commercially purchased and the epidemiological trace back showed all the biosecurity measures were respected.

The last pig replacement happened six months before and no pigs were sold in the same time.

Lab test results were negative for SVD, FMD and parvovirosis. Blood parameters didn’t reveal significative alterations and mycotoxins levels in the feed resulted within the normal ranges.

Lesions resolved in nearly three weeks time.

In the last two years we observed, always in fattening farms and in the same season, two other episodes characterized by similar lesions.

The first case was referred to high levels of Deoxynivalenol and the second one to a mistake in the organic acids inclusion in the feed.

In this case, looking the lab results and the symptomatology we reasonably suspect Idiopathic Vesicular Disease (IVD) even if a definitive diagnosis was impossible to achieve.

Idiopathic Vesicular Disease (IVD) is a sporadic condition affecting swine already reported in Australia, New Zealand, Canada and USA. It is characterized by a seasonal pattern (spring – autumn). Although, it isn’t a severe disease for pigs and economically heavy for breeders, IVD represents an important differential diagnostic condition must be considered for SVD and FMD diagnosis.

We have to bear in mind predisposing factors can play an important role to exacerbate the clinical symptoms. In this case the particular shape of the nipple-drinkers could be contributed to complicate the symptoms.

Prevalence and risk factors of lameness and claw lesions in two types of group housing for pregnant sows

Liesbet M. Pluym1 Sebastiaan Van Hoorebeke1 Alfonso Lopez Rodriguez1 Jeroen Dewulf1 Frédéric Vangroenweghe2 Frank Tuyttens3 Dominiek Maes1

1. Dept. of Reproduction, Obstetrics and Herd Health, Faculty of Veterinary Medicine, Ghent University, Merelbeke, Belgium; 2. Diergenezondheidszorg Vlaanderen vzw, Torhout, Belgium; 3. Animal Sciences Unit, Institute of Agricultural and Fisheries Research, Melle, Belgium

Introduction
Claw lesions and lameness in sows are an important welfare concern as well as a cause of considerable economic loss for pig producers. These problems are more common in group housing than in individual housing systems1. Given that group housing for pregnant sows will become mandatory in the EU from 2013 onwards, the aim of the present study was firstly to determine the prevalence of lameness and claw lesions, and secondly to analyze type of group housing and sow related risk factors associated with lameness and claw lesions.

Materials and methods
Eight Belgian pig herds with loose housing of pregnant sows were selected. In four of them, sows were housed in pens with electronic sow feeders, the other four herds used free access stalls (table 1). At the end of gestation, sows were investigated for lameness by visual judgement of their gait (lame or not lame). Within 3 days after farrowing, possible lesions of the claws of their hind limbs were scored using a standardized scoring system2. Information about feed, housing conditions and culling (strategy) was collected as well as information about parity and breed of each sow. Logistic regression analysis was used to evaluate risk factors (type of group housing, breed, parity and lesion score) for lameness. The dataset of claw lesion scores was analyzed by using linear mixed model analyses. All analyses were performed using SPSS version 16.00. A P value <0.05 was considered significant.

Results
Of the total of 421 sows that were investigated, 9.7% was lame (min. 2.4% max. 23.1%). No significant difference for lameness was found between the two types of group housing (mean prevalence: 7.4% in free access stalls, 13% in pens with electronic sow feeders). The prevalence of lameness significantly increased with increasing parity of sows. Claw lesions were seen most frequently on the wall and heel area of the claw - almost every sow had heel lesions - and there were significantly more lesions found on lateral claws than on medial claws. Only lesions on the heel area differed significantly between both types of group housing with higher scores in free access stalls (mean total score 8.3 versus 7.7). The prevalence of side wall lesions and overgrown (dew-)claws was increased with increasing parity. Breed was not significantly associated with lameness or claw lesions.

Conclusions
Lameness and claw lesions in sows housed in group during gestation are commonly found in Belgian pig herds, and their prevalence was higher in older sows. This indicates that a balanced parity distribution of sows is not only important for productivity reasons but also from a health and welfare point of view. Further research will focus on ways to control or prevent claw lesions in group housed sows.

Kyphosis and lordosis: possible link to nutrition

Jesus Borobia Belsué
MOSSVET, Portadown, UK

Introduction
In September 2008 two 600 sow birth to bacon units reported an increase of "humpy-backs" from 6 – 8 weeks of age and lameness from 6 weeks of age during the previous 5 months. There was no response to antibiotic treatment.

Farm B re-stocked from Farm A. Both units are closed to outside pig introductions other than semen.

Both units are negative to major pathogens other than Porcine Circovirosis and Mulberry Heart Disease.

Materials and Methods
Clinical investigation consisted of a farm visit in September 2008 and every 3 months thereafter. Three live 10 week old and one 16 week old pig were submitted to the laboratory (AFBI, Omagh, Northern Ireland). A blood sample was taken from the three 10 week old pigs for biochemistry (Ca, Mg, P, CPK, GPX, vitamin E). The vertebrae and ribs of all 4 pigs were analysed for Ca, Mg, P & Ash.

Ca, P & Mg were analysed in dry sow, lactating and grower diet in an independent laboratory (Anser Laboratories, Moy, Northern Ireland).

Vitamins A, E & D3 were examined in all pig diets.

Results
Post-mortem examination of the pigs revealed lordosis from T9 to T10; T8 to T10; T5 to T12; T7 to T11 and kyphosis from T12 to T13; T12 to L1; T13 to L2; T12 to L2. Midshaft bony exostoses were found half way between the costrochondral junctions and the vertebral bodies in 3 pigs and thickened costrochondral junctions in one animal.

No significant findings detected at histological examination. Immunofluorescence negative to PCV-2. No significant bacteria isolated.

Biochemistry of the blood was within normal range parameters apart of one pig with 3.72 mM P (upper limit: 3.4) and 7956 U/l CPK (upper limit: 5000).

Biochemistry of the bones detected values ranging from 18.6 to 27.0% Ash (Normal Values: >50%) and slightly high P values ranging from 19.6 to 20.6% (Normal Values: 17 -19%).

Ca, P & Mg in dry sow, lactating and grower diet were analysed (Ca Dry Sow: 1.35%, Ca Lactating Sow: 1.12%, Ca Grower: 1.01%; P Dry Sow: 0.56%, P Lactating Sow: 0.51%, P Grower: 0.50%; Mg Dry Sow: 0.21%, Mg Lactating Sow: 0.14%, Mg Grower: 0.14%).

Vitamin A in Dry Sow diet was 15,000 mg/kg.

Vitamin E in 1st & 2nd stage diets were 124 mg/kg & 125 mg/kg, respectively.

Discussion
Kyphosis in pigs is similar to Scheuermann’s Disease in humans (Lowe, 1990). This lesion could be a factor in carcass downgrading and limit the number of replacement gilts. “Humpy-back” is described as an idiopathic lumbar kyphosis with thoracic lordosis which has no hereditable basis and is associated with management and environmental factors (Penny et al., 1984). According to Lahrmann et al., 1993, it is secondary to a number of different primary lesions located in the vertebrae, e.g. osteomyelitis, fractures, neoplasm and metabolic diseases. Other possible causes are painful conditions of the legs and back (Lahrmann, 1990), musculo-mechanical stress on the lumbar spine (Corradi et al., 2004), early onset of puberty in male pigs (Done et al., 1988) and intrauterine viral infections (Done et al., 1999). Furthermore, there are suggestions of genetic involvement (Foster, 1986; Pearson et al., 2004; Laitat et al., 2006).

Infections, genetic, managerial and structural factors were removed as causes in this case. However, metabolic diseases could not be ruled out. This statement agrees with Lahrmann et al. (1993).

The thickening of costrochondral junctions is a failure of bone mineralisation and growth plate cartilage. Ca, P and Vit. D deficiencies are the common cause (Muirhead et al., 1997; Jackson et al., 2007).

Ca:P ratio in bone ash analysed was normal. However, bone ash percentage was low. This decreased mineralisation could have been the cause of bony exostoses and Lordosis/Kyphosis. These diets had phytase incorporated in order to reduce addition of inorganic P in the diet and reducing contamination. 500 UF (Phytase Units) = 0.8 – 1g/kg of P (0.08 – 0.1%). Heat treatments of the feed, such as pelleting, could destroy phytase in feed (Pérez, 2009). All these diets were pelleted. As a consequence of this, Ca & P in the diets was re-formulated (Ca Dry Sow: 1.1%, Ca Lactating Sow: 1.12%, Ca Grower: 1.01%; P Dry Sow: 0.6 – 0.8%, P Lactating Sow: 0.7 –0.9%, P Grower: 0.6 – 0.8%).

High levels of vitamin A lead to lameness, decreased bone weight and narrow metaphyseal growth plates in the vertebrae (Taylor, 1995). Furthermore, it interferes with normal growth of epiphyseal plates leading to osteochondrosis (OCD) (Muirhead et al., 1997). OCD of vertebrae, with or without spondylosis, results in kyphosis (Hill, 1990).

European Food Safety Authority (EFSA) recommended the revision of maximum vitamin A level in feed for main food producing animals as a consequence of link to bone health problems (osteoporosis and bone fracture). The Panel proposed setting a level for fattening pigs at 1⁄2 the current amount allowed by EU Regulation (EC) No 1831/2003.

Vitamin A in sow’s diet was reduced to 8,500 mg/kg.

Vitamin E in 1st and 2nd stage was increased to 250 & 200 mg/kg, respectively.

Genetics were not changed.

Control program was successful in this case. No further cases were seen since May 2009.
Porcine Postweaning Wasting/Catabolic Syndrome (PWCS): pathological features
John Harding1 Yanyun Huang1 Henry Gauvreau2
1. University of Saskatchewan, Saskatoon, SK, Canada; 2. Warman Veterinary Services, Warman, SK, Canada

Introduction
Porcine Postweaning Wasting/Catabolic Syndrome (PWCS) is an emerging condition causing elevated nursery mortality1. Affected pigs, weaned in robust body condition, develop anorexia and most become severely emaciated and die within 3 weeks of weaning. Mortality rates wax and wane and reach 10% in peak months. The cause of PWCS is unknown, but an infectious etiology suspected. Pathogens including PRRSV, porcine circovirus 2, rotavirus, transmissible gastroenteritis virus, influenza virus, Lawsonia intracellularis, Mycoplasma hyopneumoniae, Helicobacter spp., Campylobacter spp., calicivirus and coccidia were not causally related to PWCS2 (and unpublished data). The objective of the current study was to characterize the pathologic changes in PWCS-affected pigs.

Materials and Methods
Five emaciated pigs (PWCS-E) and 3 age-matched healthy pigs (PWCS-H) from a PWCS-affected farm, and 4 healthy age-matched pigs from each of two PWCS unaffected farms (CTR1, CTR2; 8 pigs in total) were selected 2 to 3 weeks postweaning. Necropsy examinations were performed immediately after humane euthanasia. Gross and histologic lesions were assessed and multiple fresh and fixed tissues processed routinely. Morphometrics of villi lengths of duodenum, jejunum and ileum (at least 10 villi from each section) were conducted on all PWCS-E and PWCS-H pigs, 2 CTR1 and 4 CTR2 pigs. The average villi length was calculated for each tissue and pig. Potential group differences were examined using a Kruskal-Wallis H followed by a post-hoc Mann-Whitney U test with P < .05 considered significant.

Results
No gross lesions were observed in any PWCS-H, CTR1 or CTR2 pig. Of PWCS-E pigs, 4/5 had severe thymic atrophy and 3/5 had mild to moderate bronchopneumonia. Histologically, the thymic atrophy was mainly due to the reduced thickness of the cortex. Small intestinal villous atrophy was readily observed histologically in PWCS-E pigs. Mean villi lengths in duodenum, jejunum and ileum (at least 10 villi from each section) were conducted on all PWCS-E and PWCS-H pigs, 2 CTR1 and 4 CTR2 pigs. The average villi length was calculated for each tissue and pig. Potential group differences were examined using a Kruskal-Wallis H followed by a post-hoc Mann-Whitney U test with P < .05 considered significant.

Discussion
The results of this study indicate the principle lesions associated with PWCS are thymic and intestinal villous atrophy, and colitis. Villous atrophy was highly prevalent but less severe in the PWCS-H compared to the PWCS-E pigs suggesting the former were either subclinically affected, in the early stages of the disease before notable loss of condition, or villous atrophy is a predisposing risk factor for PWCS. The presence of thymic atrophy in PWCS-E pigs may be the direct consequence of the condition, or an indirect result of prolonged anorexia. The latter is supported by the absence of thymic atrophy in PWCS-H pigs and in one PWCS-E pig that was only moderately affected. Colitis may be a direct result of the disease or indirectly associated with small intestinal pathology including villous atrophy. Bronchopneumonia was not observed previously in PWCS1. Its importance cannot be ruled out but it is less likely because clinical respiratory signs (coughing, dyspnea) were not observed. Further efforts to identify the cause of PWCS are underway.

Table 1. Mean intestinal villous lengths (μm ± SD) of emaciated (PWCS-E) and age-matched healthy (PWCS-H) pigs from a PWCS-affected farm, and from age-matched pigs (CTR) from 2 unaffected farms

Porcine Postweaning Wasting/Catabolic Syndrome (PWCS): the initial diagnostic investigation

John Harding1 Yanyun Huang1 Henry Gauvreau2 Brendan O’Connor3

1. University of Saskatchewan, Saskatoon, SK, Canada; 2. Warman Veterinary Services, Warman, SK, Canada; 3. Prairie Diagnostic Services, Saskatoon, SK, Canada

Introduction
Since 2008, veterinarians have reported persistent and sometimes extensive nursery mortality associated with anorexia and weight loss in PCV2-vaccinated pigs1. We have performed a diagnostic investigation in an affected farm and have temporarily named the condition Postweaning Wasting/Catabolic Syndrome (PWCS). Evidence suggests PWCS is likely infectious. The etiology is unknown, but common porcine pathogens have been ruled out. The objective of this report is to summarize the diagnostic investigation in the PWCS-affected farm.

Clinical Presentation and Intervention:
A well-managed, high health (PRRSV, Mycoplasma hyopneumoniae negative, PCV2 positive) 100-sow farrow-finish farm experienced elevated nursery mortality since 2007 (Table 1) almost exclusively due to PWCS. Affected pigs in good body condition at weaning develop anorexia, lethargy and emaciation shortly thereafter. Most PWCS-affected pigs die within 3 weeks. Survivors grow slower than their pen-mates. Management interventions targeting ventilation, piglet comfort, diet and water quality have not reduced PWCS-losses. PCV2 piglet vaccination and all antimicrobial strategies attempted have been unsuccessful. Losses have been partially mitigated following aggressive sanitation of farrowing and nursery rooms using either strong sodium hypochlorite solution or hydrated lime.

Diagnostic Investigation
In response to the elevated mortality, live pigs or tissues from 4 pigs in poor body condition were submitted for routine diagnostics. Lesions were non-specific, the etiology was undetermined, and adjunct testing for PRRS (IHC), PCV2 (IHC), Leptospira spp. (silver staining) was negative. There was no evidence of coccidiosis. A specialized disease investigation team was recruited and more extensive diagnostics on 7 cases were undertaken. Histological examination revealed severe thymic atrophy (7/7), moderate to severe colitis (6/7), mild interstitial thickening of lung (7/7), moderate to severe lymphoplasmacytic rhinitis (4/5) and mild lymphoid depletion (4/7). Bacteria culture of various organs did not yield significant findings in 7/7 pigs. Complete blood counts in 3/3 pigs were unremarkable. Serum chemistry in 3/3 pigs was consistent with cholestasis, gastric stasis, anorexia and dehydration. Adjunct testing of appropriate tissues from selected pigs failed to conclusively identify common swine pathogens (Table 2). Feces subsequently submitted from 5 healthy suckling (1-18 day old), 5 thin and diarrheic nursery (25-35 day old), and 2 grow-finisher pigs was examined by electron microscopy (EM) to detect possible gastrointestinal pathogens. Six of 12 samples were negative. Calicivirus was observed in 4/12 (1 suckling, 3 nursery, 1 grower) samples. Rotavirus, coronavirus, and either parvovirus or enterovirus were observed in 1 nursery sample each.

Discussion and Conclusions
Major porcine pathogens have been ruled out as the cause of PWCS. Scant PCV2-positive staining with/without mild lymphoid depletion is not uncommon in commercial pigs. Failure of PCV2 vaccination to control PWCS in this farm makes PCVD unlikely. Calicivirus is highly prevalent but not reported to cause disease in commercial pigs2. Moreover, porcine enteric Calicivirus DNA2 was demonstrated in 2/3 healthy and 2/5 sick pigs subsequently submitted from the farm. Further efforts to identify the cause of PWCS are underway.

Emergence of a new type of porcine circovirus (PCV1/2a) in swine in Canada

Carl A. Gagnon; Nedzad Music; Guy Fontaine; Donald Tremblay; Josée Harel

Université de Montréal, Faculté de médecine vétérinaire, St-Hyacinthe, QC, Canada

Introduction

Between September 2008 and January 2009, three cases (FMV08-1114252, FMV08-1133505 and FMV09-1134568) were submitted to the Veterinary diagnostic service of the University of Montreal. None of the three submitted cases were related to “Porcine circovirus associated diseases” (PCVAD). Several diagnostic assays were performed including a multiplex real-time quantitative PCR assay (mrtpPCR) for the detection and differentiation of porcine circovirus (PCV) type 2a and 2b genotypes in the lung and lymph nodes(1). Odds results were obtained with the mrtpPCR assay, suggesting genomic mutations in the viral genome.

Materials and methods

To confirm the genomic nature of the three PCV positive cases, specific PCR assays were performed to detect the ORF1 of PCV1 and the ORF2 of PCV2 genes. A third PCR assay was selected to amplify both ORF1 of PCV1 and ORF2 of PCV2 genes simultaneously. The entire PCV genome was amplified by PCR that produced 2 overlapping PCR products. Both strands of the purified DNA PCR products were sequenced(2). Virus isolation was conducted using the PK15A cell line as previously described(2) and an immunofluorescence assay (IFA) was performed to confirm the presence of PCV using an anti-PCV2 pig serum as described previously(3).

Results

All the obtained results converge to demonstrate the emergence of a new PCV. In addition, infectious viruses were isolated from 2 out of the 3 submitted cases and expression of the viral Cap protein encoded by the ORF2 gene was confirmed by IFA in PCV infected cells. The results indicate the presence of both PCV1 ORF1 and PCV2 ORF2 genes in the PCR products. To confirm the genomic nature of the new PCV, its viral genome was sequenced. The ORF1 was more genomically related to the ORF1 of PCV1 with a nucleotide (nt) identity of 99.7% compared to ORF1 of PCV2a and 2b with nt identities of 82.5% and 82.8%, respectively. On the other hand, the ORF2 was more genomically related to the ORF2 of PCV2a with a nt identity of 98.5% compared to ORF2 of PCV1 and PCV2b with nt identities of 66.7% and 92.5%, respectively. The nt identity of the entire viral genome of the new PCV was 86.4%, 88.7% and 86.5% compared to PCV1, PCV2a and PCV2b, respectively.

Discussion

It is proposed to name this new PCV by taking into account previously described nomenclature(4) and by indicating the origin of the ORF1 at first and the origin of the ORF2 in second. Consequently, the name proposed for this new PCV is PCV1/2a. The prevalence of PCV1/2a seems to be very low in Quebec, Canada (2.5% of PCV positive cases), and its origin is now in debate. Two hypotheses could explain the emergence of the PCV1/2a in swine: (a) the natural genetic recombination between PCV1 and PCV2a in infected animals; or (b) a human made virus originating from a chimeric killed vaccine strain. Still, even if PCV1 and PCV2a are found in low amount in Quebec swine, the genetic recombination between PCV1 and PCV2a is a possible explanation. In early 2008, a new vaccine was commercially available in Canada (Suvaxyn® PCV2). This vaccine uses a chimeric killed or inactivated PCV(5, 6). This chimeric PCV genome is composed of the ORF1 of PCV1 and the ORF2 of PCV2a. The nt sequences of the PCV1/2a strains were found to possess 5 to 6 nt differences compared to the chimeric PCV vaccine strain with a nt identity of 99.6–99.7% and all nt differences were located in ORF1.

Mutations of the PCV-2 capsid motif, specific of each PCV-2 genogroup, attenuate virulence in vivo

Beatrice Grasland; Aude Allemandou; Anne-Cécile Nignol; Nicolas Rose; François Madec; André Kéranflec'h; Roland Cariolet; André Jestin
AFSSA, Ploufragan, France

Introduction

The porcine circovirus of type 2 (PCV-2) is a non-enveloped, small single-stranded DNA virus. It is the causal agent of post-weaning multisystemic wasting syndrome (PMWS) and is involved in “porcine circovirus diseases”. After the re-emergence of PMWS in North America in 2005, the presence of new circulating PCV-2 isolates belonging to PCV-2b genogroup raises the assumption that this genogroup is more virulent than the PCV-2a one. Viruses of each genogroup contain a distinct motif of amino acid in the capsid protein (amino acids 86 to 91), the unique component of the virus outer structure. In this study, we investigate if PCV-2 genetic variation is responsible of virulence and check if the capsid motif contributes to this difference.

Materials and Methods

Two infectious clones representative of both PCV-2 genogroups were constructed (PCV-2a and PCV-2b clones). Two mutants were generated by directed mutagenesis. The PCV-2a (PCV-2b motif) mutant has the capsid motif of PCV2b genogroup into the backbone of PCV-2a and the PCV-2b (PCV-2a motif) mutant, the capsid motif of PCV-2a genogroup in the backbone of PCV-2b. The infectious clones and the mutants were characterized in vitro. Then their virulence was assessed by an experimental trial on PCV-2 free SPF (Specific pathogen free) piglets. Forty 6-weeks-old SPF piglets were divided into six groups as shown on Table 1. The experiment ended between 35 and 40 dpi.

Results

Both parental clones and both mutants were infectious in vitro. The results of the experimental trial are summarized in Table 2. All the controls were negative for the presence of PCV-2.

Discussion and Conclusion

In vitro, both PCV-2 parental clones and both capsid motif mutants were infectious. In vivo: (i) The PCV-2b strain induced an earlier seroconversion and a higher genomic load in serum than the PCV-2a strain. The PCV-2b strain was more virulent than the PCV-2a one. (ii) The PCV-2b (PCV-a motif) mutant showed similar features to the PCV-2a parental strain with a moderate virulence attenuation. (iii) The PCV-2a (PCV-2b motif) mutant was highly attenuated.

In conclusion, these results showed that the PCV-2 capsid motif specific of genogroup is a molecular marker of virulence of PCV-2.

Tissue samples were collected at necropsy. The PCV-2 seroconversion was monitored using ELISA test. Quantification of viral genomes and infectious particles were respectively assessed by quantitative PCR and by IPMA2.
Cell-dependent susceptibility to Porcine circovirus ORF3-induced apoptosis

Mark Chaiyakul1 Karolynn Hsu1 Avril Hatherell1 Rkia Dardari1 Frank Marshall1, 2 Markus Czub1

1. University of Calgary, Calgary, AB, Canada; 2. Swine Health Services, Calgary, AB, Canada

Introduction

Porcine circovirus associated disease (PCVAD) has caused considerable economic impact worldwide since its first description on a Canadian pig farm in the 1990s. PCVAD, a wasting and immunosuppressive disease in post-weaned pigs, is caused by Porcine circovirus type 2 (PCV2). Despite the availability of effective vaccines, little is known about the molecular pathogenesis of the disease. Belonging to the Circoviridae family, PCV2 and PCV1 are closely-related viruses with a 1.7kb, ambisensed and circular ssDNA genome 1. While PCV2 is pathogenic, PCV1 is not. Investigating the differences in the genomic composition of these viruses will provide clues to the molecular pathogenesis of PCVAD. ORF3 is a good candidate as a determinant of PCV pathogenicity because PCV1 and PCV2 ORF3 share only 60.6% amino acid (aa) sequence identity in the translated region. In addition, a consistent single nucleotide (nt) substitution in the PCV2ORF3 coding region resulted in a stop codon, leading to PCV2ORF3 that is half the length of PCV1ORF3 (104aa versus 206aa). PCV2ORF3 was shown to induce apoptosis and a mutant virus devoid of ORF3 expression did not induce apoptosis in Cos-7 and PK-15 cell lines 2. Abrogation of ORF3 expression appeared to reduce PCV2 virulence in a specific-pathogen-free (SPF) piglet model 3. Due to the differences between PCV1 and PCV2 ORF3 and what is known about PCV2ORF3, it is hypothesized that ORF3 determines the pathogenicity of PCV. Thus, the objective of this study is to compare and contrast the pro-apoptotic capability of PCV1 and PCV2 ORF3.

Materials and Methods

PCV1 and PCV2 ORF3 genes were cloned into mammalian expression peGFP-C1 vector to create fusion proteins with eGFP at the N'terminus. Flow cytometry was used to assess cell viability and apoptosis. Immunoblot was used to detect protein expression and PARP cleavage associated with apoptosis. Z-Asp-CH2-DCB was used as a caspase inhibitor. Three cell lines were used in this study: human epithelial 293T, porcine kidney epithelial PK-15 and porcine primary kidney (PPK) cells. Statistical analysis was performed, using ANOVA and Tukey’s multiple comparison tests with p<0.05 considered as statistically significant.

Results and Discussion

In all three cell lines, eGFPPCV1ORF3 significantly induced higher cell death. Meanwhile, eGFPPCV2ORF3 significantly induced higher cell death only in PK-15 cells. It was also consistently observed that eGFPPCV1ORF3 was a more potent inducer of cell death than eGFPPCV2ORF3. During apoptosis, a programmed cell death process, phosphatidylserine molecules become externalized to the outer surface of the cell membrane. This externalization is important for macrophage recognition, phagocytosis and clearance of apoptotic cells without causing an inflammatory response 4. In addition, caspases become activated and cleave PARP molecules, DNA repair enzymes, leading to apoptosis 5. In this study, significantly higher percentage of phosphatidylserine externalization as well as the presence of a cleaved PARP fragment was observed in cells transfected with eGFPPCV1ORF3. Moreover, addition of increasing concentration of a caspase inhibitor reduced the level of cell death induced by eGFPPCV1ORF3. Hence, cell death induced by PCV1ORF3 occurs via a caspase-dependent apoptotic pathway, similar to what was reported for PCV2ORF3 5.

While PCV1 does not cause disease, PCV2 causes PCVAD. Their distinctly different ORF3 protein was hypothesized to be the factor for their different pathogenicity. Although both PCV1 and PCV2 ORF3 can induce cell death via apoptosis, it is not completely surprising because they share 60.6% aa sequence identity. However, PCV1ORF3 appears more potent than PCV2ORF3 in inducing cell death despite the lack of cytopathic effects in cells infected with PCV1 6. It is speculated then that PCV1ORF3 expression is absent or is tightly regulated by other viral protein(s), incapacitating PCV1 from causing PCVAD in pigs. Different cell death profiles seen with different cell lines and even within the same cell population suggest a cellular-dependent response to ORF3-induced apoptosis.

Introduction
PCV2 may cause reproductive failure in the field (1), and therefore the effects of experimental PCV2 infections, mainly PCV2a, on reproduction have been studied extensively (2). Recent field observations on the occurrence of PMWS suggest that PCV2b may be more pathogenic than PCV2a (3). The aims of the present study were to investigate if there are differences in viral replication and clinical outcome between PCV2a and PCV2b infections in porcine foetuses.

Materials and Methods
Four conventional sows were submitted to laparotomy at 55 days of gestation. In each of four sows, three foetuses were inoculated with PCV2 and one foetus was mock inoculated. Inoculations were performed by transuterine injection with 10^4.3 TCID_50 of PCV2 into the peritoneal and amniotic cavities of the foetuses (4). In the first sow, two foetuses were inoculated with PCV2a strain Stoon-1010 and one with PCV2a strain 1121. In the second sow, two foetuses were inoculated with PCV2b strain 48285 and one with PCV2b strain 1147. In the third sow, one foetus was inoculated with PCV2a strain Stoon-1010, one with PCV2a strain 1121 and one with PCV2b strain 1147. In the fourth sow, one foetus was inoculated with PCV2a strain Stoon-1010, one with PCV2a strain 1121 and one with PCV2b strain 1147. In the fourth sow, one foetus was inoculated with PCV2a strain 1121, one with PCV2b strain 48285 and one with PCV2b strain 1147. Twenty-one days post inoculation (dpi), the sows were euthanized and all foetuses were collected. All foetuses were examined for gross lesions and tissue samples from various organs were taken for titration on PK-15 cells and for localization of viral antigens. In order to verify that the foetuses had been inoculated with the specific PCV2 strain, the capsid gene was amplified using heart and/or lung tissue from infected foetuses followed by sequencing. Abdominal fluids were tested for the presence of PCV2-specific antibodies by IPMA.

Results
All PCV2-inoculated foetuses, except one PCV2 (1147)-inoculated foetus, were oedematous and had distended abdomens (Fig.1.a). Haemorrhages and congestion in internal organs and liver enlargement were observed (Fig.1.b). One PCV2 (1147)-inoculated foetus had a normal external appearance, but liver enlargement and generalized lymph node enlargement were observed. Gross pathological lesions were not observed in mock-inoculated and non-inoculated foetuses. High PCV2 titres (> 10^4.3 TCID_50 / g tissue) were found in all PCV2-inoculated foetuses, especially in the heart, spleen and liver. High numbers of PCV2-infected cells (> 1,000 infected cells / 10 mm^2 tissue) were observed in the heart (Fig.1.c). PCR and DNA sequencing of the capsid gene recovered pure PCV2a and pure PCV2b sequences from PCV2a- and PCV2b-inoculated foetuses, respectively. No evidence for mixed samples (e.g. containing more than one PCV2 strain) was seen. All adjacent foetuses of PCV2-inoculated foetuses were negative in PCR assays with the exception of one adjacent foetus of Stoon-1010-inoculated foetus, which was positive in PCR assays and a pure Stoon-1010 sequence was obtained. All mock-inoculated foetuses and their adjacent foetuses were negative in PCR assays. Three PCV2-inoculated foetuses had a low anti-PCV2 Ab titre of 10 to 40.

Conclusions
From this model, it can be concluded that different PCV2 strains of both genotypes induced similar gross pathological lesions and replicated to similar high titres in different foetal organs.

Singular PCV2a or PCV2b infection results in apoptosis of hepatocytes in clinically affected gnotobiotic pigs

Avanti Sinha¹ Kelly Lager² Chong Wang¹ Tanja Opriessnig¹

1. Iowa State University, Ames, IA, USA; 2. National Animal Disease Center, USDA-ARS, Ames, IA, USA

Introduction

Systemic infection with porcine circovirus type 2 (PCV2) is often clinically associated with respiratory signs, failure to thrive and diarrhea (1). Currently, PCV2 can be further subdivided into two main genotypes, PCV2a and PCV2b which under experimental conditions result in very similar macroscopic and microscopic lesions in conventional pigs (2). Viruses are often associated with apoptosis of host cells but there are conflicting results of the role of PCV2 in this pathway (3,4). The objective of the present study was to assess the association of PCV2 antigen with apoptosis in liver tissues from gnotobiotic pigs experimentally inoculated with PCV2.

Materials and Methods

Forty-eight gnotobiotic pigs were separated into five groups based on inoculation status and development of clinical disease: (1) Non-inoculated, healthy (n=4), (2) PCV2a, healthy (n=10), (3) PCV2a, clinically affected (n=6), (4) PCV2b, healthy, (n=13) and (5) PCV2b, clinically affected (n=15). Formalin-fixed and paraffin-embedded sections of liver from all pigs were subjected to a CCaspase-3 (CCasp-3) immunohistochemistry (IHC) assay, a TUNEL assay, and a PCV2 IHC (5). For each slide, 10 random 40x fields were scored for presence of characteristic staining. The scoring scheme used ranged from 0 (no signal) to 3 (high degree of staining in the majority of the cells and fields examined). All sections of liver tissue were also scored for the presence of the following microscopic lesions: Presence of neutrophils and presence and degree of necrosis, degeneration and inflammation. The sum scores were used for analysis. The following nine comparisons were made using the Fisher's Exact Test for dependency between the categorical variables in paired situations: (1) TUNEL score versus disease status, (2) CCaspase-3 score versus disease status, (3) PCV2 IHC score versus disease status, (4) PCV2 IHC versus TUNEL score, (5) PCV2 IHC versus CCaspase-3 score, (6) Lesion sum versus CCaspase-3 score, (7) Lesion sum versus TUNEL score, (8) Lesion sum versus PCV IHC and (9) Lesion sum versus disease status. A statistically significant difference was defined as a P-value of less than 0.05.

Results

Sixteen of 21 (76.2%) clinically affected PCV2-inoculated pigs and 11/27 (40.7%) clinically unaffected PCV2 inoculated pigs had moderate-to-severe hepatic lesions characterized by severe diffuse lymphohistiocytic hepatitis associated with degeneration and loss of hepatocytes. Specific CCasp-3 staining and TUNEL labeling was detected in the nuclei of hepatocytes in PCV2a and PCV2b infected pigs with significantly (P < 0.05) higher levels of apoptotic cells in clinically affected pigs. Clinically affected pigs also had significantly (P < 0.05) higher levels of PCV2 IHC stain compared to non-affected pigs. The lesion sum score was also significant in the clinically affected pigs (P < 0.05).

Discussion

This experiment was conducted in order to delineate the role of PCV2a and PCV2b genotypes in apoptosis of hepatic cells in gnotobiotic pigs. According to the results obtained, the gnotobiotic pigs when experimentally inoculated with PCV2a or PCV2b developed clinical disease which was associated with severe hepatitis, abundant amount of PCV2 antigen in inflammatory cells and hepatocytes, and apoptosis occurred in hepatocyte-like cells detectable by CCasp3 stains and the TUNEL assay. The pig experiments were of limited duration and it is not known if the 11/27 infected, but healthy pigs that had hepatic lesions and minimal apoptosis, would manifest clinical disease with a significant increase in CCasp4 and TUNEL stained cells. In conclusion, PCV2 infection regardless of genotype resulted in apoptosis of hepatocytes in clinically affected gnotobiotic pigs and apoptosis appears to be one pathway by which PCV2 induces disease.

High prevalence of porcine circovirus viremia in newborn piglets in five clinically normal swine breeding herds in North America

Huigang Shen; Darin Madson; Tanja Opriessnig
Iowa State University, Ames, IA, USA

Introduction
Porcine circovirus type 2 (PCV2) has been associated with a number of disease manifestations in pigs including reproductive failure (1). It has been demonstrated that PCV2 can be transmitted horizontally and vertically; however, it is unclear to what extent vertical PCV2 transmission occurs under field conditions especially in farms subclinically infected with PCV2. The objective of the current study was to evaluate the rate of intrauterine PCV2 infection in healthy piglets born on commercial farms in North America and to further characterize dam viremia, dam antibody levels, and piglet antibody levels.

Materials and Methods
Five commercial breeding herds were selected to participate in this study, with one farm located in Mexico (Farm A) and the remaining four farms located in the U.S. (Farms B-E). A total of 128 clinically healthy sows and 504 live-born normal appearing piglets born to the dams were randomly selected at a rate of three to four piglets per litter. Serum and colostrum samples of the dams were collected immediately after parturition and before suckling. Piglet serum samples were collected after birth and prior to colostrum uptake. All samples were tested for the presence of anti-PCV2 IgG antibodies using a PCV2 ORF2-based ELISA (2) and for the presence and amount of PCV2a and PCV2b DNA by a multiplex differential real-time PCR (3).

Results
All (128/128) dams and 21.2% (107/504) of the piglets were positive for anti-PCV2 IgG antibody. The overall PCV2 DNA prevalence was 66.4% (85/128) in dams and 43.1% (217/504) in piglets. In general, more dams and piglets were positive for PCV2b (71.8 and 75.1%, respectively) compared to PCV2a (12.9 and 15.1%, respectively). Concurrent PCV2a/b infection was detected in 13/128 dams and in 21/504 piglets on all five farms. Piglets born to dams with higher PCV2 DNA loads had increased frequency of PCV2 viremia and elevated PCV2 DNA copy numbers in serum. Higher amounts of PCV2 DNA were detected in PCV2 seronegative piglets compared to seropositive piglets indicating that some level of protective humoral immunity developed in utero.

Discussion
Vertical transmission is an important means of PCV2 transmission in clinically normal herds. In the selected farms, PCV2b was more prevalent than PCV2a in piglets, and virus transmission through breeding herds may result in continuous PCV2b exposure to grow-finish herds. Dam viremia was associated with the frequency and level of PCV2 infection in the piglets. The piglet anti-PCV2 antibody could alleviate PCV2 infection, indicating humoral immune responses occurring in the fetuses may play a protective role. Dam PCV2 antibodies did not necessarily alleviate PCV2 infection in fetuses.

Assessment and quantification of Post-weaning Multi-systemic Wasting Syndrome (PMWS) severity at farm level.

Pablo Alarcon; Martina Velasova; Dirk Werling; Katharina D.C. Stärk; Yu-Mei Chang; Amanda Nevel; Dirk U. Pfeiffer; Barbara Wieland
Royal Veterinary College, London, UK

Introduction
Post-weaning Multi-systemic Wasting Syndrome (PMWS) causes major economic losses in the English pig industry (1). Severity of clinical signs and economic impact vary considerably between affected farms. Appropriate diagnosis and determination of PMWS severity on the farm are crucial for informing decision about control measures. The present study aimed to define and quantify severity levels of PMWS observed on farms using a novel approach based on morbidity, mortality and presence of porcine circovirus type 2 (PCV2).

Materials and Methods
In 2008-2009, 147 pig farms across England and not vaccinating against PCV2 were enrolled in a cross-sectional study, and retrospective data on PMWS morbidity and production indicators were collected. Classical data collection methods were combined with tools used in participatory epidemiology. In addition, on each farm serum samples from 20 pigs of four different age groups were collected and tested for PCV2 antigen and antibodies against other important pathogens (2). After correcting for misclassification, factor analysis was used to generate a small number of factor variables representing biological meaningful aspects of variation among morbidity variables and these were then together with relevant risk factors variables subjected to principal component analysis to derive an algorithm for PMWS severity.

Results
Evidence of PCV2 presence was found on all farms enrolled in the study. Factor analysis performed on morbidity data resulted in two factors: Morbidity Factor 1 (MF1) representing mainly weaner and grower morbidity, and Morbidity Factor 2 (MF2) which mainly reflect variation in finisher morbidity. Principal component analysis was performed on the identified morbidity factors, all production variables and laboratory results. This resulted in the extraction of one component representing variation in MF1, post-weaning mortality and percentage of PCV2 PCR positive animals. The extracted component accounted for 60% of the total variance of these three variables. The distribution of the resulting values for each variable is shown in Figure 1. The scores from the resulting component were normalised within a value range from 0 to 10. Cut-offs values were identified and farms were classified into: non or slightly affected farms (24%) with a score <4, highly affected farms (23%) with a score >6.5 and, the majority of the farms (53%), considered to be moderately affected farms with middle scores (4 – 6.5).

Discussion
The factor analysis indicated a clustered pattern of PMWS morbidity, with farms either having high morbidity in weaners/growers or mainly in finishers. The principal component measures PMWS severity on the farms and establishes weaners and growers as the main age groups affected by the disease. The distribution in the three severity categories is believed to reflect the situation of PMWS in the English pig population before the onset of PCV2 vaccination and will be used in further research to investigate risk factors associated with different PMWS severity levels and to measure PCV2 vaccination efficacy at each of these. The outcomes will then inform economic models for the development of cost-effective disease control measures for PMWS.

Effects of supplementation of omega-3 fatty acids to gilts on subsequent reproductive performance and growth performance of their litters

Miranda N. Smit, Jennifer L. Patterson, Steve K. Webel, Rose A. O’Donoghue, George R. Foxcroft

1. University of Alberta, Faculty of Agricultural, Life and Environmental Sciences, Edmonton, AB, Canada; 2. JBS United Inc., Sheridan, IN, USA

Introduction
Dietary supplementation of omega-3 polyunsaturated fatty acids (n-3 PUFAs) during gestation and/or lactation is reported to increase litter size in pigs (Spencer et al., 2004; Webel et al., 2003) and is believed to be beneficial for reproductive performance in sows (Webel et al., 2004). However, results are inconsistent. This study re-assessed the effects of n-3 PUFA supplementation to gilts during late gestation and lactation on the subsequent reproductive performance and the growth performance of their litters.

Material and Methods
At day 60 (d60) of gestation 117 pregnant gilts were pair-matched by weight and litter of origin, and allocated to one of two treatments:

• Control gilts (CON, N=56) fed standard gestation and lactation diets, or
• Treated gilts (FP10, N=61) fed the standard diets supplemented with 84 g/d of Sow Fat Pack 10 (JBS United, Sheridan, IN), a fish-oil based supplement rich in omega-3 fatty acids.

Gilts were fed CON or FP10 diets from d60 of first gestation, through a 21-d lactation, and until euthanasia at d30 of their second gestation. All sows were feed restricted during the last week of lactation (fed 60% of expected feed intake).

Sow body weight, and backfat and loin depth, were measured at d60 of gestation, d1 of lactation, 7 days before weaning, at weaning, after last breeding and at d30 of second gestation. Net energy balance was calculated as reported by Vinsky et al. (2006). Individual piglet weights were measured on d1 of lactation, 7 days before weaning and at weaning in all litters, and at the end of the nursery phase in a subset of litters.

After weaning, sows were heat checked twice daily and bred by AI using semen from the same boars for both treatments. Sows were euthanized on-site at d30 of gestation, reproductive tracts were recovered, and the number, crown-rump length and weight of embryos, placental fluid volume, ovulation rate (CL number) and CL weight were recorded, and embryonic survival was calculated.

Results
Net energy balance during lactation and sow body composition were not different between CON and FP10 sows. The total number of piglets born (13.0 ± 0.4 vs. 12.9 ± 0.3) and average piglet birth weight per litter (1.32 ± 0.03 vs. 1.34 ± 0.03 kg) were also not different between treatments. Repeated measures analysis for average piglet weight per litter showed that litters from FP10 sows compared to litters from CON sows were heavier at weaning (5.57 ± 0.10 vs. 5.88 ± 0.10 kg, respectively; P<0.05) and had improved overall growth performance to the end of the nursery stage (P<0.05). Weaning-to-estrus interval, ovulation rate, and embryo weight/crown-rump length and survival to d30, did not differ between treatments. However, average weight of the CL’s at d30 was higher in FP10 compared to CON sows (378.1 ± 6.9 vs. 341.0 ± 7.1 mg, respectively; P<0.001).

Discussion
Supplementing gilt diets with omega-3 fatty acids during late gestation and lactation positively impacted litter weight after birth, but did not affect the most common reproductive characteristics in sows after rebreeding.

Evaluation of an aluminosilicate to decrease the toxic effects of Aflatoxin B1 in swine

Juan C. Medina¹ Jose A. Fierro¹ Ruben Perez-Franco¹ Elizabeth Rodriguez² Leticia Duran¹ Mariana Altamirano¹ Veronica Moreno²
1. NUTEK S.A de C.V., Tehuacan, PUE, Mexico; 2. Investigación Aplicada S.A. de C.V., Tehuacan, PUE, Mexico

Background
Aflatoxin B1 (AFB1) is a mycotoxin with carcinogenic, teratogenic, mutagenic and immunosuppressant properties; it is produced by several species of the Aspergillus genus (flavus, parasiticus, nomiusy pseudotamarii). Its target organ is the liver (hepatotoxic). The effects of aflatoxins (AFs) in swine depend on the age, concentration in feed, and exposure periods. Problems related to contamination with these toxins have been reported in all stages of swine lifespan. Several aluminosilicates have been reported to reduce the effects of aflatoxins in swine diets (Ramos and Hernandez, 1997).

Aim
To evaluate the efficiency of a mycotoxin binder to decrease the toxic effects of a diet contaminated with 680 μg/kg (ppb) of AFB1 in swine balanced feeds.

Materials and Methods
18 swine were used, weaned at 21 days of age divided into 3 groups with 6 repetitions. They were housed in individual corrals with swine use floor. A week of conditioning was considered. Commercial feeds were used, they were proven to be free of contamination with other mycotoxins (AFs, fumonisin B1, Ochratoxin A, DON and T2). The treatments were: 1. Negative control diet, 2. Positive control diet with 680 ppb of AFB1, 3. Challenge diet with adsorbent: 5 kg/t + 680 ppb of AFB1. The experiment took 21 days. Swine were weighed at the beginning of the experiment and individual weights were recorded weekly. Feed conversion was calculated weekly. At the end of the experiment all swine were sacrificed; during the necropsy, samples of tonsils, lungs, livers, gallbladders, kidneys, spleens and mesenteric lymph nodes. All organs were previously weighed. Samples were submitted to histopathology studies. Fat, iron, vitamin A and AFM1 were quantified in livers. Biochemical parameters were analyzed in sera (aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, gamma-glutamyltransferase (GGT), glucose, local proteins, albumen, creatinine, triglycerides, cholesterol, urea, uric acid) and vitamin A. The information obtained was analyzed with the Tukey test using the SYSTAT statistical software; the significance value was based on a probability of 0.05.

Results and Discussion
Significant statistical differences were observed in animal weight gain, total weight, feed consumption, alkaline phosphatase, GGT and total proteins. In animals in which damages produced by aflatoxins were observed, a recovery was obtained from the challenge diet that included the adsorbent. The decrease in weight gain of the positive control group was of 31.2% compared to the negative control group. 52.3% of the weight gain difference was recovered in the challenge group. The rest of the evaluated parameters only showed numeric differences. The histopathological analysis showed the effects of consuming aflatoxins in livers and kidneys.

Conclusion
AFB1 at the concentrations used in the experiment affected animals. The increase of the concentration of alkaline phosphatase and GGT enzymes indicate the effects of AFB1 in swine. The decrease of these enzymes in the group given a diet with adsorbent is another proof of the protection afforded by the adsorbent. Adding mycotoxin adsorbents in the diets of animals exposed to contamination with aflatoxins diminished economic losses attributable to these toxins, especially in large productive facilities.
Effect of energy intake during gestation on performance and blood parameters of primiparous sows

Octávio H. Eckhardt1 Felipe C. Horta1 Larissa J. Parazzi1 Esther R. Afonso1 Simone M. Martins1 Carolina I. Silva1 José E. Junior2 Francisco P. Rennó2 Aníbal S. Moretti1
1. Laboratory of Swine Research, University of Sao Paulo, Depto. Nutrição e Produção Animal (VNP), Pirassununga, SP, Brazil; 2. Laboratory of Biochemistry and Animal Physiology, University of Sao Paulo, Depto. Nutrição e Produção Animal (VNP), Pirassununga, SP, Brazil

Introduction
The relationship between productivity and metabolic status, especially in gilts, is of great interest. Greater energy intakes during late gestation have been linked to lower lactational feed intake, resulting in catabolism and a poorer reproductive outcome in the next parity1,2,3. The aim of the study was to investigate the effects of energy intake in primiparous sows’ performance and metabolic state.

Materials and Methods
Twenty three hybrid gilts, with 75 days of gestation, were fed according to 2 treatments until farrowing: (P; n=12) 2,9kg of a pre-lactation diet (3203 kcalME/kg, 17,25%CP),and (G) 2,5kg gestation diet (2930 kcalEM/kg, 16,43%CP). Gilts were weighted at 75 days of gestation, 3 days before farrowing, at farrowing, and weekly during lactation until weaning. Animals were fed to appetite during lactation. Blood collections were made during gestation (days 82, 89, 96 and 103), at farrowing, lactation (days 7 and 14) and weaning, to evaluate HDL, LDL and VLDL cholesterol, triglyceride (TGL), and non-esterified fatty acids (NEFA) (Laborlab®/Randox® kits, SBA200 Celm® analyzer/Asys Expert Plus microplate reader). In a random design the performance variables and blood parameters were analysed with the PROC GLM and MIXED of SAS4, respectively.

Results
Daily weight gain from d75 until farrowing was higher for treatment P (Table 1). Energy intake during late gestation did not influence lactational feed intake or weights. Although there was not significant difference regarding the animal’s weights during lactation, 3 days before farrowing, at farrowing, and weekly during lactation until weaning. Animals were fed to appetite during lactation. Blood collections were made during gestation (days 82, 89, 96 and 103), at farrowing, lactation (days 7 and 14) and weaning, to evaluate HDL, LDL and VLDL cholesterol, triglyceride (TGL), and non-esterified fatty acids (NEFA) (Laborlab®/Randox® kits, SBA200 Celm® analyzer/Asys Expert Plus microplate reader). In a random design the performance variables and blood parameters were analysed with the PROC GLM and MIXED of SAS4, respectively.

Discussion
Unlike other reports1, higher gestational energy intake did not influence fed intake and weight during lactation. HDL and LDL levels remained higher for P during gestation, as a result of a higher energy intake and thus a numerically higher TGL liver production, requiring transport through lipoproteins. Higher TGL concentrations for G during lactation, as a result of high consumption, led to higher VLDL levels for transport from liver and HDL for reverse transport to that organ. Higher NEFA concentration for P is due to a peak during parturition, suggesting a higher response to lipolytic stimuli in heavier animals. In conclusion, blood parameters reflected the higher energy intake during gestation for treatment P, and despite this treatment lost more weight during lactation, this fact did not affected the metabolic state of the females.

Effects of feeding oregano essential oil to sows on performance of her offspring from weaning through market

Claudia Ariza-Nieto2, 3 Roger D. Walker2 Martha A. Mellencamp1 Samuel K. Baidoo2
1. Ralco Nutrition, Inc., Marshall, MN, USA; 2. Southern Research and Outreach Center, University of Minnesota, Waseca, MN, USA; 3. CORPOICA, Bogota, Colombia

Introduction
It has long been acknowledged that some plant essential oils exhibit diverse functional activities. Oregano essential oil (OEO) has been shown to possess anti-bacterial, anti-fungal, and anti-oxidant activities (1). Analysis of the chemical components of OEO has shown that it contains high levels of carvacrol and thymol. The phenolic nature of these two compounds is responsible for the potent activities associated with OEO. Results from several studies have shown that OEO supplementation positively influences sow reproduction and litter health (2, 3). In this study, we investigated the effects of feeding OEO to sows on performance and carcass characteristics of her offspring.

Materials and Methods
This experiment was carried out at the University of Minnesota Southern Research and Outreach Center. A total of 384 early weaned piglets (d19) from sows fed control (corn-soy) or OEO (control+250 ppm OEO, Ralco Nutrition, Inc., Marshall, MN) diets during lactation and gestation were randomly assigned to 48 pens. Each pen was randomly assigned to one of four dietary treatments: control, antibiotic (Mecadox® 10kg/ton phase 1 and 2), OEO (1000 ppm phase 1 and 2, 500 ppm phase 3, 250 ppm phase 4 and 5) and antibiotic+OEO. Pigs were weighed at weaning (19d), phase 1 (33d), phase 2 (54d), phase 3 (89d), phase 4 (131d) and phase 5 (152 d). Twenty-seven pigs per treatment were randomly selected for collection of carcass data. Pigs were shipped to a commercial abattoir for slaughter at the end of phase 5. Standard carcass measurements were collected, including carcass weight, carcass yield, fat depth, loin depth, lean percentage, carcass premium score and carcass value.

Results
Analysis of variance showed that sow treatment significantly affected ADG. At the end of phase 1, pigs from OEO-fed sows grew faster than controls (175 v. 153 g/d). When measured over the entire wean-to-finish period, pigs from OEO-sows grew faster than pigs from control sows (817 v. 789 g/d) and ate more feed (20g/d) compared to pigs without supplementation. Pig treatment effect was significant for OEO. Supplementation of OEO in pig diets showed an increase in ADG (20g/d) compared to pigs without supplementation.

Dietary supplementation with OEO to sows significantly increased body weight of offspring at slaughter (116 v. 112.6 kg) (Table 1). Sow treatment effects were observed for several carcass traits. There was no pig treatment effect observed for body weight or carcass traits, except for a sow treatment by pig treatment interaction for carcass premium (grade index). Carcass value showed that offspring from OEO-sows earned an additional $4.90 when compared with pigs from control sows.

Discussion
In this study, administration of OEO to sows significantly improved her offspring's post-weaning growth and overall carcass quality and value. The effect of OEO in sow diets was first apparent in the higher litter weaning weights compared with control offspring. OEO-sows had better quality colostrum (more IgG and lymphocytes) than control sows, and this may have contributed to improved weaning weights (2). Study of post-weaning performance showed that the offspring of OEO-sows gained more weight during the first two weeks post-weaning than controls. Pig performance following weaning is a known predictor of subsequent performance. The underlying mechanism responsible for improved post-weaning performance seems likely related to gut structure. OEO supplementation was shown to reduce the negative morphological changes that occur in the small intestine during the post-weaning period (4). Feeding OEO in sow gestation and lactation diets supports nutritional programs designed to increase post-weaning pig performance and subsequent growth through slaughter. Pigs from OEO-fed sows showed clear benefits to the producer in higher carcass weight, greater loin depth, improved premium score and additional value.

**Introduction and Objectives**

The exogenous enzyme use is an alternative to increase ingredients digestibility and interest is growing in the use of enzymes to improve animal performance. One of the responses to dietary changes at weaning is the modification of the epithelium structure\(^1\). Absorption in the small intestine depends on the villus-crypt relation. The objective of the present study was to investigate the effect of multi-enzyme preparations in the growth performance and jejunum morphology in weaned pigs fed a wheat-barley diet.

**Material and Methods**

269 pigs (Landrace x Large White x Pietrain) were assigned at weaning (28 days old) to one of three treatment diets (16 pen per treatment) during 14 days: Control without enzymes; 0.25 g per kg of Hostazym\(^{®}\) suis 2000; and 0.50 g per kg of a commercial Multi-Enzyme Preparation (MEP). Individual Bodyweight (BW) was measured on days 0, 7 and 14 and Average Daily Gain (ADG), Average Daily Feed Intake (ADFI) and Gain to Feed (G:F) were calculated during first week and overall study. Two pigs per treatment were slaughtered on days 7 and 14 to collect intestinal jejunum samples, from the proximal (PJ) and distal portion (DJ), to measure Villus Height (VH) and Depth of Crypt (CD).

Data were analyzed with an ANOVA test. Pen was the experimental unit to productive variables and pig to morphological ones, the pig error term was used to perform statistical tests.

**Results and Discussion**

In pigs fed diets containing Hostazym\(^{®}\), ADG was 45 g/day higher (p<0.01) during first week and 49 g/day higher (p<0.05) on overall compared with pigs fed the Control diet. These higher ADG changes conduces Hostazym\(^{®}\) pigs to had significantly higher BW at days 7 (p<0.01) and 14 (p<0.05). There were no differences in productive performance between MEP and CONTROL diets. Compared with MEP treatment, diet containing Hostazym\(^{®}\) tended to had higher ADG during first week (+26 g/day, p=0.09) and BW on day 7 (184 g, p=0.09) but these statistical tendency disappeared in the overall. There were no differences (p>0.05) in ADFI and G:F between groups.

Hostazym\(^{®}\) tended to have higher VH compared with Control on day 7 in proximal jejunum (p=0.082). On day 14, Hostazym\(^{®}\) diet had longer villus than Control diet and MEP diet in proximal jejunum and in distal jejunum (p<0.05). Depth of Crypt was not affected (p>0.05). Villus Height and Depth of Crypt are important indicators of the digestive health and directly related to the absorption capacity of the mucus membrane\(^2\). Effects on VH may be due to enzyme supplementation reduces erosion of the villus\(^3\) due to improved digestibility of nutrients\(^4\), thus could improve ADG.

The use of bone metabolites excreted in urine as markers for evaluation of the phosphorus retention and status in grower-finisher pigs

Kristina U. Sørensen; Hanne D. Poulsen
Dept. of Animal Health and Bioscience, Faculty of Agricultural Sciences, Aarhus University, Tjele, Denmark

Introduction
Phosphorus (P) has several physiological functions and is vital for the maintenance of the skeletal tissue. Due to environmental concern, P supply in feed is lowered in order to reduce P excretion. However, pigs may develop hypophosphatemia if P is not supplied in sufficient amounts resulting in reduced performance and bone strength. This project addresses the effect of lowering the dietary P content. The overall aim was to combine results on P retention and excretion with physiological responses in urine and bones in order to evaluate if the urinary compounds are correlated to P intake and thus may serve as markers for sufficient P intake.

Material and Methods
Grower-finisher female pigs were fed LP (4.1), MP (6.2), or HP (8.8 g P/kg dry matter) from 40 to 105 kg body weight (BW). No microbial phytase was added. Determinations of P, calcium (Ca) and nitrogen (N) balances were performed at 40, 70, and 105 kg BW. Furthermore, urine was analyzed for metabolites released during bone turnover reflecting the degradation of the bone collagen matrix. Bones were collected at slaughter (105 kg), defatted, dried, and analyzed for mineral content and bone mineral density.

Results and Discussions
The preliminary results show that P retention was lowered by 50% and up to 60% in pigs fed LP compared with MP and HP (Table 1).

Table 1. Phosphorus (P), calcium (Ca), and nitrogen (N) retention, g day\(^{-1}\). Mean values for three periods.

<td>9.66</td>
</tr>
<tr>
<td>N retention, g day(^{-1})</td>
<td>23.0</td>
<td>27.7</td>
<td>27.2</td>
</tr>
</tbody>
</table>

At 40 kg BW, P retention was identical for pigs fed MP and HP whereas P retention was higher in pigs fed HP at 70 and 105 kg BW. These results indicate that the P retention capacity was met at MP at 40 kg BW but not in the heavier pigs. Comparable results were obtained on Ca whereas the N retention was identical for pigs fed MP and HP but almost 20% lower in pigs fed LP. Seven different bone turnover metabolites were measured in urine; among these were pyridinoline, deoxypyridinoline, and hydroxylysine (HYL). The results showed that some metabolites were affected by the dietary P content and the excretion was generally increased by 35-75% in pigs fed LP compared to HP. However, other traits were more affected by ageing showing an increase in urinary excretion by 15-75% from 40 to 105 kg BW.

Conclusions
Lowering the dietary P supply greatly affect nutrient balances and bone turnover. There seems to be correlations between urinary metabolites and bone characteristics. Thus, these metabolites found in urine seem to be useful as non-invasive markers for the evaluation of sufficient P supply to grower-finisher pigs.

References
Introduction
Pig meal is a heterogeneous mixture of different particles. Each particle has a specific size but also a specific nutritional value. The particle size profile as well as average nutrient content of fattening meal is mostly quite similar between different batches. However, different manipulations of a batch such as emptying the feed silo or distribution of the meal throughout the stable by a feed conveyor can affect the particle profile of the feed. The particle size of pig feed is related to feed digestibility (Al-Rabadi et al, 2009) and voluntary feed intake (Anguita et al, 2007), but it also affects the incidence of gastric ulceration (Dirkzwager et al, 1998) and the occurrence of tail biting (Brumm et al, 2008). This study aimed to investigate possible variations in nutrient content of fattening pig meal between the point a new batch of meal is delivered in the silo and the point when the silo is almost empty. Secondly the effect of transport of meal by different types of conveyors on the nutrient content of feed was investigated.

Materials and Methods
The study was performed in four different farms. In each farm, feed samples were taken one day after the feed silo was filled with a new batch of growing pig meal (BEGIN) and again when the feed silo was almost empty (END). Every time, samples were taken in the feeding troughs in the pens on four different places along the feed conveyor: in the first pen of the first compartment (DISTANCE 1, 2, 3, 4). Two of the sampled farms used screw conveyors (SCREW) to transport the pig meal from the feed silo to the feed troughs in the pens, the two other farms used round-bottom drag conveyors (DRAG). Secondly, two of the farms offered their pigs standard meal (STANDARD), the other two farms added corn cob mix (CCM) on a daily basis to the standard meal before it was delivered to the different feeding troughs. The nutrient content of all feed samples was analysed for the following parameters by using near infrared spectroscopy: dry matter (DM), crude fibre (CF), crude fat (CFAT), crude protein (CP), crude ash (CA), sugar (SU) and starch (ST). All data were statistically analysed by using SPSS 17.0 statistical software.

Results
The amount of CP and ST was significantly higher when samples were taken shortly after filling the silo than samples taken when the silo was almost empty (P < 0.001). For CFAT, CF and CA the opposite was true, these nutrients were lower in the beginning of the silo than at the end (P < 0.001 for CFAT and CF and P < 0.05 for CA). The SU content of the feed samples was lower at the end of the silo than at the beginning, although this was not significantly (0.1 > P > 0.05). The differences between BEGIN and END for CFAT, CF and CA were significantly larger for stables using DRAG than those using SCREW (P < 0.05). Also the difference is SU content was numerically larger for DRAG (0.1 > P > 0.05). The differences in RE and ST were not affected by the conveyor type. Feed type did not significantly affect the differences in nutrient content between BEGIN and END but numerically, CCM had a more stable nutrient content than STANDARD. Distance, neither at BEGIN nor at END, significantly influenced the nutrient content of the feed. However, some numerical trends could be observed which are similar to those seen between BEGIN and END of the silo.

Discussion
The results indicate that manipulation of feed by emptying of the silo and distribution throughout the stable by automated feed conveyors can affect the nutrient content of the feed. Although differences are small from a first point of view, they can have an effect on the performance and health of the pigs in the different pens of a stable. There for the link of these differences in nutrient content will be further linked with differences in particle size and profile. In a following study the link between the variation in nutrient content throughout the stable will be studied in relation to feed intake and growth performance of pigs.

**Effects of reduced stimulation of sows during insemination – a field trial**

Claus Hansen; Gunner Sørensen; Flemming Thorup; Anja K. Olesen; Niels Jorgen Kjeldsen

Pig Research Centre, Agriculture & Food Council, Copenhagen, Denmark

---

**Introduction**

Efficient heat detection is crucial for correct timing of insemination. Before insemination, correct stimulation consists of the five point plan: 1. elevating the inguinal fold, 2. pushing the flanks, 3. applying pressure below the vulvae, 4. applying pressure on the pelvis and 5. riding test, where the inseminator sits on the back of the sow. During this manual stimulation, a boar should be present in front of the sow. Stimulation increases contractions in the uterus [1], which is expected to support sperm transport. After inserting the catheter, the technician should sit on the back of the sow during the insemination. Some technicians exclude this during insemination. It has never been investigated if this reduced stimulation effects farrowing rate or litter size. The aim of this study was to investigate the effect of reduced stimulation during insemination of sows.

**Materials and Methods**

The experiment included 2912 multiparous Danbred L x Y sows in 4 commercial herds. The herds all displayed a farrowing rate above 86 per cent at start of the trial, to avoid management failures or infections to affect the study. Heat detection was performed once a day from day 4 after weaning. A boar was present in front of the sow during heat detection. Duration of heat detection using the five point plan was approximately 1 minute per sow. If the sow was in standing heat, the five point plan was also the stimulation before introducing the insemination catheter. Sows were assigned randomly into two groups.

- **Group 1**: Traditional stimulation, where the technician sat on the back of the sow during insemination.
- **Group 2**: Restricted stimulation. No stimulation of the sow during insemination. Semen entered the cervix passively in both groups.
- **Group 2A**: If semen did not enter within twenty minutes, sows in group 2 were stimulated by back pressure to achieve semen uptake. These sows were transferred to group 2A.

Date of farrowing and total born piglets were recorded for all sows in the experiment.

Significant difference between groups were analyzed using Mixed model for total number born and logistic regression was used to analyze for differences in farrowing rate.

**Results**

There was no statistically significant difference between groups when results from the four farms where pooled. Table 1 shows, that none of the farms experienced significant differences in farrowing rate nor total born piglets between the groups. There was a large difference between farms in percent sows transferred from group 2 to group 2A.

**Discussion**

The results indicate that one minute of stimulation prior to insemination including use of the boar is enough stimulation to assure sperm transport. The number of sows in farm 4 was low, but a numerically lower farrowing percentage and number of total born in group 2 in this farm may indicate a problem in some farms, when sows are not stimulated during insemination. Farm 4 had diagnosed leptospirosis in the sow population during the experiment, which may have influenced the experiment, although this remains unknown.

Productivity in sows nursing large litters

Flemming Thorup
Center for Pig Production, Agriculture and Food Council, Copenhagen, Denmark

Introduction
Litter size in Danish production herds increased from 11 to 14 live born piglets from 1996 to 2009. The average sow has 14.3 productive milk glands. Can they assert high piglet survival and growth, and still achieve high fertility in the following litter?

Materials and Methods
In two production herds three sows with at least 15 productive milk glands were selected at least 12 hours after farrowing. From these three sows 39 piglets were selected. The rest (the smallest piglets) were transferred to nurse sows (1). The 39 piglets were randomized back to the sows with 11, 13 and 15 piglets per litter. This was repeated 44 and 43 times in the two herds, including 261 sows in the study. The next 22 days, the litters were managed following standard management in the two herds. In case a piglet fell behind, it was transferred to a runt nurse. No new piglets were added to the litters. Piglets were weighed at weaning, and the sows were followed through the next cycle.

Results
Data for piglet mortality and piglet removal is given in table one. Mortality includes mortality among piglets transferred to runt nurses. Herd 2 saw only minor differences in mortality between the three groups. The high piglet survival in this trial may be caused by the removal of the smallest piglets to nurse sows to achieve the low litter sizes. Also only healthy sows were included in the study. Figure 1 and 2 indicates how many piglets were still with the mother at 22 days, when the sow was given 11, 13 and 15 piglets. Table 2 gives the effect of litter size nursed on days to mating, farrowing rate and total born piglets in the next litter.

Discussion
Mortality and number of transferred piglets increased, when litter size was increased. The number of piglets weaned per sow and per pen did also increase. Most sows weaned 12 to 14 piglets. Only 10 per cent of the 87 sows nursing 15 piglets weaned all 15 piglets (Fig. 1 and 2). More knowledge to evaluate the capacity of the specific milk glands will give the manager a better chance to predict the optimal capacity of a specific sow. Glands not used in the previous lactation, were less productive in the succeeding lactation (2). Thus when increasing litter size at the sows, it is important first to challenge the youngest sows in the herd. Neither farrowing percentage nor litter size in the following litter was significantly affected by the number of piglets nursed.

Objective
The purpose of this study was to determine the incidence of early parturition (<114 days of gestation) and to investigate the effect of early parturition on the reproductive performance in sows.

Material and Methods
This study was based on reproductive data records (Cercosoft NV, Oudenaarde, Belgium) of 37 pig herds that were willing to collaborate with the study. Two of these herds were excluded because the insemination date was not recorded for each individual sow and/or altrenogest was administered at the end of gestation. The database of the remaining 35 herds contained 87,978 farrowing records of which 26,988 records were excluded because induction of parturition was performed or due to missing information on farrowing data. Hence, 60,990 farrowing records of 17,401 sows were used for further analyses. The association of the outcome variables (total litter size, live born piglets, stillborn piglets) with the gestation length (GL) (categorized in 4 groups: 109-111d, 112-113d, 114-117d, 117-121d) was assessed using a multilevel linear mixed effect model, with herd included as random factor, and parity and breed as fixed factors. The influence of the duration of the previous gestation on the next was also determined. All statistical analyses were performed in MLwiN 2.0.

Results
The mean gestation length was 115.4 ±1.62 days. Early parturition occurred in 10% of all farrowing events (Fig 1).

Table 1 shows that sows with GL <112d have more stillborn piglets (Odds ratio/OR: 5.8) and less piglets born alive (OR: 0.2) compared to those with GL 114-117d. A GL of 112-113d was associated with more total born piglets (OR: 1.7), more piglets born alive (OR: 1.1) and more stillborn piglets (OR: 1.5). Sows with GL ≥ 118d were more likely to have less total born piglets (OR: 0.3) and less piglets born alive (OR: 0.3) compared to those with GL 114-117d. Sows with a gestation length of < 114d were more likely to have a gestation length of < 114d at the subsequent parity (OR: 1.2) as those with a gestation length of ≥ 114d (P<0.05).

Fig 1: Frequency distribution (%) of gestation length in 60,990 farrowing records.

Discussion and conclusion
The present study showed that early parturition (<114d) occurred in 10% of the farrowing events. Early parturition significantly increased the risk for stillborn piglets, especially in sows with a GL <112d. This is likely due to the relative immaturity of the piglets at parturition (1). Large litters and more piglets born alive were associated with a GL <114d, while small litter size and low numbers of live born piglets were related to a GL ≥118d. This is in agreement with Sasaki and Koketsu (2007). Sows with a short gestation length were more likely to have an early parturition at the subsequent parity. This information may be important for producers to identify potential sows-at-risk. It may enable them to improve the reproductive performance by assisting farrowing or by preventing an early parturition.

**Relationship between pre- and post freezing semen quality characteristics and field fertility**

Eveline Willems¹ Hanneke Feitsma² Jascha Leenhouwers²

¹. TOPIGS S&D, Vught, Netherlands; ². Institute for Pig Genetics, Beuningen, Netherlands

**Introduction**

In pig breeding, frozen semen is used for global linkage of nucleus herds. The objective of this study was to investigate the relationship between fresh and post thaw semen quality characteristics and fertility in sows.

**Materials and Methods**

A database (Cryobase) was set up with semen variables of ejaculates used for freezing. All ejaculates have been analyzed for several semen quality characteristics; Fresh ejaculates were evaluated for motility, progressive motility (0, 24 & 72 hours after collection) and morphology. Frozen-thawed ejaculates were evaluated for motility, progressive motility (0, 24 & 48 hours after thawing), morphology and for % membrane intact cells (0 and 24 hours after thawing) using Nucleocounter SP100. Fertility results of TOPIGS nucleus herds are recorded and exchanged with a breeding database (PigBase) at the Institute for Pig Genetics. In order to analyze the fertility results of frozen semen PigBase and Cryobase were merged, corrected for outliers and standardized for farm, parity and boar line. This resulted in a dataset of 742 frozen ejaculates from 400 boars. The analysis was performed using SAS statistical package.

**Results**

Variables with a significant effect on farrowing rate (FR) and total number born (TNB) are found in this analysis. In table 1 the different P-values for the variables tested are mentioned.

Some motility variables of the evaluated ejaculates shown to have a significant effect on field fertility. Mainly fresh motility variables have a significant effect on FR and TNB. For example FR was 21,7% less when fresh semen had a progressive motility 24h of <70% compared to fresh semen progressive motility of ≥70%.

**Discussion**

Significant relationships between fertility and fresh semen quality could lower the production costs of frozen semen, due to more adequate approval guidelines for evaluating suitability of ejaculates for freezing.

When the dataset increases, there may be more variables significantly important for field fertility.

UltiMate™ Computer Assisted Semen Analysis (CASA) systems are implemented since 2006 to check the motility and progressive motility of the ejaculates objectively, but not enough data were available for analysis yet.

In general more fresh semen quality characteristics have a significant effect on fertility than post-thawing semen quality characteristics.
Quality parameters assessment of boars seminal doses which were delivered to farms by artificial insemination centres in Spain during 2009

Yahya Dahmani; René Mozo-Martín; Carmen Larraz; Juan Luis Úbeda
R&D Department, Magapor SL, Ejea de los Caballeros. Zaragoza, Spain

Introduction
The methodology of analyses and process of swine ejaculated change among Artificial insemination centres in Spain. This change can affect the quality of semen doses delivered to farms for the insemination process. The analysis and control of the quality of seminal doses has a great importance as the productive improvement of the farms will depend on it. These parameters should comply minimum values required of semen quality standards for the swine artificial insemination (1). Therefore, the aim of this study is to assess quality parameters of boar seminal doses delivered to farms, by artificial insemination centres in Spain during 2009.

Materials and methods
For this study, we assessed 1678 boars seminal doses from 20 swine artificial insemination centres in Spain. The analyzed parameters of seminal doses were: concentration, pH, osmolarity, agglutination, sperm motility, whole acrosomes, abnormal morphology and the hypo-osmotic (Host) test. All analyses were carried out by the same person and by microscopic standard examination. Data were processed by StatView 5.0 software(2). Normal distribution was checked by Kolmogorov Smirnov test. Variance of quality parameters of seminal doses between centres was analysed by ANOVA 2x2 way, and Fisher’s PLSD test. Values are presented as means ± standard deviation, and significant differences are considered when p<0.05.

Results
ANOVA analysis of the different seminal parameters has showed a significant difference among AI centres (P<0.0001). In the table 1, we illustrated only the most important parameters: motility, concentration, abnormal morphology and Host test. Despite these differences among centres, almost all values of the parameters fulfill the recommended standards limits for the seminal doses analysis in swine, except for the motility parameter and abnormal morphology of sperm. Only in the centres C05 the seminal doses presented an average lower than the standard limit (64.6%) for motility, meaning the possible rejection of 12.9% of all 1678 doses. However, differences in the parameter in an abnormal forms, have been very pronounced statistically. Values of abnormal forms sperm were higher than standard limit (>30%) in the majority of centres. This result mean that 67.3% of total samples can be discarded. Concerning the concentration of doses 21.6% of samples showed values not conform with standard limit, however, the doses should not be rejected for this motif as we don’t know if the samples were destined to post-cervical AI. The remaining parameters showed acceptable values and were within standard limits.

Discussion
Values were within standard limits in most of the cases, but for the parameter of sperm abnormal forms. This result is coherent with the diversity in the methodology of work and process of swine semen doses. Besides, other factors interfere in this variability, such as the reception and transportation, temperature of doses, type of semen extender...etc. Nevertheless, it is surprising that the sperm abnormal forms parameter is out of the standard limits, since it depends on semen extender, temperature of transportation, boar and process of spermatogenesis. In addition to it, determination of this parameter was objective, contrary to others. Therefore, this anomaly would also be due to the high extraction rhythm of ejaculated, which can affect the sperm morphology.

Summing up, due to the fact that all seminal quality parameters should fulfill standard limits, without exception, it is necessary to maximize the precaution and to guarantee the quality of the seminal dose delivered to farms.

Table 1. Means distribution of sperm motility, concentration, abnormal morphology and Host test, in 20 centres (CRI) from Spain. Values are presented as means ± standard deviation. AF: Abnormal forms. Conc: concentration. LS: limits standard (1).

Influence of organic selenium supplementation on lipid peroxidation of boar sperm membranes

Simone M. Martins2,1 André F. Andrade2 Larissa J. Parazzi1 Fabiane G. Zaffalon2 Carolina I. Silva1 Andres M. Gallego2 Aníbal S. Moretti1 Rubens P. Arruda2

1. Laboratory of Swine Research, University of Sao Paulo, Depto. Nutrição e Produção Animal (VNP), Pirassununga, SP, Brazil; 2. Laboratory of Semen Biotechnology and Andrology, University of Sao Paulo, Depto. Reprodução Animal (VRA), Pirassununga, SP, Brazil

Introduction

Boar spermatozoa are characterized by a high level of poly-unsaturated fatty acids. Lipid peroxidation (LP) may be one of the mechanisms responsible for the negative biochemical and physiological changes during sperm storage. However, data on the changes in sperm lipid composition and their susceptibility to peroxidation during storage are limited1. Previous results demonstrated that boar spermatozoa contains glutathione peroxidase and α-tocopherol, suggesting that both selenium and vitamin E have a role in preventing peroxide damage to the sperm cell2. Therefore, the aim of this study was to evaluate the effect of dietary organic selenium on the membrane lipid peroxidation in the boar semen diluted with BTS and stored for 3 days.

Materials and Methods

Fifteen boars were kept on the same conditions and were fed the same standard diet during training. The animals were fed with three experimental diets: 0.3ppm sodium selenite (Control); 0.5ppm sodium selenite (Inorganic) and 0.5ppm selenium yeast (Organic). Ejaculates were collected from each boar once per week using the gloved-hand technique. Semen was diluted with standard extender to 3x10⁹ cells/dose and stored for 3 days at 18ºC. The peroxidation of the membranes was measured with the use of the fluorescent probe C11-BODIPY581/591. Semen aliquots were collected during the analysis steps to obtain samples. These were then stained with 0.5μL of probe C11-BODIPY581/591 (1mg/mL, Molecular Probes) for 30 minutes at 37ºC. Then, 3μL of propidium iodide (PI) (0.5mg/mL, Sigma) was added to the sample to mark the cells with damaged plasma membranes, when they were analysed by flow cytometry. The viable sperm cells (PI negative) were stained with probe C11-BODIPY581/591 and analysed as the mean intensity of fluorescence emission (arbitrary units-a.u.) captured in the photomultiplier with a long pass of 502 and a band pass of 530±15nm. The experimental design was a randomised block. Data were analyzed using the PROC repeated from SAS4 and outcomes were compared among the three treatments by the orthogonal contrast method with P<.05 level of significance.

Results

No interaction was found between the independent variables time and treatment during the analysis of the dependent variable fluorescence intensity emitted by the sperm with plasma membrane that was intact and stained with the fluorescent probe C11-BODIPY581/591. Therefore, it was possible to carry out the analysis of the main effects separately. There were no changes in the fluorescence intensity emitted by viable cells independently of the treatment added. When analysing the time effect, it was verified that the fluorescence intensity emitted increased within 24 hours and decreased after that (Graphic 1).

Graphic 1 – Means ± SEM of the fluorescence intensity of the sperm with intact plasma membrane and stained with a fluorescent probe C11-BODIPY581/591

Values with a different letters differ (P<.05)

Discussion

Higher lipid peroxidation was found within 24 hours, this was probably due to a high cell metabolism in the beginning of the cooling process5. The cooling led to a reduction in metabolism, which in turn, decreased lipid peroxidation after 48 hours, probably by the action of antioxidant systems of their own sperm.5 In conclusion, the selenium yeast showed no better results in comparison to others treatments regarding lipid peroxidation.

Practical review on reproductive testis pathology in boar

Juan Luís Úbeda¹ María Victoria Falceto² Yahya Dahmani¹ René Mozo-Martín¹ José Antonio Bascuas²

1. R&D Department, Magapor SL, Ejea de los Caballeros, Zaragoza, Spain;
2. Departamento de Patología Animal. University of Zaragoza, Zaragoza, Spain

Introduction

The boar low fertility depends on many factors like nutrition, stress, season, libido problems, anatomical problems of the reproductive organ, infections, as well as genetic transcendence causes.

Artificial insemination centres (AIC) discard boars when they start to present fertility problems or low seminal quality due to unknown causes, since animals maintenance supposes a considerable cost. In several cases, the reason for rejection is some reproductive pathology of testis misdiagnosed which is manifested as low seminal quality or bad fertility.

The aim of this study is to determine possible reproductive pathologies of testicle in culled boars from AI centres, which were sent to the slaughterhouse because of low fertility, low seminal quality or unknown causes. Seeking also a possible treatment, through morphological and histological studies of testicles.

Material and methods

More than 500 testis of slaughtered boars were collected. All animals were coming from AIC because of their low fertility or low semen quality or other unknown causes.

Biological material was conducted to the laboratory for processing and analyses. First morphologic exam of testis was performed, followed by processing of fixation and histological preparation (head, tail, epididymis body and the pampiniform plexus). Samples obtained were analyzed by microscopy illustrating every case by pictures.

Results

Several pathological reproductive incidences of the testicle were detected and registered (varicocele, fibrosis, inflammation, haemorrhages...etc). Figure 1 and 2 illustrate cases of varicocele and injuries with inflammation, respectively. The most frequent pathology was varicocele and lesions.

Discussion

It is very remarkable the frequency of the cases found of testicular pathology in the culled boars. This finding concord with some reported studies (1). In the majority of the cases in which boars were eliminated without specific cause, we found different degrees of fibrosis, as well as inflammatory focus.

Theses symptoms are difficult to diagnose in farm without anatomy assessment and they are related to the low semen quality or low seminal production. This fact explains the lost of males productivity, the difficulty of covering seminal doses purchase orders from farms, as well as the dissatisfaction of the customers because of the seminal dose bad quality.

Similarly, testicular injuries take time to recover and many of them are chronic which involves a substantial increase in the final cost for the boar-stud. Finally, even though discarding animals seems to be the best solution in this case, we should increase inspection in slaughterhouse to examine the testicular pathologies in sacrificed boars, and try to give treatment to correct this fault and avoid animal sacrifice.

Considerations in assessing the serological cross-reactivity of pig and novel H1N1 influenza viruses

Jaime Maldonado1 Laura Valls1 Eva Martínez1 Montserrat Aguero2 Dolores Buitrago2 Enric Espunya1
1. Laboratorios Hipra, Amer, Spain; 2. Laboratorio Central de Veterinaria, Algete, Spain

Introduction

The novel human H1N1 (nH1N1) virus can infect pigs and its occurrence in swine farms has been reported recently in several countries. Besides, it has been shown that nH1N1 cross-react with porcine viruses in the hemagglutination inhibition assay (HI). This work reports on the observed antigenic and genetic relatedness between nH1N1 and swine H1N1 viruses.

Materials and Methods

Two groups of H1N1 viruses isolated from swine (SIVs) in the 80s (early = 8) and 2000s (recent = 7) in Spain, together with the Sw/California/07/2009 virus of human origin were analyzed. Cross-HI was performed using antisera against each virus group. Partial nucleotide (nt) sequences (450nt) of the hemagglutinin segment (HA) were obtained and analyzed by multiple alignments (MEGA 4, ClustalW and BLAST).

Results and Discussion

HI antibodies against early SIVs, recent SIVs and nH1N1 showed cross-reaction to viruses in each group to a variable extent (Table 1). Geometric Mean Titters (GMT) for early sera against early and recent SIVs were 269 and 98, respectively. GMTs for recent sera were 538 and 80, respectively. nH1N1 antisera also showed cross-reactivity against early and recent SIVs with GMTs of 160 and 80, respectively. These findings indicate that cross-reactivity among nH1N1 and SIVs occurs, regardless of the virus isolation period or the nature of antiserum tested in the HI assay (hyperimmune or convalescent in Table 1). Thus, the broad cross-reactivity of SwCA09H1N1 antiserum and SIVs isolated more than 20 years apart may suggest the existence of cross-reactive epitopes conserved between the hemagglutinins of influenza A H1N1 viruses. However these findings deserve further studies.

Nucleotide sequence analysis of the HA segment allowed clear differentiation among early, recent and the nH1N1 viruses. However, early SIVs showed slightly higher similarity to nH1N1 (73%) than recent SIVs (range 69%–71%). Furthermore, BLAST search against all GenBank HA nucleotide entries returned significant (>90% similarity) matches to several avian species for early (10–12 out of 100 hits) compared to recent (1 out of 100 hits) SIVs, suggesting adaptation to the swine host in recent SIVs. To what extent the observed cross-reactivity is influenced by such differences that should be investigated further. Taken together, the additional data presented here support previous observations that demonstrate serologic cross-reactivity with nH1N1 virus in pigs in Europe. The repercussions that could have this in diagnosis and vaccination are yet to be assessed.

Implications of clinical, virological and epidemiological findings in the first cases of pandemic (H1N1) 2009 virus infection in English pigs for the control of swine influenza

Susanna Williamson1 A W. Tucker2 I S. McCrone2 J L. Wood2 H Habernoll3 K Yuill3 S C. Essen4 I H. Brown4
1. Veterinary Laboratories Agency, Bury St Edmunds, UK; 2. Dept. of Veterinary Medicine, Cambridge, UK; 3. BQP, Ltd, UK; 4. Veterinary Laboratories Agency, New Haw, Surrey, UK

Introduction:
Since pandemic H1N1 infection in humans began its global spread, countries around the world have reported spread of infection to pigs. This paper describes the clinical, epidemiological and virological findings in the first three pig farms found to be infected with pandemic (H1N1) 2009 influenza virus in England. These showed interesting differences in disease presentation, spread and likely sources of infection and the findings have implications for the control of swine influenza infection in commercial breeding and growing pig units.

Materials and Methods:
Tonsil, trachea and lung samples were collected from pigs submitted for diagnostic postmortem examination with a history of respiratory disease or with respiratory pathology. Nasal swabs and sera were collected from pigs on farms where pandemic H1N1 was detected in submitted pigs. Nasal swabs and tissues were tested by influenza M gene PCR, positive samples were then tested by PCR for pandemic H1. Sera were tested for antibodies using the haemagglutination inhibition assay (HAIT).

Results:
The first three pandemic H1N1 infected units identified in England were an outdoor breeding unit (farm A) and two indoor nursery-finishers (farms B and C). Morbidity ranged from 0 to 75% within groups and mortality was negligible or low. Clinical signs varied from inapparent infection to non-specific without respiratory signs in breeding pigs on farm A, to typical acute respiratory disease with rapidly spreading coughing highly suggestive of influenza infection in growing pigs (farms B and C). The breeding unit from which growing pigs derived (which was not farm A) was suspected to be the source of infection for farm A, for an 8-week period, as infection spread from one pig source to another; within any one shed of pigs the maximum duration of active infection detected was 4 weeks although pigs showed clinical recovery within 2 weeks. Circumstantial evidence suggests that a pig lorry driver was the possible origin of infection for the outdoor breeding unit (farm A). Active infection was present on this unit over at least a seven-week period at the end of which four week-old weaners moved to an indoor unit on which active infection was detectable three weeks later. On several occasions, PCR positive nasal swabs were obtained from pigs in which significant antibody titres could be detected. There was no or insignificant cross reactivity of HAIT antibody to pandemic virus with other UK endemic influenza strains (avian-like H1N1, H1N2, H3N2) in recovered pigs. The H1N1 virus isolated from all three farms was 99.7% identical to pandemic H1N1 (2009) circulating in the human population.

Discussion:
The main implications of these findings for the control of infection of pigs with pandemic (H1N1) 2009 are:

a) vigilance for clinical signs as a means of surveillance for suspect pandemic H1N1 infection in adult breeding pigs is unlikely to be effective as many undergo inapparent infection, or mild non-specific signs which could go unnoticed, particularly in an extensive outdoor setting.

b) in extensive outdoor situations where pigs are in the open air and stocking density is low, spread around the unit may occur more slowly and less predictably than on indoor units. Without the use of serology, it would be difficult to determine whether susceptible groups remain. In such situations, it may be appropriate to deliberately seed infection into potentially susceptible groups (for example unserved gilts) to avoid possible reproductive or respiratory problems during acute infection later.

c) influenza infection may persist within some types of unit for a more extended period than expected and movement of pigs on or off the unit should be undertaken in the knowledge that clinical recovery alone may not be sufficient evidence that the unit is no longer infected.

d) seropositive pigs can still shed virus during recovery and detection of seropositive groups does not necessarily mean that infection has fully resolved; infection can persist in batches of pigs weaned off site from sows following an outbreak. Further evaluation of these findings is in progress.

e) the serology results show that HAIT can be a useful means of surveillance for pandemic H1N1 influenza in pigs in some settings, but HAIT with endemic strains should be included to exclude cross reactions.

Introduction

The gene constellation of the 2009 pandemic H1N1 virus is a unique combination from swine influenza A viruses (SIV) of North American and Eurasian lineages, but prior to April 2009 had never before been identified in swine or other species (1). Although the hemagglutinin gene is related to North American H1 SIV, the infection potential in pigs was unknown immediately following the emergence of the virus in the human population. The objective of this study was to evaluate two isolates of 2009 pandemic H1N1 in a pathogenesis and transmission study in weaned pigs.

Materials and methods

Pathogenic and transmission characteristics between A/CA/04/2009 (CA/09) and A/Mexico/4108/2009 (MX/09) were compared in pigs. A total of 30 4-week old pigs were inoculated with A/CA/04/2009 H1N1 (n=15 pigs) or A/Mexico/4108/2009 H1N1 (n=15 pigs) with approximately 2 x 10^5 TCID50/ml of each respective virus. Pigs were sampled at 0, 2, 3, 5, 7, and 9 days post infection (dpi) by nasal swab. Direct (n=5) and indirect (n=5) contact pigs were placed with each of the primary infected pig groups on 2 days post infection (dpi) and nasal swab samples were collected at 0, 3, 5, 7, and 9 days post contact (dpc). Five primary challenged pigs were necropsied on days 3, 5, 7, and 21 pi. Contact pigs were necropsied on day 20 pc. Hemagglutination inhibition (HI) assays were done with 21 dpi and 20 dpc to evaluate sero-conversion using challenge virus as well as a panel of North American H1 SIV isolates representing each phylogenetic cluster (2).

Results

Pigs experimentally infected with pandemic H1N1 2009 influenza A viruses developed similar respiratory disease and demonstrated equivalent macroscopic lung lesions on each given necropsy day. Virus titers in the lung were not different between CA/09 and MX/09 infected pigs, with mean titers of 10^4.8 and 10^4.5 respectively on 3 dpi, 10^4.8 and 10^4.5 respectively on 5 dpi, and undetectable on 7 dpi. However, differences in viral replication in nasal secretions and transmission to contact pigs were detected between CA/09 and MX/09 (Figure 1). CA/09 inoculated pigs shed virus from the nose in a higher percentage of pigs as well as at higher viral titers. Additionally, direct and indirect contact pigs shed CA/09 virus at levels similar to primary inoculated pigs and for an extended time course. In contrast, MX/09 inoculated pigs shed virus in a lower percentage of pigs and at lower virus titers. A limited number of nasal swabs were positive from pigs in direct contact with MX/09 inoculated pigs and no samples from indirect contact pigs were found to be positive for MX/09 virus. Serologic cross-reactivity was demonstrated between the 2 pandemic isolates and with North American H1 isolates, although significant reductions in HI titers were detected.

Discussion

Understanding the shedding and transmission patterns of different genotypes of H1N1 2009 in swine is important as several countries are now reporting outbreaks in commercial pig herds. The difference in the patterns of shedding and transmission may partially explain why some swine outbreaks have been relatively self-limiting. Virus variants that replicate to higher titers in the nose of pigs and easily transmit from pig to pig could present a greater threat to animal and human health. Based on sequence analysis, the HA genes from CA/09 and Mexico/09 differ by 4 or 5 amino acids depending on the reference sequences compared. Further work must be done to correlate the changes in the HA gene to the reduced shedding and transmission of the MX/09 virus.

Introduction

The Center for Veterinary Biologics (USDA/APHIS/ CVB) provided Master Seed Viruses (MSV) to veterinary biologics manufacturers for developing a conditionally-licensed pandemic H1N1 (pH1N1) swine influenza virus (SIV) vaccine for use in the US swine herd.¹ The objective of these studies was to demonstrate a reasonable expectation of efficacy to support USDA requirements for conditional licensure and to evaluate the vaccine in a vaccination-challenge model in pigs.²

Materials and Methods

Three studies were conducted in SIV negative pigs.³ In all studies, pigs were vaccinated on Days 0 and 14 and an adjuvanted placebo (T01) was included. In Study 1, pigs were vaccinated with adjuvanted, killed pH1N1 vaccines prepared from A/California/04/2009 (T02) or A/Mexico/4108/2009 (T03). In Study 2, pigs were vaccinated with low (T02), mid (T03) or high (T04) doses of A/CA/04/2009 pH1N1 vaccine. Sera from both studies were tested for hemagglutination inhibition (HI) antibodies to pH1N1. In Study 3, pigs were vaccinated with the A/CA/04/2009 pH1N1 vaccine formulated at a high (T02) or low (T03) dose. Lung lesions were scored at necropsy, 5 or 10 days after challenge with A/Mexico/4108/2009 pH1N1 virus. The studies were conducted in accordance with the Institutional Animal Care and Use Committees at the PAH, MVS or BBL sites.

Results

Cross-reactivity between the two pH1N1 viruses was apparent in Study 1 (Figure 1). In Study 2, the GMT, and individual HI titer of all vaccinated pigs, were ≥ 40 in sera collected 7 or 14 days post-revaccination (data not shown). In Study 3, the mean percent lung lesion scores for both vaccine groups were significantly lower (P≤0.0001) than that of the placebo group (Figure 2).

Discussion

Pigs vaccinated with the A/CA/04/2009 pH1N1 vaccine developed HI titers of ≥ 40, generally considered as a protective level.⁴ ⁵ The vaccine also significantly reduced lung lesions in pigs challenged with a heterologous pH1N1 virus.

Experimental infection with H1N1 European Swine Influenza virus protects pigs from a subsequent infection with the 2009 pandemic H1N1 human influenza virus

Nuria Busquets1 Joaquim Segales1,2 Lorena Cordoba1 Tufaria Mussa1 Elisa Crisci1 Gerard E. Martin-Valls1 Meritxell Simon-Grifé1 Marta Pérez-Simó1 Monica Perez-Maillo1 Jose I. Nunez1 Francisca X. Abad1 Lorenzo Fraile1 Sonia Pina1 Natalia Majo1,2 Albert Bensaid1 Mariano Domingo1,2 Maria Montoya1

Introduction
The recent pandemic human influenza virus A(H1N1) 2009 contains gene segments from ancestors in North American and Eurasian swine lineages as well as from avian and human lineages. The emergence of this A(H1N1) 2009 virus poses a potential global threat for human health. Importantly, the fact that it can infect other species, like pigs, favors a possible encounter with other influenza virus circulating in swine herds. In Europe, H1N1, H1N2 and H3N2 subtypes of swine influenza virus (SIV) currently have a high prevalence in commercial farms. To achieve a better assessment of the risk posed by the A(H1N1) 2009 virus in the actual situation of swine farms, it was analyzed whether a previous infection with a circulating European avian-like swine influenza virus generated cross-protective immunity against a subsequent infection with the new human influenza virus A(H1N1) 2009.

Material and methods
Two Influenza A virus isolates were used in this study: a circulating European avian-like swine influenza virus strain (A/Swine/Spain/53207/2004 (H1N1)) (GenBank accession number CY010587 and hereafter referred to as V1) and the new human influenza virus A(H1N1) 2009 (A/Catalonia/63/2009 (H1N1)) (GenBank accession numbers GQ464405-GQ464411 and GQ168897, hereafter referred to as V2). Twenty-two snatch-farrowed, colostrum-deprived Large White x Landrace piglets were obtained from a herd with a standard health status. At the age of 40 days, pigs were randomly distributed into four groups, namely C/C (n = 6), V1/C (n = 4), C/V2 (n = 8) and V1/V2 (n = 4) balanced by sex and weight. Group V1/C animals were intranasally inoculated with 3.5 ml of 10^7.04 tissue culture infectious doses 50% (TCID50) per ml of V1 on day 0. Pigs from group C/V2 received 3.5 ml of 10^6.15 TCID50 per ml of V2 on day 21. Finally, pigs in group V1/V2 were inoculated with both viruses, V1 on day 0 and V2 on day 21, whereas C/C pigs served as control animals.

Pigs were clinically monitored daily until the necropsy day (28 days post-inoculation). Blood and nasal swabs were taken regularly during the experimental period. Anti-influenza A virus nucleoprotein (NP) antibodies (IgG in serum and IgA in nasal swabs) levels were also measured. Samples were analyzed by ID Screen® Influenza A Antibody Competition ELISA (ID-Vet, France). Primers and probes were modified to improve the European avian-like swine and new human influenza virus A(H1N1) 2009 detection based on sequences database and previous reports (1). V1 and V2 viral loads in nasal swabs and lung tissue were assessed by a TaqMan quantitative RT-PCR. Inhibition of hemagglutination on serum was performed following standard procedures (2). The test was standardized at four hemagglutinin units and the starting dilution was 1:20.

Results
Pigs only infected with V2 had mild to moderate gross lesions (broncho-interstitial pneumonia). However, pigs inoculated with V1 virus and subsequently infected with V2 had very mild lung lesions, apparently attributed to the residual lesions caused by V1 infection. These later pigs also exhibited boosting levels of specific IgA antibodies in nasal swabs and IgG in sera. This boosting effect was also apparent for inhibition of V1 and V2 hemagglutination levels. Finally, in all animals from group V1/V2, neither virus shedding nor viral load in lungs or in nasal swabs were detected after challenge with V2, indicating a cross-protective effect in which specific anti-influenza antibodies seem to play a crucial role.

Discussion
A previous infection with one of the circulating European avian-like SIV H1N1 in the field was able to confer protective immunity to pigs against a challenge with the new variant influenza virus A(H1N1) 2009 virus. These data pave the way for understanding the intimate immune responses generated between different influenza viral infections, within the same subtype. Further characterizations are required to understand the whole picture and all the mechanisms involved in protection.

Introduction

Pigs can be infected with avian, swine and human influenza A viruses and, historically, swine was proposed to be the mixing vessel where reassortant influenza strains arise; however the H5N1 incidents showed that avian influenza viruses could be transmitted directly to humans. The recent emergence of a human pandemic influenza A virus harbouring genes thought to be originally of swine influenza viruses (SIV) fuelled again the interest in the epidemiology of influenza in pigs. Swine influenza is a common respiratory pathogen of pigs causing a disease clinically similar to human influenza although, as suggested by others (1), subclinical infections might be common, particularly when considering the high seroprevalences (2) and the relatively low incidence of confirmed influenza outbreaks. It is worth to note, that the precise dynamic of SIV infection within a farm is scarcely known beyond the situation of an epidemic clinical outbreak. The present study was aimed to determine the infection dynamics of SIV in a farrow-to-finish farm.

Material and methods

A farrow-to-finish farm previously known to be positive for SIV antibodies was selected for the present study. The farm had 300 sows in stock and the annual replacement percentage in average was a 55%. Farrowing batches were scheduled every 3 weeks. A whole weaning batch (n=121) of 3-week-old piglets was selected for the study. Nasal swabs and sera were taken weekly between the 3rd and the 13th week of age and afterwards, pigs were sampled again at 15, 17, 20 and 24 weeks of age. In each visit to the farm a clinical inspection of pigs was performed. Serum samples were tested for antibodies against swine influenza nucleoprotein using a commercial indirect ELISA (CIVTEST influenza, HIPRA, Spain). Samples were considered to be positive when the sample-to-positive control (S/P) ratio ≥ 0.2. SIV shedding was determined in nasal swabs by means of a TaqMan one-step qRT-PCR using a Fast7500 equipment (Applied Biosystems, Foster City, CA). Primers and probe were adapted from a previous report (3) and the design was based on sequences of European SIV strains retrieved from Genbank to improve the SIV matrix (M) gene detection.

Results

No clinical signs of influenza were observed for the duration of the study. However, seropositive animals were detected by ELISA at all sampling times (Figure 1). Initially, (3 weeks of age) seroprevalence was of 56.2% (68/121) declining until a low of 10.4% (12/115) at 6-weeks of age. Afterwards and until 13 weeks of age, seroprevalence showed ups and downs. From 15 weeks of age, all remaining seronegative animals seroconverted. Based on RT-PCR results, shedder pigs were observed at 3, 4, 7, 13, 15, 17, 20 and 24 weeks of age with point prevalences ranging from 1 to 25%. As shown in Figure 1, four waves of viral circulation were observed: weaning (3-4 weeks of age), 7 weeks of age and 20 weeks of age. Interestingly the same animal could be shedding SIV in different infection waves.

Discussions

Results of the present study showed that SIV may circulate subclinically in an endemic farm. Maternal-derived antibodies (MDA) probably persisted for at least 6 weeks and, most probably, very early infections became softened because of those MDA. The results also show different consecutive viral waves that were not translated to an explosive spread in the farm (general seroconversion) except for the last two waves, suggesting the introduction and circulation of a strain previously absent in the population in late stage fatteners and finishers. In summary, the present data suggests an endemic and subclinical circulation of SIV in consecutive viral waves.

Development of an experimental aerosol infection model for swine influenza

Ralf Dürrwald
IDT Biologika GmbH, Dessau-Roßlau, Germany

Introduction
The use of an appropriate challenge model is of considerable importance for any demonstration of the efficacy of a vaccine. Experimental induction of swine influenza is a difficult process. Pigs very often show no clinical signs of disease, or only a few such signs, upon experimental infection with influenza A viruses. Intratracheal infection is the method recommended by the European Pharmacopoeia (1), but this method is not entirely satisfactory in terms of disease induction. Therefore a new aerosol challenge model for swine influenza was developed using a nebulizer.

Materials and Methods
The nebulizer (SAG-1) generates very fine droplets in a stable aerosol. Nebulization was performed in isolation rooms, with the generators suspended from the ceiling above the pigs, and all swine were in one room. The containers were filled with medium from tissue-cultivated virus (around 6 l of medium with 10^{6.0-8.0} TCID_{50}/ml on average), the doors to the isolation rooms were closed and an air pressure of 3-4 bar set on the generator. Principally the generator produces droplets in the range 0.5 to 20 micrometers. Droplets in the range 5 to 20 μm are deposited in the trachea, bronchi and alveoli. Smaller droplets of 2 – 5 μm reach the alveoli and very small droplets of 0.2 – 0.5 μm are exhaled again. Once nebulization was started the ventilation system was switched off so that the aerosol was constant for at least 1 hour. Intratracheal challenge tests were also performed for comparison purposes by two different methods i) injection through a needle positioned close to the larynx in the cartilage without narcosis, ii) injection through a tube after intubation under narcosis.

In total, 60 infection trials with 2346 pigs using 46 strains of swine influenza A viruses of subtypes H1N1, H1N2 and H3N2 including the new pandemic H1N1 2009 virus were carried out. Vaccinated and unvaccinated pigs were investigated in trials for proof of onset of immunity and duration of immunity as well as in dose titration trials comprising > 100 pigs in one trial.

Results
Within 24 hours of aerosol nebulization the unvaccinated pigs developed elevated body temperatures of around 41 °C, tachypnea and dyspnea characterized by frequent labored abdominal breathing. The animals had a remarkable loss of appetite. Infected pigs generally recovered very soon. Body temperature and breathing normalized within 3-4 days of infection. Coughing was observed during that period and disappeared a few days later. Virus was shed over seven days. First antibodies occurred after 5-7 days. Vaccinated animals did not have elevated body temperature or only a low temperature rise. They were free of clinical signs of disease or had only very minor signs compared to unvaccinated pigs. Whereas unvaccinated pigs reached a plateau in body weight development, vaccinated pigs were not influenced by the infection. Strains of the subtypes differed in their virulence. Strains of subtype H3N2 were always virulent inducing severe respiratory disease and isolated cases of death. H1N2 strains were also virulent whereas H1N1 strains reflected a great variation in virulence but being in the majority of the experiments very mild (weak respiratory symptoms, no, or a very short period of fever induction). Aerosol infection did not harm the animals whereas after intratracheal infection single pigs suffered from the procedure due to either narcosis or injection which influenced the clinical outcome. Moreover, after intratracheal injection lungs had strong atypical lesions whereas lungs after aerosol injection reflected lesions in the apical parts of the lungs comparable to those after natural infection.

Discussion
The newly developed aerosol infection model is superior to intratracheal infection. It allows infecting a large number of pigs (up to 200) in one single trial within a very short period of time and without harm to the animals. Disease is induced within 24 hours and is either more severe after aerosol challenge in comparison to intratracheal challenge or comparable to it. In contrast to intratracheal infection there are no artificial lung lesions. The newly developed model is a valuable tool for vaccine development and research.

Susceptibility of swine to low pathogenic H5 and H7 avian influenza viruses

Introduction

The emergence of the 2009 pandemic H1N1 influenza virus from swine origin viruses1 reinforced the concern about transmission of animal influenza viruses to man. This follows the transmission of highly pathogenic H5N1 viruses from birds to people identified in the late 1990s and continuing today.2 These two events demonstrate the transmission of novel influenza viruses to man. In addition, the discovery of a unique H2N3 reassortant virus in swine3 provided insight into the introduction and adaptation of low pathogenic avian influenza virus (AIV) genes into a mammalian host. To explore the likelihood of swine serving as an indirect host for AIV, we tested the susceptibility of swine to low pathogenic H5 and H7 viruses isolated from North America.

Materials and Methods

Four-week-old influenza-free pigs were randomly allotted to one of 12 groups (Table 1). All pigs in each group (n=12) were inoculated with a sham (Group 1) or virus inoculum (Groups 2-12). Virus challenge dose was about $1 \times 10^6$ EID$_{50}$ in a two ml volume that was dripped behind each lower eyelid and into each naris. Group 6 was given a swine virus to serve as a positive control; the remaining groups received either an H5 or H7 AIV. At 3, 5, 7, and 28 days-post-inoculation (dpi), three pigs were euthanized in each group for virus detection and lesion evaluation. At 2 dpi, five contact pigs were comingled with each group and maintained as a group until 28 dpi when all pigs were euthanized. Nasal swabs were collected on days 2, 4, and 6 pi from all live pigs in each group. Bronchioalveolar lavage fluid (BALF) was collected at necropsy. Nasal swabs and BALF were tested for viral nucleic acid with real-time RT-PCR.4 Day 28 pi sera was tested for influenza virus antibody with a commercially available ELISA.5

Results

No virus, antibody, or lesions were found in the negative control group, Group 1 pigs (Table 1). Challenge virus was only detected in NS from group 6 pigs challenged with the swine H1N1 at 2, 4, and 6 dpi (data not shown). Group 6 contact pigs were the only contact pigs that seroconverted by 28 dpi. AIV challenge virus was detected in the BALF from one or more pigs in each challenge group. Except for group 7, one or more inoculated pigs developed antibody by 28 dpi; however no contact pigs in the AIV groups seroconverted. Mild lung lesions were observed in each group of pigs.

Discussion

Challenge virus was detected in the BALF from one or more pigs in each of the AIV-challenged groups indicating that swine were susceptible to infection via a mucosal exposure. Although pigs were susceptible to infection, lung lesions were mild and variable. There was no virus detected from or serologic evidence of virus transmission from AIV-inoculated pigs to their respective contacts. In contrast, the contact pigs for group 6 were infected with the swine challenge virus and each pig seroconverted. Moreover, this was the only contact group from which viral nucleic acid was detected in nasal swabs. Some pigs were negative following mucosal challenge with AIV suggesting innate resistance or a challenge dose at the minimal threshold of infection.

*Number of PCR positive BALF samples out of 3 pigs/ Mean lung lesion score for the 3 pigs. **IN=inoculated (positive out of 3) DC=direct contact pigs (positive out of 5)
**Introduction**

Swine influenza virus (SIV) is a common pathogen in pigs. In Denmark 90% of the sow herds are influenza A positive. The most common serotypes are H1N1, H3N2 and H1N2. Clinical signs are often manifested as acute respiratory disease with fever, anorexia, weight loss, lethargy, coughing, dyspnea, nasal, and ocular discharge. Reproductive failure and abortions can be seen in sows (1). Secondary infections and increased use of antibiotics are common sequelae (2). The economic importance, the within-herd infection dynamics and the clinical impact of the disease on piglets are, however, not fully elucidated. The aim of this study was to examine the clinical impact and the infection dynamics of SIV in a Danish sow herd. Furthermore, the effect of the age of the sows on SIV infection in the piglets was studied.

**Materials and Methods**

A total of 44 sows of Danish landrace and Yorkshire crossbreds and 199 piglets were included. From each sow, five randomly selected piglets were earmarked. Blood samples (serum) were collected from each sow prior to the transfer to the farrowing unit and 4 weeks after transfer. Nasal swabs were collected 5 days after transfer. Rectal temperature were taken at each sampling and the sows were monitored clinically daily during the first week after farrowing.

The piglets were observed clinically daily until weaning and a detailed clinical examination were performed 10-14 days after birth. The piglets were weighed 0-5 days after birth, 10-14 days after birth and at weaning (approx. day 28). From each piglet, nasal swabs were collected from both nostrils and pooled by litter (10 swabs per pool/litter). The nasal swabs were collected in 1 ml saline, sent to the laboratory at the day of sampling and kept at -80°C until test. Serum was separated from the blood samples by centrifugation and stored at -20°C. The nasal swabs were tested for SIV by real-time SYBR RT-PCR using primers previously described (3) and the serum samples were tested for antibodies by the standard haemagglutination inhibition test against the common SIV subtypes present in Denmark.

**Results**

SI virus was detected by RT-PCR in 12 out of the 43 tested litters (28.6%). In contrast, SI virus was not detected in any of the 43 tested sows. Of the 43 sows, however, 12 (27.9%) showed a significant (minimum 2-fold) increase in HI titer against at least one of the tested SIV subtypes. There was no significant relationship between SIV positive litter and increased antibody titer of the mother sow. The 1st and 2nd. parity sows had significantly more SIV positive litters compared to the older sows. Accordingly, the younger sows had a statistically significant higher risk of having a minimum 2-fold increase in antibodies against SIV in relation to farrowing. Apart from coughing, there were no significant differences in the incidences of individual clinical symptoms of SIV positive and negative litters, however, when the clinical signs were scored and summed up for each litter there was a significant higher score in litters with SIV positive piglets. The average daily weight gain was not different between SIV positive and negative litters.

**Discussion and conclusion**

The present study showed that a relatively high proportion of young piglets in a farrowing unit of a herd with circulating swine influenza virus were positive for SIV during the first weeks after birth. This was surprising since we expected that the piglets were protected by maternal antibodies. Interestingly, piglets from young sows had a higher risk of being infected by SIV compared to piglets from older sows. Since all the sows were negative for virus in nasal swabs and there was no correlation between seroconversion of a particular sow and the risk of her litter being positive, the piglets are probably not infected by their mother-sow. Thus, the increased risk of piglets from young sows being infected by SIV may be due to sub optimal quality of the passively acquired immunity. Thus, in relation to the handling of SIV in breeding units, the focus should be on the offspring of gilts and young sows.

Tetracycline administered in water: pharmacokinetics and lessons for administration of other medications via water

Sharon Mason1 Ronald Baynes1 Glen Almond1 Jim Riviere1 Alan Scheidt2
1. North Carolina State University, Raleigh, NC, USA; 2. Pfizer Animal Health, Kalamazoo, MI, USA

Introduction

The use of medications dosed in water is a common occurrence in swine medicine. However, no published pharmacokinetic (PK) studies are available on tetracycline dosed in water in swine or the factors that determine the plasma concentration levels achieved in medicated swine.

Materials and Methods

Study. Twenty-four castrated male swine, 9 weeks of age (early grower), divided into 4 groups (n=6), were exposed to tetracycline powder administered exclusively in water at 0, 125, 250 and 500 ppm via a randomized block design (1). Blood samples were collected before and at 4, 8, 12, 24, 32, 48, 56, 72, 80, 96 and 104 h post-exposure. All plasma samples were assayed using HPLC-UV with a LOD of 0.05 μg/mL within 7 days of collection (1). Statistical analysis across groups and covariates using a one-way ANOVA (SAS 9.1, Cary NC) revealed no bias. All animals were healthy and the protocol met IACUC standards at NC State University College of Veterinary Medicine.

Pharmacokinetic analysis. Non-compartmental analysis was performed on plasma concentrations. Population PK analysis using a one-compartmental model was performed in Phoenix WinNonMix NLME 1.0 (Pharsight, Mountain View, CA). The developed model was improved and validated by two additional data sets from Dorr et al (2). Potential covariates considered were body weight, ambient temperature, water consumption, water concentration of tetracycline and health status of the animal.

Results

Non-compartmental PK analysis and statistical analysis showed that all plasma levels were above control (no exposure). Average plasma concentration levels for the 125- and 250-ppm groups were not significantly different from one another, but were significantly less than the 500-ppm group (Table 1). Population PK analysis showed that for tetracycline, health status did not improve the ability of the model to predict plasma concentrations. The population model included body weight, medication and water use. The population model was able to predict plasma concentrations of tetracycline and PK values (Vd, Cl) similar to previously published values. Bio-availability for the population model was similar to oral bioavailability (F) from the in vivo study.

*Cmax, maximum plasma concentration; Css, steady state concentration; Cl, clearance; Vd, volume of distribution at steady state, F, bioavailability.

Discussion

Tetracycline water medication PK parameters were consistent with values from the literature. Plasma levels were lower than those from observational studies in which animals were fasted. Low plasma concentrations may be due to low oral bioavailability and cation chelation of tetracycline by food.

Body weight, water consumption and water concentrations of the medication are the most important covariates for population PK analysis. Temperature was important in the initial study; however, ambient temperatures were not recorded for validation data. Temperatures appear important when large fluctuations are present, because this changes the baseline water consumption.

Population analysis on other medications is necessary for further validation of the above factors and to elucidate other potential covariates. In conclusion, tetracycline exemplifies how drugs with poor absorption have decreased ability to achieve adequate blood levels when dosed via water.

Changes in antimicrobial sensitivity of fecal *E. coli* in pigs exposed to enrofloxacin by different dosing routes: evidence for the “Mutant Selection Window”

Romain Béraud; Louis Huneault; Dave Bernier; Francis Beaudry; Ann Letellier; Jérôme R. del Castillo

*Université de Montréal, St-Hyacinthe, QC, Canada*

**Introduction**

The fluoroquinolones (FQ) are synthetic, broad spectrum bactericidal antibiotics which use in Canada is restricted to companion animals and beef cattle. Since their introduction in veterinary medicine, FQ-resistant bacteria are emerging in domestic animals, but the relationship between drug use and drug resistance awaits elucidation. Recently, the “mutant selection window” (MSW) concept has been proposed to explain the enrichment of resistant bacteria during FQ exposure [1]. Because drug efflux transporters excrete FQ into the intestinal lumen, where drug-resistant zoonotic pathogens may be selected, we hypothesized that the level of selection pressure will vary depending on the FQ dosing route. The study objective was to compare the changes in fecal *E. coli* population size and antimicrobial sensitivity of pigs treated with enrofloxacin (EFX) orally, intramuscularly, or by way of local delivery implants.

**Materials and Methods**

Parts of the study have been published elsewhere [2]. Briefly, 21 healthy pigs (13.6 ± 5.9 kg) with no previous exposure to antibiotics, and instrumented with a jugular catheter were randomized across EFX-dosing groups: oral (O), intramuscular (I), or local (L: peri-femoral implants with 65 mg EFX). Pigs in groups I and O were dosed daily for 15 days with 5.0 mg·kg⁻¹·d⁻¹ EFX. Feces were sampled rectally for 7 days prior to and during exposure to FQ. Jugular blood was sampled during treatment, and plasma EFX and ciprofloxacin (CFX) concentrations were measured with tandem mass spectrometry. Individual daily fecal *E. coli* counts, and disk diffusion testing of 12 antibiotics (3 colonies/pig) were performed daily. The effects of dosing route and time (as divided in first-exposure, bactericidal effect, and bacterial regrowth phases) on *E. coli* inhibition diameters were estimated with a repeated-measures linear mixed model. The effect of dosing route on the duration of FQ bactericidal phase was analysed with survival analysis. The α-level was set to 0.05 for all statistical tests.

**Results**

Average plasma EFX concentrations in pigs of group L were 4.5% of those in the other two groups, and plasma CFX concentrations were 8.5% of those of EFX. Fecal *E. coli* were undetectable during the bactericidal phase in all 3 groups. The sensitivity of fecal *E. coli* to EFX (Fig. 1), CFX, nalidixic acid, ampicillin, and trimethoprim-sulfamethoxazole was significantly affected by dosing route (P<0.05) and time (P<0.05). In contrast, these factors had negligible effect on *E. coli* sensitivity to amoxicillin, ceftiofur, streptomycin, apramycin, gentamicin, florfenicol, and tetracycline.

**Discussion**

Our hypothesis was verified: the local EFX delivery minimized both the intestinal efflux and selection of drug-resistant *E. coli*. Moreover, oral EFX maximized the bactericidal effect on *E. coli*, which retarded the resistance selection process. Exposure to EFX co-selected resistance to other antibiotic classes. The i.m. dosing of EFX causes significant resistance selection pressure on potentially zoonotic intestinal bacteria such as fecal *E. coli*. Because the intestinal FQ efflux exists in other mammals, these drugs should be used with caution.

Pleuromutilin susceptibility of *Clostridium perfringens* and *Clostridium difficile* isolates from pigs in Italy and Denmark

**Fabrizio Agnoletti**1 Ilenia Drigo1 Luca Bano1 Ulrich Klein2 Josef Szancer3

**Introduction**

*Clostridium perfringens* type A is a causative agent of diarrhoea in neonatal piglets with widespread occurrence in many pig producing areas; indeed the consensus B2 toxin (cpb2<sup>con</sup>) was recently considered the key virulence factor characterising the strains involved in neonatal enteritis of pigs (1, 2). The role of *Clostridium difficile* in neonatal diarrhea is increasing and becoming of greater clinical importance (3, 4) in many countries. Aim of the study was to assess the MIC values of toxigenic *C. perfringens* and *C. difficile* isolates from neonatal healthy piglets (less than 7 days old) or affected by enteritis, collected in Italian and Danish farms, against the pleuromutilin antibiotics, tiamulin and valnemulin (Denagard® & Econor® respectively - Novartis Animal Health Inc.)

**Materials and methods**

**Strains**: Sixty-eight *C. perfringens* isolates (30 strains from Italy, 38 strains from Denmark) were used for the study. The Italian strains were recovered from 30 different farms in 2007-2008 and the Danish strains from 20 different farms in 2006. Fifteen *C. difficile* strains (10 from Italy and 5 from Denmark) were recovered in 2007-2008 and originated from different farms.

**Genetic characterization of isolates: Clostridium perfringens** strains were toxin-typed by a multiplex PCR for the detection of major toxin encoding genes (*cpa*, *cpi*, *cpetx* and *cpb*) (5) and B2 gene presence was evaluated according to Baums et al. (6). Cpb2 positive strains were further characterized according to Jost et al. (2) by PCR detection of consensus or atypical cpb2 alleles. *Clostridium difficile* strains were tested for the presence of toxin A and B (*tcdA* e *tcdB*) encoding gene and the presence of binary toxin genes (*cdtA* and *cdtB*) was also evaluated (7, 8). MIC testing: The MICs of tiamulin hydrogen fumarate and valnemulin hydrochloride were evaluated using the agar dilution method and concentrations ranged 0.016-256 μg/ml. MIC testing was performed according to the CLSI guidelines (CLSI document M11-A7).

**Results**

The MIC values of the tested antimicrobial agents for *C. perfringens* and *C. difficile* isolates are shown in Tables 1 & 2.

**Table 1: Tiamulin MIC values.**

</tbody>
</table>

**Discussion**

The Danish isolates of *C. perfringens* were more susceptible to pleuromutilins compared to the Italian isolates. Results for the tested *C. perfringens* and *C. difficile* strains show a higher susceptibility to valnemulin compared to tiamulin. Tiamulin pharmacokinetic data at doses of 15-20 mg/kg bodyweight/day showed that after oral or parenteral application concentrations in colon contents between 13-18 μg/ml can be achieved (9,10). Based on these data all Danish *C. perfringens* isolates could be considered susceptible to tiamulin. Twenty percent of the Italian *C. perfringens* isolates with MIC values between 32 & 128 μg/ml were considered resistant to tiamulin. All Danish and 90% of the Italian strains of *C. perfringens* could be considered susceptible to valnemulin due to colon concentrations (1.7-5.2 μg/ml) achieved after oral application of valnemulin at doses of 3.8 & 11.6 mg/kg bodyweight/day (11). All 15 *C. difficile* isolates showed susceptibility to valnemulin and tiamulin.

Introduction
Iron is an essential mineral for composition of blood cells, muscle and various enzymes and it is directly related to the cellular respiration of the body, as well as enzymatic reactions and immune cells in the animal organism (1). The current system of intensive pig farming deprives the animal's access to soil, the main natural source of iron supplementation for this species. In order to prevent iron deficiency anemia cases, it is recommended the application of dextran iron injection at the 3rd day of life of piglets. However, this management practice can bring a lot of inconveniences to the development of these animals. In the practice of human medicine for over 3 decades is made of iron supplementation with oral presentations (capsules and tablets) in order to prevent various types of anemia. One of the molecules of iron commonly used for this purpose is the carbonyl iron, due to its high content if organic iron available and high intestinal absorption (2). The purpose of this study was to evaluate the effectiveness of iron carbonyl orally in the iron supplementation in piglets.

Material and Methods
The experiment was conducted in a farm producing piglets in the state of Santa Catarina – Brazil. A total of 60 piglets (initially 1.95 ± 0.45 Kg) from 12 sows with same age and number of births and receiving the same management were used in this study. The experiment design was randomized blocks with 5 treatments and 12 repetitions, with each sow representing one experimental block. The treatments were: T1 – non iron supplementation, T2 – 2000mg dextran iron injectable the 3rd day, T3 – 150mg carbonyl iron orally the 3rd day, T4 – 200mg dextran iron injectable the 5th day; T5 – 150mg carbonyl iron orally the 5th day. No source of iron supplementation was used in addition to the treatments. The data were compared by Tukey test at a significance level of 5% for analysis of variance (ANOVA). The parameters evaluated were weight gain (at 21 and 57 days old) and blood parameters (hemoglobin, packed cell volume (at 21 days old).

Results
The evaluation of weight gain of piglets at 21 days of age showed a non-significant difference (P > 0.05) among animals not supplemented and supplemented (dextran iron and carbonyl iron). However, analysis of blood parameters in the same period showed that piglets which did not receive iron supplementation had lower (P <0.05) weight gain (less 10.31%) than those who received dextran iron supplementation the 3rd day. There was not difference (P >0.05) in weight gain of piglets according to the source of iron supplementation (dextran or carbonyl) and the timing of supplementation (the 3rd or 5th day).

Discussion
The data are consistent with (3), showing that piglets kept in intensive system of production and did not receive iron supplementation develop early iron deficiency anemia, evidenced by lower levels of hemoglobin and packed cell volume at 21 days old. However, the negative effect of livestock of iron deficiency in piglets may have a delayed response in relation to blood parameters, since the difference in weight gain among supplemented and non supplemented animals only became evident at 57 days old. The supplementation of carbonyl iron orally was shown to have a positive effect in preventing iron deficiency anemia in sucking piglets, and the administration the 5th day most appropriate. Even so, piglets supplemented with dextran iron the 3rd day had superior results for the blood parameters than piglets non supplemented and the supplemented with carbonyl iron.

Effectiveness of tulathromycin injection for the control of porcine pleuropneumonia on a grower-finisher farm in an outbreak situation

Kristen Reynolds; Zvonimir Poljak; Robert Friendship; Cate Dewey
Department of Population medicine, OVC, University of Guelph, Guelph, ON, Canada

Introduction
Outbreaks of diseases that result in acute death such as pleuropneumonia caused by Actinobacillus pleuropneumoniae are a great concern in some swine facilities. Porcine pleuropneumonia is partly controllable through good management practices (1,2), though sudden outbreaks can periodically occur. Tulathromycin (Draxxin™, Pfizer Animal Health) has been proven effective for the treatment of multifactorial swine respiratory disease (3,4), as well as the treatment of porcine pleuropneumonia caused by A. pleuropneumoniae (5) if given up to 9 days prior to known exposure (6). The objective of this study was to evaluate the efficacy of tulathromycin in preventing losses in swine herds due to Actinobacillus pleuropneumoniae under field conditions.

Materials and Methods
Three field trials were carried out in a farrow-to-finish herd located in Ontario. The finisher barn had a continuous pig flow, and pigs of different ages were frequently housed in the neighbouring pens. The swine herd was endemically infected with a number of swine pathogens including Mycoplasma hyopneumoniae, Actinobacillus pleuropneumoniae, and PRRS virus. In late September 2007, the herd started to experience a sudden increase in mortality during the finisher phase, with both clinical signs and gross pathological lesions indicative of porcine pleuropneumonia (PP). Presence of A. pleuropneumoniae (susceptible to penicillin and ceftiofur) was confirmed in typical lung lesions using bacteriological culturing.

Three trials performed in the finisher barn compared treatment with tulathromycin to treatment with long-acting penicillin, ceftiofur hydrochloride, or a combination of the two. Three different types of mortality (overall, reported and mortality due to A. pleuropneumoniae) were analyzed using logistic regression and Cox’s proportional hazard models. Linear regression was used to analyze average daily gain (ADG).

Results
Serotypes 5A and 5B were detected in samples of pigs that died with typical PP lesions. The hazard of dying (Hazard Ratio = HR) was higher in treatments other than tulathromycin in trials 1 (HR=2.36, P=0.05) and 2 (HR=3.66 P=0.02) for reported mortality. Similar results were attained for mortality due to A. pleuropneumoniae (Figure 1). Tulathromycin was found to increase average daily gain of pigs in trials 2 (ADG, Beta=120 g/day, P<0.001) and 3 (ADG, Beta=52.6 g/day, P<0.01).

Discussion
It was concluded that under the conditions of this study and sufficient exposure to A. pleuropneumoniae, tulathromycin would significantly reduce pig mortality and improve growth performance relative to similar treatment with either penicillin or ceftiofur.

Marbofloxacin achieves high concentration in pig tonsils according to a dose dependent fashion

Lorenzo Fraile¹ Carles Vilalta¹ Rosa López-Jimenez¹ José M. Caballero³ Marcelo Gottschalk⁴ Marc Schneider²
¹. CReSA, Bellaterra, Spain; 2. Vetoquinol R&D Department, Lure, France; 3. Vetoquinol E.V.S.A, San Fernando de Henares, Spain; 4. Faculté de médecine vétérinaire, Québec, QC, Canada

Introduction
Actinobacillus pleuropneumoniae (APP) is the causative agent of porcine pleuropneumonia. Pigs can become asymptomatic carriers of the organism in their tonsils for long periods. Attempts to eradicate APP from pig herds have been made with antibiotics but there is a paucity of information about the penetration of antibiotics in tonsils. Marbofloxacin (MB) is a fluoroquinolone widely used in veterinary medicine to control APP under field conditions. The goal of this study was to quantify the MB penetration in tonsils after applying several MB regimen dosages.

Material and methods
Pigs were randomly divided in three groups (control, P1 and P2) of ten animals each one. The control group received 2 mL of serum saline. On the other hand, P1 group received a dose of 2 mg of MB/Kg every day for three consecutive days and P2 group received a dose of 4 mg of MB/Kg every 48 hours two times. The animals were sacrificed 24 hours after finishing the treatment to obtain tonsils and serum samples. The concentration of marbofloxacin in sera and tonsils was quantified by an HPLC analytical method. Finally, It was also calculated the ratio MB tonsil concentration versus APP MIC90 value (0.03 mg/mL) determined following the CLSI recommendations (4, 7). This ratio is one of the PK/PD efficacy parameters described for fluoroquinolones (5).

Results
Average marbofloxacin serum concentration (AMSC) was 0.16 and 0.24 mg/mL for the P1 and P2 group, respectively. Average marbofloxacin tonsil concentration (AMTC) was 0.50 and 0.70 mg/gr for the P1 and P2 group, respectively (see figure). Thus, AMSC and AMTC increased in a dose-dependent fashion. However, the tonsil MB versus serum MB concentration ratio was close to 3 independently of the dose administered to animals.

Moreover, the MB tonsil concentration: APP MIC90 ratio was 16.6 and 23.3 for P1 and P2 groups, respectively.

Discussion
Marbofloxacin achieves a good penetration in tonsillar tissue, which compares favourably with tonsil/plasma mean concentration ratios reported for other fluoroquinolones (2,3). However, tonsil/plasma ratio observed for MB was very similar to the described by Esposito et al. (2006) for moxifloxacin in humans.

A great deal of information is now available on the PK/PD relationships for fluoroquinolones. Ratios of 125 for AUC0—24:MIC and 10 for Cmax:MIC have been recommended to achieve high clinical efficacy for concentration-dependent antimicrobial drugs like MB. The MB tonsil:MIC ratio described is above the threshold value (10) that is associated with clinical efficacy for all the doses studied (6). Thus, all the posology regimens tested might be efficacious to eliminate APP from tonsils. Obviously, the information provided here paves the way to carry out studies whose main goal could be to detect APP in tonsils of animals receiving several posology regimens of marbofloxacin.

Assessment of decisions pertaining to antimicrobials used in nursery pigs

Rebecca Robbins1 Sam Copeland2 Glen Almond1 Maria Correa1
1. North Carolina State Univ. College of Veterinary Medicine, Raleigh, NC, USA;
2. North Carolina State Univ. Department of Animal Science, Raleigh, NC, USA

Introduction
Judicious use of antimicrobials is a public health and civic responsibility and one of the most controversial of all therapeutics currently in use. Surveys of United States and Canadian pig producers indicate that the greatest proportions of antimicrobials are administered to nursery pigs. Guidance on antimicrobial use has been developed but no single treatment standard established. Thus, we conducted the first of a series of studies to determine patterns in antimicrobial treatment based on current practices in commercial nurseries.

Materials and Methods
The use of antimicrobials via injection or water was observed for 123 conventional health nursery barns. Barns housed pigs from weaning until 9-10 weeks of age and were isolated from farrowing or finishing barns. During the six month study period, 368 barns were observed. The unit of analysis was the barn (ecologic design). Antimicrobials delivered through the feed did not vary during the study and were not described. Reason for administration, clinical diagnosis, severity of disease, and antimicrobial regimen were recorded. Descriptive statistics were conducted in SAS (v. 9.1, Cary, NC, USA).

Results
There were 136 reports of barns that used an antimicrobial via water or injection representing 37% of nursery barns observed. Of the 136 medicated barns, 28 (20.6%) were received antimicrobials more than once. Pigs ≤7 weeks old received antimicrobials with the greatest frequency (63%). Water was the favored route of administration at 61%. We observed 65% of antimicrobials were for treating disease as opposed to metaphylaxis and 87% of disease was considered mild or moderate rather than severe. The majority (75%) of clinical diagnoses had signs of respiratory disease; other diagnoses were systemic (18%) or enteric (7%) conditions. The antimicrobial regimens favored the use of chlortetracycline plus tiamulin (31%) in water and enrofloxacain (29%) by injection. The remaining 40% was spread over 8 other regimens. We also observed that the route of antimicrobial administration was influenced by disease severity (p=0.002), purpose of administration (p=0.019), and clinical diagnosis (p<0.001). The relationships were further expressed in odds ratios (OR) with 95% confidence limits (CL) and p-value reported in Table 1.

Discussion
A previous report found that treatment frequency could approximate disease prevalence. If this observation is valid, then we expect at least 1/3 of nurseries to be diseased in a 6 month period. We would expect most disease to be respiratory in nature. The frequency of antimicrobial regimens applied also supports this expectation. Although we observed a preference for administration through water, the route was influenced by other factors. There is a strong preference for injectable antimicrobials when nurseries are severely diseased. Therefore, we believe that disease severity and route of administration are proxies of one another. Unfortunately, we could not obtain OR for clinical diagnosis due to sparse data. No enteric cases received antimicrobials by injection and this is likely due the exclusive use of single injection products having regulatory prohibitions in the U.S. as well as the pharmacodynamics of oral medications. In summary, decisions regarding antimicrobial use in pig populations are complex and are related to factors other than the antimicrobial or route of its administration.

Compatibility of vaccines against atrophic rhinitis and neonatal E. coli diarrhea

H. M. J. M. Swarts¹ M. Murmans² M. Witvliet²
1. ISPAH, Global Marketing Swine, Boxmeer, Netherlands; 2. ISPAH, Microbiological R&D, Boxmeer, Netherlands

Introduction
In modern swine production sows are vaccinated against several diseases, either to protect the sows or to protect the sows' progeny (or both). This leads to the fact that sow vaccination schemes can become very extended and very complex. To be able to work more practical and to reduce the number of injections for the sows, farmers are eager to look for options to combine vaccines without compromising on the efficacy.

Porcilis AR-T DF (1) and Porcilis Porcoli DF (2) are two vaccines that are given to pregnant sows to pass on passive immunity through MDA to their offspring to protect them against atrophic rhinitis and neonatal E. coli diarrhea, respectively. Porcilis AR-T DF contains a subunit of the P. multocida toxin (PMT) in combination with B. bronchiseptica (Bb) cells and Porcilis Porcoli DF contains purified fimbrial adhesins (F4ab, F4ac, F5 and F6) and the E. coli heat labile toxin (LT). Since both vaccines require the same vaccination schedule (basic vaccination 8-6 weeks and booster / re-vaccination 4-2 weeks before farrowing) and both vaccine use Diluvac Forte (d,l-α-tocopheryl acetate) as the adjuvant, it was tested in the present study if injection of the vaccines after mixing would influence the antibody responses against the individual vaccine antigens.

Materials and Methods
Three groups of 10 pigs of 8 months of age with no or low antibody titers against the vaccine antigens were injected twice intramuscularly with a 4-week interval with Porcilis AR-T DF (2 ml), Porcilis Porcoli DF (2 ml) or both products after mixing (4 ml). Two weeks after the second vaccination, serum samples were taken. Antibody titers were determined in a toxin-neutralization assay (PMT), a micro-agglutination test (Bb) or by ELISA (E. coli antigens).

Results
The serological responses after vaccination with the two vaccines given individually or mixed are presented in Table 1.

Discussion and Conclusion
For nearly all antigens, there was no significant difference between the antibody titer induced by the single vaccines or by the mixed products.

However, for the F5 and LT antigens, the antibody levels induced after mixing of the two vaccines were significantly lower than those induced by Porcilis Porcoli DF alone. In both the single and the combined group uniform titer values were reached after vaccination, which allowed for detecting significant difference between for the F5 and the LT titer values, however the serum antibody levels against these two antigens after mixed vaccination were still above the level that can be considered to provide protection via the colostrum (2).

Possibilities of overcoming the inhibitory effect of colostrum-derived antibodies using intradermal immunization and immunization via mucosae

Katerina Nechvatalova; Martin Faldyna; Eduard Gopfert; Pavlina Knotigova; Hana Kudlackova; Lenka Leva
Veterinary Research Institute Brno, Brno, Czech Republic

Introduction and objectives
The colostrum-derived antibodies protect piglets in early life. Levels of these antibodies gradually decrease in sera of growing piglets and according to the prevailing opinion they decline so much at a certain time point that they cannot protect the organism against infection and even block the onset of active immunity. This period has been generally designated as the “immunity window” (1). On the other hand, our previous studies and studies of other authors (1-3) indicated that colostrum-derived antibodies do not completely prevent the immune response after immunization and that this period could be overcome or shortened by properly timed vaccination, local administration of antigens and/or by the use of proper type of adjuvant.

The aims of this study were to verify the possibility of overcoming the inhibitory effect of colostrum-derived antibodies in piglets using immunization via the skin or mucosae and to test the effect of higher proportions of adjuvant and/or higher concentrations of model antigen on quality and quantity of induced local and systemic immune responses.

Materials and methods
Piglets (5 animals in each group) with colostrum-derived antigen-specific antibodies were intranasally (i.n.), intratracheally (i.tr.) or intradermally (i.d.) immunized with increasing concentrations (3 mg, 5 mg or 10 mg/piglet) of a model antigen – Keyhole Limpet Hemocyanin (KLH; Pierce, France) and increasing proportions of adjuvant Montanide IMS 1312 (Seppic, France) per immunization dose (50-75%), i.e. at ratios of adjuvant to KLH from 1:1 to 3:1; the volume of each immunization dose was 1 ml. Immunization of respective groups started at different age (2, 4 or 6 weeks of life) i.e. at periods of high and subsequently decreasing levels of total and local antigen-specific antibodies. All piglets were reimmunized 3 weeks after the first administration of KLH.

Blood samples, nasal and bronchoalveolar lavage samples from all pigs were taken regularly for immunologic examination (isotype–specific indirect enzyme linked immunosorbent assays with purified KLH antigen and for the KLH-driven lymphocyte transformation test).

Results
The piglets were able to give a quantifiable (cell-mediated and antibody) primary immune response to i.n., i.tr., and i.d. immunization with KLH already at the age of 2 weeks of life in the presence of high levels of colostrum-derived antibodies, but only after use of higher concentrations of KLH and/or addition of higher amounts of adjuvant. Immunization led to production of local IgA and IgG and systemic IgM antibodies in these piglets. The levels of systemic IgG antibodies increased only in older piglets (aged 4 and 6 weeks) after i.d. and i.tr. immunization with KLH, using the highest proportion of the adjuvant (75%). Generally, the use of higher concentrations of KLH and higher proportions of adjuvant per immunization dose resulted in a faster and more intense immune response. On the other hand, the immunization dose containing 10 mg of KLH elicited excessive but transient local inflammation of the respiratory tract. The immune response intensity after i.n. immunization was generally lower than after i.tr. immunization; moreover, the former provided weaker systemic immune response than i.d. immunization. After revaccination, no significant differences were observed in the immune responses of piglets with higher and lower levels of colostrum-derived antigen-specific antibodies at the time of primary vaccination.

Discussion and conclusions
The present study confirmed in accordance with other authors (4) that vaccination might be successful even in piglets with high levels of colostrum-derived antibodies at the time of immunization. Inhibitory effect of colostrum-derived antibodies was overcome in this study using local administration of antigen and proper balancing between the antigen concentration and adjuvant proportion in the immunization dose which were of crucial importance.

Time point for vaccination sows with *E. coli* vaccines may influence the protection of the offspring

Thersa Salwén² Per Wallgren¹

¹ Dept of Animal Health and Antimicrobial Strategies, Uppsala, Sweden; ² Sanna Norrgården, Vintrosa, Sweden

Introduction

Neonatal diarrhoeas induced by *E. coli* are commonly prevented by vaccination of sows that are booster vaccinated 2-3 weeks before farrowing (1). However, the transfer of immunoglobulin from serum to colostrum is initiated at least four weeks prior to farrowing. (2). Therefore, vaccinating sows at an earlier time point appears tempting in herds that are affected by neonatal diarrhoeas caused by *E. coli* despite vaccinating sows.

Materials and Methods

The study was conducted in a multiplying herd with 160 landrace sows producing Landrace-Yorkshire hybrids. Forty sows farrowed every fourth week in an age segregated system, and the piglets were weaned at an age of 4 weeks. Despite vaccinating sows with *E. coli* vaccines (Porcovac, Plus vet/Porcilis/Porcoli Diluvac Forte) during late pregnancy the herd had a high incidence of neonatal diarrhoeas. *E. coli* serotype O149 had repeatedly been diagnosed as the cause of these diarrhoeas by laboratory analyses.

The productivity of sows and piglets was documented in which the birth weight was standardised to 1.5 kg. Piglets attended with diarrhoea were medically treated and recorded at an individual and litter level. 43 batches boostering sows with E coli vaccine two weeks before farrowing, were compared with 28 batches following altering the booster vaccination to six weeks before farrowing No other measures were carried out with the aim to control *E. coli* associated neonatal diarrhoeas. The statistical calculations were carried out using t-tests.

Results

Piglets were weaned at a somewhat higher (p<0.001) weight before altering the time point of vaccinating sows. However, this was achieved by a higher (p<0.001) weaning age as also demonstrated by an equal daily weight gain of the two groups (Figure 1). Also the productivity of the sows was equal in the two goups.

The incidence of diarrhoeas during the suckling period was decreased, both at individual (p<0.001) and at litter (p<0.05) level following the change of time for vaccinations (Figure 2).

Discussion and Conclusions

The incidence of diarrhoea during the suckling period decreased following vaccinating sows at an earlier time point which was a positive welfare issue, both for the piglets and the staff. Thereby the use of antimicrobials also decreased, which ought to be favourable from an antimicrobial resistance point of view. Yet, the productivity in itself was not affected by the altered vaccination strategy, which probably could be explained by an alert staff treating piglets with neonatal diarrhoeas at an early stage - thereby preventing increased piglet mortality.

This work concludes that vaccinating sows at an earlier point of time than generally recomended could be worth testing in herds with *E. coli* associated neonatal diarrhoeas despite vaccinating sows.

**Agreement between culture of intestinal and fecal samples for Escherichia coli and Brachyspira spp.**

Ken S. Pedersen¹ Jens P. Nielsen¹ Øystein Angen²

1. University of Copenhagen, Frederiksberg, Denmark; 2. National Veterinary Institute, Technical University of Denmark, Frederiksberg, Denmark

**Introduction**

Culture of fecal samples is often applied for examination of intestinal pathogens. Culture of feces may not reflect the intestinal microbiology and result in biased estimates of pathogen prevalence or incorrect diagnosis. The objective of the current study was to evaluate agreement between culture of intestinal and fecal samples for E. coli and Brachyspira spp.

**Materials and Methods**

Fecal samples and intestines were collected in a case control study conducted in 20 Danish herds. All herds were visited the day following notification from the farmer/veterinarian of an acute treatment requiring outbreak of diarrhea in pigs between 10 and 70 days post weaning. The farmer was not allowed to medicate before the pigs were examined. A sample of 80 pigs in each herd was selected by systematic random sampling among all pigs in the nursery room where the outbreak of acute diarrhea occurred. The pigs were subjected to a clinical examination and a fecal sample was collected. Among the examined pigs a simple random sample of 8 pigs with diarrhea and 8 pigs without diarrhea was selected and euthanized. Fecal samples from all euthanized pigs were examined for Escherichia coli and Brachyspira spp. by standard culturing methods. Small intestinal content was examined for E. coli and large intestinal content was examined for Brachyspira spp. Dry matter (DM%) was determined for the fecal samples. DM% ≤ 18.8 was considered as diarrhea and was used (if necessary) to reclassify the pigs as diarrheic or non-diarrheic in the statistical analysis. For each Brachyspira spp., hemolytic E. coli, non-hemolytic E. coli (if found in pure culture or as the dominant bacterial flora) diagnostic sensitivity and specificity of the fecal culture were evaluated using the culture of the intestinal samples as reference standard. Further, differences between diagnostic sensitivity and specificity in pigs with or without diarrhea were evaluated using a Chi-sq test.

**Results**

Diagnostic sensitivity and specificity for fecal culture are displayed in table 1. In pigs with diarrhea and pigs without diarrhea the diagnostic sensitivity was significant different for hemolytic E. coli and borderline significant for non-hemolytic E. coli (p=0.068) and B. innocens/B. murdochii (p=0.066).

**Discussion**

A clear correlation between fecal and intestinal cultivation was only found for hemolytic E. coli. A difference in diagnostic sensitivity between pigs with and without diarrhea was also only observed for hemolytic E. coli. However, culture from intestinal content may not always be considered a true gold standard and the obtained estimates of sensitivity and specificity should therefore be interpreted with caution. The results imply that culture of fecal samples can either under or over estimate prevalence of these pathogens compared to culture of intestinal content. The study also demonstrates that diagnostic test have different performance in various subpopulations. The relatively low sensitivity for Brachyspira spp. may have implications for surveillance of swine dysentery.

**Table 1. Diagnostic sensitivity and specificity of culture of fecal samples for E. coli and Brachyspira spp. using culture of intestinal content as reference test.**

Factors associated with the occurrence and the level of *Isospora suis* infection in Greek pig herds

Vasilis Skampardonis¹,² Smaragda Sotiraki² Polychronis Kostoulas ¹ Leonidas Leontides¹

1. University of Thessaly, Karditsa, Greece; 2. Veterinary Research Institute, National Agricultural Research Foundation, Thessaloniki, Greece

Introduction

Neonatal coccidiosis, which is due to *Isospora suis* parasitism, occurs in all types of farrowing facilities and under all types of management systems (Lindsay and Blagburn, 1994; Meyer et al., 1999; Mundt et al., 2005). In this study, we identified herd- and litter-level factors associated with the odds and the level of *I. suis* oocyst excretion in Greek pig herds.

Materials and Methods

Data were collected from 55 farrow-to-finish herds with continuous farrowing. From each herd, depending on the herd size, at least five and up to ten litters, in their second week of life, were coprologically sampled. Each litter-sample comprised a pool of individually collected faeces from half of the piglets. Oocyst excretion, expressed as oocysts per gram of faeces (OPG), was determined, by a modified McMaster technique, for all samples. A standard risk-factor questionnaire was used to collect information on the use of toltrazuril (BAYCOX® 5%) and other herd- and litter-level factors that could be associated with *I. suis* infection. To simultaneously identify factors associated with the odds of and/or the amount of litter-level oocyst excretion we employed a two-part model (Liu et al., 2008). Presence or absence of oocyst excretion was the response variable in the logistic part of the model, while the natural logarithm of the non-zero OPG values was the response in the linear part (parts I and II, respectively). Initially, all factors were screened one by one in univariable models. Those with \( P < 0.25 \) in any part of the model, were offered to the full model, which was further reduced by backwards elimination until only significant \( (P < 0.05) \) variables were left. In all models, the herd was incorporated in both parts as random-effects term and the likely cross-equation correlation \( (\rho_{CEC}) \) of the herd-level random-effects between parts I and II was accounted for. A weighting method, which adjusted for the unequal selection probabilities of litters in herds was applied in all models. Models were built in the aML software.

Results and Discussion

The odds of *I. suis* litter-level excretion were reduced when piglets were treated with toltrazuril, when the farrowing rooms were completely emptied and cleaned after weaning, when piglets were not cross-fostered between litters after the 1st day of life and when the flooring of the pens was plastic. Further, larger farrowing rooms and more caretakers in the farrowing rooms reduced the odds of excretion. The level of OPG was decreased with toltrazuril-treatment, larger farrowing rooms and caretakers avoiding walking into farrowing pens. Thus, additionally to toltrazuril treatment, control of neonatal coccidiosis can be bettered by other factors.

Likely carriage of Brachyspira hyodysenteriae in cockroaches and flies on pig farms

Ruth Blunt; Laura Hancox; Ken Mellits; Steven McOrist
University of Nottingham, Sutton Bonington, UK

Introduction
Insects on pig farms can cause loss in various ways, including an ability to spread disease within and between farms. This may conceivably include re-infection of eradication project farms by insects travelling from adjacent farms when infected with the agent in question. Some 1980’s research documented the occurrence of enteric pathogens, such as Brachyspira hyodysenteriae among possible vectors on pig farms. However, no information exists on a truly wide range of vectors or on the movement of exact strains or isolates around farms. Vector types may also have altered in pigs now facing PRRS, PMWS etc. Other studies have indicated that some floor-dwelling insects, such as cockroaches and beetles, may be capable of carrying other enteric agents such as Salmonella and E. coli for significant periods on commercial pig and chicken farms. Increases in farm bedding usage will presumably also increase populations of potential infected vectors. This study aimed to investigate carriage of Brachyspira among farm insects.

Materials and Methods
We constructed a set of 15 case study farms in England and Ireland to include the following: mixed-age farms, breeder only farms, recently depopulated farms, empty farms and various other scenarios. Most farms were Lawsonia and PCV-2 positive, as determined by clinical signs and faecal PCR results. Farms that are positive and negative for Brachyspira hyodysenteriae (swine dysentery = SD) were targeted, as determined by clinical signs and faecal PCR and cultures.

At each farm, numerous longitudinal and age-group specific vector samples and population-stratified faecal samples were collected. Insects were collected via aerial sticky traps, motorised vacuum devices, floor and pitfall traps and sweep nets and identified by trained entomologists. DNA was extracted from the GI tract of larger insects and from whole body samples of smaller insects. PCR was performed on pig and insect origin DNA by published duplex species-specific methods for Brachyspira – both B hyodysenteriae and B pilosicoli. At present, strain or isolate typing methods are not readily available for B hyodysenteriae.

We also conducted separate experimental challenge exposure studies of housed cockroaches and Musca domestica flies, dosed orally with 107 live B hyodysenteriae derived from a confirmed SD case. We cultured and PCR tested both the intestinal tracts and faeces of dosed and control insects.

Results
A wide range of insects were found at varying levels in the 15 study farms. Prominent groups of flies were found – Diptera, including Musca domestica (house fly), Muscina stabulans (false stable fly), Ophyra spp (garbage fly), Stomoxys calcitrans (stable fly) and Syrphidae, including Eristalis sp (hover flies), as well as numerous floor-dwelling beetles associated with feed storage. The oriental cockroach, Blatta orientalis was detected in considerable numbers on 2 farms. One of these farms was also positive for SD signs and B hyodysenteriae (by faecal PCR) in its pigs. B hyodysenteriae PCR products were also detected in the faeces of several pigs on 3 other swine dysentery-positive farms (with no cockroaches). No clear Brachyspira positive fly or other vectors were noted on these 3 farms. However, PCR products indicative of Brachyspira hyodysenteriae were also detected in 30% of cockroaches, caught in association with the SD pig-positive farm. This agent was not detected in cockroaches on the other cockroach-positive but SD-negative farm.

Separate challenge exposure studies of Musca flies and cockroaches indicated that these potential vectors may hold B hyodysenteriae in their gastrointestinal tracts for periods of 1 to 3 days. We determined that these insects could not only retain these bacteria in their GI tracts, but also excrete viable culturable B hyodysenteriae for these periods, via their faeces.

Brachyspira pilosicoli was only noted in pig faeces collected on one farm, no clear positive B pilosicoli infection was noted in any potential vector.

Discussion
We found a wide range of flies, beetles, midges and cockroach activity on British and Irish pig farms – some of these appear to have the potential to carry and transmit pathogens, such as PCV2. In particular we found that cockroaches had the potential to carry Brachyspira hyodysenteriae for a potentially important period of 3 days. Cockroaches form large indestructible communities on pig farms when they are introduced – usually via food waste or other waste products. They may assist transmission of the SD agent within and between farms. This suggests that a program aimed at reducing infection levels or post-eradication re-infection with this agent should include not only appropriate biosecurity and pig medication, such as pleuromutilins, but also anti-insect population control measures, targeted at cockroaches and flies in association with pigs.
Sub-clinical ileitis: Technical and economic impact of nutrition and therapeutic measures implemented

Annick Saives1 Jeanne Dupuis2 Alban Chauvin3
1. Elanco Europe, Brussels, Belgium; 2. Selas Veterinaire de la Hunaudaye, Lamalle, France; 3. Cooperl Arc’atlantique, Montfort Sur Meu, France

Introduction
Lawsonia intracellularis is responsible for an infection known as ileitis, of which the sub-clinical disease leads to decreased zootechnical performance (1). The symptoms are therefore non-specific and differential diagnosis is essential for determining the prevention and treatment measures to be implemented. The purpose of this study is to describe the use of diagnostic tools in farms affected by sub-clinical ileitis, enabling therapeutic and zootechnical measures to be applied, and to evaluate their effect on zootechnical performances.

Materials and methods
A site 3 finishing barn with 320 pigs per batch, of a single animal origin and showing lack of uniformity at the entry of the animals (84th day of life) and also in the last part of the finishing stage, was selected (period 1, tab 1).

An anti-Lawsonia Ab serum profile was carried out in April 2008 using the IFAT (indirect fluorescence antibody technique (Ileitest®)) method, by collecting samples at 95, 125 and 167 days of age.

At 95 days of age, 10 out of 10 samples were negative; at 125 days of age, 10 out of 10 samples were positive; at 167 days of age, 5 samples out of 5 were positive.

Seroconversion occurs around 100 days of age, and according to experimental infection studies (2), spread probably primarily takes place at the entry.

An initial dose of Tylan was introduced into feed (100 ppm for 10 days) upon entry of the animals, followed by a second dose in the drinking water mid-finishing stage (10 days at 5 mg/kg), due to the 2nd period of heterogeneity.

After the treatment, an improvement in the ADG was seen (period 2, tab 1) but performances are still unsatisfactory at the end of the complete period. In October 2008, Lawsonia excretion FIRSTtest® was carried out to know if the problem persists. The FIRSTtest® is a single-use test for the colorimetric detection of Lawsonia using the ELISA technique, which identifies the bacterial surface antigen.10 samples were collected per age.

At 110 days of age, 9 out of 10 samples were negative and at 150 days of age, 10 out of 10 samples were negative.

As the herd was not excreting Lawsonia on this period, a change in feed rationing plan was decided in November 2008 (changes in formulation and schedule plan at the beginning of fattening period) and the 2nd soluble Tylan treatment was reduced from 10 to 7 days (period 3, tab 1).

Results

Discussion and conclusion
The 2 diagnostic tools described here are complementary. Serum testing made it possible to understand how Lawsonia circulates in the herd and to target the ideal treatment time. The FIRSTtest® made it possible to understand that the diarrhoea at the end of the finishing stage and heterogeneity were not related to Lawsonia and could therefore be improved by zootechnical measures (rationing and formulation).

Administration of Tylan treatments led to an improvement of 1.6 kg in average cold carcass weight and formulation adjustment led to a 1.1 kg gain.

Evaluation of efficacy of oral toltrazuril (Baycox 5 %®) for the improvement of post-weaning gut health in pigs in Spain

Alberto M. Alujas & Ruth Blunt & Steven McOrist
1. University of Nottingham, Sutton Bonington, UK; 2. Tests and Trials Ltd, Lleida, Spain

Introduction

Isospora suis disease often occurs around the second week of life, through to the normal pig weaning age of 3-weeks-old. It is characterized by yellowish pasty diarrhoea for one to several days; with dehydration evident even though nursing from the mother often continues. Oocysts can survive outside the pig, in the farrowing area, for many months and are resistant to most disinfectants. The time for intervention in piglets with a control strategy is critical; use of a preventive drug usually take place at 3 to 4 days of age so that it can kill appropriate stages of the parasite within newly infected piglets. Various anti-coccidial drugs have been developed and tested against porcine neonatal isosporosis, such as sulphadimidine. However, in the European Union, the symmetrical triazinetrione toltrazuril is the only coccidiocidal registered (since 2002) specifically for the control of porcine neonatal coccidiosis in a single oral dose format of 20mg per kg bodyweight. Clinical studies of toltrazuril after weaning have not been comprehensive and have not usually included information on the possible beneficial effects on gut health in the dosed pigs in the later post-weaner, grower or finisher stages. This is an important issue in pigs, which are considered to show limited compensatory growth in animals recovering from a previous illness or weight check around weaning age. The exact reasons for this are not clear, but could include better intestinal maturity and enzymatic activity and a lower susceptibility to further post-weaning infectious agents, in those heavier pigs at weaning. The aim of this on-farm study was to evaluate the efficacy of toltrazuril (Baycox™) for coccidiosis prior to weaning and demonstrate specific beneficial effects on gut health and feed conversion after weaning. We also found that post-weaning enteric diseases including both ileitis and swine dysentery due to Brachyspira hyodysenteriae were more severe in pigs untreated for coccidiosis.

Results

There was a markedly improved feed conversion in grower-finisher pigs in Group A, particularly in the finisher period, but similar weight gains throughout. Lawsonia serology results indicated an early (before day 56) and moderate on-farm exposure. Titres in Group B pigs were higher, with fewer negatives throughout (p< 0.01), suggesting that the intestines of these pigs were more receptive to pathogenic Lawsonia infections, just after weaning. Four Group B pigs, 77 to 105-days-old, but no Group A pigs, had putative positive faecal PCR results for Brachyspira hyodysenteriae (swine dysentery). Salmonella, PCV2, Brachyspira pilosicoli, E coli and Clostridia results were not noteworthy. There was more diarrhoea noted (p<0.05) in the piglets up to weaning age in group B (untreated), by blinded investigators.

Discussion

These results confirm the protective effect of toltrazuril (Baycox™) for coccidiosis prior to weaning and demonstrate specific beneficial effects on gut health and feed conversion after weaning. We also found that post-weaning enteric diseases including both ileitis and swine dysentery due to Brachyspira hyodysenteriae were more severe in pigs untreated for coccidiosis.

We therefore suggest there are two main reasons why the lifetime effects of small weaning weight and peri-weaning infections of rotavirus and coccidia are so important and detrimental. First, there is an innate anatomical issue in that smaller, gut-damaged piglets being weaned with a limited supply of mature villi units, will grow more slowly and second, there is the likelihood that pre-weaning infections can carry forward into an increased number of post-weaning infections such as ETEC, Lawsonia and Brachyspira.

In the past 5 years, novel and effective preventive programs for Lawsonia and Isospora been introduced, related to an oral live attenuated vaccine (Enterisol ileitis™) and the oral anti-coccidial medication toltrazuril (Baycox™), respectively. Unlike coccidiosis in chickens, no major vaccines have been identified for coccidiosis in pigs.
O.058

Early farrowing, possibly induced by intoxication via feed, reduced piglet survival with 70%

Per Wallgren
Dept of Animal Health and Antimicrobial Strategies, Uppsala, Sweden

Introduction
Survival of piglets is depending of a full length gestation, and events leading to farrowing earlier than expected may seriously affect piglet survival. This report describes two groups of sows mated at the same time and standing in adjacent units, but with dissimilar results at farrowing.

Materials and Methods
Three weeks prior to farrowing, 69 sows belonging to the same group of sows at the central unit of a multisite production system (sow pool) were transported to a satellite herd and divided into two groups. Group A with 36 sows was placed in unit A, and Group B with 33 sows was placed in unit B. All sows were offered a wet feed from the same batch and prepared at the farm. Piglets born were registered as live born, and still alive at three, 35 (weaning) and 70 (allocation) days of life.

Results
Sows in group B started to farrow six days prior to expected farrowing with a mean of -3.0 ± 1.9 days. Piglets born were premature and the mortality was significant. In mean these sows gave birth to 10.0 ± 3.0 live born piglets of which 3.4 ± 3.5 still were alive at three days of age. The mortality was 100% in litters born 5 or 6 days earlier than expected. The liquid feed was replaced with dry feed to the sows at the third day after the first farrowing, but only 4 out of 33 sows in group B farrowed at the expected day or later. The survival rate at 3 days of age in these 4 litters was 88% (Fig 1).

In contrast, sows in unit A farrowed at the expected time (at day -0.1 ± 1.1), with expected number of piglets born (13.3 ± 3.8) and still alive at three days (10.8 ± 2.2). From the third day of life, mortality was near to zero in both groups (Fig 1).

Necropsy of 6 stillborn piglets including placenta in group B excluded infections as a cause of the incidence. Instead they supported, but did not prove, intoxication (of the sows).

Discussion and Conclusions
The incident in Group B clearly demonstrated the importance of the last days of the gestation for the survival rate of the piglets born.

It is also interesting that the sows in group A farrowed at the same time in the adjacent unit with perfectly normal results. Due to the necropsy results and the lack of clinical signs in any other unit, infections were concluded less likely to have caused the incident in group B. Instead the feed was focused.

Liquid feed systems hold 3 kg feed per meter and the systems are generally neither emptied nor cleaned. Instead, unwanted microbial growth is assumed to be controlled with a low pH.

However, aggregations of food may arise, eg following curvatures, creating other conditions where growth of bacteria or fungi may take place. Considering the high water activity in the liquid feeding systems, bacterial growth probably appear first, with risk for bacterial toxins/endotoxins. With time, mould growth could also occur with subsequent mycotoxin formation.

If such an aggregate let go from the tube, pigs fed from the valves downstream will be exposed to its content, including endotoxins/mycotoxins which both have been proven able to induce abortion in sows (1, 2). However, as any toxin provocation will precede the abortions in time, a true relationship may be impossible to certify - even when strongly suspected as in this case. The feed loop to Unit B was opened by saw, cleaned and re-sealed. Subsequent farrowing batches have been normal.

References
Acute selenium toxicity in finishing pigs due to a contaminated feed supplement

Catrina M. Ritchie

SAC Veterinary Services, Aberdeen, UK

Introduction
Selenium toxicity in pigs is often due to accidental contamination of the diet (1-5). The acute form may present as sudden onset paralysis due to poliomyelomalacia of the spinal cord and it can be fatal. If finishing pigs ingest high levels of selenium the elevated tissue selenium levels present a potential risk to food safety. The mean blood selenium elimination half-life in pigs has been estimated to be 12 days (4). Selenium levels in liver and kidneys can still be elevated two months after a toxicity incident, with the kidney having the highest level (1). Livestock owners have a responsibility to produce food that is safe for human consumption. In the UK the Food Standards Agency (FSA) provides advice if there is a potential risk to the food chain, such as from a contamination incident. The financial losses due to selenium toxicity in finishing pigs are mainly due to culling of paralysed pigs, deaths and reduced marketability of exposed pigs. The consequences of the exposure are described and the loss due to acute selenium toxicosis in finishing pigs has been calculated.

Materials and methods
Fifty out of 316 twelve to fifteen-week-old pigs developed acute onset paralysis following the ingestion of a commercial, selenium contaminated, feed supplement. Two groups of pigs had clinical cases and a third group of 100 pigs, which had ingested the high selenium ration but for a shorter period, showed no clinical signs. Quadriplegia of alert pigs was the main finding. Affected pigs were usually willing to eat when presented with food. Alopecia developed in exposed pigs.

Results
Serum selenium levels in six pigs from the clinically affected groups ranged from 740 to 1880ng/ml, with a mean of 1310ng/ml (reference range 140-190ng/ml). Histopathological examination of the spinal cords from two pigs showed severe, bilaterally symmetrical lesions of poliomyelomalacia affecting the cervical and lumbar enlargements. The two, necropsied, quadriplegic pigs had pre-mortem serum selenium levels of 1370 and 1620ng/ml. Three other quadriplegic pigs had liver selenium levels of 9.49-13.2mg/kg DM (reference range 0.7-1.8mg.kg DM). Analysis of the commercial feed supplement detected a selenium content of 3090mg/kg, which was approximately 1000 fold higher than on the label. The complete diet was analysed and found to have a selenium content of 42.6mg/kg.

Discussion
The clinical signs, histopathological findings, blood and liver selenium levels were consistent with a diagnosis of selenium toxicity. The source was confirmed to be a feed supplement, which had been contaminated with a high level of selenium due to an error at the production plant. As the pigs were destined for the food chain at 24 weeks of age the Food Standards Agency (Scotland) was informed of the incident and the potential risk to food safety. They advised a 114 day withdrawal period from the time the pigs last consumed the contaminated feed and if this was not possible the offal had to be discarded at slaughter. The long withdrawal period meant that the pigs would be overweight for their market specification and only suitable for the cull sow market but they would not have been suitable for the export market due to the selenium exposure. Removing the offal at the abattoir posed practical difficulties and the risk that misidentification could occur for which there could have been liability. There was also concern over potential damage to the reputation of the Scottish pig industry if it became known that the pigs had entered the food chain. All 416 exposed pigs were euthanased on farm and their carcases disposed of.

The cost incurred per pig was calculated as CAD$39 (GBP23.32). The culled pigs were valued at CAD$63500 (GBP38040). The compensated loss was CAD$192 (GBP115) per exposed pig.

A case on chronic salt intoxication in growing pigs

Carmen Alonso¹ Nuria Llanes¹ Joaquim Segalés²
1. Cooperativa d’Ivars, Ivars d’Urgell, Spain; 2. CRESA, Barcelona, Spain

Introduction

Sodium (Na+) is necessary for the electrolytic balance in animals. Most ion sodium in the diet of different livestock species, including swine, is given by means of salt (sodium chloride). The standard recommendation of 0.2-0.25% meets the dietary Na+ and Cl- requirements of growing and finishing pigs for most meal diets. Sodium ion toxicosis is also called water deprivation or salt poisoning, and it is rather well documented in swine (1). The occurrence of this toxicosis is inversely related to water intake, usually related to water deprivation due to inadequate water supply or changes in husbandry. Based on available data, salt intoxication results in an acute or sub-acute clinical problem. Chronic salt toxicity has not been reported so far in pigs. Therefore, the objective of the present study is to report the clinical, pathological and laboratorial findings of a chronic salt intoxication case in growing pigs.

Materials and Methods

Pigs from a single-origin fattening farm located in North Eastern Spain displayed increased mortality. Historical mortality records in the finishers ranged between 5-7%, but in May 2008, mortality percentage increased dramatically to 49%. Approximately, 30% of the pigs developed central nervous disorders and 70% of them respiratory problems. Affected pigs displayed hyperesthesia, paddling and, usually, lack of palpebral reflex, with no fever. Animals with respiratory clinical signs (dyspnea) adopted dog-sitting position. Also, affected pigs showed paleness of the skin, and diarrhoea was identified occurring in all pens of diseased animals. A number of pigs were on-farm necropsied. Based on gross findings, oedema disease, postweaning multisystemic wasting syndrome (PMWS) and porcine reproductive and respiratory syndrome (PRRS) were suspected, besides the existence of concomitant bacterial-like pneumonia. Based on suspected etiologies, antibiotic was prescribed in water (neomycin) and several drugs were used parenterally (including enrofloxacyn, florfenicol and apramycin) in the different groups of affected animals. No significant response to antibiotic treatment was noted after 5 days of application. A number of laboratorial studies were implemented, including necropsy and histopathology of two pigs with central nervous clinical signs, antibody profile against PRRS virus, and urea and creatinine levels in serum. Further studies included determination in feed of heavy metals (cadmium and mercury), vitamin E, vitamin D, selenium, ochratoxine, oxalates and sodium chloride content were measured.

Results

The most significant pathological findings in both animals were a severe, bilateral, diffuse interstitial fibrosis in the middle and deep area of the renal cortex, with loss of glomeruli and glomerulosclerosis and a mild mononuclear multifocal meningoencephalitis with very occasional presence of eosinophils. Both pigs were also positive to PRRS virus detection in lungs. Both pigs had very high levels of both urea and creatinine. Obtained results so far, mainly the diffuse renal fibrosis, pointed out to a potential chronic toxicity scenario. Among the feed analyses performed, all determinations were within the normal ranges, but the sodium content of the ration, which was 2.21% on dry matter (those pigs ingested 30 times more sodium than that recommended for dry feeding with free access to drinking water (2). To determine the origin of these abnormally high salt levels, feed mix compounds were analysed for sodium chloride. Among 8 sources of whey, 2 of them had values of 17.2 and 21.3% of salt on dry matter; the remaining whey samples had values from 3.5 to 10.6% on dry matter.

Discussion

The present case report describes a complex situation in which clinical signs pointed towards an acute process, while kidney pathological features suggested a potential chronic toxicity process. Therefore, once the clinico-pathological findings were obtained, laboratorial investigations were directed towards a potential intoxication process. The confirmation of extremely high levels of salt in the diet, not previously reported in the literature as far as the authors’ know, allowed confirming a diagnosis of salt toxicosis in the affected herd. Moreover, the presence of an apparent novel kidney lesion (characterized by diffuse cortical fibrosis and glomerulosclerosis) associated to this intoxication let us classify the clinical problem as chronic.

Carbon monoxide intoxication in weaned pigs

Christina L. Planz\textsuperscript{1} Heiko Nathues\textsuperscript{1} Ulrich Brinkmann\textsuperscript{2} Elisabeth Große Beilage\textsuperscript{1}

\textsuperscript{1}University of Veterinary Medicine Hannover, Bakum, Germany; \textsuperscript{2}Praxis an der Maiburg, Bippen, Germany

\textbf{Introduction}

Carbon monoxide intoxication in pigs, although not often observed, occurs in connection with dysfunction of heating devices and poorly ventilated compartments. Depending on the level of carbon monoxide in the air and the time of exposure it can take peracute to chronic courses. This case report describes the occurrence of acute carbon monoxide intoxication in weaned pigs. It points out the course of actions to approach the diagnosis.

\textbf{Materials and Methods}

In February 2009, on a piglet production farm almost all piglets of one batch, which was stocked in one compartment, died within few hours after weaning. The pig farmer had not noticed any symptoms of disease at the point of weaning. In addition to a clinical observation of the piglets in all compartments of the stable, six of the dead piglets were subjected to a pathological and histopathological examination. Furthermore, a thorough examination of the environment of the animals was conducted, comprising a simulation of the climatic conditions in the unit on the day of re-stocking. Therefore the gas-fired heater, which was used to heat up the compartment on that day and had been maintained recently, was put into operation. After some hours, the concentration of carbon monoxide in the air of the compartment was measured via gas detection pump under strict safety precautions, supervised by experts from the local fire department.

\textbf{Results}

The examination of the animals in the barn did not give any clinical evidence; the piglets did not show any specific signs of disease. Feed and water could be excluded as source of the disease for the piglets had still not received feed, and the water was the same as in other compartments. During pathological examination of six piglets there could not be detected any abnormalities that could have explained the cause of death. Especially the colour of blood and tissues could be ascertained as physiological. Also the findings in the histopathological examination were unspecific. The measurement of the carbon monoxide content in the air during simulation of the climatic conditions in the compartment revealed a concentration of 3000 ppm.

\textbf{Discussion}

Contrary to expectations, pathological as well as histopathological examination did not contribute to the diagnosis of carbon monoxide intoxication. None of the symptoms described in literature as typically being related to carbon monoxide poisoning, such as cherry-red blood, rose-coloured tissues or meningoencephalitis, could be detected in the examined animals. The diagnosis was only made after intensive examination of the environment, including running the gas-fired heater which was used in the relevant compartment. The measured concentration of 3000 ppm was clearly above the minimum lethal concentration of 1000 ppm. This demonstrates that in cases of suspected carbon monoxide intoxication it is indispensable to take even more elaborate diagnostic measures like the described reconstruction of the climatic conditions in the compartment: In the absence of clinical and (histo)pathological findings this might possibly be the only successful way to confirm and prove the diagnosis.

The excess in carbon monoxide in the unit was attributed to a malfunction of the gas-fired heater. Especially in combination with very low ventilation rates as common during winter time, this can easily lead to high carbon monoxide levels in the air of the compartment. Therefore veterinarians should urge pig farmers to exercise due care in the use of these devices, not only for reasons of animal welfare but also for their own safety.

Assessment of vitamin E levels, selenium levels and presence of viral pathogens as the etiology of mulberry heart disease

Paul Thomas1 Giacomo Bortoletto1 Peter Kirkland2 Wonil Kim1 Alan Loynachan1 Steve Ensley1 Tanja Opriessnig1
1. Iowa State University, Ames, IA, USA; 2. Elizabeth Macarthur Agricultural Institute, Camden, NSW, Australia

Introduction
Mulberry heart disease (MHD) in swine usually manifests as sudden death in young, fast-growing, apparently healthy pigs. The hallmark lesions are acute hemorrhagic myocarditis and myocardial necrosis resulting in heart failure. It has long been suspected that MHD is linked to deficient levels of vitamin E and/or selenium (3,4,5,6). However, the exact relationship is still unclear and vitamin E and selenium deficiency are not observed in all cases of MHD (3). Furthermore, recent evidence suggests that infectious disease may be associated with similar heart lesions in pigs (1,2). We investigated the relationship between MHD and vitamin E, selenium, and 13 other mineral levels in heart and liver tissues. Additionally, several PCR assays were conducted on heart tissues to explore a possible relationship between viral pathogens and MHD.

Materials and methods
Tissues were collected at the Iowa State University Veterinary Diagnostic Laboratory from 83 pigs representing 38 farms. On the basis of histological examination 42 of the pigs were classified as MHD-affected and 41 classified as MHD-unaffected. The farms ranged in size from 800 to 4,500 head and most had a history of increased incidence of MHD. Mineral panels were completed on all heart and liver tissues using a Varion 820 ICP-Mass Spectrometer. The panel included tissue levels for cadmium, calcium, chromium, cobalt, copper, iron, magnesium, manganese, molybdenum, phosphorus, potassium, selenium, sodium and zinc. In addition, vitamin E levels were also obtained from heart and liver tissues. Seventy-seven of the 83 heart tissues were tested using real-time and conventional PCR assays for pan-morbillivirus, pan-coronavirus, pan-pestivirus, porcine enterovirus (PEV), pan-herpesvirus, porcine circovirus type 1 (PCV1), PCV2, porcine parvovirus (PPV), European and North American porcine reproductive and respiratory syndrome virus (PRRSV), Bungowannah virus (BGWV) and West Nile virus (WNV). Pairwise t-test was used to analyze the data. A P value < 0.05 was considered significant.

Results
Significant differences (P < 0.05) were observed in levels for sodium, copper and vitamin E in heart tissues and sodium, magnesium, phosphorus, selenium and vitamin E in liver tissues. Mean values were often higher in affected pigs compared to non-affected pigs; however, they were still within the normal parameters reported for tissue levels in healthy pigs (3). Vitamin E levels for both groups also resided within the normal range (3). Affected pigs had a trend for a higher incidence of PEV (P = 0.25), and pan-herpesvirus (P = 0.25)

Discussion
The difference between affected and unaffected groups observed among heart vitamin E, liver vitamin E, and liver selenium is in agreement with the traditional etiology of MHD (3,4,5,6). While many of the pathogens were isolated from several pigs among the groups, they did not appear to be associated with MHD status in the pigs. Although selenium deficiency has not been shown to cause MHD, it has once again been illustrated that MHD is associated with decreased selenium levels. There does seem to be a relationship between MHD and PEV and herpesvirus. This needs to be further explored experimentally as it could provide researchers a better model to study MHD and eventually provide producers tools to prevent its occurrence.

First record of a clinical outbreak of EMCV in The Netherlands

Manon Houben1 Leo van Leengoed2-1 Rudolf Raymakers3 Joep Gerards3 Norbert Stockhofe-Zurwierden4 Mark d. Groot5
1. PorQ BV, Breugel, Netherlands; 2. Veterinary Faculty, Utrecht, Netherlands; 3. Veterinary Centre Someren, Someren, Netherlands; 4. Central Veterinary Institute, Wageningen UR, Lelystad, Netherlands; 5. Intervet International, Boxmeer, Netherlands

Introduction
Encephalomyocarditis virus (EMCV) is endemic on many pig farms worldwide. EMCV is a Picornavirus and may infect a wide variety of animals like rodents, pigs and also man. Most important features in porcine EMCV infection are myocarditis and reproductive failure. Most clinical outbreaks in Europe were reported during the 1990’s in Belgium, Italy, Greece and Cyprus (1). Many Dutch sow herds have antibodies against EMCV (2), but neither clinical signs nor pathological lesions were reported until now.

Materials and methods
The infected herd of this study has two separate sites located 80 km from each other in the southern Netherlands. The main location is a 1400 sow herd while the other location houses all breeding stock for replacement. Mated gilts are transported to the main farm and added to the herd after a six-week quarantine period. Signs of EMCV were noted from March 2008 on by farmer, veterinarian and veterinary consultant. Necropsies were performed at the Faculty of Veterinary Medicine in Utrecht and at the Central Veterinary Institute in Lelystad. EMCV RT-PCR was performed by CODA-CERVA (Veterinary And Agrochemical Research Centre, Belgium)

Results
In March 2008 a high mortality was observed in newborn piglets of multiparous sows. Apparently healthy well-grown piglets with good body condition died without previous clinical signs. Some litters stayed unaffected, while mortality of 2 to 4 days old piglets in other litters went up to 100 %. Sows showed no clinical signs. Cross-fostered piglets from unaffected litters stayed unaffected. Four piglets that died were necropsied. These piglets were pale, with severe hydrothorax, hydropericardium and pulmonary edema. Myocardia were severely pale with occasional petechia. Histological examination displayed a severe lymphohistiocytic myocarditis and a mild lymphocytic meningitis. EMCV was demonstrated in myocard by RT-PCR.

During March 16 abortions occurred, and involved 3 sows and 13 (81%) gilts. Herd performance data were negatively influenced from March till May (figure 1). Surprisingly, only litters of multiparous sows were affected by sudden death of piglets, whereas none of the litters of gilts were affected.

Piglet mortality by sudden death persisted for 3 months. Thereafter, signs of EMCV-infection faded away and technical performance of the herd returned to pre-infection levels.

Discussion
Sudden death of suckling piglets from multiparous sows was the major clinical sign of this outbreak. Retrospectively, these signs appeared to be preceded by an increased abortion rate, mainly in gilts. No diagnosis was made upon the cause of abortions, and EMCV may be involved.

As litters of first parity sows stayed unaffected, we assume that these piglets were protected against EMCV by maternal derived antibodies.

In most cases rodents introduce and spread EMCV in swine herds (3). On this farm vermin is strictly controlled. Direct transmission of EMCV between pigs is in most cases limited, but may occasionally cause a large EMCV-outbreak (4). Although EMCV is endemic in many herds in The Netherlands, clinical signs of EMCV are rare. The outbreak of EMVC in this herd is most likely due to presence of high numbers of susceptible sows that were infected during late gestation. Theoretically, this can be an introduction of EMCV in a naive herd, or an introduction of an EMCV strain that differs in pathogenicity and immunogenicity from endemic EMCV strains. Closer monitoring might elucidate whether a new more virulent strain of EMCV circulates in The Netherlands. Therefore, veterinarians and veterinary pathologists should consider EMCV as a differential diagnosis in case of mortality in suckling piglets and abortions.

Investigation of risk factors for porcine circo virus type 2 (PCV2) following an outbreak of Post-weaning Multi-systemic Wasting Syndrome (PMWS) on a large commercial pig farm

Barbara Wieland; Dirk Werling; Dirk U. Pfeiffer; Amanda Nevel; Andrew Rycroft; Christopher M. Wathes
Royal Veterinary College, Hatfield, UK

Introduction
Porcine circo virus type 2 (PCV2) has been widely acknowledged as the necessary agent for post-weaning multi-systemic wasting syndrome (PWMS) in pigs. Various studies have identified potential risk factors, but it is still not fully understood what triggers the onset of this multi-factorial disease.

The present study aimed at evaluating the presence of porcine circovirus 2 (PCV2) and other pathogens before and during an outbreak of PMWS on a large commercial pig farm in the UK. Further we investigated the effect of environmental conditions and the parity and PCV2 immune and infection status of sows on presence of PCV2 in growing pigs.

Material and Methods
The study was based on data collected in two different research projects ongoing on a large commercial farm when a PWMS outbreak hit the farm. One project was a large scale experimental study on the impact of environmental conditions (dust and ammonia) on the onset of respiratory disease in 960 weaned pigs divided in 8 batches, batches were run one at a time over 2 years. At the end of the 42 day exposure experiment, serum samples were collected and post-mortem carried out on randomly selected pigs. The other project was a longitudinal study on the reproductive performance during the first three parities and involved 188 gilts originating from eight different breeders. Serum samples of 371 growing pigs, aged 10-12 weeks, were tested for antibodies to PCV2 and other endemic pig pathogens. In addition, presence of PCV2 antigen was determined by semi-quantitative PCR. Fifty gilts and sows produced 135 of the 371 growing pigs of which serum samples had been collected. These 50 gilts and sows had been repeatedly sampled at different time points in the reproduction cycle resulting in a total of 296 samples which were tested for PCV2 antibodies and PCV2 antigen.

Results
Results show that PCV2 sero- and PCR-positive pigs were already present on the farm long before the actual PMWS outbreak. Prevalence of PCV2 antibodies and antigen in growing pigs was low in the first batches of the respiratory experiments, but reached up to 100% in the late batches. The weight gain in PCV2 PCR positive pigs was significantly lower than in negative pigs \( (p<0.01) \) and PCV2 PCR positive pigs had a significantly higher overall pathological score in the post-mortem examination with a mean of 10.8 compared to 8.5 in PCR negative pigs \( (p<0.01) \).

In sows, differences in sero-prevalence was observed for different stages in the reproduction cycle and sows in the second half of gestation and around farrowing seemed more likely to have measurable titres of PCV2 antibodies. Over a period of two years, most sows showed fluctuations in PCV2 antibody titres. When combining laboratory results of sows and growing pigs, growing pigs had higher odds to be PCV2 PCR positive if the sow tested positive for PCV2 antibodies in the time period around farrowing \( (OR 24.5, p=0.01) \), the sow was of parity 3 or higher \( (OR 40.9, p<0.01) \) and were less likely to test PCR positive if the sow originated from certain breeders \( (OR 0.04, p<0.01) \).

Discussion
Through previous research it is well understood that maternal PCV2 antibodies prevent onset, or delay onset, of PMWS in the weaner. The results of this study further highlight the role of the sow for PCV2 in weaners (parity, PCV2 status around farrowing and breeding background). Our results indicate that in future studies on PMWS more sow data should be included. The trend of increased sero-prevalence in the second half of gestation and around farrowing may indicate latent PCV2 infection in sows and that increased stress levels result in reactivation of PCV2, followed by the observed PCV2 antibody response.

PCV2 in extended pooled semen from US boar studs

Johannes Kauffold1 Friedrich Schmoll2 Gary C. Althouse1

1. Department of Clinical Studies - New Bolton Center, School of Veterinary Medicine, University of Pennsylvania, Kennett Square, PA, USA; 2. Large Animal Clinic for Internal Medicine, University of Leipzig, Leipzig, Germany

Introduction

Prior studies have demonstrated PCV2 DNA and the virus itself in raw and extended semen from healthy naturally or experimentally infected boars [1-4]. To provide an epidemiological context to this finding, our group recently reported that of 472 German and Austrian raw semen samples screened for PCV2, 86 (18.2%) were found to be positive [4]. In our continued work to provide a more global perspective of the epidemiology of PCV2 in boar semen, a cross-sectional study was performed to determine the occurrence of PCV2 in extended semen produced in US boar studs.

Materials and Methods

Randomly selected extended pooled semen samples (n = 198), 18-30 hours post-processing, originating from 17 studs located in different states of the US were tested for PCV2 using a nested PCR technique [4]. Extended-chilled samples submitted to the Andrology Laboratory at the University of Pennsylvania were centrifuged at 4,000 rpm for 10 min to produce sperm-rich and supernatant fractions. Fractions were cataloged and then stored at -20 degree C until subsequent analysis. For all sample positives, all fragments obtained with the internal nested PCR were additionally sequenced to confirm PCV2 identity. A chi-square test was used to determine differences (P < 0.05).

Results

A total 49 (24.7%) extended pooled semen samples were PCV2 positive (Table 1). Samples from 5 studs were negative; all other studs had at least one positive sample (range: 10 – 50%). Positive results were more often obtained with the sperm-rich pellet (n = 34) than with the supernatant (n = 8). A small number of samples (n = 7) were positive for both the sperm-rich pellet and corresponding supernatant.

Discussion

This study confirms that PCV2 is shed in semen and can still be detected after semen is extended and stored for 18-30 hours. The percentage of samples found positive corresponds well with previous results from North America and Europe [1-4]. Of particular interest in the present data set was the differences observed between studs. Also, the fact that most samples were positive in sperm-rich pellets may indicate that the virus is sperm associated rather than a loose component in seminal plasma. All semen samples tested in this study were pooled semen originating from several boars. It is thus not known if one or more boars contributed to the PCV2 contamination. Also virus quantification was not performed which might have been necessary in order to better determine the risk of venereal transmission.

Table 1. Results of analysis of extended semen samples for PCV2 by nested PCR and sequencing (n = 198)

Use of IgG and IgM differentiation of antibodies to detect primary and secondary immune response to Porcine circovirus type 2 (PCV2)

Christoph Keller¹ Takeshi Yamaguchi² Mali Miyashita² Ohlinger F. Volker¹
¹. bioScreen EVDMC GmbH, Münster, Germany; ². Boehringer Ingelheim Vetmedica Japan Co., LTD, Kawanishi, Japan

Introduction
PCV2 is the causative agent for porcine circovirus associated diseases (PCVAD), which clinically affect pig herds worldwide.¹ As antibody titres are usually high in affected and in not affected herds² serological tests are not suitable for laboratory diagnostics for PCVAD. Recently commercial vaccines to protect pigs from PCVAD became available³. In this study IgG and IgM type antibodies to PCV2 in vaccinated and not vaccinated pigs were examined to demonstrate the effective priming of the immune system for contact to the pathogen.

Materials and Methods
In a GCP conform field trial on a Japanese pig farm a group of animals were vaccinated against PCV2 at 3 weeks of age (Ingelvac CircoFLEX®, Boehringer Ingelheim). A not vaccinated control group was housed comingled. Blood samples from 20 randomly selected pigs each from both groups were taken at the time of vaccination (3 weeks of age) and 4, 6, 8, 10 and 12 weeks after vaccination. All samples were tested for antibodies specific to PCV2 ORF2 antigen using a commercially available ELISA kit (INGEZIM CIRCOVIRUS IgG/IgM ELISA, Ingenasa, Madrid, Spain). The ELISA was performed according to the manufacturers instructions. In addition PCV2 genome load was quantified in the samples using a quantitative real-time PCR according to the method published by Brunborg et al.⁴

Figure 1: Results of the ELISA (n positive results) and qPCR (% PCR positive pigs) tests for vaccinated and not vaccinated pigs (n=20 per group).

Results
Results of the tests are summarized in figure No. 1. Four weeks after the vaccination in both groups two animals were positive in the IgM specific ELISA. At this time the first samples from the control group were detected to be positive for PCV2 virus genome in the qPCR. In the following weeks the percentage of viremic animals in the control group increased. In parallel the number of IgM positive pigs rose in the control group. In the vaccinated group no more IgM positive samples were detected, but the number of IgG positive samples rises. Twelve weeks after vaccination still three samples from the control group were positive for IgM. The number of IgG positive samples was comparable in both groups at this time.

Discussion
The results presented in this study clearly demonstrate the effective priming of the porcine immune system after vaccination against PCV2. Not vaccinated pigs react against field virus exposure with the production of IgM (primary immune response), whereas vaccinated pigs react with a secondary immune response (predominantly IgG). The detection of many IgM positive animals in a group of pigs indicates a primary immune response. As the majority of vaccinated pigs does not react with IgM, but with IgG (secondary immune response) to clinical exposure to PCV2, the differentiation of IgG and IgM against PCV2 could be used as a diagnostic tool to differentiate not vaccinated groups of pigs from vaccinated ones.

Diagnosis of Porcine Circovirus Diseases (PCVDs) by serology and qPCR

Lars E. Larsen¹ Peter Aastrup² Charlotte K. Hjulsager¹ Kirsten V. Larsen²

1. National Veterinary Institute, Copenhagen, Denmark; 2. Intervet/Schering-Plough Animal Health, Copenhagen, Denmark

Introduction

Porcine circovirus type 2 (PCV2) is considered the essential infectious agent of postweaning multisystemic wasting syndrome (PMWS). PCV2 is an ubiquitous virus and most if not all pigs become infected during their life, but only a proportion of them develop PMWS (1,2). A threshold of 7 log10 PCV2 DNA copies/ml serum has been suggested to establish a PMWS diagnosis (2-4), however limited information are available on the use of PCR in the diagnosis of other PCV2 related diseases (PCVDs). The present study describes the results of serological and virological profiling from 14 Danish herds with symptoms of PCVD.

Material and Methods

Sixteen Danish swine herds were included. Fourteen of herds had one or more of the following clinical symptoms in weaners, growers and/or finishers: Pneumonia, diarrhea or unspecific symptoms and/or wasting. None of the herds vaccinated the pigs against PCV2. The last two herds were control herds without any symptoms of PCV2 related diseases. In each herd, information on production type, health status, number of pigs produced, mortality, weight gain, antibiotic usage and clinical symptoms were recorded. Blood samples were taken from 5 pigs from each of 6 age groups: 3-4 weeks after weaning, 2 weeks before transfer to the fattening unit, 1-2 weeks and 7-8 weeks after transfer and finally just before slaughter. Serum was separated and kept at -80°C until test for antibodies against PCV2 using an in house ELISA and for PCV2 virus load by qPCR (5).

Results

Several different serological and virological profiles were found in the 16 herds, however basically the profiles could be grouped into two groups represented by herds 5 and 11 (figure). This grouping was independent of production type, size, health status etc. Apart from one herd, no virus was found in the samples taken 3-4 weeks after weaning. In the group of herds represented by herd 5, PCV2 viraemia and increased level of PCV2 antibodies were observed in weaners. In the other group of herds, represented by herd 11, viraemia and increased levels of antibodies were seen in older pigs – either in growers early after transfer or in finishers. In general, increased levels of antibodies were concurrent with increased PCV2 load. The level of antibody and virus in serum were very uniform within the sampling groups. The level of virus in serum were in most of the viraemic pigs between 4-6 log10 DNA copies/ml, however, a few pigs in some groups had higher levels (7-9 log10/ml). In some herds increased viral load in serum were seen in the groups of pigs concurrent with appearance of clinical signs whereas no correlation was seen in other herds. Furthermore, comparable levels of viraemia were also seen in the two control herds.

Discussion and conclusion

The present study showed that PCV2 profiles on serum for the diagnosis of PCV2 related diseases in herds can be a valuable tool to confirm that PCV2 is circulating. However, the results of the profiling should be carefully accessed and related to herd management factors, the presence of other pathogens and the clinical symptoms. Increased serum PCV2 load in itself are not diagnostic for clinical PCVD.

Comparison of PCV2 viremia between heavy and light weight pigs at marketing age in farms with routine PCV2 vaccination

Kwang Soo Lyoo1 Han Soo Joo1 Brian Caldwell2 Peter Davies1
1. University of Minnesota, St. Paul, MN, USA; 2. Choice Connection, Mapleton, MN, USA

Introduction
Because of the economic significance, PCV2 vaccine is now routinely used on most US swine farms. Although vaccinated pigs perform significantly better in terms of survivability and growth performance, subpopulations of light weight pigs in late finishing phase still are observed in farms with routine PCV2 vaccination. Swine producers and veterinarians have expressed concerns over this problem and questioned whether protection by the PCV2 vaccine may be inadequate to prevent poor growth in some cases. Therefore, it is hypothesized that a protection of light weight pigs could be attributed to PCV2 infection at late finishing age. This preliminary study was designed to compare PCV2 viremia and the antibody status of the lightest weight and the heaviest weight pigs at the marketing age in farms that routinely vaccinated against PCV2.

Materials and Methods
Seven different finishing farms that routinely used a commercial PCV2 vaccine and were experiencing no evident PCV2 associated clinical disease were selected. Within 2 weeks before the marketing on each farm, 30 lightest and 30 heaviest pigs in a group were identified visually by each farm manager, and blood samples from these 60 pigs in each farm were collected. PCV2 IFA titer was tested by a protocol used routinely in our laboratory. A differential nested PCR assay for PCV2a and 2b was conducted as the method previously described1. For PCV2b specific real-time PCR, a PCV2b specific primer set was used, and the assay was performed using PerfeCTa SYBR Green SuperMix and Mx3005P. One-way repeated measure ANOVA and Student t-test was used to test for statistical significant differences.

Results
Overall, the IFA titers of the light pigs were higher than those of the heavy weight pigs (Fig. 1). Percentages of PCV2a and PCV2b viremic pigs in the 7 different finishing units tested by nPCR are shown in Table 1. There was no significant difference in PCV2a viremic pigs between the light and the heavy weight groups. However, percentages of PCV2b viremic pigs were higher in the light pigs than the heavy pigs in 6 of the 7 farms. The real-time PCR results for the pigs in each farm showed that average amount of PCV2b genomic DNA was higher in the light pigs than in the heavy pigs.

Discussion
The present results indicate a potential association between PCV2 infection and the marketing weight in swine farms. Negative effects on production may still occur from PCV2 infection of vaccinated pigs when clinical diseases are not apparent. Although statistical significance was not always observed, higher PCV2 IFA titers and more viremic pigs were evident in the light weight pigs at marketing age. This finding also support a greater role of PCV2b compared with PCV2a suggesting that PCV2 vaccination should be focussed on the protection from PCV2b genotype infection. We could not determine when pigs may have been exposed to PCV2 on these farms but vaccination program may need to be adjusted to protect pigs from PCV2 infection until late in the finishing phase.

Distribution of ORF2 and ORF3 genotypes of Porcine Circovirus Type 2 (PCV2) in wild boars and domestic pigs in Germany

Gerald Reiner1 Bastian Bronnert1 Christina Fresen1 Corinna Hohloch2 Manfred Reinacher2 Stephan von Berg1 Hermann Willems1
1. Department of Veterinary Clinical Sciences, Justus-Liebig-University, Giessen, Germany; 2. Institute for Veterinary Pathology, Giessen, Germany

Introduction

Porcine circovirus 2 (PCV2), the essential infectious agent in PCVAD (porcine circovirus associated diseases) circulates at high rates among domestic pig and wild boar populations. Wild boars may be viremic and shed the virus with excretions and secretions, and thus serve as a reservoir for domestic pig PCV2 infection. We hypothesize that PCV2 strains circulating in wild boars and in domestic pigs are significantly different and thus, partially independent. To prove this hypothesis, the distribution of ORF2 and ORF3 genotypes of PCV2 within wild boars and domestic pigs from overlapping greater areas of Germany was investigated.

Materials and Methods

Samples from 40 wild boars from 17 different hunting grounds and tissue samples of 60 apparently healthy domestic pigs from 18 provenances located in the same greater areas as the wild boars were analyzed. PCV2-specific DNA was amplified by nested PCR (nPCR). PCV2 genotypes were classified based on ORF2 sequences as described by Olvera et al. (2007) and Segalés et al. (2008). ORF2 and ORF3 genotypes were detected by pyrosequencing on a PyroMark ID (Biotage, Sweden) system. Genotypes were compared with PCV2 sequences from the Genbank database (520 entries).

Results

Two ORF2 and nine ORF3 genotypes were detected in twelve combinations, with significant differences between wild boars and domestic pigs. Distribution among the federal states did not differ significantly within species. PCV2-2b was the most common genotype in both species. Almost 60% of the infected wild boars but only 4.8% of the infected domestic pigs carried the PCV2-2a subtype. ORF3 genotype frequencies differed also significantly between wild boars and domestic pigs. Some ORF3 genotypes were detected in domestic pigs only, others exclusively in wild boars. The genotypes of domestic pig PCV2 samples were dominated throughout the country by 2b/ORF3-1 and 2b/ORF3-3 types. PCV2 genotypes of the wild boars were, however, more heterogeneous than those of domestic pigs. Two different PCV2 genotypes in one animal have been isolated from 27% and 4% of wild boars and domestic pigs, respectively (P<0.001), and at least two different PCV2 genotypes have been isolated from 90% of hunting grounds and 50% of domestic pig provenances. The five Genbank database PCV2 sequences from German domestic pigs (from 1999/2000) differed significantly from the "domestic" sequences of the present study (2004/2007) and from 124 sequences obtained from different European countries. However, European and the "domestic" sequences of the present study were in good agreement. The six Genbank sequences of European wild boar isolates agree with the major genotypes of the wild boars of the present study. Some of the wild boar derived genotypes are not present or very rare among "domestic" and wild boar Genbank sequences worldwide.

Discussion

Differences in "domestic" PCV2 genotypes of the present study and Genbank entries from Germany may indicate the general switch from PCV2-2a to genotype PCV2-2b after the year 2003 that has been generally described by Dupont et al. (2008). Differences and conformity of PCV2 genotypes derived from wild boars and domestic pigs, either from this study or from European Genbank database entries, indicate that wild boar and domestic pig PCV2 do coexist with some exchange. More than 50% of the wild boar PCV2 genotypes are extremely rare in domestic pigs in Europe (Genbank) and Germany (this study), even worldwide, inferring a certain independence of wild boar and "domestic" PCV2 genotypes. The fact that genotype 2a is prevalent in wild boars (57.5%), but rare in domestic pigs (4.8%) and that genotype 2b is the almost exclusive genotype in domestic pigs and also prevalent in wild boars, argues for the hypothesis that exchange of PCV2 between both species emerges primarily from domestic pigs to wild boars and less in the reverse direction. This hypothesis is supported by the finding that PCV2 loads of wild boars are significantly lower than those of domestic pigs (see abstract on the opposing page).

Evaluation of alternative vaccination programs to control PCVAD

Glen W. Almond¹ Martin Liebstein¹ Matthew Turner² Patricia A. Routh¹
1. College of Vet Med, North Carolina St Univ, Raleigh, NC, USA; 2. Prestage Farms, Clinton, NC, USA

Introduction
Porcine circovirus 2 (PCV2) is the primary pathogen associated with PMWS and porcine circovirus associated disease (PCVAD; 1). In North Carolina, the primary clinical manifestation of PCVAD was marked mortality in grower-finishing facilities. Producers dramatically reduced the mortality associated with PCV2 by vaccinating pigs; however, the costs of vaccinating nursery pigs can be overwhelming. Therefore, the primary goal of this study was to examine a less expensive approach by vaccinating sows with products intended for nursery pigs.

Materials and Methods
The study was conducted on commercial sow, nursery and finishing farms. Three commercial vaccines, approved for nursery pigs, were given to sows at 5 and 3 weeks prior to farrowing. For each vaccine, at least five gilts and five 4+ parity sows were vaccinated and farrowed. In addition, two control groups (6 sows/parity) were injected with saline. At 7 days after farrowing, two lightweight piglets and two heavy piglets from each sow were weighed and ear tagged. Due to attrition in the sows from death or abortions prior to farrowing, only 45 sows farrowed and a total of 180 piglets were used in the study. Blood samples were collected from the sows prior to the first vaccination and before farrowing. Blood samples also were collected from piglets at approximately 7, 14, 52, 70 and 155 days of age. All serum samples were submitted to Iowa State University for the determination of PCV-2 SP ratios.

Results
From birth until 155 days of age, mortalities for pigs from sows vaccinated with Vaccines 1, 2, 3 and 4 (controls) were 13.6%, 10%, 18.2% and 19.2%, respectively. The “heavy” and “light” pigs weighed 3.2±0.08 kg and 2.1±0.05 kg at 7-10 days of age, respectively. There were no differences in body weights among piglets from sows given the different vaccines. PCV2 titers did not differ between 4th parity sows and gilts prior to vaccination (1.03±0.03) and sow titers increased slightly after vaccination (1.10±0.04). Piglets from vaccinated sows had higher (P<.05) titers than piglets from the control sows at 7-10 days after birth (Fig 1). With the notable exception of 155 d, this difference was evident for most time points. At 14-16 days after birth, PCV2 titers were greater in piglets from sows vaccinated with Vaccine 2 than in piglets from the other three groups. This was also evident at 70 d (1 wk after placement in the finishing sites). At 155 days of age, PCV2 titers were the lowest in pigs from sows vaccinated with the Vaccine 2, while pigs from control sows had the highest titers.

Discussion
The results indicate that gilts and older parity sows had prior exposure to PCV2. Based on a previous report (2), low sow antibody titers against PCV2 increased the risk of pigs subsequently dying from PCVAD. It was evident that the titers of young pigs (7-10 days) were greater when the sows were vaccinated for PCV2, particularly with Vaccine 2. The decrease in titer with age represents declining maternal antibodies. Perhaps the most striking results were the PCV2 titers in pigs at 155 days of age. The PCV2 titers continued to decrease in pigs from sows vaccinated with Vaccine 2, thereby indicating that the pigs were not actively challenged with wild virus or that they were protected when exposed to wild virus. In contrast, the titers of control pigs and pigs from sows vaccinated with Vaccine 3, increased dramatically while in the finishing phase. Evidently, these pigs responded to exposure to wild virus during finishing. Overall, the results demonstrated that PCV2 vaccination of sows has potential to reduce losses associated with PCVAD.

A comparison between sow and piglet PCV2 vaccines; effects on pig performance and viraemia in three crossbred types

Helen M. Miller1 Stan Done2

Introduction

The effects of PCV2 have devastated the pig industry in recent years. PCV2 infection increases mortality and feed costs and reduces growth rate and feed efficiency. Two different types of vaccine are now available to counteract this disease; one is given to the sow prior to farrowing, hence acting to provide passive immunity via colostrum, and the other is given directly to individual piglets. These vaccines were compared on a PCV2 affected farm where post weaning mortality had been steady at around 12% for the previous two years. Three crossbred genotypes, Large White, Hampshire and Pietrain, were used in the experiment to determine the impact of the vaccines on the health and performance of different genotypes. It has been suggested that PCV2 vaccination will be more beneficial to Large White type pigs as these are considered to be more susceptible to PCV2 associated diseases.

The objectives of the experiment were to compare the efficacy of the two vaccines when delivered either singly or in combination; to investigate the effect of vaccination on the virology of PCV2 and to compare the response of different genotype crossbreeds to vaccination.

Materials and Methods

The experimental design was a 2 x 2 factorial generating the following 4 treatments:

- Unvaccinated piglets from unvaccinated sows (unvaccinated control)
- Unvaccinated piglets from vaccinated sows
- Vaccinated piglets from unvaccinated sows
- Vaccinated piglets from vaccinated sows

Sows were batch farrowed in groups of approximately 24 every 3 weeks; sow vaccination status was applied across a whole batch generating 4 unvaccinated batches and 4 vaccinated batches. Within each litter in all batches every second piglet was vaccinated against PCV2 at 3 weeks of age. A total of 183 Large White x Landrace sows were used in the experiment divided across the two vaccination treatments so that the parity profile was similar in both groups. Sows were mated to Large White, Pietrain or Hampshire type boars.

Cross-sectional blood sampling performed prior to the start of the experiment established that PCV2 viraemia occurred after 12 weeks of age in growing pigs. During the experiment six sows per batch were blood sampled on transfer to the farrowing house and 48 pigs per treatment were blood sampled at 3, 9, 12, 15 and 18 weeks of age.

Results

Both vaccines were effective in improving lifetime performance and shortening time to slaughter. Interestingly the effect of the sow vaccine was most pronounced during the early growth of the pig, whereas, piglet vaccination, but not sow vaccination, significantly improved growth rate between 7 weeks of age and slaughter. Maximum effect was gained when the two were used together which resulted in 6 days advantage in slaughter age over the unvaccinated animal. Using either vaccine singly halved this advantage.

Overall post weaning mortality declined from 12 % to 6 % during the experiment however there was no significant benefit associated with any particular vaccination strategy. PCR analysis indicated that peak viraemia was evident after 15 weeks of age (6 weeks later than in the pre-experimental sampling) and that viral load was significantly reduced in animals which had received the piglet vaccine.

Both genotype and pig sex influenced the response to vaccination. In contrast to our initial hypothesis that Large White type pigs would benefit more from PCV2 vaccination in fact the opposite was observed: The Large White showed the poorest response to vaccination with a reduction in slaughter age of 5.7 days between unvaccinated female and double vaccinated male, a similar comparison in the Hampshire reduced time to slaughter by 12.4 days and in the Pietrain by 15.6 days.

Discussion

Vaccination resulted in improved performance throughout the growing period and not specifically during the period of maximum viral load in agreement with Cline et al. (2008). The best vaccination strategy for maximizing performance was to use the sow and piglet vaccines together, also reported by Pejsak et al. (2009). However the level of improvement that can be expected is further influenced by the pig genotype, therefore the cost effectiveness of a double versus a single vaccination strategy should be considered with this in mind.

One-dose vaccination against Mycoplasma hyopneumoniae and Porcine Circovirus Type 2

Alexander A. Eggen; Maarten Witvliet; Ulrike Schmidt; Maurice Raes

Intervet/Schering-Plough, Boxmeer, Netherlands

Introduction
Mycoplasma hyopneumoniae (M.hyo) and Porcine Circovirus Type 2 (PCV2) are the two most prevalent pathogens that are encountered in the pig industry. Vaccination against M.hyo is already standard practice, and the same will be the case for PCV2. As vaccines against these two pathogens are preferably given at a young age, it would be advantageous if vaccinations against these two pathogens are combined. However, no interference between vaccinations is acceptable as that could lead to poor vaccine efficacy. In a previous study, it has been shown that the ISPAH vaccines Porcilis M Hyo and Porcilis PCV can be given concurrently without any negative consequences for the efficacy (1). Also, the efficacy and safety of simultaneous use (mixing) of both vaccines has been evaluated in the field without evidence of interference or apparent safety problems (2). Here, we report a series of studies on possible interference between vaccination with Porcilis PCV and M+PAC, and the efficacy of especially prepared ready-to-use M. hyo-PCV2 combination vaccines.

Materials and Methods
Groups of 8 conventional piglets, with maternally-derived antibodies against both M.hyo and PCV2, were vaccinated at weaning (3-4 weeks of age) with M+PAC (and Porcilis PCV), or with ready-to-use M.hyo-PCV2 combination vaccines. At 7 weeks of age, the pigs were infected with an M.hyo field isolate. Challenge infection was performed with a culture of strain 98 (obtained from Dr. N. Friis, Danish National Veterinary Laboratory) by intratracheal inoculation on two consecutive days, followed by necropsy to evaluate M.hyo-induced lung lesions (LLS) three weeks later.

Serum samples taken at the time of vaccination and at 10 weeks of age were analyzed for antibody titers against PCV2 in a specific ELISA.

The vaccines were based on M+PAC (Emunade adjuvant) and Porcilis PCV (X-solve adjuvant). Both adjuvants are emulsions of light mineral oil in water, but Emunade also contains alhydrogel, and d,l-α-tocopheryl acetate is part of the X-solve adjuvant. Combination vaccines were formulated with the same antigens that are used in the single vaccines. For M. hyo either the antigen that is used in M+PAC (Mh1) or in Porcilis M Hyo (Mh2) was used.

Results and Discussion
As shown in Table 1, all vaccines tested provided similar levels of protection against M.hyo (53% - 61% reduction in lung lesions) after challenge at 7 weeks of age. There were no significant differences between the vaccinated groups. Whereas the mean antibody titers against PCV2 had declined in the M+PAC only and control groups from 7.4 log2 at the time of vaccination to 3.8 and 3.7 at 10 weeks of age, all animals that had been vaccinated against PCV2 showed a titer increase at 10 weeks. Piglets that have an antibody titer of 11.9±2.1 at 10 weeks of age after vaccination with Porcilis PCV at 3 weeks are protected against PCV2 challenge at the end of the fattening period (3). In the present study, all groups were at or above that antibody level.

</tbody>
</table>

Groups with different superscripts are significantly different (p<0.05, Mann Whitney U-test for LLS and 2-sample t-test for PCV2 antibody titer). LLS were corrected for outliers.

It can therefore be concluded that there is no immunological interference between the M.hyo and PCV2 antigens of M+PAC, Porcilis M Hyo and Porcilis PCV, independent of whether they are given concurrently as separate single vaccines or combined in a ready-to-use vaccine with either Emunade or X-solve as the adjuvant.

Further proof for lack of interference comes from a recent field study in which M+PAC and Porcilis PCV were mixed just before administration (4). There was no significant difference between the anti-PCV2 antibody titers in groups of pigs that were vaccinated with the mixed products or that received the two vaccines by separate injections.

Results of one-shot piglet vaccination at 0.5 ml with Circovac® assessed by viremia and seroconversion in a farm affected by porcine circovirus type 2 diseases (PCVD)

Bernhard Heissenberger; Christiane Lang; Andrea Ladinig; Christiane Püschel; Mathias Ritzmann

Clinic for Swine, Vienna, Austria

Introduction
Circovac® (Merial, Lyon, France), an inactivated PCV2 vaccine, was previously evaluated under field conditions in piglets (1). In order to assess the effect of the vaccination on seroconversion and viremia in piglets, serum samples were analyzed serologically for the presence of PCV2 IgG and IgM antibodies and for the presence and the quantity of specific PCV2 DNA. Furthermore, the reduction of infection pressure after vaccination was investigated.

Materials and Methods
A controlled, blinded and randomized field study was performed on an Austrian 250-sow farrow-to-finish farm that experienced severe problems with PCV2 and 1105 piglets were included in this trial. Three consecutive batches were included at birth and piglets were randomly allocated to a Circovac® or to a placebo treated control group. Vaccination was performed at three weeks of age. Control and vaccinated piglets stayed intermingled. Only batch 1 and batch 3 were chosen for collection of laboratory data in order to assess the impact of vaccination on viral pressure over time. Blood samples were collected regularly and serum samples of Circovac® vaccinated (1st batch: n = 20, 3rd batch: n = 18) as well as of control animals (1st batch: n = 20, 3rd batch: n = 15) were analyzed via the Ingezim Circovirus IgG/IgM ELISA kit (Ingenasa, Madrid, Spain) and quantitative PCR (qPCR).

Results
The median logarithmic values of copies/ml serum of the Circovac® and the control group of both batches are presented in fig. 1. Between week 14 and 22, the pigs of the control group of batch 1 were viremic. The vaccinated pigs of batch 1 showed peaks only in week 16 and 20, which were lower than the one of the control group at the respective points of time. The control animals of batch 3 underwent a shorter and lower viremic phase than the ones of batch 1. The median values of the vaccinated group of batch 3 remained completely at the baseline. According to the qPCR results the main viremia period occurred around the weeks 14 to 20. Fig. 2 a,b shows the percentage of pigs positive for specific PCV2 IgG and IgM antibodies of the vaccinated and the control group of batch 1, fig. 2 c,d for the animals of batch 3. The vaccinated animals had a general lower incidence of IgM antibodies than the controls. Batch 3 showed a lower percentage of positive animals than batch 1 in both control and vaccinated pigs.

Discussion
According to viremia and seroconversion results, a positive effect of the vaccination of piglets with Circovac® has been observed. Vaccinated animals had a lower incidence for PCV2 specific IgM antibodies and the vaccination seemed to reduce the viral pressure in the facilities, as the occurrence of positive animals was in general lower in the 3rd batch. This observation is supported by the qPCR data, which showed, that vaccinated animals had a lower serum viral load. Those facts suggest a reduction of virus shedding after vaccination in this trial.

Field Efficacy of Suvaxyn® PCV2 in a Large Commercial Piggery in South East Asia

Ming Yong1, Fook K. Ng2, Philip Lehrbach3
1. Pfizer animal Health (Asia Pacific), Shanghai, China; 2. Swine Consultant, Singapore; 3. Pfizer Animal Health, Melbourne, VIC, Australia

Introduction
Porcine Respiratory Disease Complex (PRDC) is a continuing problem in the swine industry. PCV2-associated disease (PCVAD) such as post weaning multisystemic wasting syndrome (PMWS) has emerged as a serious complicating factor. Vaccination has been found to be effective in controlling PCVAD. The objective of this trial was to evaluate the field efficacy of Suvaxyn PCV2 based on reducing mortality and the cost of managing PRDC on a commercial farm in South East Asia.

Material and Methods
The trial involved a very large commercial piggery with a history of unacceptably high mortality in the grow-finish pigs (including respiratory distress and poor weight gain). Post mortem/laboratory testing indicated the presence of PRRS, MH and APP. In addition, histopathology and PCR results indicated the presence of PCV2. Most of the pigs examined became viraemic with PCV-2 by 13 weeks of age.

There were 9,289 piglets enrolled in the study (see Table 1). All piglets in the vaccinated group were administered intramuscularly with a single 2 mL dose of Suvaxyn PCV2 at 5 weeks of age. Serum samples were collected just prior to vaccination and at 4 weeks post vaccination (9 weeks of age) for serological testing. PCV2 viraemia in sera was detected using the PCV2 specific PCR (serum from batch B pigs only). Average body weights were recorded at marketing age; pig mortality and rejects were also recorded.

Results and Discussion
Herd performance
Vaccination improved the performance of the herds (see Table 2). All vaccinated groups demonstrated a remarkable decrease in mortality (4.05% and 11.04% reduction for Batch A and Batch B respectively). The vaccinated group in Batch B also showed better body weight gain (additional 4.11kg per pig) and a lower number of rejected pigs. The calculated return on investment (ROI) was 2.7:1 and 18.2:1 for Batch A and B vaccinates respectively (based on Margin over feed costs=50%). There was a noticeable saving in antibiotic treatment, especially in Batch A (US$0.20 per pig).

Figure 1. PCV2 Viraemia in Sera from Batch B Pigs at 9 weeks of age

Conclusions
These results demonstrate that vaccination using Suvaxyn PCV2 in pigs, reduced PCV2 viraemia, total mortality and the cost of managing PRDC, as well as improving the growth performance on a commercial farm in South East Asia.

Long term evaluation of using PRRS MLV and a subunit PCV2 vaccine to reduce post-weaning loss in Thailand

Jitjaroen Channarong; Sopon Kongtes; Nathaya Duangwhae; Lerdtida Meedacha
Boehringer Ingelheim (Thai), Bangkok, Thailand

Introduction
PRRSv and PCV2 are the two major pathogens causing swine production loss worldwide.
The objective of this study was to confirm the consistency and long-term efficacy of a PRRS MLV and a subunit PCV2 vaccine to reduce post-weaning losses (mortality and culls) on a commercial pig farm in Thailand.

Materials and method
The single site conventional commercial farm, 1,700 sows level was positive for PRRS. In November 2006 – March 2007 this farm experienced a PRRS outbreak in the breeding herd causing reproductive failure followed by high post weaning losses (mortality and culls) caused by PRDC in nursery pigs and grower-finishers from January to August 2007. Average nursery and grower-finishers loss in this period was 9.76% and 9.30% respectively. Clinical signs observed in nursery pigs started from 5–6 weeks of age with thumping, eyelid edema and conjunctivitis, in line with seroconversion in nursery pigs at 7–8 weeks as measured by PRRS ELISA (HerdChek PRRS 2XR, IDEXX laboratory). PRRS vaccination (Ingelvac® PRRS MLV) started in sows, gilts and piglets in September 2007. Piglets were vaccinated at an age of 10–14 days.

Breeding herd vaccination resolved the reproductive problems and reduced losses in nursery pigs. However the grower-finishers loss remained at a high level. Clinical signs, including wasting, paleness, PRDC, jaundice and diarrhea, started in 12–14 week old animals. Some pigs showed signs of PDNS skin lesion. Main lesions found in post mortems were spleen and kidneys enlargement, swelling of inguinal and enteric lymphnodes, indicating PCV2 infection.

As a consequence, PCV2 piglet vaccination (Ingelvac CircoFLEX®) at 21 days old was introduced to control PCVAD problems in grower-finishers period.

Weekly post weaning losses of 124 batches (about 99,000 pigs) were evaluated between January 2007 to October 2009, divided into 3 phases: Jan 07-Aug 07 (before vaccination), Sep 07–Jul 08 (PRRS vaccination) and Aug 08 – Oct 09 (PRRS + PCV2 vaccination).

Results
Average nursery mortality decreased from 9.76% to 2.70% after introduction of PRRS MLV vaccination (Fig. 1), while average grow-finish mortality remained at 7.53% in PRRS vaccinated pigs (Fig. 2). In PRRS plus PCV2 vaccinated piglets, nursery mortality further decreased to an average of 1.83%. A more pronounced effect was observed in grow-finish, with an average mortality of 2.84% in PRRS+PCV2 vaccinated piglets (Fig. 2).

Average post-weaning (wean-to-slaughter) losses were 19.2% in non-vaccinated batches, 10.2% in PRRS vaccinated and 4.6% in PRRS+PCV2 vaccinated batches.

Discussion and conclusion
This farm was co-infected with PRRSv and PCV2. PRRS vaccination had a clear and consistent effect on nursery losses, but it could not control the losses in grow-finish due to PCV2 infection. Only when piglets were vaccinated against both, PCV2 and PRRSv, post-weaning mortality was reduced consistently. PRRS and PCV2 vaccination were shown to be very effective providing consistent protection in this long-term evaluation.
Antimicrobial resistance in *E. coli* and *Salmonella* from surveillance of Canadian swine at farm, abattoir and retail

Introduction

Antimicrobial resistance (AMR) in the human and animal population is an issue of increasing public concern. The misuse of antimicrobials in human medicine has been associated with AMR but there is also concern with antimicrobial use in the food animal population. The Public Health Agency of Canada and its federal and provincial partners developed the Canadian Integrated Program for Antimicrobial Resistance Surveillance (CIPARS) to monitor AMR and antimicrobial use (AMU) in humans and the agri-food sector in Canada (1). The program includes active surveillance of cattle, swine and broiler chicken at abattoir and at retail. In addition, there is active surveillance of swine at the farm level. The primary organisms of interest are *Salmonella*, *E. coli*, *Campylobacter*, and *Enterococcus*. The focus of this work is antimicrobial resistance in *E. coli* and *Salmonella* from swine at the retail, abattoir and farm levels.

Materials and Methods

Samples and data for this work were collected in 2008 through CIPARS. CIPARS Retail conducts weekly/bi-weekly sampling of pork chops from retail food outlets in randomly selected census divisions, weighted by population, in the Atlantic Provinces, Quebec, Ontario, Saskatchewan and British Columbia. CIPARS Abattoir samples cecal contents from swine at 13 federally registered abattoirs in 8 provinces. The number of samples per abattoir is proportional to annual slaughter volume. CIPARS Farm is based on sentinel grower-finisher swine herds in the 5 major pork producing provinces. The number of herds per province is proportional to the number of grower-finisher units in each province. The program is administered through 29 herd veterinarians who have enrolled 108 herds. Pooled pen fecal samples are collected from pigs at >175 lbs once per year. All samples were cultured for generic *E. coli* and *Salmonella* using standard CIPARS methodology (1). Susceptibility testing was performed on 3 *E. coli* and 1 *Salmonella* isolate per sample. Minimum inhibitory concentrations (MIC) for 15 antimicrobials were established for all isolates using the Sensititre® Microbiology System (Trek Diagnostic Systems, Cleveland, OH, USA). CIPARS results are categorized according to the individual antimicrobial’s importance to human medicine as determined by the Veterinary Drug Directorate (VDD) of Health Canada (2). The antimicrobials tested are categorized as Category I: Very High Importance (amoxicillin-clavulanic acid, cefotaxime, ceftriaxone, ciprofloxacin), Category II: High Importance (amikacin, ampicillin, cefoxitin, gentamicin, kanamycin, nalidixic acid, streptomycin, trimethoprim-sulphamethoxazole), Category III: Medium Importance (chloramphenicol, sulfisoxazole, tetracycline), and Category IV: Low Importance (no antimicrobials tested).

Results

CIPARS 2008 surveillance of swine resulted in 318 *E. coli* isolates from Retail, 150 from Abattoir and 1425 from Farm. In addition there were 151 *Salmonella* isolates from Abattoir and 61 from Farm. The prevalence of *Salmonella* from retail pork in the CIPARS program was 2%, which did not result in sufficient isolates for meaningful AMR evaluation. The top three *Salmonella* serovars from Abattoir were Derby (33 isolates, 21.9%), Typhimurium var 5. (31 isolates, 20.5%), Typhimurium (17 isolates, 11.3%). The top three *Salmonella* serovars from Farm were Typhimurium var 5. (17 isolates, 27.9%), Brandenburg (9 isolates, 14.8%), and Derby (7 isolates, 11.5%). Resistance to ceftriaxone and ciprofloxacin was only found in *E. coli* isolates from retail pork (prevalence = 0.3%). There was no resistance to amikacin in any *E. coli* or *Salmonella* isolates. There was no resistance to nalidixic acid in *Salmonella* isolates from Farm or Abattoir and less than 2% resistance to this antimicrobial in *E. coli* isolates from Farm, Abattoir, and Retail. Less than 5% of *E. coli* and *Salmonella* isolates from all sectors were resistant to amoxicillin-clavulanic acid, cefotaxim, ceftriaxone, and gentamicin. There was a substantial percentage of *E. coli* and *Salmonella* isolates that were resistant to kanamycin (range: 3.1-21.3%), ampicillin (range: 17.3-34%), and streptomycin (15.1-44.4%). The most common resistance in *E. coli* and *Salmonella* from all sectors was to tetracycline (range: 37.4-84.7%).

Discussion

The presence of resistance to all Category I antimicrobials in retail pork is of significance due to the proximity of these samples to the consumer and the importance of these drugs in human medicine. Current levels of resistance in these antimicrobials are very low, which is consistent with previous CIPARS results but continued monitoring is essential (1). The low prevalence of *Salmonella* in retail pork is important from a food safety perspective.

The association between antimicrobial resistance in fecal *E. coli* from swine at arrival in the finishing barn and close-to-market

Anne E. Deckert1,2, Cara Sheppard2, Sheryl Gow3, David Leger1, Richard Reid-Smith1, Scott McEwen2

1. Public Health Agency of Canada, Guelph, ON, Canada; 2. University of Guelph, Guelph, ON, Canada; 3. Public Health Agency of Canada, Saskatoon, SK, Canada

Introduction

Antimicrobial resistance (AMR) reduces our ability to effectively treat bacterial infections in animals and humans and is an issue of increasing public concern. AMR has been associated with the misuse of antibiotics in the human population but there is also concern with antimicrobial use (AMU) in agri-food production. The Public Health Agency of Canada and its federal and provincial partners developed the Canadian Integrated Program for Antimicrobial Resistance Surveillance (CIPARS) to monitor AMR and AMU in humans and the agri-food sector in Canada (1). The CIPARS Farm component was implemented in 2006 to provide information on AMR and AMU in swine at the farm level. It also has provided information on the role of AMR on arrival at the grower-finisher (GF) unit on AMR at Close-to-Market (CTM).

The objective of this study was to investigate the associations between AMR in fecal *E. coli* from groups of swine entering the GF unit and the same group of pigs at CTM.

Materials and Methods

Samples and data for this work were collected in 2007 through the CIPARS Farm Program. There were 108 herds enrolled in the 5 major pork producing provinces of Canada: AB, SK, MB, ON and QC. In each province, the number of CIPARS herds is proportional to the national total of GF units. To provide producer anonymity, herd veterinarians selected the producers and participated in the sample and data collection. Twenty-nine swine veterinarians from private and corporate practice have enrolled producers that are CQA* validated, produce more than 2000 market hogs/year, and are representative of herds in the veterinarian’s swine practice. Herds that were regarded to be organic, feeding edible residual material or pasture-raised were excluded. These criteria helped ensure that the program was representative of the majority of hog production in Canada. In a subset of 66 herds, pooled fecal samples were collected from two pens of pigs at arrival in the finisher unit and from the same two pens at CTM (>175 lbs). In the remaining herds, samples were collected at CTM only and those results are not included in this analysis. All fecal samples were cultured for generic *E. coli* using standard CIPARS methodology (1). Susceptibility testing was performed on 3 *E. coli* per sample. Minimum inhibitory concentrations (MIC) for 15 antimicrobials were established for all isolates using the Sensititre Microbiology System (Trek Diagnostic Systems, Cleveland, OH, USA). AMU data (feed, water and injectables), management and production information was collected using questionnaires. The relationship between AMR at Arrival and at CTM was investigated using multilevel logistic regression models with random intercepts for pen and herd. The outcome of interest was resistance to a specific antimicrobial in fecal *E. coli* from pens of CTM pigs, while the main potential risk factor of interest was resistance to the same antimicrobial among fecal *E. coli* from pens of pigs at arrival. Other potential risk factors that were investigated included season of sampling, barn capacity, number of pigs per pen, number of pigs at risk, biosecurity variables, barn flow (all-in-all-out or continuous) and the use of antimicrobials (feed, water, injection), the use of the same antimicrobial, the antimicrobial class and the number of antimicrobial classes used.

Results

There were 28 herds that provided matching Arrival and CTM samples in 2007, resulting in 164 Arrival and 168 CTM *E. coli* isolates. Twenty-one herds provided AMU data. No Arrival samples and only three CTM samples were susceptible to all antimicrobials tested. At the herd level, all herds were resistant to at least one antimicrobial at Arrival and at CTM. Resistance to ceftiofur(TIO), amikacin (AMK), cefoxitin (FOX), and gentamicin (GEN) was found in Arrival samples but not CTM samples. No resistance was found to ceftriaxone (CRO) and ciprofloxacin (CIP). Of 9 models that were examined only 3 models (kanamycin(KAN), trimethoprim-sulphamethoxazole(SXT), streptomycin(STR)) still included a variable representing AMR at Arrival either as a significant variable (P < 0.05) or a confounder (>20% change in the coefficient). The final model for KAN CTM isolate resistance included the number of antimicrobial classes used on farm and arrival pen resistance to KAN. Having two or more SXT resistant isolates in the arrival pen was the only significant variable for SXT resistance at CTM. Arrival pen resistance to STR was a confounder for the relationship between the use of antimicrobials in water and STR resistance at CTM.

Discussion

Based on these results, AMR data from pigs arriving in the GF unit provide limited information regarding AMR at CTM for specific antimicrobials. Resistance at Arrival is generally more prevalent than at CTM. The absence of resistance to CIP and CRO in CTM samples is of significance due to the proximity of these animals to the food chain and the importance of these drugs in human medicine.

Analysis of antimicrobial susceptibility profiles of Salmonella Serotypes using survival analysis

Charles A. Haley1 Francisco Olea-Popelka2 Bruce A. Wagner1 David Dargatz1
1. USDA:APHIS:VS:CEAH:NAHMS, Fort Collins, CO, USA;
2. College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO, USA

Introduction.
Salmonella is an important cause of illness among swine and can cause foodborne illness in people1. There is growing global concern for the amount of resistance to antimicrobial drugs among Salmonella isolates. Many groups have called for more surveillance of antimicrobial resistance and the identification of factors that play a role in the emergence or amplification of resistance in populations including people, pets and animals used for food. Previous studies have been primarily confined to using established antimicrobial concentration cutoffs to declare isolates susceptible or resistant.

The objective of this study was to use survival analysis to identify factors associated with changes in concentrations of antimicrobials that inhibit Salmonella isolates with various MIC to better understand the ecology of antimicrobial drug resistance among salmonellae in swine farms.

Materials and Methods

Questionnaire data and fecal samples were collected as part of the National Animal Health Monitoring System’s (NAHMS) Swine 2006 study. Fecal samples were collected from the pen floor for grower/finisher pigs. Up to 60 fecal samples per farm from a maximum of 10 pen floors containing late finishers (20 to 32 weeks of age) were collected and tested for Salmonella as previously described2.

Salmonella spp. antimicrobial susceptibility testing was conducted using a semi-automated system (SensititreTM, TREKTM Diagnostics, Inc., Cleveland, Ohio) as previously described2. S. Derby, the most common serotype isolated (29.6% of isolates), was selected for this analysis. Two antimicrobials (Amoxicillin/Clavulanic Acid and Ampicillin) were chosen from among a panel of 15 antimicrobials tested to demonstrate the technique.

Survival analysis was done using Cox proportional hazards modeling using previously described methods3.

Results

Of the 173 S. Derby isolates that were tested in increasing two fold concentrations (from 1 to 32 μg/ml) most (134 for Amoxicillin/Clavulanic Acid and 129 for Ampicillin) were either inhibited at the first concentration or not at all even at the highest concentration (32 μg/ml). Because of this highly skewed distribution of the MIC values for these isolates, we dichotomized the MIC values. Concentration until event (inhibition) for each antibiotic was tested for change with farm level factors: herd size, total confinement of grower/finisher pigs and usage of complimentary antimicrobials in the nursery or grow/finish phase in feed or water in the study. Farm of origin of the isolates were treated as random effects.

For the S. Derby and Amoxicillin/Clavulanic Acid model, the hazard or rate of inhibition was reduced nearly 100% when grower/finisher pigs were housed in total confinement or Amoxicillin was used during the nursery or grower/finisher phase. As herd size increased by 500 pigs the hazard of inhibiting S. Derby with Amoxicillin/Clavulanic Acid increased by 31%. The proportion of variance at the farm level (intra-class correlation coefficient) or correlation of results within herds was 0.74. The results with these variables were similar but less dramatic for the S. Derby and Ampicillin model.

Discussion

Survival analysis methods show some promise for analysis of MIC data. Management confinement methods and the use of select antimicrobials in feed or water in the nursery or grow finisher phase increased survivability of S. Derby to these two antibiotics. Additional research is planned to continue analyzing antimicrobial use and inhibition data using these techniques.

An experimental Helicobacter suis infection reduces daily weight gain in pigs

Smitha Kumar1 Freddy Haesebrouck1 Frank Pasmans1 Bram Flahou1 Jeroen Dewulf2 Koen Chiers1 Richard Ducatelle1
1. UGent, Faculty of Veterinary Medicine, Department of Pathology, Bacteriology and Poultry Diseases, Merelbeke, Belgium;
2. UGent, Faculty of Veterinary Medicine, Department of Reproduction, Obstetrics and Herd Health, Merelbeke, Belgium

Introduction
Helicobacter suis (H. suis) is a Gram negative, long, spiral-shaped bacterium colonizing the stomach of more than 60% of pigs at slaughter age3. The prevalence is very low in sucklings, increases from the time of weaning and is highest in adult animals. This bacterium is considered to be one of the risk factors associated with gastric ulcers in pigs2. Recently, H. suis has been successfully cultured in vitro1. The purpose of this study was to evaluate the effect of an H. suis infection on the daily weight gain in pigs.

Materials and Methods
In 5 different experimental set-ups, a total of 44 medicated early weaned piglets were intragastrically (n=39) or orally (n=5) inoculated once (n=30) or thrice (n=14) with a fresh (n=24) or frozen and thawed (n=20) culture of H. suis strain 5 at the age of 3 (n=5), 6 (n=14), 7 (n=10), 8 (n=5) and 9 (n=10) weeks. All animals were euthanized 4 (n=39) or 6 (n=5) weeks post-inoculation. All experimental set-ups included medicated early weaned animals as negative control groups (N=29) that were sham inoculated with sterile culture medium. The animals were fed a finely ground feed (n=34), coarsely ground feed (n=5) or milk replacement (n=5). All animals were housed under identical environmental conditions. Each animal was weighed at the time of inoculation and at euthanasia. Daily weight gain was calculated over the period after inoculation. In the combined results of the 5 experiments, the effect of inoculation with H. suis on the daily weight gain of inoculated animals was compared to the non-inoculated animals using a multivariable linear regression model including all variables that varied between the experiments as co-variables to correct for their effect (SPSS 17).

Results
After correcting for the effect of experimental set-up, type of feed, age at the time of inoculation, weight at the time of inoculation, number of inoculations, and the period after inoculation, there was a significant reduction of approximately 20 g/day (5%) in the daily weight gain of experimentally infected animals compared to the non-infected control animals.

Discussion
Results of the present study indicate that an H. suis infection reduces daily weight gain in pigs and thus may result in substantial economic losses. Clearance of infection with this bacterium may therefore have an economically beneficial effect.

Occurrence of MRSA in conventional and organic pig herds as well as in wild boars in Germany

Thomas Blaha; Miriam Ostmeier; Birgit Brockers; Lars Meyer; Susanne Fischer; Ulrike Heine; Regina Tegeler; Diana Meemken
Field Station for Epidemiology, University of Veterinary Medicine Hannover, Bakum, Germany

Introduction

The occurrence of MRSA (Methicillin-resistant *S. aureus*) as nasal colonizer of pigs in conventional herds has been reported in several countries with quite often a very high intra-herd prevalence (1, 2, 3). Little is known about the frequency of MRSA in organic pig herds. Furthermore, there is only one report on a lower frequency of MRSA as nasal colonizer in “organic pig farmers” compared to “conventional pig farmers” (4). There are no publications on the occurrence of MRSA in wild boars. The objective of our study was to increase the knowledge on the occurrence of MRSA in different pig husbandry systems (organic and conventional) as well as in wild boars.

Materials and Methods

Our investigations on the occurrence of MRSA in different pig populations with different husbandry systems were carried out as follows:

- Occurrence of MRSA in collective dust samples (one pool of dust from different sample sites) from 85 conventional and 27 organic pig herds
- Occurrence of MRSA as nasal colonizer of pigs in 26 conventional and 20 organic pig herds by testing herd-size adjusted random samples to detect at least a 5% intra-herd prevalence of MRSA by testing 10 to 60 pigs per herd (in total 1760 nasal swabs), as well as of 120 hunted wild boars. All samples were collected, selectively enriched and cultured according to the EU-guidelines (SANCO/3100/2007 – Rev.2).

Results

The occurrence of MRSA in dust samples from conventional and organic pig herds are shown in Table 1.

Tab. 1: Occurrence of MRSA in collective dust samples

<table>
<thead>
<tr>
<th>Husbandry system</th>

<td>85</td>
<td>67 (79%)</td>
</tr>
<tr>
<td>organic</td>
<td>27</td>
<td>4 (15%)</td>
</tr>
</tbody>
</table>

The frequency of MRSA-positive herds, identified by nasal swabs is demonstrated in Table 2. A herd was defined as MRSA-positive, if one nasal swab turned out to be MRSA-positive.

Nine of the 120 tested wild boars (8%) were carrier of Methicillin-sensitive *S. aureus* (MSSA) in their nasal cavity.

Discussion

In our still ongoing studies, the MRSA results (nasal swabs and dust samples) in conventional husbandry systems point to a measurably higher MRSA frequency than the MRSA results in organic husbandry systems. This preliminary assumption needs to be verified by further comparative studies. Possible reasons for the expected higher MRSA detection rate in conventional than in organic pig herds could be the circulation of MRSA between conventional herds (animal movements from conventional to organic herds are very seldom), the higher animal density in conventional herds (i.e. better transmission conditions), and the differences in the use of antibiotics in the two different husbandry systems. The fact that no MRSA, but MSSA were found in wild boars shows that there is no natural non-susceptibility of the wild boar for *S. aureus*. The differences in the MRSA frequency found in our studies do not justify a direct link between the occurrence of MRSA and the actual use of antibiotics at a specific farm, since the spread of MRSA between conventional herds and the lack of this spread to organic pigs and to wild boar alone can sufficiently explain the differences as well. More detailed research into the risk factors of MRSA is presently carried out.

MRSA in herds of fattening pigs in Germany: Typing results and factors associated with the detection in herds

Bernd-Alois Tenhagen; Alexandra Fetsch; Katja Alt; Beatriz Guerra; Stefan Hertwig; Jens A. Hammelr; Annemarie Kaesbohrer; Juliane Bräunig; Bernd Appel

Federal Institute for Risk Assessment (BfR), Berlin, Germany

Introduction

Methicillin-resistant Staphylococcus aureus (MRSA) has been demonstrated to be endemic in pig herds in Europe, Canada and the USA, posing a risk for colonization and infection to people in contact with these animals.

Materials and Methods

To assess the situation in herds of fattening pigs in Germany, dust samples (n=5) of 290 farms from different regions in Germany were collected in 2008. A questionnaire provided information regarding herd characteristics and management practices. Dust samples were pooled per farm and cultured using selective enrichment and chromogenic media. Presumptive MRSA isolates were confirmed by triplex-PCR for the detection of 16S rRNA, nuc and mecA genes. Confirmed isolates (1/herd) were tested for antimicrobial resistance, spa- and SCCmec typed. Selected isolates were also MLST-typed.

Results

MRSA were identified in 152 herds (52.4%). Univariate analysis revealed an association of a number of factors with the detection of MRSA on a farm.

Larger herds were more likely to be positive for MRSA. Herds that had used antimicrobials on a group level, were also more likely to be positive. Tetracyclines (28.3 % of herds), amoxicillin (19.7 %) and tylosin (17.6 %) were most frequently used. The occurrence of diseases in the herd was not related to the detection of MRSA.

Buying pigs from several different farms or from weaner to grower operations was associated with MRSA in the herd. Type of pig farm was closely related to this factor. Farrow to finish units were less likely to buy pigs from several sources than weaner to finish or grower to finish operations.

Fully slatted floors and an all in / all out pig flow were associated with the isolation of MRSA from dust. Multivariate analysis revealed multicollinearity between variables. For example larger farms used antimicrobials more often and bought pigs from more sources. In the final model, only farm size and farm type remained as significant risk factors. However, it can be assumed, that other related factors contributed to the effect of these two factors.

Twelve different spa-types were identified in the tested isolates. All isolates were belonged to spa-types related to the multilocus sequence type ST398, with t011 (66.4%) and t034 (23.0 %) as the predominant spa-types. There were substantial regional differences in the spa-type patterns. In one region, more than 90 % of the isolates were spa-type t011 while in others, t011 and t034 were of similar frequency.

Most isolates (85 %) carried SCCmec-type V, 11 % belonged to SCCmec-type III that has been shown to carry features of type V and type III.

Discussion

The results are in line with studies in slaughter pigs that were carried out in the North-West of Germany and with the results of the EU-baseline survey on MRSA in breeding herds (EFSA 2009, Tenhagen et al. 2009)

The latter has shown that MRSA is also prevalent in herds with breeding pigs in most European countries with an intensive pig production. From breeding herds, MRSA can easily be transmitted to fattening units via colonized weaners or growers. With a given proportion of positive herds in the population any further herd that pigs are bought from increases the risk, that one of the herds is positive for MRSA. Biosecurity protocols of pig farms so far did not include S. aureus as it was not regarded as a major pathogen for pigs. In fact, MRSA is only associated with clinical disease in pigs in exceptional cases and this study showed no relation between the disease status of herds and the prevalence of MRSA.

The risk factor having the strongest association with a positive test result was herd size. This might be due to buying more pigs in larger herds increases the risk of introduction of MRSA into the herd via colonized pigs.

Antimicrobial use was not a significant risk factor in the multivariate model. Apparently the introduction of the resistant clone is most likely to occur via colonized animals. Antimicrobials may add to the within herd spread, but this was not measured using the dust sample. In a Dutch study on veal calves that considered risk factors on animal level, antimicrobial use in the group proved to be a significant risk factor (Wagenaar and van de Giessen 2009).

Prevalence study and risk factor analysis on MRSA in sow-herds

Els M. Broens1 Elisabeth A. Graat2 Peter van der Wolf1 Arjen A. van de Giessen3 Mart C. de Jong2
1. Animal Health Service, Deventer, Netherlands; 2. Group of Quantitative Veterinary Epidemiology, Wageningen University, Wageningen, Netherlands; 3. Centre for Infectious Disease Control Netherlands, National Institute for Public Health and the Environment, Bilthoven, Netherlands

Introduction

In 2005 a distinct clone of methicillin resistant Staphylococcus aureus (MRSA ST398) was found in pigs and people in contact with pigs (1). Several studies report prevalences of MRSA-positive farms and identified risk factors for people working with pigs (2,3). Little is known on risk factors associated with MRSA on pig farms. The objective of this study was to estimate a reliable prevalence for MRSA-positive farms and to identify and quantify risk factors.

Materials and Methods

During 2007 and 2008 a study on 202 pig farms, 171 farms with sows and 31 farms without sows, was performed. On these farms a nasal swab was taken from 60, randomly selected, pigs. Additionally, 5 environmental samples were taken. On the first 50 farms, the people working and/or living on the farms and the sample takers were sampled (nasal swab) as well. These results were published by Van der Broek et al (2). Information was gathered on farm characteristics (e.g. management, hygiene and antimicrobial use). Microbiological analysis was done on individual environmental samples and pooled pig samples (6 swabs per pool; per pool one age-category). A farm was classified positive if at least one of the samples was MRSA-positive. Statistical analysis to identify risk factors was done on data from 171 sow-farms.

Results

The overall prevalence of MRSA-positive farms was 68.3%; for farms without sows the prevalence was 71.0% and for sow-farms the prevalence was 67.8%. On positive sow-farms, on average 63.3% of the pools and 33.8% of the environmental samples was MRSA-positive. In total, 18 different spa-types were identified, t011 and t108 being the most frequent ones, resp. 52.5% and 34.1%. Ninety-eight percent of the MRSA-isolates belonged to ST398. All ST398-isolates were sensitive to mupirocin and linezolid and resistant to tetracycline. Resistance to other antimicrobials varied between and within spa-types. In the final statistical model, 2 risk factors were associated with MRSA: herd size (number of sows) and time (months). Prevalence of MRSA-positive farms increased in time: from approximately 30% at the beginning of 2007 to approximately 75% at the end of 2008. Prevalence of MRSA-positive farms increased when the number of sows on a farm increased: approximately 40% of small herds (< 250 sows) was MRSA-positive versus > 80% of large herds (> 500 sows). Other risk factors, e.g. presence of finishing pigs, purchase of gilts, rodent control and hygiene, dropped out of the statistical model but were associated with herd size. Antimicrobial use and MRSA on a farm were not significantly associated, though antimicrobial use was associated with herd size. Farms that apply antimicrobials as group medication have significantly more sows (486 sows) than farms that use antimicrobials just in case of disease (415 sows). Farms that use no antimicrobials at all were the smallest farms (355 sows).

Discussion

MRSA is present on a large number of Dutch sow-farms and the prevalence increases in time. Most likely MRSA was spreading among Dutch pig herds during the study period. A plausible transmission route seems to be the trade of animals, however farms without supply of pigs were found to be MRSA-positive as well (4,5). Large herds have a higher risk, which can be explained by herd size itself and by the factors that are associated with herd size, e.g. antimicrobial use, the purchase of gilts and rodent control. The same positive association between herd size and disease has been reported for other swine diseases, e.g. influenza and pseudorabies (6-8). Herd size is therefore a compilation of several risk factors, which makes that larger farms are more often MRSA-positive.

Prevalence of MRSA among Danish participants at a conference for Danish pig producers

Margit Andreasen1 Charlotte S. Kristensen1 Robert Skov2 Elisabeth O. Nielsen1

1. Pig Research Centre, Copenhagen, Denmark; 2. Statens Serum Institut, Copenhagen, Denmark

Introduction

In 2008, the presence of MRSA CC398 was confirmed in several Danish pig herds. All participants at the yearly conference for Danish pig producers, were offered a test for MRSA, to gain an estimate of the nasal carrier status of MRSA among persons working in the Danish Pig Production. A total of 1945 persons working within various fields of pig production (pig producers, veterinarians, consultants etc.) participated in the conference.

Materials and Methods

Participation was on a strictly voluntary basis. Nasal sampling was performed by swabbing both nostrils. Prior to sampling a standardized questionnaire on profession (farmer, veterinarian, consultant or other), weekly hours of contact with pigs, working within sow units, finisher units or both, visits to pig units abroad and previous hospitalisation of the participant was completed. All swabs were screened for MRSA using incubation in enrichment broth followed by plating on chromogenic agar. MRSA was confirmed by PCR, typed by sequencing the staphylococcal protein A (spa) gene and susceptibility tested.

Results

Questionnaires and samples were obtained from 791 persons, of whom 22 were excluded (13 were foreign visitors and 9 did not complete the questionnaire). The remaining 769 persons comprised 487 farmers, 109 agricultural consultants, 25 veterinary practitioners and 150 persons working in other fields. The distribution of MRSA-positive persons on professions is shown in Table 1. Of the 19 CC398 isolates, 3 belonged to spatype t011, the remaining 16 to spatype t034. Two persons, both farmers, carried other MRSA-types (t032 and t044). All MRSA CC398 positive persons had weekly contact with pigs. However, the duration of contact with pigs was not statistically associated with the MRSA CC398 carrier status. Persons working only in finisher units had a significantly lower risk of carrying MRSA CC398 compared with persons working in sow units.

Discussion and Conclusion

The results implied that MRSA CC398 carriage is more frequent among persons working within the Danish pig industry than in the population in general. However, the CC398-prevalence of 3.1 % among Danish pig farmers was much lower than those reported from e.g. Holland and Canada (app. 20%) 1, 2. Also, a newly published report 3 establishes that Danish herds have a low prevalence of MRSA compared to other comparable European countries. Working in sow units increased the risk of being an MRSA CC398 carrier. These findings support previous reports 4, indicating that intensive and regular exposure to pigs increases the risk of humans getting colonized with CC398.

Introduction

Recently, Methicillin-resistant Staphylococcus aureus (MRSA) have emerged in pigs in most European countries (1,3). Predominantly, porcine MRSA colonization and infection is caused by an MRSA clone characterized by clonal complex (CC) 398 as determined by multi-locus sequence typing (MLST) and Staphylococcus aureus protein A (spa) types t011, t034, t108 and relatives. This MRSA clone was hitherto rarely observed among patients in German hospitals (5). Since numerous studies indicated a frequent exchange of MRSA between animals and humans, we investigated the prevalence of MRSA CC398 in pig holdings in the area characterized by the highest pig density in North Rhine-Westphalia (NRW), Germany, and patients admitted to acute care hospitals in this region.

Methods

Within the framework of the Euregio project SafeGuard VetMed-net, five dust samples were collected in a total of 86 pig holdings in the Euregio (NRW part) in 2009 using a sterile wipe and sampling a standardized area of 50cm x 50cm. MRSA diagnostic was performed using a double enrichment in selective broth (Phenol Red Mannitol Broth with 5 mg/L ceftizoxime, 75 mg/L aztreonam) and plating on a chromogenic medium (Brilliance MRSA, Oxoid, Wesel, Germany). MRSA was confirmed using coagulase tube test and mecA-PCR. All MRSA isolates were typed using the Staphylococcus aureus protein A (spa) approach (4).

Human samples were derived from inpatients attending the acute care hospitals in the Euregio participating in a network for the prevention and control of MRSA (EUREGIO MRSA-net). In 2009, every first MRSA isolate per patient from nasopharyngeal and cutaneous screening specimens and from blood cultures was spa typed and entered into a common MRSA database (www.mrsa-net.eu). Clustering of spa types in spa clonal complexes (spa-CCs) was performed using the Based Upon Repeat Pattern (BURP) algorithm of the Ridom StaphType software.

Results

We identified MRSA in dust samples from 51 pig holdings (59%). Among 103 MRSA isolates we found seven different spa types including t011 (69%), t034 (20%), t2510 (5%), t1456 (3%), and t108, t588, t1606 (each 1%).

A total of 1,695 human isolates from screening specimens as well as n=38 blood culture isolates were obtained in the MRSA-net hospitals in 2009. Among the isolates from screenings 305 (18%) were associated with spa-CC398 (spa types: t011, t034, t108, t1197, t2582, t2741, t3934, t567, t571). Among n=38 blood culture isolates only one (2.6%) was associated with spa-CC398 (t011).

Discussion

The prevalence of MRSA CC398 in environmental samples from pig holdings in the Euregio VetMed-net is higher than the overall prevalence for Germany observed in a recent report published by the European Food Safety Authority (1). As in other countries it was shown that the spa types t011 and t034 are predominant (3). This confirms the results of previous investigations (2).

MRSA CC398 are frequently introduced in German hospitals located in an area with a high density of pig-production by inpatients colonized at admission. Despite the high burden of colonization, invasive human infections due to MRSA CC398 are rare until now.

Introduction

Although Staphylococcus aureus belongs to the common skin flora of animals and humans this opportunistic pathogen can cause various skin and organ infections [1]. In particular methicillin resistant S. aureus strains (MRSA) gain more attention in recent years. In pig production units in Europe and Canada the special sequence type (ST) 398 was detected [2, 3] which can colonize animals and humans and is transmissible between them. To investigate the spread and transmission of MRSA fast and reliable methods are required by which these bacteria can be detected and monitored on pigs and in their housing environment. This paper reports about first results from investigations in piggeries comparing the efficiency of swab sampling at five locations on the pigs and of seven sampling methods to detect MRSA in the housing environment.

Materials and Methods

31 farms (15 fattening farms and 16 breeding farms) were presently sampled. Nasal swabs were taken from 60 randomly selected animals of all farms and examined as pooled samples (five swabs per pool). Skin swabs were taken from the neck region of 60 animals from 13 farms and were also analyzed as pool samples (five swabs per pool). Vaginal swabs were collected three to five times from four selected sows of 11 farms during the investigation period from September to December 2009. In three of these farms also the perianal region and the teats of the same sows were sampled with swabs.

From 26 piggeries pooled dust samples were taken from five different locations (sampling area approx. 500 cm², at least 15 ml dust per pool). Sedimentation dust was sampled in the center of four animal houses in two meters height on sterile surfaces with a defined area of 0.4 m² (sampling time about 28 days). In 25 barns boot swabs were taken by walking with one pair of boots twice along the middle corridor. Pooled fecal samples and feed samples from feeders were taken from 13 farms and swabs from drinking nipples were sampled in 5 holdings. In 11 pig houses airborne bacteria were sampled by impingement (AGI-30) and a filtration method.

MRSA were grown after selective enrichment and direct plating on CHROMagar. Coagulase positive Staphylococci were identified with biochemical tests and the isolates were confirmed as MRSA by a triplex PCR method.

Results

MRSA was found in 27 (87%) out of 31 investigated farms in at least one sample. The detection efficiencies of samplings from pigs and of samples from the housing environment in relation to positive tested farms were: Nasal swabs = 100%; Skin swabs = 100%; Vaginal swabs = 73%; Perianal swabs = 67%; Teat swabs = 67%; Pooled dust = 78%; Sedimentation dust = 33%; Boot swabs = 91%; Pooled fecal = 60%; Drinking nipples = 0%; Feed = 56%; Air = 100%.

Discussion

MRSA was found in 87% of the investigated piggeries. The efficiency of the sampling locations on the animals and the methods used for environmental sampling varied considerably. Nasal swabs and swabs of the neck seem to be more efficient to detect MRSA on a pig than samples from vagina and teats. 100% of the air samples were MRSA positive followed by boot sampling, pooled dust, feces and feed. Less successful was the detection in sedimentation dust which may has to do with the sampling period and the survival of Staphylococci in dust. No MRSA were found at drinking nipples.

The high air contamination and the contamination of surfaces in the direct environment of the pigs may contribute to the high positive results from nasal and skin swabs. Positive feed samples may also be a consequence of environmental contaminations. The results of this current study indicate that the most promising sampling locations to detect MRSA on pigs are the nose and the skin on the neck. For environmental sampling air, boot swabs and dust can be recommended.

The current investigations continuous and more detailed results will be presented on IPVS in 2010.

This study funded by the German Federal Ministry of Food, Agriculture and Consumer Protection.

The over-muscled sow syndrome: a new emerging syndrome in a hyperprolific sow herds: Preliminary observations on farrowing duration

Thierry Solignac¹ Alassane Keita² Eric Pagot² G-P Martineau³
1. Coopagri Bretagne, Landerneau, France; 2. CTPA Zoopole, Ploufragan, France; 3. Ecole Vétérinaire, Toulouse, France

Introduction
Many factors can affect duration of farrowing such as breed, litter size, parity, body condition and housing (Farmer and Robert, 2002, Oliveira et al., 2008). Fat sows are classically reported having long farrowing but the correlation was not very high (Oliveiro, 2009).

We reported the emergence of a new building syndrome that we call “Over-muscled sow syndrome” (Solignac and Martineau, 2010a). It emerges as a consequence of the selection for deposition of lean meat and hyperprolificacy (Tribout et al., 2003, Bazin et al., 2003).

Materials and Methods
Duration of farrowing has been registered from 482 sows of 14 commercial herds in Brittany (France) with different hyperprolific genetic. For each sow, we measured body fat (BF) and body muscle (BL) (Noveko AC037L, 3.5 MHz) on site P2 at farrowing. Each sow was then classified according to the BF and BL median values of data: BL+ when the value was above the median value and BL- when it was below. The same procedure was applied for BF (Table 1). Data were analysed using a 3 factorial (BF, BL and genetic line, coded A, B and C) ANOVA test with p<0.05 as level of significance.

<td>15.9</td>
<td>47.6</td>
</tr>
</tbody>
</table>

Results
Major results are reported in Figure 1. There is a statistically significant effect of BL on duration of farrowing (p=0.04). BL+ sows showed a farrowing duration of 3.9 versus 3.6 for BL- ones. The effect of BF (p=0.599) and that of genetic (p=0.790) are not significant.

Figure 1: Morphotype and duration of farrowing

On the figure 2, is shown the distribution of Back lean (BL) according to Back fat (BF).

Figure 2: Correlation between BF (x) and BL (y)

The correlation coefficient is 0.328 and the coefficient of determination is 0.108, which means that only 10.8% of BL are explained by BF and vice versa.

Discussion and conclusion
In 2005, Foxcroft et al., wrote: “Accepting the risk of being considered some what heretical, most of our recent experiments with the lactating and weaned sow lead to the conclusion “that from a fertility and prolificacy perspective, fatness is simply not the key risk factor”. We would like to add that over-muscled sows are candidates to long farrowing. Management of lean deposition is of crucial importance. There is a need to modify our paradigmatic view of sow nutrition according only to their needs. Indeed, we have to take into account the fact that selection for high capacity of lean deposition has negative consequences on many parameters (Solignac and Martineau, 2010a,b).

Chronopart in catheterized commercial sows in conventional herds: Physiological, biochemical and hormonal follow-up in “easy” farrowing and “difficult” farrowing sows

Jean-Noel Sialelli2 Fabien Vautrin2 Pauline Bories1 Sylviane Boulot3 Marie-Christine Pere4 Guy-Pierre Martineau1
1. National Veterinary School, Toulouse, France; 2. Farm’apro, Lamballe, France; 3. IFIP, LeRheu, France; 4. INRA, St-Gilles, France

Introduction
Observational study on enzootic neonatal diarrhea (END) in Brittany lead to a link between END and the process of parturition (Sialelli et al., 2009, Bories et al., 2010). Pre-partum investigations are mainly limited on experimental sows (Oliviero et al., 2007).

Intensive physiological investigation have been registered in 4 commercial hyperprolific herds (>14 TB) selected according to history of farrowing difficulties, high stillbirth (>1.2/litter), and good records.

Material and methods
Sows (19 P1 and 9 P2) were catheterized at day 109 (Figure 1) and intensively followed before and during farrowing. According to speed of farrowing, sows were classified in three groups: <3hrs (SF for short farrowing), between 3 and 4 hrs (IF for intermediate farrowing) and > 4hrs (LF for Long farrowing). Stillborn and manual assistance were also taken into account.

Finally, sows classified with an “easy” farrowing are sows having a SF or IF without manual assistance and only stillbirth piglets at the end of farrowing. Sows with a “difficult” farrowing are LF and IF with manual intervention and stillbirth during farrowing (Table 1).

Sequence of sampling is reported on Figure 1A: Sampling procedure in catheterized sows; vertical arrow correspond to a blood sample.

Physiological, biochemical and hormonal investigations: Rectal temperature, hematocrit (Ht) and Hemoglobin (Hb, test Hemo-Cue®) were performed on farm. Plasma progesterone (P4), Estradiol (E2), Glucose (Glu), total magnesium (Mg), total calcium (Ca), Non Esterified Fatty Acid (NEFA), total protein (Prot), lactate (Lact), bicarbonate (HCO3) and creatine phospho-kinase (CK) have been determined using commercial kit.

Results and discussion
The progress of parturition (prolonged fast, uterine and muscular contractions, stress and hyperventilation) creates the conditions to a mobilization of the reserves and to a metabolic acidosis (fast increase of NEFA, lactate and bicarbonate in the beginning of birth, followed by a high level during all parturition). The significant correlation between the levels of lactate 3 hrs after the first piglet and the duration of parturition (r=0.580 p < 0.01 and r=0.326 p=0.09) suggests a high risk of weakness in long farrowing.

Figure 1B: Follow-up of progesterone (left) and rectal temperature (right) by % of sows with °C > 39.5°C according to “easy” and “difficult” farrowing. Figure 1C: Calcium follow-up according to “easy” and “difficult” farrowing

Conclusion
Pre-farrowing high blood progesterone may have consequences on uterus myometre and thereafter on farrowing. Other analysis are in progress (ocytocin, albumin, …) and will be reported. Understanding of pathophysiology is probably the first step for the control.

Birth weight implications for postnatal development of the reproductive tract in gilts

Fernanda R. Almeida; Ana Luisa N. Alvarenga; Letícia P. Moreira; George R. Foxcroft; Helio C. Garcia

Universidade Federal De Minas Gerais, Belo Horizonte, MG, Brazil

Introduction

Selection for prolificacy appears to have created an imbalance between the number of conceptuses surviving to the post-implantation period and uterine capacity. These animals show characteristics of Intra-Uterine Growth Restriction (IUGR) due to a great competition among fetuses for nutrients and oxygen, resulting in lighter fetuses at term. The effects of IUGR on development of the reproductive tract in gilts have not been demonstrated so far. The present study evaluated those effects on the reproductive tract of light-weight offspring.

Material and Methods

New-born female pigs (n = 28; DanBred X PIC terminal line), born to 4th- 6th parity sows and in litters of 10 to 15 pigs, were identified as falling into two birth weight groups: high (HW: range 1.8 to 2.2 kg) and low (LW: range 0.8 to 1.2 kg). They were reared until the finishing period (~150d) and data on growth performance were collected. Gilts were slaughtered at 150 days of age and their reproductive tract was collected. The parameters measured were: length of the vaginal canal, uterine body and uterine horns. Additionally, the whole reproductive tract was weighed. Data were analyzed as a fully randomized design and the comparison between means was performed by t-test.

Results

HW gilts had a higher postnatal growth performance compared to their LW counterparts (P<0.05 – Table 1). Moreover, the biometric data of the reproductive tract showed that the vaginal canal length was lower in LW gilts (P<0.05). However, the other parameters measured were similar between the experimental groups (Table 2).

Discussion

Evidence of a better growth performance in high birth weight animals has been previously demonstrated (1). Additionally, high growth rate gilts attain puberty earlier than low growth rate gilts (2). In fact, gilts that attain puberty earlier are the most fertile in the breeding herd. Moreover, these results suggest that light birth weight animals have a smaller vaginal canal. It has been shown a positive relationship between the vaginal canal length and the total number of pigs born (3). Therefore, light birth weight gilts may have poor reproductive performance.

Effects of birth weight and prenatal maternal dexamethasone treatment on leukocyte subsets in piglets

John Harding; Crissie Auckland; Cheryl L. Waldner
University of Saskatchewan, Saskatoon, SK, Canada

Introduction
In humans, adverse events impacting fetal and infant growth are associated with the onset of metabolic1 and autoimmune2 diseases later in life. In developing nations, maternal malnutrition is associated with increased risk of infection-related death3, decreased response to S. typhi vaccination4, and decreased thymopoietin production (a thymic growth marker)5 in adolescence. In swine, prenatal maternal stress occurring in late gestation decreased the offspring’s lymphocyte proliferation response to T- and B-cell mitogens in early life6,7. The objective of this experiment was to assess the relationship between leukocyte subsets and birth weight, and to determine if prenatal dexamethasone treatment in early- and mid-gestation affects leukocyte numbers in 2 week old pigs.

Materials and Methods
Pregnant PIC sows were given dexamethasone at a high anti-inflammatory dose8 (0.2 mg/kg) IM daily for 7 days; on gestation days 30-36 (Dex30; n = 27) or 60-66 (Dex60; n=27). Treated and non-treated control (CTR; n=25) sows were induced to farrow on day 115. Judicious cross-fostering was encouraged to ensure the best perinatal conditions supporting piglet survival and growth. Blood was collected from 3 sibling piglets of low, average and high birth weights (BW) between 11 and 14 days of age. Complete blood counts and flow cytometry for CD3+, CD21+, CD4+, CD8+, monocyte, granulocyte and gamma-delta leukocytes were performed. The absolute number of leukocytes in each subset was calculated (subset proportion x total WBC x10^9). Generalized linear mixed models were used to estimate the difference in cell numbers across treatment group. Estimates were adjusted for clustering within litter by including a random intercept for litter in the model (PROC MIXED). Potentially important co-factors including BW category and birth week were retained in the final model if they changed the regression coefficient by more than 10% or if statistically significant (P < .05).

Results
CD8+ lymphocytes were significantly lower in the Dex60 (0.50 x10^9/L; P = 0.01) and trended lower in the Dex30 (0.53 x10^9/L; P = 0.07) compared to CRT (0.63 x10^9/L). No other dex-treatment group differences were found. Total white blood cell (WBC), CD3+, CD21+, CD4+, CD8+ and gamma-delta lymphocytes were significantly lower in low versus high BW piglets (Table 1). CD3+, CD8+ and gamma-delta lymphocytes were significantly lower in average versus high BW piglets. Neither dex-treatment nor birth weight impacted monocyte or granulocyte number.

Columns with different superscripts within rows differ statistically at P < .05

Discussion
While changes in absolute lymphocyte numbers may not reflect altered immune function, these results provide evidence that the immune response may be compromised in fetal growth-restricted piglets. Moreover, dexamethasone treatment, a proxy for prenatal maternal stress, may adversely affect the development or maturation of CD8+ lymphocytes. More research is warranted to characterize functional immunologic changes associated with restricted fetal development. Immunologic programming has substantial implications for both the swine industry and public health in terms of disease control, food safety and zoonosis.

Effects of short-term prenatal maternal dexamethasone treatment on piglet growth from birth to day 50

John Harding; Crissie Auckland; Cheryl L. Waldner
University of Saskatchewan, Saskatoon, SK, Canada

Introduction
The performance and health of livestock species is influenced by prenatal events, such as maternal malnutrition, stress and placental insufficiency that adversely affect embryonic and fetal development during sensitive periods. Humans at greatest risk of metabolic programming experience poor fetal and infant growth, rapid weight gain in childhood and obesity in later life1. These metabolic changes may be mediated directly or indirectly by excessive fetal glucocorticoid (GCC) exposure2. In swine, restricted fetal growth results in similar postnatal metabolic programming, affecting birth weight, survivability, growth rate, muscle development, glucose metabolism, blood pressure, and the stress response (as reviewed by Harding3). The objective of this experiment was to determine the effect of short-term prenatal dexamethasone treatment occurring in early- and mid-gestation on birth weight and early postnatal growth.

Materials and Methods
Pregnant PIC sows were given dexamethasone at a high anti-inflammatory dose4 (0.2 mg/kg) IM daily for 7 days; on gestation days 30-36 (Dex30; n = 27) or 60-66 (Dex60; n=27). Treated and non-treated control (CTR; n=25) sows were induced to farrow on day 115. On the day of birth (D0), and prior to any cross fostering, the litter size was recorded, and the body mass index (BMI; birth weight/crown rump length squared) determined. Judicious cross-fostering and split suckling was encouraged to ensure the best perinatal conditions supporting piglet survival and growth. Piglets were weaned at 19-22 days and piglets were sorted by size, treatment group and gender into nursery pens containing 10-13 pigs depending on the production week. Piglet weights were measured on day 0, 20, 34, and 50 and the average daily gain (ADG) calculated. Generalized linear mixed models (SAS) were used to estimate the difference in birth weight and ADG across treatment groups. Estimates were adjusted for clustering within litter by including a random intercept for litter in the model (PROC MIXED). Biologically relevant co-factors were tested and retained in the final model if they changed the regression coefficient by more than 10% or if statistically significant ($P < .05$).

Results
Birth weight, litter size and body mass index did not differ between groups. The ADG was higher in the Dex60 offspring than CTR between D20-50 and D0-50, and was higher in Dex60 than Dex30 between D34-50 and D0-50 (Table 1). The ADG of the Dex30 and CTR offspring did not differ statistically.

Discussion
Excess fetal GCC exposure affects the development of all tissues and organ systems, and is the most likely hormone to metabolically program in-utero. Moreover, fetal GCC exposure permanently resets several endocrine axes, including those involved in fetal and postnatal growth (i.e. GH-IGF-1), potentially altering the postnatal growth trajectory in situations when caloric intake is restored5. This present research provides experimental evidence of "catch-up growth" during the first 30 days post-weaning in piglets exposed prenatally to a potent GCC for a short-term period. However, the effects of prenatal GCC exposure on post-natal growth appear to be gestation-stage dependent. Importantly, evidence of a prenatal mechanism causing an altered postnatal growth trajectory in pigs that is potentially independent of birth weight may further explain causes of biological variation in growth in commercial pork production.

Parity of the rearing dam can influence progeny innate immune responses

Yvette J. Miller1 Alison M. Collins2 David Emery3 Douglas Begg4 Rob J. Smits4 Patricia K. Holyoake5

Introduction

Progeny from gilts have greater susceptibility to disease both pre- and post-weaning compared to sow progeny (Miller, 2006). This could result from differences in innate (non-specific) or adaptive immune responses in gilt compared to sow progeny. The aim of this experiment was to determine the innate immune responses of piglets born to or raised on gilts compared with sows. The null hypotheses were that innate immunity does not differ between progeny: (1) born to gilts and sows or (2) in the pre- and post-weaning period irrespective of the parity of the rearing dam.

Materials and Methods

This experiment was designed to differentiate between effects due to birth and rearing dam parity by cross-fostering progeny pre-suckling. Gilts (parity 0) and sows (parities 2-5) were induced to farrow on Day 114 of gestation. Piglets were collected pre-suckling and individually weighed and ear-tagged before being randomly transferred to a gilt or a sow. Sixteen gilt and 16 sow litters were assembled, each consisting of 5 gilt-born and 5 sow-born piglets. No piglets were returned to their birth dam. No deformed piglets or piglets <900 g live weight were kept on trial. A blood sample was collected from 3 gilt-born and 3 sow-born piglets per litter at 2 and 7 weeks of age in lithium heparin blood tubes for the following tests:

Immune cell stimulation - Whole blood from each animal was stimulated with pokeweed mitogen (PWM; general immune cell stimulant) or phosphate buffered saline (PBS; negative control). The IFN γ concentration was measured in the supernatant using an sandwich ELISA (Miller, 2008). A sample to positive (SP) ratio (%) was calculated for each sample.

Phagocytic assay – Whole blood was mixed with a solution of killed yeast spores. A blood smear was stained with Diff Quik. The phagocytic index was determined, after counting 100 cells, from the proportion of cells containing yeast spores and the yeast spores/cell. All statistical analyses were done using REML linear regression in GenStat Release 10. For each analysis, birth dam parity, rearing dam parity, pre- or post-weaning, and birthweight were included as fixed effects. Random effects included litter and shed/pen effects.

Results and Discussion

Birth dam parity had no significant effect (P>0.05) on any piglet innate immune system measures indicating that adaptive immunity or rearing dam parity was likely to be more important in disease susceptibility.

Rearing dam parity only influenced the phagocytic index; gilt-reared progeny had a significantly (P<0.05) higher percentage of active phagocytes compared to sow-reared progeny both pre- (39% and 34%) and post- (48% and 43%) weaning. Phagocyte activity can be stimulated by inflammation which also leads to the production of acute phase proteins (APP). These results may therefore support findings by Morales et al. (2006), where it was concluded that gilt-reared piglets, who had a higher concentration of APP compared to sow-reared progeny, had greater antigenic challenge to their immune system. While further research is required, this higher antigenic challenge could result from the comparatively reduced effectiveness of the maternal antibody and cell protection that progeny receive in colostrum and milk of gilts compared to older parity sows allowing disease to occur. Alternatively, there may be more pathogens being shed by gilts than sows but this is only likely to affect pre-weaning disease susceptibility.

Piglet age had a significant effect on all innate immunity measures with a greater number and activity of immune cells post-weaning compared to pre-weaning (Table 1). This was expected as immune system maturity occurs over the first 7 weeks of life (Stokes et al, 2004) and confirmed that the tests were capable of detecting this change in innate immunity.

**Effect of housing system on reproductive performance of gestating sows**

Annop Suriyasomboon; Mongkol Techakumphu
Chulalongkorn University, Bangkok, Thailand

**Introduction**

There are several factors that influencing the pig reproduction such as breeds, parity number, nutrition, season, and temperature. The harsh climate condition was a major disadvantage for pig producing in tropical climate, such as Thailand, which resulted in lower reproductive performance of sows (1, 2, 3). In recent years, a new closed housing system, evaporative system (EVAP), has been introduced to improve the microclimate for pig farms in Thailand. EVAP is aimed to reduce the temperature inside the building by a humidification process. Some pig farmers already applied this system with the boar (4). The gestating and lactating sows were also using this housing system. To my knowledge, no comprehensive study on the effect of temperature and humidity, based on daily recordings within the EVAP stable, on the reproductive performance of gestating sows has been performed. This study was to investigate the effect of housing systems on reproductive performance of gestating sows in Thailand.

**Materials and Methods**

Data were collected from 13 pig farms (range from 1,000-5,000 sows) in the intensive pig raising area in Thailand during the period September 2007 to August 2008. Seven of these farms had conventional (CON) housing system and six farms had EVAP housing system for the gestating sows. All herds had been operating for at least 5 years and the EVAP herds had used this system for at least 2 years before the start of this study. Temperature and humidity were recorded automatically inside the gestating housing by using Hobo® data logger. Reproductive data were obtained from the pig’s herd management program i.e. PigLIVE® (Version 2.0, Live Informatics Co., Ltd., Thailand). Data were statistically analyzed using the SAS program (Version 9, SAS Institute Inc., Cary, NC, USA). ANOVA was applied to the litter size, total number of piglets born, in relation to the climate at previous weaning, at mating (NTB-m), and at farrowing.

**Results**

There was a higher variation and range of the maximum temperature and the minimum humidity in the CON system than in the EVAP system in all three seasons. The average maximum temperature was lower, and the average minimum humidity was higher in the EVAP system than in the CON system. There was no significant effect of housing system on any of the reproductive variables analyzed. However, the interaction between housing system and 2-month periods was significant (P<0.01). The litter size of sows kept in the EVAP system was higher than sows kept in the CON system over the year. Increasing temperature resulted in lower subsequent litter size and number of born alive piglets (NBA) (P<0.05). Increasing humidity in the housing resulted in decrease NBA and increase number of still born piglet (P<0.05).

**Discussion**

The overall results reveal that not only elevated temperature but also elevated humidity has a negative impact on reproductive performance in sows. In this study, there was a significant interaction between housing system and 2-month periods on NTB-m, which indicates differences between seasonal variations in the ovarian function from the sows kept in the two housing systems. The smaller litter size in the CON system might be explained by a poor fertilization rate, high embryonic death, and more discomfort and/or heat stress of the sows. Thus, using the EVAP system might be an alternative choice for improve the reproductive performance of gestating sows.

A retrospective analysis of results from laboratory tests to assess the cause of reproductive failure in sows

Heiko Nathues1 Regina Tegeler2 Elisabeth Grosse Beilage1
1. Field Station for Epidemiology, University of Veterinary Medicine Hannover, Bakum, Germany;
2. Field Station for Epidemiology in Bakum, University of Veterinary Medicine Hannover, Bakum, Germany

Introduction
Diagnosis of the cause of reproductive failure in sows is seldom straightforward and is frequently unsuccessful (1). In order to confirm or to rule out infectious agents as the cause of a reproductive failure, practitioners often tend to submit material from abortions, cervical swabs, organs of the genitourinary system from slaughtered sows or serum samples for further examination to a laboratory. The aim of this study was to analyze data from a nationwide operating laboratory for routine diagnostics, where samples had been examined by standardized methods for various infectious agents that might be involved in reproductive diseases.

Material and Methods
A retrospective analysis was applied to data obtained by routine diagnostics over four consecutive years in Northwest Germany. All laboratory work was conducted and documented as specified in the ISO/IEC 17025:2005. Material from abortions (fetal lung, liver, kidney, spleen and heart muscle or placenta) was examined for the presence of PRRSV EU genotype and NA genotype (in Germany exclusively Ingelvac PRRS MLV), PCV2 and PPV, as for Leptospira and Chlamydia species by single PCR tests or by PCR screening (all five PCR tests from fetal liver). These PCR tests were performed by IVD-GmbH (Hannover, Germany). The cervical swabs and smears of organs from the genitourinary system were tested for presence of various bacteria by standard cultural methods. Serum samples were only submitted to PRRSV (EU and NA genotype) and PCV2 specific PCR tests. Data were stored in and later extracted from a SQL database.

Results
Material from abortions (n=788) was examined as often as cervical swabs (n=881). The detection rate for viral and bacterial pathogens by PCR was low in material from abortions (Tab. 1). On the opposite, 75.1% of all cervical swabs were tested positive for the presence of potentially pathogenic bacteria (E. coli, Streptococci, Staphylococci, etc.). However, in 52.9% of all positive swabs 3 or more bacteria were identified (Fig. 1). The samples from the genitourinary organs were positive for one or two bacteria in 49.9% of all cases (Fig. 2). In serum samples, mainly originating from (weak born) suckling pigs, the average detection rate of PCV2, PRRSV EU genotype and PRRSV NA genotype was 41.6%, 23.1% and 12.9%, respectively. During the same period, the detection rate of PCV2, PRRSV EU genotype and PRRSV NA genotype in material from abortions was 14.7%, 6.8% and 1.3%, respectively.

Discussion
This study corroborates the difficulties in diagnosing the cause of reproductive failure by laboratory examination. When PRRSV is suspected causing reproductive failure, the impracticability of examining material from abortions compared to serum samples from (weak born) suckling pigs should be taken into account.

Synchronizing ovulation for fixed time artificial insemination in cyclic gilts with Porcine Luteinizing Hormone (pLH)

Audrey C. Cameron¹ Jennifer Patterson¹ Divakar J. Ambrose² George R. Foxcroft¹ Michael K. Dyck¹
¹ University of Alberta, Edmonton, AB, Canada; ² Alberta Agriculture and Food, Edmonton, AB, Canada

Introduction
Optimal timing of artificial insemination (AI) in breeding programs is crucial to ensure successful fertilization and efficient production. Variation in the duration of standing estrus, which has direct implications for timing of ovulation, has been well established in swine. Although a relationship between the time of ovulation after the onset of estrus, and estrus duration, has been reported in both sows and gilts, no other factors seem to relate to the timing of ovulation. The recorded onset and duration of estrus also depends on the frequency of estrus detection and the observational skills of the stockperson. The use of exogenous hormones to control the timing of ovulation can eliminate the need for heat detection and facilitates the use of fixed-time AI procedures. Recent research has demonstrated that porcine luteinizing hormone (pLH) (Lutropin-V, Bioniche) can reliably synchronize ovulation in weaned sows and gilts as a part of fixed time AI protocols. The primary objective of this study was to refine existing ovulation induction protocols to allow for implementation of a single fixed time artificial insemination (sFT-AI) program in cyclic gilts using porcine luteinizing hormones (pLH).

Materials and Methods
A total of 100 known-cyclic gilts were synchronized using oral progestagens (altrenogest, 15 mg/d x 18/d; Regu-Mate, Intervet Canada) and were then randomly assigned to three different breeding protocols: 1) Control-1 (CON1) gilts received a single insemination at 158 h following the last altrenogest treatment (CON1, n=30); 2) Control-2 (CON2) gilts were bred using a standard 2 insemination breeding protocol. The first insemination occurred at the initial detection of standing estrus, and then again every 24 h later. (n=35); 3) Gilts in which ovulation was induced (pLH) received 600 IU equine chorionic gonadotropin (eCG; Folligon, Intervet Canada) 24 hrs after last altrenogest. They then received 5 mg of pLH (Lutropin-V, Bioniche Animal Health Canada) 72 hours later and a sFT-AI performed 32 hours after the pLH injection (n=35). Estrus detection and transcutaneous real-time ultrasonography were performed every 8 h (8:00, 4:00, 12:00) beginning 24h after the last altrenogest treatment to determine time of onset of estrus and ovulation.

Results
LH gilts showed shorter intervals (P<0.01) between the end of altrenogest treatment and the onset of standing estrus (135.8±0.13 h) compared to CON1 and CON2 gilts (155.0±0.13 and 153.7±0.12 h, respectively) and between the end of altrenogest treatment and ovulation (154.8±0.12 vs. 187.4±0.12 and 187.1±0.17 h, respectively). Furthermore, LH gilts show the least variation in the altrenogest to ovulation interval, with all gilts ovulating within a 31.9 h period, compared to 51.6 h and 72.2 h periods for the CON1 and CON2 animals. The AI to ovulation interval was also shorter (P<0.01) for the pLH animals when compared to the sFT-AI for CON1 and first AI for CON2 (23.4±2.75 vs. 35.2±2.84 and 31.4±2.74 h, respectively). There was no significant difference in pregnancy rate between treatments with an overall average rate of 88%. Similarly treatment did not affect litter size or the number of piglets born alive with overall averages of 12.5±0.7 and 11.8±0.7, respectively.

Discussion
These results indicate that pLH is appropriate for use in cyclic gilts, and can reliably synchronize ovulation, while shortening the period between AI and ovulation. Furthermore, the application of this ovulation induction protocol in combination with sFT-AI did not detrimentally influence pregnancy rate or litter size and therefore provided acceptable reproductive performance and efficiency. This suggests that pLH based sFT-AI protocols could be successfully applied in gilts, thereby decreasing the amount of semen needed to breed a single female and allow for the more efficient use of superior sires.

References
**Introduction.** The principal goal of commercial breeding herds is to consistently meet weekly breeding targets. Weaned sows failing to return to estrus within 7 d after weaning contribute to missed breeding targets and increased non-productive sow days. However, in well managed contemporary sow farms, more than 90% of sows may return to estrus within 3 to 5 days after weaning (1). The primary objective of the present study was therefore to determine the response to gonadotrophin treatment (GT) at weaning in contemporary parity 1 commercial sows with lactation lengths typical of the North American swine industry.

**Materials and Methods**

Primiparous crossbred sows were blocked by genetic line (Pig Improvement Company (PIC) C22, n = 261; and PIC C29, n = 114), estimated post-farrowing weight and total born at parity 1 and then randomly allocated within block to either receive a combination dose of 400 IU eCG and 200 IU hCG (PG600, Intervet, USA, De Soto, KS) I.M. in the neck on the morning of weaning (PG group; n = 168), or to be uninjected controls (CON group; n = 207). From the day after weaning (D1), all sows were provided twice daily fence-line contact with mature boars for stimulation and detection of estrus. Sows were bred by artificial insemination (AI) according to established herd protocols. Reproductive parameters analyzed were estrus synchronization rate (ESR) determined as the number of sows with first observed estrus within 7 d after weaning, weaning-to-estrus interval (WEI), proportion of sows bred that farrowed (FR), total litter size born (TB) and born alive piglets (BA) at farrowing. In addition, within each treatment, the synchrony of sows returning to estrus was determined as the proportion of sows in estrus within a 3-d period (d 4, 5 and 6 for CON vs d 3, 4 and 5 for PG sows) (BRD3).

**Results**

Parity 1 total litter size (12.2 ± 0.2 vs 12.0 ± 0.3) and estimated farrowing (194.0 ± 1.7 vs 192.1 ± 1.9 kg) and weaning (189.6 ± 1.4 vs 189.3 ± 1.6 kg) weights, were similar (P > 0.05) in CON and PG sows, respectively, indicating balanced allocation of sows across treatment. Lactation length (19.5 ± 0.1 vs 19.1 ± 0.1 d) and estimated weight loss in lactation (4.6 ± 1.3 vs 2.8 ± 1.1 kg) were also not different (P > 0.05) in CON and PG sows, respectively.

**Discussion**

In the current study, excellent lactational and post-weaning management resulted in excellent fertility in untreated CON sows. Although GT treatment shortened the WEI, there was no effect on farrowing rates or subsequent litter sizes. GT treatment in more adverse times of the year may still be beneficial in terms of inducing more sows to show standing heat within the 7-day breeding week after weaning.

Fertility and prolificacy following ovulation induction (by PG600 or hCG) and a single fixed time AI

H.M J.M. Swarts1 M.A. Driancourt2 S. Ferchaud3 P. Guillouet3 K. Pere3
1. ISPAH, Global Marketing Swine, Boxmeer, Netherlands; 2. ISPAH R&D Pharmaceuticals, Beaucouze, France; 3. I.N.R.A., Rouillé, France

Introduction
The objective of the present study was to test the efficacy of two treatments for ovulation induction (PG600® (400IU PMSG and 200IU HCG) and hCG (Chorulon®) followed by a single artificial insemination (AI), on fertility and prolificacy of gilts previously synchronised with Matrix®. Target is to obtain high reproductive performance while simplifying fertility-management (less time spent for oestrus detection, less AIs and a more predictable timing of farrowing).

Materials and methods
The study was performed by INRA Rouillé (France). Thirty-six (36) Large White X Landrace pubertal gilts (129 kg average BW and 180 days old) were randomly assigned to three treatment groups, each including 12 animals. All gilts were synchronised by oral administration of Matrix® (15 mg altrenogest/animal) once daily for 14 consecutive days. Four days (96h) after the last administration of Matrix® (Day 0), animals were treated for ovulation induction as follows:
- Group 1: Non-treated animals (control)
- Group 2: I.m. administration of PG600
- Group 3: I.m. administration of hCG (500 IU)
At thirty-two hours after ovulation induction, gilts from groups 2 and 3 were inseminated once, while those of group 1 (control) were inseminated twice, 12 hours apart, at detected estrus. Ovaries were scanned (ultrasonography) starting immediately before treatment and then twice daily for the next 48 hours in order to check ovulations (based on the disappearance of the large preovulatory follicles present at earlier scans). Blood samples were collected before treatment, and 2, 4 and 7 days later, to assess changes in plasma progesterone concentrations and to document the quality of ovulation. Twenty-two days after AI (Day+23), the pregnancy status of the gilts was checked by ultrasonography. At about thirty days after AI, all pregnant gilts were slaughtered, their ovaries collected and the numbers of total and normal foetuses were determined.

Results
There was no treatment effect (P=0.11) and no treatment by time interaction (P=0.09) for changes in progesterone concentrations. Progesterone concentrations were low on day 0 and 2, and increased similarly in the three treatment groups to reach 22.8± 6.6, 18.8± 4.2 and 21.0± 5.0 ng/ml in gilts treated with hCG, PG 600 and placebos respectively.

A summary of the data describing ovulation rate, fertility, number of live embryos at slaughter and of embryonic survival (ratio between ovulation rate and total number of embryos at slaughter) is presented in the table below:

</tbody>
</table>

Discussion and Conclusion:
These results show the ability of an injection of PG600 or hCG to induce ovulation (when injected 96h after the end of Matrix®), hence allowing to obtain high fertility and prolificacy after a single fixed time AI (similar to that generated by multiple AIs at detected estrus). Although these findings need to be confirmed on a larger sample, this study establishes that the LH activity intrinsic to the hCG and PMSG molecules is suitable for ovulation induction in swine.
Effect of altrenogest on prevention of early parturition and reproductive performance in sows

Caroline Vanderhaeghe1 Jeroen Dewulf1 Jan Jourquin2 Dominiek Maes1
1. Facutly of Veterinary Medicine, Department of Reproduction, Obstetrics and Herd Health, Merelbeke, Belgium; 2. Janssen Animal Health, Beerse, Belgium

Objectives
The purpose of this study was to investigate whether the administration of altrenogest during late pregnancy was effective to prevent early parturition (< 114 days of gestation) and to improve the reproductive performance in sows.

Material and Methods
The experiment was conducted in 4 commercial pig herds located in Flanders, Belgium. Within each herd, random stratification based on parity was used to allocate the sows (n=329) into a treatment or control group. Oral administration of 20 mg of altrenogest (Regumate®, Janssen Animal Health) was performed on day 111, 112 and 113 of gestation, based on the sow's individual insemination date. Reproductive parameters recorded were: farrowing date, number of live born piglets, stillborn piglets, mortality of weak born piglets during the first 3 days postpartum, cross-fostered piglets, pre-weaning mortality, number of weaned piglets. Statistical analysis was performed by means of analysis of variance taking herd into account as a random factor (SPSS 16.0).

Results
Early parturition (<114d) was found in 14.1% of the control sows (Fig. 1). The reproductive performance of sows with an early parturition (C1) was significantly lower compared to sows with a normal gestation length (≥ 114 days) (C2) and compared to sows treated with altrenogest (T) (Table 1).

Fig 1: Frequency distribution of gestation length in 329 sows.

Table 1: Reproductive performance (mean (s.d.)) of the sows in the treatment group (T) and the control sows either with early parturition (< 114 days) (C1) or with a normal gestation length (≥ 114 days) (C2).

Within a row, significant differences are marked with different superscripts (P<0.01)

* Sows with a correct record of cross-fostered piglets and pre-weaning mortality (n= 17, 91 and 130 for C1, C2 and T, respectively)

Gestation length was significantly different between the treatment group and the total control group (C1 + C2) (115.3 ± 1.23 and 114.7 ± 1.69 days, respectively P < 0.01). In the treatment group, none of the sows started farrowing during the altrenogest treatment. For the other reproductive parameters, no significant differences were found between the treatment group and the total control group (C1 + C2) and between the treatment group and the control group with a normal gestation length (C2) (P > 0.05).

Discussion and conclusion
The present study demonstrates that early parturition adversely affects the reproductive performance of the sows. The administration of altrenogest at D111, 112 and D113 of gestation is an effective and safe method to prevent early parturition and can counteract the reproductive losses due to premature farrowing. However, it does not significantly influence the reproductive performance parameters compared to non-treated sows with a normal gestation length.

Reproduction - Sow management
**Effect of vaccination against experimental infection with highly and low virulent *Mycoplasma hyopneumoniae* strains**

Iris Villarreal; Dominiek Maes; Katleen Vranckx; Dries Calus; Frank Pasmans; Freddy Haesebrouck  
Faculty of Veterinary Medicine, Ghent University, Merelbeke, Belgium

**Introduction**
*Mycoplasma hyopneumoniae* (Mh) is the primary agent of enzootic pneumonia (EP), a contagious respiratory disease with major economical impact for the pig industry. Vaccination of piglets is widely practiced as a control strategy for this disease. However, the currently available vaccines do not induce a complete protection against colonization and transmission. Virulence differences and protein variability between Mh strains may indicate that vaccination efficacy could vary depending on the strain. The aim of this study was to assess the effect of vaccination with a commercial bacterin vaccine against low and highly virulent Mh strains at 4 and 8 weeks post infection (PI).

**Materials and Methods**

Ninety, 3-week-old, cross-bred (Rattlerow Seghers), Mh and PRRSV free, weaned piglets were moved to the experimental facilities of the Faculty of Veterinary Medicine, Ghent University, Belgium. After one week acclimatization, they were randomly allocated to 10 different groups housed in absolute filters (HEPA U15) to avoid spread of the pathogen between groups. Forty piglets were vaccinated (v) with a one-shot vaccine (Stellamune One, Pfizer), 40 were left unvaccinated (nv) and 10 were assigned to the negative nv and non-challenged (NC) control group. The experimental design is summarized in Table 1. One low (LV) and one highly (HV) virulent Mh strain were used for experimental infection. After anesthesia, the pigs were inoculated intratracheally with 7 x 107CCU of Mh in 7ml inoculum or with 7ml of sterile culture medium. Half of the piglets were euthanized at 4w PI and the other half at 8w PI. The severity of coughing was assessed daily using a respiratory disease score (RDS) (values from 0-6). At necropsy, macroscopic lung lesions were quantified using the lung lesion score diagram of Hannan et al. (1982), ranging from 0-35. Additionally, lung tissue samples were taken from each pig to assess the severity of histopathological lesions (score from 0 to 5). Nasal swabs and bronchoalveolar lavage fluid (BALF) were collected after euthanasia and analyzed using nPCR to confirm presence of Mh.

**Results**

At 4w PI, the vHV group showed significantly milder respiratory symptoms and significantly lower macroscopic and microscopic lesion scores than the nvHV group (P<0.05). The vLV group showed no significant differences for RDS, macroscopic and microscopic lesions scores, compared to the nvLV group. At 8w PI, both vHV and vLV groups had significantly lower RDS scores in comparison to the nvHV and nvLV groups, respectively (P<0.05). Only the vHV group showed significantly lower macroscopic lesions in relation to the nvHV group. Results are summarized in Table 2. As expected, all pigs, except for the nvNC group, were positive by nPCR on BALF and nasal swabs.

**Discussion and conclusions**

The results confirm the difference in virulence between the two strains (3), when measured during a period of either 4 or 8 weeks PI. Vaccination significantly reduced the severity of disease in the vHV group at 4 or 8 weeks PI for most parameters. Vaccination was also beneficial in the LV groups, but the effects were less pronounced and depended on the measured parameter. Further research is warranted to assess the precise effect of vaccination on individual strains under field conditions, since combined infections might lead to more severe clinical disease in a pig herd (4).

Introduction
Infections with *Mycoplasma hyopneumoniae* (Mh) occur worldwide and cause major economic losses to the pig industry. Knowledge about the infection pattern of this pathogen in young piglets is essential for the implementation of appropriate control measures and optimization of vaccination strategies. The aim of the present study was to investigate the prevalence of Mh infections in piglets at 3 weeks of age in different European countries by analyzing nasal swabs using nPCR. In addition, possible risk factors associated with Mh infection in young piglets were investigated.

Materials and Methods
The study was conducted between May 2008 and March 2009 in 9 European countries namely Belgium, Denmark, France, Germany, Hungary, Italy, Poland, Spain and The Netherlands. In each country, 6 single-site farrow-finish or sow herds were included (4 herds included in Germany). Selection criteria included herds of minimum 100 sows, presence of clinical respiratory problems related to Mh (coughing) in grow-finishing pigs, and no antimicrobials used against Mh in piglets less than 3 weeks of age. Thirty nasal swabs were collected per herd from piglets of 21±3 days of age. The piglets were randomly selected from as many different sows as possible. A nested PCR (nPCR) based on a modified protocol (3) described by Stärk et al. (1998) was used for detection of Mh DNA. A questionnaire of 38 questions related to respiratory disease and herd management practices was completed during the herd visit. The questionnaire was subdivided in six categories including herd information, sow population, purchase policy, housing conditions, feeding management and health control strategies. The statistical analysis was based on a generalized mixed model using the PROC GLIMMIX procedure (SAS 9.2, 2008) with country and herd nested in country as random effects. Herd positivity was the dependent variable, whereas different potential risk factors served as independent predictor variables (P≤ 0.10) in the univariate model and were subsequently included in the multivariable analysis (P≤ 0.05).

Results
In total, 52 herds and 1555 piglets were sampled for presence of Mh. The average percentage of positive piglets within the herds was 11% (95% CI 7.4-14.2). The min. and max. within-herd prevalence was 0 and 37%. The percentage of herds with at least one positive tested pig was 68% (95% CI 51.7-83.4). In 32% of the herds, more than 10% of the piglets tested positive. France, The Netherlands, Italy and Germany had the highest percentage of Mh positive herds. Only in France, 100% of the herds were positive. The highest within-herd prevalences were found in Italy, France and Germany (Table 1). From the 38 variables analysed, only SIV sow vaccination was significant (P≤ 0.05) and positively associated with a higher risk of a suckling piglet being Mh positive (OR= 3.12. 95% CI 2.03-4.21).

Discussion
The results showed that in two thirds of the study herds, there was evidence of Mh infection in 3-week old piglets. In most of the positive herds, the prevalence was between 1 and 10%. In some herds, more than 30% of the piglets was already positive. This suggests that in the selected herds, early infections with Mh are important (1,2) and that infections commonly occur in European pig herds suffering from respiratory disease in the grow-finishing pigs. The higher risk of a piglet being Mh positive in case of SIV sow vaccination is difficult to explain, but it may be due to the fact that pig herds with respiratory symptoms may tend to vaccinate against SIV, overlooking the possible influence of other respiratory pathogens such as Mh.

Introduction

Enzootic pneumonia (EP), also called mycoplasmal pneumonia, is recognized as one of the most economically significant swine respiratory diseases. The etiological agent of this disease (M. hyopneumoniae, Mh) attaches to the ciliated epithelial lining of the respiratory tract, resulting in impairment of the mucociliary mechanisms, predisposing to secondary bacterial infections. Vaxsafe®MHP is a temperature sensitive Mh strain that is being developed by Bioproperties Pty Ltd (Australia) as the first live vaccine against EP.

Materials and methods

Forty (40) SPF pigs 3 weeks of age were used in this study. All pigs were ear tagged with an individual number, weighed and assigned to 4 study groups each containing 10 pigs. All groups were housed under the same conditions in negative pressure isolation rooms. Pigs were acclimatized for 3 days before treatment. Group 1 was the Negative control. Pigs within this group were administered vaccine diluent. Group 2 was vaccinated with Vaxsafe® MHP. Pigs within group 3 were vaccinated with a commercial inactivated vaccine. Group 4 was the positive control.

Vaccination day was designated as “days post vaccination-zero” (DPV-0). Vaccination with Vaxsafe® MHP was performed by intranasal spray and the commercial vaccine by intramuscular injection. Vaccinated pigs were allowed to develop immunity over a period of 22 days and then challenged with live cultures of Mh IOWA strain 194 administered by aerosol at a dose of ~10^6.0 ccu/mL/45 minutes in an aerosol chamber. On the first round pigs were challenged three times at 4 days apart DPV-22,-27 and -32. All groups were then subjected to second round of challenge with a similar culture of Mh on 3 consecutive days (DPV-84, -85 and -86). Post-mortems were performed 18 and 19 days after the second round of challenge. A number of parameters were measured including daily monitoring for clinical signs and temperature and periodic collection of nasal swabs (nPCR) and blood sampling (ELISA).

Results

Particular attention from a safety perspective was taken in the period between vaccination and immediately prior to the first challenge regime. During that period, no mortalities or clinical signs (coughing, sneezing, fever or loss of appetite) were observed in either the negative control or the vaccinated groups. Blood samples (2-5 ml) were collected from all pigs at the start of the study and at several intervals including post mortem. All samples were subjected to ELISA analysis to detect antibodies against Mh.

</table>

Nasal swabs were collected from all groups at the start of the study (DPV-0) and at DPV-8. Swabs were subjected to nPCR analysis. Mh was not detected at DPV-8 (before challenge) in pigs within the negative control group as well as groups 3 and 4. However, Mh was detected in 55.5% of pigs vaccinated with Vaxsafe® MHP (group 2) showing what appears to be a mild and transient colonization of the upper respiratory tract. (Table 1). None of the negative control pigs had detectable antibody. Pigs vaccinated with the inactivated commercial vaccine demonstrated serological response (77.8%) while only 12.5% of the pigs vaccinated with Vaxsafe® MHP had demonstrable antibodies. In contrast 42.9% of the positive control group showed antibodies against Mh. at postmortem.

Conclusions

No adverse effects of any kind were observed during this study. Vaxsafe® MHP proved to be safe when applied in SPF pigs for the control of M. hyopneumoniae infection.

Diagnosis of Mycoplasma hyopneumoniae in growing pigs

Erin Strait1 Cassandra Roe1 Nyssa Levy1 Carly Dorazio2 Mike Kuhn3

1. Iowa State University, Ames, IA, USA; 2. TriOak Foods, West Burlington, IA, USA; 3. Pfizer Animal Health, New York, NY, USA

Introduction

Mycoplasma hyopneumoniae (M. hyo) is an important cause of pneumonia in swine around the world. M. hyo can be challenging to identify during the early stages of infection due to its often slow spread within a population. Currently, ante-mortem diagnosis relies primarily on detection of serum antibodies that may take weeks to months to become detectible by ELISA, or on nested PCR from nasal swabs which has lower sensitivity than samples collected from the lower respiratory tract1. Increasing the sensitivity of testing by nasal swabs would improve the utility of this sample. Recently, oral fluids have been described for the detection of PRRS in pig populations2. Oral fluids are easy to collect and capable of surveying a large number of pigs in a short period of time, but its usefulness for the detection of M.hyo has yet to be determined. This study sought to optimize testing for ante-mortem detection of M. hyo.

Materials and Methods

Samples were collected as part of a vaccine study in which 2 seeder pigs from each of 6 pens of 52 pigs were challenged with an intratracheal inoculum of strain 232 lung homogenate. Within each pen, serum and individual nasal swabs were collected from 10 pigs (excluding seeder pigs), and an oral fluid was collected from each pen at the following six time points: 4 weeks pre-challenge; at challenge; 2, 4, 8, and 12 weeks post-challenge (oral fluids were not collected at 4 weeks pre-challenge). Oral fluids were collected in each pen by allowing pigs to chew on a cotton rope for 30 minutes. During the collection period the two challenged pigs were removed from the pen. Oral fluids were squeezed from the rope, transferred to a snap-cap tube and frozen until tested. Swabs and oral fluids were extracted by both a bead-based extraction method (Ambion Mag MAX-Viral Isolation Kit) and a spin-column extraction method (Qiagen QIAmp DNA mini kit). Extractions performed using the Ambion kit followed the oral fluid and total nucleic acid purification protocol. Extractions using the Qiagen kit followed the blood and body fluid protocol. Extractions were tested by a previously described primer and probe set targeting the mhp183 gene of M.hyo3. PCR was performed using two different master mixes (Ambion VetMAX-Plus qPCR master mix or AB TaqMan Universal PCR master mix) to further optimize the assay.

Results

The two extraction methods for oral fluids were compared and the spin-column kit resulted in lower Ct values (ie. greater sensitivity) as compared to the bead-based extraction method. The opposite was true when extraction methods for nasal swabs were compared. Based on these results, oral fluids were extracted using the Qiagen QiAmp DNA mini kit and nasal swabs were extracted using Ambion MagMAX kit. When the two different PCR reagent mixes were compared the Ambion VetMAX-Plus qPCR master mix gave the most sensitive results regardless of sample type tested.

Significant numbers of PCR positives were not detected until 8 and 12 weeks post-challenge for both oral fluids and nasal swabs. Positives attributed to maternal antibody transfer were detected by ELISA at the earliest time points and the post vaccination/challenge antibodies appeared at 8 to 12 weeks, similar to the PCR results. Due to the limited number of collection time points in this study all 3 sample types detected positives post challenge at the same time point (8 weeks post challenge). Therefore, it was not possible to determine which of the sample types was able to detect positives at the earliest timepoint post-infection. However, differences in the sensitivities of these assays and sample types were observed. At eight weeks post challenge, 45% of serum, 72% of nasal swabs, and 100% of oral fluids were identified as positive. Stronger PCR positives were detected from oral fluid samples than from nasal swabs.

Discussion

In this study we optimized both the sample collection procedure and DNA extraction PCR protocols for nasal swabs and oral fluids and compared these results to serology. Future studies applying these techniques in the field will be needed to confirm these results, but demonstrate the potential for monitoring shedding of M.hyo through oral fluids or nasal swabs in the field.

Increased performance after combined Mycoplasma and PCV2 vaccination

Hanne Bak¹ Erik Nörregård²

¹. Boehringer Ingelheim AS, Copenhagen, Denmark; ². Swedish Animal Health Service, Tommelilla, Sweden

Introduction

Vaccination against Mycoplasma hyopneumoniae (M hyo) is widely used in the pig industry to increase the performance of pigs. During the last years, vaccination against PCV2-virus has become more and more common, and in herds vaccinating against PCV2, the usual M hyo vaccination might seem unnecessary, because the pigs perform very well with PCV2 vaccination only. This side-by-side study evaluates the benefits of vaccinating against M hyo in a Swedish herd already vaccinating against PCV2-virus.

Material and Methods

The study took place in a Swedish 2-site herd with groups of 45 sows farrowing every 5th week. One batch of pigs was divided in 2 groups; 291 pigs were vaccinated against M Hyo and PCV2 (Ingelvac MycoFLEX® together with Ingelvac CircoFLEX®) and 156 pigs were vaccinated against PCV2 only (Ingelvac CircoFLEX®). Pigs were vaccinated at 3 weeks of age, weaned at 39 days of age and moved to the fattening site at 10.5 weeks of age. Each group of pigs was tattooed with different delivery numbers before slaughter. For each pig, slaughter date, carcass weight, meat % and carcass price was recorded at the slaughterhouse, and average daily weight gain (ADWG) (birth to slaughter) was calculated. Comparison of pigs vaccinated with 2 vaccines to pigs vaccinated with PCV2 only was done with Students t-test for ADWG, weight, meat %, and price and with W-W runs test for days (significance level p=0.05).

</tbody>
</table>

*=Statistically significant difference between means

Results

Pigs vaccinated with against both PCV2 and M Hyo showed a statistically significant improvement of performance measured as ADWG, time to slaughter, carcase weight and carcase price (p-values 0.001, 0.050, 0.014 and 0.011), compared to pigs vaccinated only against PCV2 (table 1). The meat percentage was not influenced by M hyo vaccination (p=0.558). In fig. 1, the faster growth of pigs vaccinated with both vaccines is visualized. The increase in the price of the carcases was 3.6 times as high as the vaccine price.

Discussion and Conclusions

The present herd had a good performance with PCV2 vaccination only, shown by an average daily weight gain of 632 g/day from birth to slaughter. There was no evidence of M hyo problems, neither clinically or in the carcass remarks from the slaughterhouse.

Still, the performance was significantly improved by M hyo vaccination, increasing the mean price of the carcass by 2.1 € per pig. Furthermore, the pigs grew faster, meaning that the farmer would also save food expenses and empty the barn sooner to put in new pigs.

Therefore, vaccination against M hyo on top of the PCV2 vaccination gave a payback of more than 3.6 times the investment in the M hyo vaccine.
Summary of Mycoplasma Hyopneumoniae Eradication Experiences Completed in Upper Midwest USA

Paul E. Yeske
Swine Vet Center, St. Peter, MN, USA

Introduction
Mycoplasma hyopneumoniae continues to be an economically important respiratory infection in swine. There are a number of different ways to eradicate Mycoplasma from herds. Adaptations to the Swiss method have also been successful at eradication. These would include herd closures allowing the herds to continue to farrow during the process1, 2. Vertical transmission studies demonstrate that transmission occurs up to 8 months post infection3. Herd closures have typically been 8-9 months duration and may or may not have off site breeding projects incorporated. These procedures have included a whole herd medication program at the end of the closure.

Another method is whole herd medication without herd closure using a long acting antibiotic such as Draxxin® (10% Tulathromycin, Pfizer), treating all pigs on site with an injection and repeating in 2 weeks4. The advantage of this approach is that the herd returns to negative status faster.

This study looked at results of herds that have been through various versions of Mycoplasma hyopneumoniae eradication procedures and the duration of time that the herds have stayed negative.

Materials and Methods
- Identified 23 herds that had been through a Mycoplasma hyopneumoniae eradication procedure.
  - 16 herds used a herd closure and whole herd medication program.
  - 7 herds did a whole herd injection of medication program and no closure.
- All farms had negative replacement breeding stock available.
- Herd’s mycoplasma status where monitored using: pigs in the finishing flow and blood testing just prior to marketing.
  - Clinical signs of Mycoplasma (coughing) in sow herds or finishing pigs.
  - Serology of pigs at the end of the finishing phase.
  - Using IDEXX test if vaccinated

Results
Herd closure and medication (C) and whole herd medication using Draxxin® (M) were 81% and 57% successful overall respectively, and 94% and 71% successful for a period greater than 1 year. The average “survivability” of herds in the study was 31 and 20 months respectively as shown in Table 1.

Discussion
Herd closure and medication (C) has been more successful, although both methods of Mycoplasma hyopneumoniae eradication were successful over time. However implementing herd closure takes longer to obtain Mycoplasma negative pigs, and depending on the economic advantage the whole herd medication may be more attractive. Each farm will have its own unique goals and limitations that must be considered but these 23 herds represent what can be done with the various programs being used in the field in pig dense areas of production.

Effect of stopping Mycoplasma hyopneumoniae vaccination in pigs
John Carr
Portec Australia, Belmont, WA, Australia

Introduction
The timing of the Mycoplasma hyopneumoniae vaccine was changed from weaning to 30 kg live weight and then the vaccine was stopped.

Materials and methods
A 140 sow weekly batch outdoor unit was selected for the trial. 1330 pigs a batch were weaned. The unit was PRRSv and SIIV negative. No PMWS had been diagnosed on the farm. The farm was Mycoplasma hyopneumoniae and Actinobacillus pleuropneumoniae 1 and 15 positive. A few cases of Glasser’s were seen. Post-weaning mortality was normally 3% primarily associated with enzootic pneumonia complicated with pasteurella and streptococci and hind limb weakness and lameness.

A change in vaccination timing from 4 weeks (farrowing) to 10 weeks of age (nursery) was made in response to stockpeople's request. Following a 17 weeks trial the timing was moved back to 4 weeks of age. At this stage it was agreed to examine the impact of non vaccination – thus providing a 6 week non-vaccinated group. The pigs were monitored by clinical signs, post-weaning mortality and slaughterhouse examination.

Results
Change of timing of vaccination
The arrow indicates the start of the trial to administer vaccine at 10 weeks of age
There was no impact on postweaning mortality with vaccine timing changed from 4 to 10 weeks of age.

Cessation of Mycoplasma vaccination
To restore the vaccination at weaning a 6 week period of non vaccination was practiced.
The arrow indicates the 6 batches finishing without vaccine.
The lower line is the mean the upper line 2sd above. The system was out of control 4 out of 6 batches (big dots). Over the 6 weeks a post-weaning mortality of 5.4% cf. normal 3% (p=0.007).

Slaughterhouse examination
Enzootic pneumonia score:
Q1 3 Q2 3 Q3 4 Q4 1.5 Q1 12 Q2 2.5 Q3 3.5 Q4 0.5
In addition to increase in enzootic/mycoplasma pneumonia scores, pleurisy increased to 35%, normal less than 2%. Pleuropneumonia like lesions increased to 10% normal less than 1%. Pericarditis increased to 6% normally less than 1%. There was no change in dermatitis, white spot, nephritis or ileitis scores.

Cost implication: ($Au)
Extra-mortality – loss of 2,605kg deadweight/ batches - @ $3.40 a kg cost of production, removing the food not eaten - $7,781 loss/batch
Loss of production – a 12 lung score equates to an increase in FCR of 0.15. Thus an extra 21 tonnes per batch - @$370 a tonne $7,789 extra per batch
Additional costs per batch - $15,869 or $12.30 a pig.
Cost of the Mycoplasma vaccine - $1.70 (including labour and equipment) – with 1330 pigs a batch weaned – total costs - $2261 a batch.
Extra medication are not included in these costs.

Discussion
There was a 7:1 benefit of vaccination with the Mycoplasma hyopneumoniae vaccine. The benefit was shared between the cost of mortality of a nearly finished pig and the poorer food conversion of the remaining pigs. There was no impact, in a PRRSv negative herd, of vaccinating at weaning or 10 weeks of age. Please visit our website www.portec.com.au
Application of Mycoplasma hyopneumoniae P146 genotyping to an outbreak investigation

Daniel Linhares¹ Simone Oliveira² Montserrat Torremorrell³
1. College of Veterinary Medicine, University of Minnesota, St Paul, MN, USA;
2. Veterinary Diagnostic Laboratory, College of Veterinary Medicine. University of Minnesota, St Paul, MN, USA

Introduction

Enzootic pneumonia (EP) is an important respiratory disease of swine caused by Mycoplasma hyopneumoniae (Mh). EP impacts the performance of growing and finishing pigs by reducing growth rate, increasing mortality and worsening feed efficiency. MH negative pig farms have productivity advantages compared to positive systems. Therefore there is a premium in maintaining systems MH negative. However, negative systems may become contaminated and in those cases it becomes critical to understand the source of MH infection.

P146 is a lipoprotein that plays a role in Mh adhesion. It is located in the surface of the bacterial cell and contains a series of serine repeats. The gene that codes for these serine repeats was recently used for characterization and comparison of Mh isolates from different European herds and also from different continents (Mayor et al, 2007; 2008).

This study describes a case where MH genotyping using sequencing of the P146 gene was used to investigate the source of contamination of a MH negative system.

Materials and Methods

Herd A is a 1,000 daughter nucleus sow herd that delivers gilts and boars to multiplier and commercial farms. Herd A was monitored on a regular basis by weekly veterinary visits and monthly serology screening including Mh. Additionally, slaughter checks were also performed on a monthly basis.

On August 2007, 2 out of 30 pigs tested positive by serology in the routine herd testing. No lung lesions or clinical signs were observed at that time. Discrete clinical signs were observed on nursery pigs in early September. Infection was confirmed when additional samples tested positive and clinical signs of Mh infection were evident by the end of September.

Herd B, C and D were 800, 750 and 1,000 sow farms respectively that had Herd A as the only source of replacement animals for at least 2 years. These herds were also MH negative based on at least 4 years of regular serology and clinical monitoring. The last animal introduced in herd B was 5 boars (July 07), 63 gilts in herd C (June 07) and 30 gilts in herd D (May 07). Herds C and D did not have quarantine and received animals directly into their herds. Herd B had a quarantine unit where animals were allowed to enter the herd after completion of Mh serology in 100% of the animals.

On September 07 herds C and D started developing clinical signs suggestive of Mh infection. Infection was confirmed by serology and positive PCRs of pneumonia lesions. In Herd B, however, no clinical signs were observed until December 07, when Mh infection was confirmed by serology and PCR of lungs of coughing pigs.

On December 07, lungs from two coughing pigs were collected in all aforementioned farms and also from eight Mh positive herds that were unrelated to those farms. Positive samples were sequenced by targeted the P146 gene segment and results were compared among all isolates. Diagnostic testing was conducted at the U of Minnesota Veterinary Diagnostic Laboratory.

Results and Discussion

Considering that Herd A was the only source of replacement animals for Herds B, C and D, Herd A was considered the most probable source of contamination for these herds. However, the timing of seroconversion and development of clinical signs did not match the current knowledge of Mh disease incubation, especially regarding Herd B that received animals in July but clinical signs and evidence of infection was not detected until December. This delay may be explained by the low number of animals introduced, only 5 boars, and the slow spread of the infection in that population.

Considering this unusual situation, we needed a new approach to help the investigation and to answer whether the Herd A was indeed the source of infection of the other farms. The Mh isolate sequence of Herds B, C and D matched the sequence information of Herd A. These results suggested that the most likely source of infection in the studied herds was indeed the direct introduction of animals from Herd A. In addition, six out of the eight isolates recovered from the unrelated herds had a different sequence indicating that P146 gene sequencing had a good discriminatory ability to detect genetic differences among Mh isolates. In conclusion, P146 sequencing appears to be a useful tool in the aid of investigating Mh infections.

Comparison of mycoplasmal lung lesion scoring methods

Brad J. Thacker1 Erin L. Strait2 Lyle D. Kesl3
1. Intervet/Schering-Plough Animal Health, Desoto, KS, USA; 2. Veterinary Diagnostic Laboratory, Iowa State University, Ames, IA, USA; 3. Veterinary Resources, Ames, IA, USA

Introduction
There are several methods available for determining the level of pneumonia in swine lungs. These methods are often based on assessing the amount of visible lesions on the surface of the lung followed by calculating the percentage of the lung surface that exhibits the lesions to provide an overall lung score. The main methods evaluated in this paper included: 1) sketching the lesions onto a standard diagram followed by digital image analysis in order to determine the percentage of the lung surface that exhibits lesions; 2) the "PigMon" method where the extent of lesions in each of the seven lung lobes is estimated followed by placing these scores into a formula that represents the relative contribution of each lobe to the total lung area; and 3) a method used by the first author where each lobe is scored separately followed by incorporation into a formula based on the relative weight of each of the lobes to the total lung weight. In addition, a different formula (BC) was used to calculate the total score from the individual lung lobe scores.

Materials and Methods
The lungs (n = 58) evaluated in this study were part of a Mycoplasma hyopneumoniae vaccination/challenge study. At necropsy, lesion observations were done by: 1) Sketch- lesions were recorded onto a standard diagram; 2) VR (Veterinary Resources)- percent lesions in each lobe was recorded by the "PigMon" evaluator (third author); 3) BT- percent lesions in each lobe was recorded by the first author (BT) and 4) BTSK- sketches were scored using the BT observation method. This raw data was then incorporated into three formulas (PigMON, BT, BC) of which the contribution of each lobe to the total lung is presented in Table 1. An overall lung score was also assigned by the first author (BT/Total). The sketches were analyzed by digital imaging and the percent lesions generated by this method were considered the standard value for comparison with the other scoring methods. The scores generated using the various combinations of observation methods and overall score calculations were compared against the standard value on an individual pig basis. The percent differences between methods were calculated and correlations were performed.

Results
The overall lesion scores (% pneumonia) by each method, differences between the methods and correlations to the standard values are presented in Table 2. The overall percent pneumonia by the standard method (Sketch-Image) was 8.46%. The average scores by the other methods varied from 5.99% (-2.47%) to 9.89% (+1.43). R-square values (correlation) varied from 0.844 to 0.986.

Discussion
The best combination of observation and calculation methods appeared to be the BT observation method from the sketch (BT-SK) along with the BC formula to generate the overall score. Accordingly, this method can be used in place of the digital image analysis which is fairly expensive. In addition, the sketch provides a permanent record of the lung lesions which enables evaluation at a later time.

Comparison of four ELISAs for detection of antibodies against different genetic subtypes of European genotype PRRSV

Tomasz Stadejek; Ewelina Skrzypiec; Katarzyna Chabros; Zygmunt Pejsak; Katarzyna Podgorska
National Veterinary Research Institute, Pulawy, Poland

Introduction

Porcine reproductive and respiratory syndrome virus (PRRSV) strains belong to the two genotypes which are antigenically different. The genetic diversity in the European genotype (EU-PRRSV) is much higher than in the North American genotype (NA-PRRSV) (3). The evidence of the restricted serological cross reactivity between the genetic subtypes exists (1, 3) but it is unknown whether it impacts the sensitivity or specificity of the ELISA diagnostic tests methods. To address this problem 175 sera from farms where different genotypes and genetic subtypes circulated were tested with three commercial and one in house ELISA tests.

Materials and Methods

Serum samples were obtained from 3 Polish, 4 Belarusian and 1 Ukrainian farms, where different genotypes and subtypes circulated as it was determined by PCR and DNA sequencing. In 2 of 3 Polish farms subtype 1 of EU-PRRSV circulated. In one farm the NA-PRRSV strain was present. In Belarusian and Ukrainian farms diverse East European subtypes circulated (3). Additionally, 31 samples from pigs from farms free from PRRSV were used. They included 17 sera from Sweden that earlier were found to react false positive in HerdChek PRRS 2XR (IDEXX) ELISA and negative in IPMA test. The samples were tested with HerdChek 2XR and 3X (IDEXX), Ingezim PRRS DR (Ingenasa) and the in house test produced in our laboratory. The Ingezim test is specific for EU-PRRSV while the remaining tests are specific for both genotypes. Results were compared for each pair of ELISA tests separately using McNemar’s test.

Results

All ELISAs detected PRRSV specific antibodies in sera from all farms where EU-PRRSV infection was present. Both IDEXX tests and the in house ELISA detected antibodies to NA-PRRSV in all sera from the Polish farm where this genotype circulated while Ingenasa test detected seroconversion in only 5 of 12 of the samples. In case of samples from one Ukrainian farm infected by EU-PRRSV subtype 2 the Ingezim test appeared to be significantly more sensitive than PIWet and HerdChek X3 tests. The analysis of the specificity proved it to be highest in case of the HerdChek X3 test. The HerdChek 2XR test gave false positive results with most of the Swedish sera as it was found before.

Discussion

Very high genetic diversity of PRRSV poses a serious problem for PCR diagnosis, especially for the detection of the European genotype. However, our preliminary data show that it does not influence serological diagnosis by ELISA. All tests used in the study were sensitive in detection of antibodies induced by different, diverse genetic subtypes of EU-PRRSV. However, the 3X test seemed to be slightly less sensitive than the older 2XR test and the Ingezim DR. The X3 test was the most specific test of all. Further studies are necessary to fully evaluate the impact of the antigenic diversity of the EU-PRRSV on sensitivity and the specificity of the serological methods of PRRS diagnosis.

**PRRSV-neutralization test - a tool for quality control?**

Jens Boettcher; Armin Gangl; Britta Janowetz; Michaela Alex; Hermann Niemeyer

*Bavarian Animal Health Service, Poing, Germany*

**Introduction**

Vaccination against PRRSV is frequently practised in Germany to control PRRSV. Attenuated live vaccines of the North American (NA) and European (EU) genotype are used. Early after infection antibodies are detected in ELISA, however neutralizing antibodies (nAb) are detected only at low titre and late (>28 days) after infection. Additionally, detection of nAb depends on the virus isolate. Assuming that induction of homologous nAb against vaccine virus after vaccination is a positive quality criterion, a PRRSV-neutralization test (NT) using vaccine virus was established. Data obtained by analysis of field cases will be presented.

**Material and Methods**

NT with 100 CID50 of NA- and EU-vaccine virus, respectively, was performed on Marc145 cells with 2% guinea pig complement (BÖTTCHER et al., 2006). Culture was checked for CPE until day 6. Results are given as titre: <2, 2, 2.8, 4, 5.6, 8, ≥11.2.

Sera were tested by PRRSV-ELISA (Idexx) according to manufacturer’s instruction. A nested RT-PCR was performed according to PESCH et al. (2000). Blood was collected from gilts, sows at 1. and 5. parity and piglets after weaning 4, 8, 12 weeks of age. 10 animals per group were tested. For calculation of geometric mean of NT-titre a titre of ≥ 11.2 was scored as 11.2.

**Results**

1. In herds with an acute outbreak of PRRSV and absence of vaccination with NA-PRRSV, sera with high EU-NT-titres (≥11,2) were negative for nAbs to NA-PRRSV. Sera with high NA-NT-titres (≥11,2) from herds free from EU-PRRSV and vaccinated with NA-PRRSV were negative in EU-NT. Thus cross-neutralization between genotypes seems unlikely.

2. Comparison of ELISA and NT revealed that 30% of ELISA-negative sera were positive in at least one EU- or NA-NT; in contrast 67% of ELISA-positive sera were positive in NT, too. This difference between tests is explained by longer persistence and late induction of nAb, respectively.

3. As a consequence of an acute PRRSV-outbreak high NT-titres were observed in sows; maternally derived nAb (MDnAb) controlled infection in piglets until 12th weeks of age. PRRSV was detected in piglets with MDnAb by PCR when the geometric mean of the NT-titre dropped below 4.

4. Regarding vaccination 90% of piglets free of MDnAbs at vaccination (14-21 days p.n.) were positive in PCR until 8 weeks of age. A slight increase of NT-titre was observed until the 12th week of age. In contrast, only 10% of piglets with a mean NT-titre of MDnAb of 7 at vaccination were positive in PCR two days p.vacc.

5. Low or no NT-titres were frequently detected month after vaccination.

6. Sows of 5th parity had generally lower titres than sows of 1st parity, unless recent acute outbreaks in the herds were reported. Vaccination every 4 month was not effective in raising NT-titres in these animals. As a consequence offsprings of these sows are earlier susceptible to infection.

**Discussion and Conclusions**

PRRSV NT is a powerful tool in order to determine at least one side of PRRSV immunity; however, it is laborious and expensive. As a consequence NT should be substituted by an appropriate ELISA.

It is questionable if vaccination in the presence of homologous nAb is effective. This is especially important for piglets with MD-nAb. Thus prediction of an optimized time-point of vaccination is necessary. Additionally, gilts should be checked by NT before they are introduced into infected herds.

Extend of cross-neutralization within genotypes especially EU is still not sufficiently analysed. If antigenic heterogeneity of PRRSV isolates due to its high frequency of mutation is a real problem like in Influenzavirus A, Bluetonguevirus, Foot-and-Mouth-Disease Virus etc., serotypes have to be established. NT is the test of choice for establishment of serotypes.

IL-10 and TGFβ expression in the lung and tonsil of pigs experimentally infected with porcine reproductive and respiratory syndrome virus

Jaime Gómez-Laguna1 Irene M. Rodríguez-Gómez1 Immaculada Barranco1 Francisco J. Pallarés2 Francisco J. Salguero3 Antonio Bernabé2 Librado Carrasco1

1. Dept. of Anatomy and Comparative Pathology, Faculty of Veterinary Medicine, University of Córdoba, Córdoba, Spain; 2. Dept. of Anatomy and Comparative Pathology, Faculty of Veterinary Medicine, University of Murcia, Murcia, Spain; 3. Veterinary Laboratories Agency, New Haw, Addlestone, Surrey, UK

Introduction
Porcine Reproductive and Respiratory Syndrome (PRRS) is characterized by inducing an equivocal immune response (1). Immunomodulatory cytokines, namely IL-10 and TGFβ, are able to inhibit the expression of several other cytokines and the onset of an efficient immune response (2), and they are considered as possible key mediators in the impairment of host immune response observed in PRRS (1). Therefore, the main goal of this study was to study the expression of IL-10 and TGFβ in the lung and tonsil of pigs experimentally with PRRS virus (PRRSV).

Materials and Methods
Thirty-two 5-weeks-old pigs from a high-healthy farm historically seronegative for PRRSV were used for the experimental infection. Twenty eight pigs were randomly distributed in batches of four, inoculated by the intramuscular route with 1 ml of 103.0 TCID50 PRRSV strain, and killed at 3, 7, 10, 14, 17, 21 and 24 days post-inoculation (dpi). The four remaining pigs were used as controls, inoculated with 1 ml of sterile medium and killed at the end of the study (24 dpi). At the necropsy lung and tonsil samples were collected and fixed with 10 % neutral buffered formalin and Bouin solution, for the histopathological and immunohistochemical studies, respectively. In the immunohistochemical study the following primary antibodies were used: anti-PRRSV (SDOW17/SR30; Rural Technologies Inc.); anti-porcine IL-10 (AF693; R&D Systems Inc.); anti-TGFβ (AB101NA; R&D Systems Inc.), as previously described (3). Immunolabelled cells were counted and morphologically identified as macrophages, lymphocytes or neutrophils.

Results
A higher expression of IL-10 was observed at 7 dpi in the lung parenchyma of PRRSV-inoculated pigs, whereas TGFβ was enhanced at 3 and 10 dpi, and at the end of the study (24 dpi). In addition, the expression of PRRSV antigen peaked at 7 dpi, showing a positive correlation with respect to the pulmonary expression of IL-10 and TGFβ (r = 0.77 and r = 0.76, respectively).

Discussion
The correlation and similar kinetics observed between the expression of IL-10 and PRRSV antigen in lung and tonsil suggests that PRRSV replication may induce the expression of this cytokine. On the other hand, the expression of TGFβ and PRRSV antigens was correlated only in the lung but displayed a different kinetics. Thus, an indirect pathway to induce TGFβ may be activated by PRRSV. Nowadays, the regulatory T cells are considered as possible source of IL-10 and TGFβ and their role in the immune response is being studied in PRRS (4).

We have previously reported that septal macrophages were the main cells expressing IL-10 and proinflammatory cytokines (3). Interestingly, PRRSV and TGFβ antigens were chiefly expressed by pulmonary alveolar macrophages (PAMs). Thus, TGFβ may avoid the lung expression of proinflammatory cytokines and other cytokines by PAMs in PRRSV-infected pigs.

Introduction

A basic requirement of live vaccine virus strains is that natural transmission of vaccine virus is minimal or non-existent\textsuperscript{(3)}. The objectives of this study were (a) to determine the frequency of the EU and the NA genotype PRRS vaccine viruses in a large sample of pigs from North-Western Germany, (b) to assess the association between vaccine isolate detection and vaccination history and (c) to characterise the identified vaccine isolates considering their origin.

Material and Methods

During January and December 2007, 1,970 pigs were submitted to the Field Station for Epidemiology for post-mortem examination. Nine hundred and two of these pigs aged between 1 and 25 weeks of life had a history of respiratory disease and/or emaciation and were included in the study. The 902 pigs originated from 439 herds and were submitted by 141 different veterinary practices. Lung tissue from these pigs was tested for PRRSV by a nonaplex RT-PCR. Those samples positive for PRRSV were selected for further examination and genetic typing. The vaccination history was obtained from the veterinary surgeons who had submitted the pigs. Telephone interviews were conducted that followed a standardised questionnaire consisting of six closed (predefined range of answers or yes/no) questions on PRRS vaccination management/history of the herds of origin. It was hypothesised that these variables were related to the detection of the vaccine and/or wild-type viruses.

Results

Overall, 18.5\% of the samples were positive for the EU wild-type virus. EU genotype vaccine virus was detected in 1.3\% and the NA genotype vaccine virus in 8.9\% of all samples. The production stage-specific detection rates for EU wild-type virus and NA genotype vaccine virus showed the highest values in weaning and growing pigs (Fig. 1).

Material from 168 of the 259 samples found positive in the diagnostic laboratory was available for genetic typing by amplifying and sequencing the ORF5. Of these, 104 were of the EU genotype, and 64 of the NA genotype. The ORF5 nucleotide sequence of 11 of the EU genotype isolates had 99.1\%–100\% identity with the corresponding ORF of the Porcilis PRRS DV strain. Nucleotide identities of the remaining EU genotype isolates with the Porcilis PRRS-DV strain were between 85.3\% and 91.7\%, allowing their classification as EU wild-type virus. Nucleotide identities of the ORF5 of the NA genotype isolates with the Ingelvac PRRS MLV vaccine strain were between 96\% and 100\%. The detection of the EU vaccine was significantly higher in pigs vaccinated with the corresponding vaccine (OR = 9.4). Pigs vaccinated with NA genotype had significantly higher detection chances for the corresponding vaccine virus when compared to non-vaccinated animals (OR = 3.34) animals, however, NA vaccine was also frequently detected in non-vaccinated pigs.

Discussion

The spread of vaccine virus within herds has been demonstrated in several studies\textsuperscript{(1, 2)}. However, data on age-dependent detection rates of live PRRS vaccine virus have not been published. The evident similarities in the dynamics of the NA genotype vaccine virus and the EU wild-type virus strongly support the contention that spontaneous transmission of the Ingelvac PRRS MLV is a common occurrence in those countries using this vaccine. Known that an eradication of PRRSV from infected herds would require a fundamental knowledge of the dynamics of PRRS virus infection and epidemiology, the results of this study show that this is not only needed for the PRRS wild-type virus but also for live vaccine viruses. Obvious differences in the potential of spontaneous spread of different PRRS vaccine viruses should be considered when choosing vaccines to be used in an eradication program.

PRRS virus vertical transmission dynamics in a sow herd

Jean P. Cano1 Scott Dee2 Albert Rovira2 Claudia M. Zanzi2 Sukumarannair Anil2 Robert Morrison2

Introduction

After the introduction of porcine reproductive and respiratory virus (PRRSv) into a susceptible breeding herd, reproductive failure and an increase in pre-weaning mortality may be observed. Within a few months, the production parameters of the breeding herd may return to levels similar to those prior to infection. However, the presence of persistently infected individuals1 and the continuous introduction of susceptible pigs perpetuate viral transmission2. Questions regarding the prevalence of PRRSv shedding in endemically infected breeding herds and transmission of the virus in the farrowing room over time remain unanswered. Therefore, the objective of this study was to determine the prevalence of PRRSv infected piglets and litters at birth and at weaning in an endemically infected breeding herd.

Materials and Methods

A PRRSv-naïve 1500 sow farrow-to-wean farm became infected. The owners and the veterinarian decided to inject 1 mL of serum containing 101.6 TCID50 of the herd-specific PRRSv isolate to all sows in an attempt to hasten the spread of the virus3. During the 4th wk post-inoculation (PI), 59 sows farrowed. To estimate the prevalence of PRRSv infected litters, blood was collected from all pigs in a random sample of 38 litters at birth and again at weaning. The sample size was based on a desired confidence level of 95%, an expected prevalence of 6.3%, and 1.66% (1 positive / 60 litters) as the lowest possible prevalence (EpiInfo 6, Stone Mountain, GA). The expected prevalence of 6.3% infected litters per farrowing group was calculated based on detection of one positive pool by the “traditional sampling protocol”, testing 4 pools comprised of 5 piglet samples by PCR (Pool Prevalence Calculator, AusVet, Animal Health Services, Australia). The sampling/testing process was repeated on litters from another group of farrowing sows 12 wks PI. These two farrowing groups were selected as being representative of epidemic (4 wks PI) and endemic infection (12 wks PI). Serum samples were randomly pooled in groups of 5 and tested by RT-PCR. All samples in a positive pool were tested individually. Proportion of PCR-positive piglets and litters were compared using Fisher’s Exact Test (Statistix® 8).

Results

At 4 wks PI, 26% of the litters were PCR-positive at birth and 55% at weaning. At 12 wks PI, 8% of the litters were positive at birth and 31% at weaning. A significant reduction in the prevalence of positive litters at birth (P=0.03) and at weaning (P=0.04) was observed from 4 to 12 wks PI. The prevalence of PCR-positive piglets at 12 wks PI was significantly lower at birth and weaning than at 4 wks PI (P<0.01). Both at 4 and 12 wks PI, the prevalence of positive piglets (P<0.05, Figure 1) and litters at weaning was significantly higher than at birth. Between 52% and 77% of the PCR-positive litters at birth or at weaning had only 1 or 2 positive piglets within the litter.

Discussion

The results demonstrate transmission among litters in the same farrowing room and support the sampling of piglets late during lactation as a tool to monitor PRRSv transmission. The fact that PRRSv vertical transmission may occur in as few as one newborn piglet of a litter, and that this very low within-litter prevalence of infection can be maintained until weaning, makes it necessary to reassess the sampling approach used today for breeding herds. The results of this study demonstrate that PRRSv infection prevalence in suckling piglets in an endemically infected breeding herd decrease to such levels that the “traditional monitoring protocols” will have insufficient sensitivity to determine the true infection status of the herd.

Investigation of factors associated with porcine reproductive and respiratory syndrome (PRRS) herd status for production sites in a low density area of swine production in Quebec, Canada

Marie-Ève Lambert¹ Zvonimir Poljak² Sylvie D’Allaire¹
1. University of Montreal, Faculty of Veterinary Medicine, St-Hyacinthe, QC, Canada;
2. University of Guelph, Ontario Veterinary College, Guelph, ON, Canada

Introduction

Transmission of PRRS virus can occur by different ways and several factors may increase the risk of contamination of a herd. The objective of this exploratory study was to identify and quantify the effects of potential risk factors on PRRS status.

Materials and Methods

All premises containing sows in a low density area of swine production (Estrie) were included. A questionnaire was developed to assess the principal potential risks factors reported in literature for introduction of PRRS virus on a site or within a herd. The questionnaire was completed by the owner (independent farm) or by the employee (for farm under contract) and filled out by a single interviewer. Answers were obtained by phone and during a farm visit and included information about herd characteristics, geographical coordinates of the site and biosecurity requirements (layout of the site, entrance protocol, transportation of animals, dead pig disposal, pest management, feed and semen deliveries, manure management). Biosecurity was described as measures implemented by producer to limit introduction of diseases on the site and inside units. Biosecurity was described as measures implemented by producer to limit introduction of diseases on the site and inside units.

Results

On 54 production sites (participation rate of 79%), 15 and 39 were negative and positive to PRRS virus, respectively. Significant variables associated with herd status in univariable analysis are shown in Table 1. Results of multiple logistic regression for both models are shown in Table 2.

Discussion

For both models, having a site closer than 1500 m significantly increased the odds of being PRRS positive. From model 1, absence of an entrance protocol was also an important factor for positivity (OR=4.5). HPU was not kept in the final model, having a p=0.0517 in the last alternative model of the model building strategy (OR=4.8, CI=1.0-23.8). In model 2, the association with the biosecurity index was not significant when adjusting for other predictors (HPU, Neighbour). The global index being a composite of 22 different variables of which several were not significantly associated in the univariable analysis might explain the lack of association with PRRS status in the final model.

Conclusion

In this low density area, sites without an entrance protocol or located within a short distance from neighbouring pig operations were more likely to be PRRS positive. Further analyses will be performed to investigate the effect of pig-site density in order to clarify associations found with neighbourhood.

Dynamics of virus excretion and transmissibility of European-type PRRSV isolates of high and low virulence

Francisco Javier Martínez-Lobo; Francisco Díez-Fuertes; Lidia Hornillos-Gumiel; Patricia Aguilar-Calvo; Isabel Simarro; José María Castro; Cinta Prieto
Facultad de Veterinaria Universidad Complutense de Madrid, Madrid, Spain

Introduction
Porcine reproductive and respiratory syndrome (PRRS) is a disease causing high economic losses worldwide. The etiological agent, PRRS virus (PRRSV), is highly heterogenic. This variability of PRRSV has resulted in the emergence of strains differing in virulence. Previous studies carried out with American-type isolates have demonstrated that the degree of virus transmission and aerosol shedding are related to isolate pathogenicity (1). However, similar studies have never been done using European isolates. The objective of this study was to determine whether differences in virulence of European-type isolates significantly affect the frequency of shedding and transmission to sentinel pigs.

Materials and Methods
Four different isolates were used in this study: one highly virulent isolate, one isolate of low virulence, the vaccine strain included in PorcilisPRRS vaccine, and an attenuated version of the highly virulent isolate obtained after 20 passages on Marc-145 cells.

Sixty 3-week old PRRSV seronegative piglets were randomly divided into 4 treatment groups. On day 0 of the experiment five pigs per group were isolated and inoculated intramuscularly with 105 TCID50 of one of the isolates used in this study. After two days of isolation, the remaining ten pigs of each group were housed with the inoculated pigs. Blood samples were collected from all pigs on days 0, 3, 6, 10, 14, 19 and 24 post-infection (p.i.). Nasal, oral and rectal swabs were obtained the days of blood collection from principal pigs. Virus isolation was carried out on porcine alveolar macrophages (PAM) or Marc-145 cultures depending on the challenge isolate. All swabs were tested by RT-PCR for the presence of PRRSV RNA. For antibody detection, serum samples collected on Day 24 were analyzed by a commercial ELISA.

Results
Viremia in principal pigs was a frequent finding in our study. Specifically, virulent isolate and its attenuated version were detected during the entire experimental period; virus of low virulence was mostly detected from 3 p.i. to day 14 p.i. and vaccine strain was detected only sporadically. In addition, PRRSV was shed by different routes by pigs of all experimental groups, although the frequency of shedding differed significantly between groups. In this sense the highly virulent isolate was detected in most of the swabs obtained between days 3 and 14 p.i. and less frequently thereafter. The highly virulent adapted to growth in Marc-145 cells was also frequently detected although the frequency of detection was lower than in its parental virus. On the contrary, low virulent isolate was only detected sporadically and mostly in days 6 and 10 p.i. Likewise, vaccine strain was detected sporadically being the less frequently isolated virus.

Transmission to in-contact pigs, measured either by detection of viremia or seroconversion, was detected in all experimental groups. However the frequency of transmission differed significantly between different experimental groups. Particularly, all and nine out of ten pigs were infected in groups exposed to highly virulent isolate and its attenuated version, respectively, while only two pigs exposed to low virulent isolate and vaccine strain became infected.

Discussion
The objective of this study was to evaluate the impact of PRRSV isolate virulence on shedding by different routes and transmissibility to in-contact pigs. Our initial hypothesis was that highly virulent isolates would replicate more efficiently in pigs and consequently would be shed in higher amounts and readily transmitted to susceptible animals. This theory was confirmed by the fact that all in-contact pigs exposed to pigs infected with highly virulent isolate became infected while only two were infected among those exposed to either pigs infected with an isolate of low virulence or vaccinated pigs. The highly virulent isolate was adapted to grow in Marc-145 cells with the purpose of limiting its ability to replicate in natural target cells, hampering in this way its transmission capability. However our results indicate that after 20 passages in Marc-145 cells the isolate retains its parental ability to replicate and be transmitted.

The impact of respiratory disease on production in the pig industry in Great Britain

Charlotte M. Evans1 Graham F. Medley2 Laura E. Green2
1. BPEX, Kenilworth, Warwickshire, UK; 2. University of Warwick, Coventry, UK

Introduction
Respiratory disease is the most significant cause of morbidity and mortality in pigs post-weaning. This project used data gathered as part of a DEFRA/BPEX-funded project on post-weaning multisystemic wasting syndrome (PMWS) to investigate respiratory diseases in 116 pig herds. The specific aims of the project were to: 1) Estimate the prevalence and incidence of common respiratory diseases in England and investigate their associations with one another and with post-weaning mortality; 2) Investigate antibody profiles for porcine reproductive and respiratory syndrome virus (PRRSV)-infected herds and to determine management factors associated with differences in profiles between herds; 3) Investigate how PRRSV could persist within infected herds using mathematical models and available data; 4) Determine the impact of PRRSV infection on disease and explore theoretically how this could be reduced by different control and elimination strategies.

Materials and Methods
Questionnaires were completed by veterinarians that attended 116 pig herds in GB. Management factors were collected from on-farm interviews with unit managers. Management factors were investigated for their association with the within and between-herd variability in pig antibodies to PRRSV in 103 pig herds. To investigate the mechanisms that could lead to fade out of PRRSV, within-herd transmission dynamics were investigated using a mathematical model.

Results
From the results, it was shown that PRRS was frequently associated with raised mortality and morbidity when present with other disease causing agents in a herd. Antibody profiles for 103 herds were investigated (50 pigs were sampled in each herd). In 35 herds no pigs had PRRSV antibody. These were considered PRRSV negative. These herds were more likely to have less than 250 sows and be located more than two miles from another pig farm. Sixty eight herds had pigs with antibody to PRRSV (twenty seven of which were vaccination). Higher antibody levels were present in antibody positive herds that did not isolate gilts for >6 days. In 39% of antibody positive herds that were not using vaccination, only breeding sows were antibody positive, suggesting that there was antibody on the farm but no virus because the growing pigs were antibody negative. This is indicative of fade out of virus, i.e. its disappearance from a herd in which it has been present. In our mathematical models fade out was also more likely in small herds with little/no reintroduction of infectious stock.

To investigate the mechanisms that could lead to fade out of PRRSV, within-herd transmission dynamics were investigated using a mathematical model. When virus was introduced into a herd via gilts there was a high frequency of fade out in breeding pigs before the virus reached young stock. Once the virus had reached young stock there was an increased probability of virus persisting in the herd. This was also more likely in large herds, herds with increased contact between age groups and herds that had frequent re-introduction of virus (for example through purchasing infectious pigs, or wind borne spread). The results highlight the importance of determining whether a herd is truly infected or not and appropriate sourcing and isolation of new stock. The patterns observed suggest that the processes of re-introduction, persistence and fade-out of PRRSV play critical roles in the spread of PRRSV throughout the pig industry.

Mathematical models were also used to investigate the range of clinical disease observed as a result of infection with PRRSV and the result of strategies for control and elimination. PRRSV was difficult to eliminate without targeting both rearing pigs and sows. Rapid vaccination of sows once there was an increase in stillbirths reduced the risk of spread of virus to rearing pigs but not in all simulations.

Discussion
In areas where the density of herds is low it might be possible to control PRRSV by elimination in individual herds. In larger herds in pig dense regions, elimination might be difficult and control of disease might give more stability. The long-term benefits of elimination will depend on the risk of re-introduction of virus into the herd.

Introducing Airborne Transport of PRRSV and M. hyo

Airborne transport of PRRSV and M. hyo from a mixed infection in growing pigs was evaluated. Over 21-day period, air samples were collected from the source facility and at designated distances from the herd, ranging from 1.4 to 10.2 km from the source facility. A cyclonic collector (Midwest Microtek, Brookings, SD, USA) was used to collect air samples. The collector was placed downwind from the source facility in accordance with the cardinal directions: north (N), south (S), east (E), and west (W), and the four intermediate directions: northwest (NW), northeast (NE), southwest (SW), and southeast (SE). Four long-distance samples were collected each day, i.e., SW-4 km, SW-3 km, SW-2 km, and SW-1 km from the source facility. Samples were tested for PRRSV RNA and M. hyo DNA by PCR and if positive, were sequenced. Five of 114 long-distance air samples were positive for PRRSV and 6 of 114 were positive for M. hyo. The 5 PRRSV-positive samples were collected at 2.3, 4.6, 6.6, and 9.1 km from the herd. All contained viable virus (range = 1.0 x 10^4 TCID50/mL to 6.3 x 10^5 TCID50/mL) and were >99.2% homologous to PRRSV 1-8-4. No evidence of PRRSV 1-18-2 or 1-26-2 was detected in long-distance samples. All 6 M. hyo-positive samples were 99.9% homologous to M. hyo 232 and 3 samples (collected at 3.5, 6.8, and 9.2 km from the herd) were infectious as determined by the presence of M. hyo DNA in nasal swabs, tracheal and bronchial swabs as well as evidence of gross and microscopic lesions suggestive of M. hyo infection in bioassay pigs.

Results

On day 7 PI, all 3 PRRSV variants were detected in the herd; however, by day 21 PI only PRRSV 1-8-4 was found in sera and tissues from source population animals. Clinical respiratory disease indicative of PRRS and enzootic pneumonia increased from 27 cases on day 0 PI to 82 cases on day 10 PI. In exhaust air from the source population, PRRSV and M. hyo were detected in 21/21 and 8/21 air samples, respectively. Of the 21 samples, 18 contained PRRSV 1-8-4 and 3 contained PRRSV 1-18-2. The mean quantity of infectious virus across all 21 samples was 9.3 x 10^4 TCID50/mL (range = 1.0 x 10^4 TCID50/mL to 6.3 x 10^5 TCID50/mL). Five of 114 (4.4%) long-distance air samples were positive for PRRSV and 6 of 114 (5.2%) were positive for M. hyo. The 5 PRRSV-positive samples were collected at 2.3, 4.6, 6.6, and 9.1 km from the herd. All contained viable virus (range = 1.0 x 10^4 TCID50/mL to 6.3 x 10^5 TCID50/mL) and were >99.2% homologous to PRRSV 1-8-4. No evidence of PRRSV 1-18-2 or 1-26-2 was detected in long-distance samples. All 6 M. hyo-positive samples were 99.9% homologous to M. hyo 232 and 3 samples (collected at 3.5, 6.8, and 9.2 km from the herd) were infectious as determined by the presence of M. hyo DNA in nasal swabs, tracheal and bronchial swabs as well as evidence of gross and microscopic lesions suggestive of M. hyo infection in bioassay pigs.

Discussion

These results are the first proof of airborne transport of these pathogens in a viable state over this distance. The origin of these pathogens was confirmed to be the source population, since the PRRSV 1-8-4 RNA and M. hyo 232 DNA present in long-distance air samples was homologous to that found in experimentally inoculated animals and in exhausted air. In addition, the quantity of infectious PRRSV was determined by virus titration in all 5 samples and viability of both pathogens in long-distance air samples was further confirmed by swine bioassay. Whether either agent could have been transported over greater distances than those reported here cannot be answered at this time; therefore, future studies are required. In conclusion, this new information will assist swine veterinarians in the development of sustainable area/regional programs for the control and eventual eradication of these economically significant diseases of pigs.

References
Porcine reproductive and respiratory syndrome virus (PRRSV) is the causative agent of PRRS, a disease characterized by reproductive failure and respiratory distress in swine[1]. The RNA virus feature made PRRSV highly mutational and thus result various virulence differences among strains [2]. The so-called “High Fever Disease” emerged in southern China in June 2006 and rapidly spread to the whole country. This “High Fever Disease” was characterized by fast transmission, acute infection, high morbidity and mortality (20-30% average and in some cases over 50% and even reach 100%). Following research and diagnosis indicated the Disease is caused by "High Pathogenic Strain of PRRSV" with a 30 amino acids deletion in NSP2 [3].

After a two-year's stable phase, the High Pathogenic Strain of PRRS again busted out in the summer of 2009, including Jiangsu, Anhui, Henan, Shandong and Hebei provinces. In this report, we analyze the epidemiology of the disease in Shandong and lesions of infected pigs as to better understand the disease characters for future control.

Epidemiological investigation: Samples of 100 scaled pig farms and 200 backyards from 10 areas in Shandong were collected for serology analysis. Meanwhile, relevant information including vaccination procedure against PRRS, mortality and morbidity during the outbreak were also investigated by visit or by phone of the farms. The investigation clearly showed that the outbreak emerged in backyards below 50 sows first. These farms barely have any vaccination program against PRRS and the morbidity can reach up to 70%. But, comparing with backyards, outbreaks in scaled farms (48/100) in general were postponed somehow. We listed the morbidity and mortality with the different types of farm with their PRRSV vaccine in use below (Table 1).

Clinical symptoms and lesions: Finishing and sow herd were infected first, infected pigs showed high body temperature, wasting and emaciation. Most infected pigs showed dark red skin (skins colors around belly and peripheral extremities even turned purple), ear cyanosis; thumping, coughing and irregular breathing; snivel and conjunctivitis; constipation, turbid and dark color urines. Pigs with long disease course would turn pale and show anemia, some could not stand till death. In some cases, sow abortions at 100-110 days post pregnancy, mummification and death fetus or weak piglets could also be observed.

Conclusion and Discussions
Comparing with the 2006 “High Pathogenic PRRS”, the epidemic situation this time showed many differences: fewer farms were infected, low morbidity, salutatory spread, slow transmission, more sensitivity of pregnant sows and gilts, mortality varied much and had a longer disease course. This can be explained by the acquired immunity of herds survived from last out break. However, earlier infections and more severe loss in household farm remain the same between two outbreaks, suggesting factors like poor feeding, management and bio-security measures, inappropriate medication program and confection with other diseases are also main cause of the diseases.

The macroscopical and microscopical lesions of the two breaks are almost the same, while herds vaccinated against PRRS or survived from last PRRS outbreak showing less severe and atypical lesions. Moreover, Mycoplasma hyopneumoniae, PCV2, CSFV coinfection lesions become quite common, while bacterial secondary infections, like Pericarditis serofibrinosa and pleuropneumonia, were rare. Rare bacterial secondary infections were due to the massive use of antibiotic in the epidemic.

Field experiences demonstrated that killed vaccines against PRRS are safe but the efficacy is limited. Despite the homogeneity difference between classical and high pathogenic strains, the field practice revealed the effective cross protection provided by classical strain vaccines. Especially, in our investigation, we found that farms vaccinated with Boehringer Ingelheim PRRS MLV have much easier days in the break. Whether the 2009 strain possesses new mutations regarding to virulence is still under study.

Prevalence of subclinical urinary tract infections in the Belgian sow population
Frédéric A. Vangroenweghe1 Tamara Vandersmissen2 Evelyne De Graef1 Ellen Van Driessche1 Frans Castryck1
1. DGZ-Vlaanderen, Torhout, Belgium; 2. DGZ-Vlaanderen, Lier, Belgium

Introduction and Objective
The prevalence of urinary tract infections (UTI) in sows in Belgium is not well known. In the neighbouring countries, the prevalence of (subclinical) UTI is estimated to be up to 20% (1). Urinary tract infections are responsible for sow mortality (2,3) and also have an impact on the breeding performance of the sow (1,4). Total born litter size, live born litter size and weaning litter size appeared to be lower in sows with UTI, while the wean-to-oestrus interval and the wean-to-farrowing interval increases in these sows.

To investigate the prevalence of (subclinical) UTI in Belgium, a screening on Belgian sow herds was performed (project ‘Veepeilervervarken’ funded by the Sanitary Fund)

Materials and Methods
Twenty-five Belgian pig herds, with at least 100 sows and no clinical signs of UTI, were selected to participate in this screening. Drinking water supply was continuous in 11 farms, but it was restricted in 14 others. In each farm between 9 and 21 late-pregnant sows were sampled. A total of 353 urine samples was collected. Urine samples were collected in the morning, the first jets of urine were avoided. Bacteriological study of the urine was performed by inoculating 2 different media: Columbia sheep blood agar (Oxoid) and McConkey agar (Oxoid). After overnight incubation at 37°C in an atmosphere with 5% CO2, identification of grown colonies was performed. Quantitative examination was performed through dilution of the urine samples in maximum recovery diluent (Oxoid) and subsequent inoculation of plate count agar (Biorad). After overnight incubation at 37°C under aerobic conditions, colony counting was performed. Nitrite detection was performed using the strip-test (Merckoquant; Merck).

Results
The predominant germs in the urine were E. coli (27%), Streptococcus sp. (15%) and Staphylococcus sp. (14%). In 38% of the cases no growth could be observed. In total, 19% of the sows showed urine bacterial counts higher than 10E5 CFU/ml, which should be interpreted as indicative of UTI. In 16% of the cases, an UTI could be suspected since the urine bacterial counts varied between 10E4 to 10E5 CFU/ml (Figure 1). At herd level, 0 to 43% of the sampled sows could be demonstrated to suffer from a subclinical UTI. Comparing sows with continuous or restricted drinking water access, a slight but non-significant difference in the prevalences of urine bacterial counts of higher than 10E5 CFU/ml could be observed , with 17% and 20% of urine samples of sows with continuous and restricted access, respectively, showing counts indicative for UTI. The strip-test, which is indicative for an E. coli infection, demonstrated 10% nitrite positive urine samples.

Figure 1 Distribution of urine samples according to the urine bacterial count. Unsuspected (< 10E4 CFU/ml); suspected (10E4-10E5 CFU/ml); infected (> 10E5 CFU/ml)

Discussion and Conclusions
The prevalence of subclinical UTI in the Belgian sow population, based on bacterial counts, is comparable to prevalence observed in neighbouring countries. Based on the strip-test, only half of the sows with a subclinical UTI can be detected. However, not all germs responsible for UTI have the capacity to produce nitrite. Essentially, E. coli can produce nitrite, whereas Streptococcus sp. and Staphylococcus sp., which can also provoke UTI, do not have a nitrite producing capacity.

A new method for oestrus synchronizing of gilts in group housing systems

Leo Suls; Jan Jourquin
Janssen Animal Health, Beerse, Belgium

Introduction
Oestrus synchronization of breeding gilts with altrenogest is a common practice on many breeding farms, especially when a batch management system is used. The synchronization protocol implies a treatment of 18 consecutive days with an oral dose of 20 mg oil-based altrenogest solution (5 ml product). It is imperative that a correct daily dose is administered. When the gilts are housed in individual stalls, the product is easily dosed on the feed. For welfare reasons, sow stalls are banned or limited to the first 28 days of gestation. This calls for alternative ways for successfully synchronization of the gilts.

A new application method has been developed for Regumate® that allows individual treatment of gilts kept in groups.

Materials and Methods
For a farm expansion, 896 gilts were synchronized in a group housed situation administering altrenogest directly in the mouth.

The preconditions for a new method are demanding. Repetitive administration of the right dose to an individual animal, housed in group, without disturbing the group, but also convenient for the animal caretaker.

Janssen Animal Health developed a special dosing gun. This gun has a standard 5 ml dose and can be easily connected to the 1 liter Regumate® bottle. This gun allows a fast and accurate dosing with ample freedom of movement. Gilts have a very curious nature and they are very keen on soybean oil, the carrier of altrenogest. A 2-day training with a cheap vegetable oil prior to start of treatment is all that is needed. During the training period a person steps into the pen and waits until the gilts are calm and curious enough to approach. Gently one tries to squeeze a dose of oil into the mouth of all gilts. In the beginning this will take a bit of time, but after two days most animals will come spontaneously to ask for their dose of oil. After the short training, more than 99% of gilts will take the dose directly in the mouth.

Results
When the product is correctly applied, up to 95% of gilts come to oestrus within seven days after the last dose. 896 gilts were synchronized with the new method. Of these 844 gilts (94.2%) came on heat within the seven day period. This is comparable to the results achieved in individual stalls (1).

Once the training period was over, there was no need to enter the pen as all gilts lined up, eager to get their dose, making this a convenient routine.

Discussion
This new method is a safe, accurate, effective and labor sparing alternative for gilt synchronization, and not only in group housed systems. It is also a convenient method where gilts are still kept in stalls.

Extensive experience in Germany, The Netherlands and England shows many advantages in the field. No product is spilled during application or leaks back from the mouth of the gilt. Administration is done very fast. Once the gilts are trained, 15 to 20 animals per minute can be dosed.

The oestrus synchronization results obtained with this new application method in practice appears to be at least as good as with the conventional on feed application.

An additional important benefit is the socializing aspect. During the short training and the 18 consecutive treatment days the gilts develop a very positive bond with the animal caretaker.

Nitrite test for UTI diagnosis in sows: are we wrong?
Guy-Pierre Martineau; Berengere Fabre; Herve Lefebvre
National Veterinary School, Toulouse, France

Introduction
In France, urinary tract infection (UTI) is routinely screened in sow herds using nitrite dipstick testing (Sialelli, 2004). Despite a low prevalence of clinical UTI, the rational for such screening remains controversial (Martineau et al., 2007). High water intake in pregnant sows, and consequently high urine dilution, may lead to false negative results. For unknown reasons, there is also an increase of positive results in late gestation (Sialelli, 2004). The objectives of this study were i) to evaluate the day-to-day variability of the nitrite test and urine specific gravity (USG) in late gestating sows, ii) to compare nitrite test to semi-quantitative bacterial count, and iii) to assess the effect of urine dilution on the nitrite test results.

Materials and Methods
The herd- The study was performed in the same herd of 600 sows, free for clinical UTI, managed in a 7 batch farrowing system. Liquid feeding (dilution of 4L/kg of feed plus one extra “water meal” of 3L/day for a given sow).

Selection of animals- For 3 consecutive weeks, urine was collected before feeding (before 6.00 am) in 130 late gestating sows. 15/130 sows in which urine had a nitrite positive test and USG ≥1.015 (refractometry) were included in the study.

Study design- For each included sow, urine was collected at least 3 times over the same week (same conditions as described above). USG and nitrite test was performed on each individual sample every day. The pink colour change of the reagent pad was assessed by the same investigator using a -/+/++/+++ scale. Moreover, a semi-quantitative microbiological culture (Count Exact®) was done on the first positive sample in each animal. Furthermore, a 2- and 4-fold dilution of each first sample with NaCl 0.9% was performed and nitrite test repeated again on the so diluted samples.

Results and discussion
There was no association between strong nitrite positive urine (+++) and USG. Day-to-day variability of positive nitrite test results was high (Figure 1A) in 8/15 sows, suggesting that diagnostic interpretation from a single sample may be misleading.

The relationship between nitrite test results and semi-quantitative bacteriological counts was poor (Table 1).

Some mildly nitrite positive urine has a relatively high bacteria counts and inversely.

Dilution induced also a decrease in positivity of the nitrite test (Figure 1B).

Conclusion
The poor relationship between positive nitrite test and semi-quantitative as well as the large day-to-day intra-individual variability in nitrite positive test indicates that nitrite dipstick testing for screening UTI sows is questionable, especially when performed on a spot urine sample. Moreover, USG should be used to interpret adequately any positive results, as dilution of urine secondary to high water intake can lead to false negative results.

Shoulder lesions in loose-housed lactating sows on partly slatted floors

Nils Holmgren2 Nils Lundeheim1

Introduction
Shoulder lesions (SL) were on average found in about 1/3 of loose-housed lactating sows in 78 Swedish herds (3). Main risk factors are poor body condition, parity number, lameness and MMA (1,2). In addition, environmental factors such as floor type may contribute to the development of SL during lactation (1,2).

Material and methods
The trial was conducted as a prospective cohort study in a piglet producing herd. Consecutive batches of 40 loose-housed sows farrowed in pens with partly slatted floors. Half of the pens had 1.3m² concrete lying area for sows and 2.8m² plastic slatted floors (open area 34%) with square formed 3mm raised edges. Remaining pens in the same barn had 2.1m² concrete lying area and 2.8m² plane slatted floor (open area 34%). Sows allocated into different pen types had no SL before farrowing, were matched for parity numbers and had all good body condition scores. Six times, once before farrowing and at weekly intervals until weaning at 5w, body condition scores and SL were monitored. At this occasion, 1h after morning feeding when all sows laid down, the lying position of the sows was recorded: heads and shoulders on concrete area or slatted floor located (SFL). Temperatures in barn were also measured. Differences in prevalences were studied by chi-square test.

Results
Prevalences of sows with SL increased linearly during lactation and reached 35-45% at weaning. Size of concrete lying area (2.1m² or 1.3m²) and structure of slatted floor (edges or plane) did not significantly influence on the occurrence of SL.

For each sow, sum of SFL sows was calculated (0-6 for each sow). Among sows often in SFL-position, prevalence of SL at weaning was significantly higher compared to sows that were in SFL-position more seldom (Fig.2).

Discussion
At farrowing, sows prefer to lie on a warm area of the pen (5). Due to increased feed consumption and metabolic activity during lactation, the body temperature will increase (4). A high temperature in barn will contribute to this. To maintain thermal comfort during lactation the alternative for the sow is to lie on the slatted floor area. This is especially comfortable for loose-housed sows in modern farrowing pens as the slatted floor area is usually larger than the concrete lying area. However, increased pressure from slatted floors on shoulder tissues will result in SL (6).

In conclusion, to prevent SL in loose-housed lactating sows, slatted floor areas should be made uncomfortable to lie on and the concrete lying area should be made as large and comfortable as possible.

Before farrowing, 10-20% of the sows were SFL and from 2w after farrowing until weaning, 40-50% of the sows were SFL (Fig.1). When barn temperature was 18-21°C during lactation, significantly (p<0.05) more SFL sows (41%) were observed compared to when barn temperature was 17°C, (31%).
Hemoglobin varies with parity and stage in cycle

Inge Larsen1 Flemming Thorup2
1. LVK, Oestervraa, Denmark; 2. Pig Research Centre, Danish Agriculture and Food Council, Copenhagen, Denmark

Introduction

Various reference values are published for hemoglobin, however very few references distinguish between young and mature animals, nor to the different stages in a sows reproductive cycle.

</tbody>
</table>

The objective of this study was to determine the level of hemoglobin in Danish gilts and sows at different stages of the reproductive cycle.

Material and Methods

This study was performed in one Danish 360 sow herd participating in the Danish SPF programme. The farm was free from Mycoplasma hyopneumoniae, PRRS and Actinobacillus pleuropneumoniae (AP) type 2, but AP type 6 and 12 positive.

Blood was collected during pregnancy and lactation from 152 sows between April and December 2008. 900 blood samples were included in the calculations.

Blood samples were mailed by post, and analysed one or two days later at Idexx VetMedLab in Germany. Statistical analysis were carried out using Microsoft Office Excel 2007.

Results

The average level of hemoglobin of all blood samples in this study was 10.4 g/dL (900 samples) with a standard deviation (st.d.) of 1.1.

The average level of hemoglobin in gilts was 11.0 g/dL (st.d. = 1.0) (31 gilts, 193 samples). The average level of hemoglobin in pregnant 2nd to 9th litter sows was 10.2 g/dL (st.d. = 1.0) (101 sows, 625 samples). The difference was statistical significant (p= 2 x 10^-21).

The level of hemoglobin was significantly higher in pregnant gilts than in sows at all points during gestation, while the level in gilts approaches the level of sows during lactation.

Discussion

When is a pig anemic?

To render a sow anemic or normal, should be based on an evaluation of what level of hemoglobin has an effect on sow welfare and productivity.

In this study no negative correlations were observed between level of hemoglobin end frequency MMA treatments, nor to the level of still born piglets.

The present experiment is extensive but performed in one herd only. A study in more herds, preferably covering more countries or continents are needed, to cover management, feeding and genetic differences as well.

Facilitation of nursing behavior in primiparous sows during colostrum phase improves piglet condition

Jorge Miquet\(^1\) Gustavo Viana\(^2\)

\(^1\) I.P.B.-C.I.C.V.-INTA, Morón, Argentina; \(^2\) Janssen Animal Health Argentina, Buenos Aires, Argentina

Introduction

The development and wellbeing of a piglet are determined by its ability to fulfill the need for homeostasis, growth and resistance to sanitary challenges. Early colostrum intake is the key for success. For the first two days of their lives, colostrum provides the required nutrients to the piglets and during their first weeks, the immunoglobulin (Ig) fraction passively protects the piglets from disease (1). Critical factors for early life survival are the ability of the piglet to suckle, the available volume of colostrum, the udder quality and the behavior of the sow during the colostrum phase. For primiparous sows, farrowing is a stressful new experience which can result in savaging and crushing of neonatal piglets. The introduction of the group housing system potentially increases this problem, as primiparous sows get confined for the first time in their life at parturition. Azaiprine is a sedative used to calm pigs at stressful moments, such as transport, regrouping and aggression.

In this study, the effect on piglet development after an injection of azaiprine at the end of the partus of primiparous sows, was investigated in two farms with different housing systems. One farm had conventional farrowing crates (CF) the other outdoor huts (OH).

Materials and Methods

50 primiparous sows per farm were included in the study. Both farms (BF) belonged to the same organization, with comparable genetics, nutrition and health care plan. Half of the sows were randomly allocated to either a azaiprine treated group (AZA) or a non-treated reference group (NT). The AZA group was injected IM, 2 mg azaiprine per kg body weight (BW) (= 5 ml Stresnil\(^\text{®} \) per 100 kg BW) at the moment of expulsion of the placenta. To assess the condition and health status of the piglets in field conditions, mortality rate and weight gain were used as parameters. The piglets were weighed and identified individually at birth and at weaning. Farrowing and weaning date, number of piglets born alive (BA), pre-weaning piglet mortality, mortality reason and number piglets weaned (W) were recorded.

A t-test was used for comparison of continuous variables and a Chi-square test for comparison of categorical variables (Statistix 1.0 for Windows).

Results

Lactation length and BA were comparable in both groups (Table 1). Mortality however, was higher in the NT group. Mortality reasons were similar for both groups, except for crushing (NT n=35, AZA n=16) and cannibalism (NT n=7, AZA n=0), which was significantly higher in the NT group (p<0.01). There was an increase of W and the average weaning weight of the piglets was higher in the AZA group.

</tbody>
</table>

Data presented in **bold** are statistically different (p<0.05)

This resulted in a significantly higher litter weight at weaning in the AZA group in both housing systems. The number of piglets weaned and the average individual weaning weight of the treated animals was significantly higher for AZA in BF.

Discussion

The present study showed the benefit of an azaiprine injection of primiparous sows at the end of the partus. Piglet survival increased and they thrive better, resulting in a 11.3% litter weight increase at weaning.

In conventional farrowing crates, the difference was mainly due to an increased weight gain of the piglets, while in outdoor huts, a decrease of early mortality was the cause of the difference.

Calm sows in the first hours after farrowing are less likely to kill their piglets and they allow them access to the colostrum. Not only more piglets survive, but they develop better during lactation, a clear sign of their wellbeing.

A study to evaluate the use of Elastrator® rings for treatment of umbilical hernia

Kaj Vestergaard1 Kristian Vieikilde2 Poul Bækbo1

1. Pig Research Centre, Danish Agriculture & Food Council, Copenhagen, Denmark; 2. PORCUS Pig Practice, Ringe, Denmark

Introduction

Umbilical hernia is one of the most frequent developmental defects in pigs. Most investigators have hypothesized that hernia is inherited, although there is dispute about the mode of inheritance (1). Umbilical infections have also been claimed to cause umbilical hernias in pigs (2). In other species, breed and sex have been identified as risk factors, but no association between umbilical infection and umbilical hernias has been detected (3). The disease causes significant losses due to decreased productivity, including increased mortality, and, above all, umbilical hernia has important implications for pig welfare. For that reason, PORCUS Pig Practice and Pig Research Centre initiated a study to evaluate the efficacy of using Elastrator® rings to treat umbilical hernias in young pigs (4).

The purpose of the study was to determine whether surgical treatment of umbilical hernia using Elastrator® rings increased the pig’s chance of reaching slaughter weight.

Materials and Methods

The study was conducted under the authorization of the Danish Animal Experiments Inspectorate. A total of 192 pigs with umbilical hernia were collected from herds throughout Denmark, independent of herd management and health status. On arrival at the research farm, the umbilical hernia of each pig was examined to determine whether the hernia was reducible through the abdominal wall. Pigs with irreducible hernias were excluded from the study. The pigs included in the study were randomly divided into two groups:

Group A: Treatment with Elastrator® rings
Group B: No treatment

An Elastrator® ring was fixed on the hernial sac close to the abdominal wall. All other medical treatments and causes of death among the pigs were recorded. The data analysis was conducted using R version 2.9.2. A logistic regression model described the risk of death from umbilical hernia, with treatment, sex and weight as explanatory variables. The design of the study had a power of 80% to show a 50% reduction in death from complicated umbilical hernia.

Results and Discussion

The lower number of male pigs included in the study (Table 1) was mostly due to the risk of placing the Elastrator® ring close to the prepuce.

The results of the logistic regression showed a significant increase in mortality in the control group compared to the treatment group. The odds ratio was 4.75 (1.40, 18.72). Furthermore, the greater the start weight, the lower the risk of dying. The odds ratio was 0.87 (0.78, 0.95). Sex did not influence the risk of dying from umbilical hernia

Of the 20 pigs that died during the trial period, 9 were put down and 11 were found dead. The death of four pigs (two from each group) seemed to be unrelated to complications due to the umbilical hernia. The mortality among the excluded pigs (127; Table 1) was the same as for the pigs in group B (45%). The 43 pigs that survived were all approved for slaughter, but they all received a remark by the meat inspectors at the slaughterhouse concerning internal signs of umbilical hernia.

Even though the study showed a significant result in favour of using Elastrator® rings, one has to be aware of the number of pigs that were excluded. According to this study, out of nearly 800,000 Danish pigs developing umbilical hernia every year, only one third (264,000 pigs) can be given the treatment. Nevertheless, the results from this study indicate an additional survival of 76,000 pigs per year, which can be estimated to provide the Danish pig farmers with a bonus of € 4,500,000.

Piglet serum IgG, a non disruptive method to measure colostrum distribution

Jan Jourquin¹ Marrit van Engen² Lieve Goossens¹
¹. Janssen Animal Health, Beerse, Belgium; ². FormulaOne, Best, Netherlands

Introduction

Colostrum intake is critical for the survival of the piglet. The first 2 days of their lives, colostrum provides the nutrients to fulfill the piglets needs for homeostasis and growth and during their first weeks, the immunoglobulin (Ig) fraction passively protects the piglets from disease (1). It is estimated that a piglet needs 160 to 170 ml of colostrum per kg bodyweight to survive (2). Immunoglobulin G (IgG) is absorbed by the gut wall during 24 to 48 hours, but the IgG content of the colostrum decreases quickly after birth (1). Next to total colostrum yield and IgG concentration, the distribution of the available quantity amongst the different littermates is becoming more important with increasing litter size. Several methods to estimate colostrum intake have been described in the past but they all share one disadvantage being the extensive manipulation of piglet and or sows during the colostrum intake phase. To eliminate the impact of manipulation on sow and piglet behavior, an alternative method without extra manipulations is required.

In this study, a method based on piglet serum IgG concentration was used to measure the impact of litter size on colostrum distribution.

Materials and Methods

In a commercial sows farm, 114 litters were included in the study. The farm data recording system was used to retrieve the relevant reproductive data. All normal farm procedures were continued. At tail docking (day 3 post partum) a blood drop of the remaining tail bud from six randomly chosen litter mates was sampled. These samples were analyzed with a DAS-ELISA test (3) (Colostrum Quality Counter™). There is a great variability in colostrum yield and colostrum IgG concentration between sows. Therefore the absolute IgG concentrations have poor predicting value on colostrum intake. Within the litter however, these variables are not relevant. In order to be able to compare the distribution for colostrum between sows, the coefficient of variation of the piglet serum IgG (CV IgG) was calculated. This is the standard deviation divided by the average of that litter.

The statistical analysis was performed with the SAS® program. A Poisson regression model on the number of died piglets per sow was used. The total number of piglets with the sow was included as covariate.

Results

It was demonstrated that the variation in IgG levels increased with litter size (Figure 1).

Figure 1: Impact of litter size on IgG distribution and piglet mortality

The mortality rate over all litters is strongly correlated with litter size (p < 0.0001). Lower birth weight and vitality compromise the colostrum intake. With an increasing number of piglets, total colostrum volume becomes a second critical factor. The distribution of that colostrum should therefore be optimal. However, the data show that the distribution gets worse with increasing litter size. All measures that increase the colostrum production and facilitate the distribution of the colostrum increases the chance of the piglets to survive.

Discussion

In this study, it is shown that by using serum IgG concentrations of three day old piglets, the distribution of the colostrum can be estimated. Both pre-weaning mortality and variation in colostrum uptake (represented as CV IgG) are positively correlated with litter size. This underlines the increasing importance of individual colostrum uptake with increasing productivity of our sow farms.

Comparison of body surface temperature and rectal temperature after administration of pyrogenic lipopolysaccharides

Jan Bernardy
University of Veterinary and Pharmaceutical Sciences, Brno, Czech Republic

Introduction
Aim of the study was to contribute to the assessment of the feasibility of using infrared thermography as a method for routine diagnosing and treatment decision of diseased pigs and animal welfare monitoring. Infrared thermography is a non-invasive method, able to measure the surface temperature via emitted energy (infrared radiation) from the surface of the animal body(1).

However the method brings time-savings and facilitate handling with animals, it is still seldom used, partially due to conservative approach of veterinary surgeons, partially due to missing relevant data of veterinary infrared thermography. Lipopolysaccharide was used to induce pyrogenic reaction and compare core and surface temperature reactivity, and both values were compared.

Material and Methods
Twelve piglets 8 weeks old were used and randomly allocated into the two groups, a trial group and controls (n=5). Temperature was measured at both groups either by infrared thermometer at thorax (measurement IR-LPS at trial group and IR-C at control group) or rectally (measurement TR-LPS at trial group and measurement TR-C at control group). Pyrogenic agent (lipopolysaccharide from Escherichia coli 0111:B4, lyophilized powder, sample No L2630, Sigma-Aldrich) was dissolved and administered intravenously to the trial group in amount of 0.1ug per kg of body weight. Temperature was measured every 30 minutes for 8 following hours. The data were evaluated by non-parametric Wilcoxon pair test, Spearman correlation and visualized by Statistica v.9 software.

Results and Discussion
Both values of temperatures measured rectally and superficially showed significant Spearman correlation rate (0.703, calculated at level of significance p<.05), and difference between measurement at the hour 0 and 1 or between hour 1 and 8 showed significance higher than p<.05). However some papers did not find correlation of skin and rectal temperature not satisfying enough, increased correlation in the postparturient period was noted (2) another papers assessing wound severity with colour and infra-red imaging of reactive hyperemia (3), life-threatening complication (4) or significant linear relationship was observed between ambient temperature and mean body surface temperature at inoculated febrile pigs(5). The results obtained in the trial imply possibility to rely on correlation between rectal and superficial temperature. However there are some physical values to be considered, as airflow, humidity and some other values, refining and improvement the method of body surface temperature measurement in pigs would be helpful diagnostic tool.

Evaluating PCV2 immune status of a herd and determining the value of vaccination

Cristina Venegas-Vargas; Barbara Straw

Michigan State University, East Lansing, MI, USA

Introduction
Porcine Circovirus type 2 is an important viral pathogen worldwide. PCVAD was first described in Canada in the early 1990s as PMWS\(^1\).\(^2\). The Michigan State University swine herd experienced moderately severe PMWS accompanied by 5-10% nursery mortality. A vaccination program was initiated in 2007. Signs of clinical disease disappeared after implementing the program and remained inapparent for the next 2 yrs, and mortality of pigs in the nursery remained below 2%. Potter et al. (2009) documented reduction in viral load following vaccination. There is the assumption that vaccination could minimize viral shedding and reduce environmental contamination to a no-effect level; allowing elimination of vaccination programs\(^3\).\(^4\). Two ways of determining if infectious levels of virus are present in a vaccinated herd were compared; monitoring disease in sentinels and recovery of virus through PCR.

Materials and Methods
Three replicates of 20 pigs each and one replicate of 22 pigs were weighed and ear tagged at weaning for use in the study. Pigs were matched in pairs by sex, weight and dam. Matched pairs of pigs were randomly allocated to sentinel (non-vaccinated) and control groups. Control pigs received a Killed Baculovirus vector PCV2 vaccine at weaning and 2 wks later per label directions. Blood samples were taken at weaning, 9 and 20 wks of age. ELISA, IFA-4 dilution and PCV2 PCR (Pools of 2 animals) were performed. Twelve ropes were placed in pens of common vaccinated pigs four times at one-month intervals. PCV2 PCR was performed. Pigs were weighed again at completion of the trial (20 wks of age) and ADG was calculated.

Discussion
Monitoring sentinels did not demonstrate presence of virus in the herd either through reduced pig performance, ELISA testing or PCR serum samples at normal cut offs (35 Ct). But it did through IFA-4 dilution, and PCR serum samples at a later Ct cut offs (40 Ct). Sentinel monitoring required 4 months to complete while oral fluid PCR results were available immediately. Cut off value of PCR test on saliva and serum in a vaccinated herd may need to be changed.

**Effect of CIRCOVAC® vaccination of sows on their reproductive performance**

John Hayden¹ Ricardo Neto² François Joisel³

1. Integra Veterinary Services, Mundford, Thetford, UK; 2. Merial Animal Health Ltd, Woking, UK; 3. Merial S.A.S., Lyon, France

**Introduction**

Recent studies have shown that PCV2 is involved not only in PMWS, but also in several other disease presentations, including reproductive disorders, deteriorating sow performance (1, 2). The objective of this study was to assess the impact of CIRCOVAC® on the reproductive performance of a sow breeding unit weaning pigs on-site and selling them at 35kg.

**Material and Methods**

A 1000-sow outdoor breeding unit started vaccinating the breeding animals in May 2007 with a PCV2 inactivated vaccine, CIRCOVAC. The first vaccinated sows farrowed in July 2007. PCVD has been clinically diagnosed on the nursery and finishing units. The number of pigs born alive per litter and weaned per litter was routinely recorded using herd management software.

Historical data, since 2005 were collected. The data were divided into blocks of 6 months from the start of vaccination for the periods before and after. The data were also compared for a period of 1 year before and after PCV2 vaccination was implemented. Statistical analyses were undertaken using the two sample t-test with unequal variances and a two-factor (month and year) analysis of variance. Tests were carried out using proprietary statistical software.

**Results**

Live born piglets per litter after CIRCOVAC vaccination were increased by 1.425 pigs, p<0.001 (t-test) compared to the period before (2004 to July 2007).

Analyzing the data before and after July 2007 by a t-test shows that there is an improvement in the mean number of pigs weaned per sow per litter after CIRCOVAC vaccination started.

Regarding pigs weaned per sow per litter, (Table 1) there was no significant difference between the first 6 months of 2005, 2006 and 2007 (before vaccinated sows started farrowing) but these were significantly different to the first 6 months of 2008 and 2009 (CIRCOVAC vaccinated sows started farrowing in July 2007), p<0.001. Similarly that there was no significant difference between the second 6 months of 2004, 2005 and 2006 (before vaccinated sows started farrowing) but these were significantly different to the second 6 months of 2007 and 2008.

**Discussion and conclusion**

This study shows the impact of using CIRCOVAC on the reproductive performance of vaccinated sows. Improving the number of pigs weaned per sow per litter optimizes the sows’ performance. This increase reduces the cost of production and considerably increases profitability.

The constant number of pigs born alive and weaned per litter during the post vaccination period indicates that the improvement achieved with CIRCOVAC vaccination resulted in a stable and sustained increase of the number of piglets born alive and weaned per litter.

Efficacy against porcine circovirus type 2 of a single dose of Porcilis PCV given to MDA-positive piglets of either one or three weeks of age

Andreas Palzer1 Beate Rist2 Mathias Ritzmann3, 2 Christiane Lang3 Stefan von Rueden4 Karl Heinritzni2 Alex Eggen5 Jos Smeets5
1. Tierarztpraxis Scheidegg, Scheidegg, Germany; 2. Clinic for Swine of the LMU Munich, Oberschleissheim, Germany; 3. Clinic for Swine of the VUW, Vienna, Austria; 4. Intervet Deutschland GmbH, Unterschleissheim, Germany; 5. Intervet/Schering-Plough Animal Health, Boxmeer, Netherlands

Introduction
Infections with Porcine Circovirus type 2 (PCV2) are ubiquitous in the swine population and are associated with many disease complexes. The object of this study was to compare the efficacy of a single dose of Porcilis PCV (Intervet/Schering-Plough Animal Health), with a placebo, Diluvac Forte®. The study was performed on a German 500-sow farm on which PMWS had been diagnosed clinically as well as by pathology, and the presence of PCV2 confirmed by serology. Vaccination of sows with Circovac® had ceased 7 months before the trial began.

Materials and Methods
In this partly blinded study, a total of 416 piglets were selected to receive a 2 ml dose i.m. of either Porcilis PCV or of placebo (Diluvac Forte®) at 1 and 3 weeks of age (Table 1).

The piglets were weighed at 1, 3, 11 and 24 weeks of age. All the individual piglet treatments were recorded as a measure of morbidity. Post-mortem examination was performed on each piglet to determine the cause of death. Average daily weight gain (ADG), morbidity and mortality were compared between groups, analyzed using ANOVA and the Chi-square test.

Blood samples (serum) were taken from 20% of each group at intervals of 2 weeks until the start of the fattening period, and every 4 weeks thereafter. The sera were tested by ELISA for antibodies against PCV2 (log2) at the R&D Service Laboratory (Boxmeer, The Netherlands) and by Ingezim Circovirus IgG/IgM (pos/neg., Ingenasa, Madrid, Spain) at the Clinic for Swine, University of Veterinary Medicine, Vienna. Viremia was determined by qPCR (log10 copies/ml) at the Clinic for Swine in 17 samples from each group taken in weeks 3, 7, 11, 14, 18, 22 and 25.

Results
During the fattening period, pigs in group A (vaccine at 3 weeks old) performed significantly better than those in Group C (placebo) and group B (vaccinated at 1 week of age). The differences were 32.1 gm/day (p=0.0110) between groups A and C, and 26.7 gm/day (p=0.0416) between Groups A and B.

There were 9 deaths in each group. In the most cases the pigs were culled because of locomotion problems (n=13). Group C (placebo) had more PCV2-related cases (n=5) than the other two groups (A: n=2; B: n=1).

The mean PCV2 antibody titer across all groups at 1 week of age was high at 12.4. It declined until week 18, but at that time was higher in Group A (6.3) than in Groups B (4.3) or C (2.7). Then, because of an active PCV2 infection the mean titer increased to 11.6 in week 25.

Discussion
The efficacy of vaccination was clearly shown by the significantly improved weight gain during the growing period, as well as the low percentage of PCV2-PCR positive animals in the group vaccinated at 3 weeks.

Only the piglets of Group A had a detectable IgM titer (Ingezim Circovirus IgG/IgM) between weeks 5 and 11 which was a reaction to vaccination. However, after the field infection, animals in Group A (vaccine at 3 weeks) had less IgM than those of Group C (placebo) or Group B (vaccine at 1 week).

Pigs of 22 weeks of age in the placebo group had the highest PCV2 viral load. In groups A and B, viremia was significantly reduced compared to the placebo group. These results demonstrate that there was a PCV2 infection towards the end of the fattening period, and that the vaccinated pigs were protected.

**Study Group** | **1 week of age** | **3 week of age**
--- | --- | ---
A Porcilis PCV 3 weeks | Diluvac Forte | Porcilis PCV
B Porcilis PCV 1 week | Porcilis PCV | Diluvac Forte
C Placebo | Diluvac Forte | Diluvac Forte

Introduction
Porcine Circovirus type 2 (PCV2) infection in pigs is regarded as the most important causative factor in the development of Porcine Circovirus Disease (PCVD). The first description of PCVD (initially called PMWS) involved young pigs (Harding 1998). More recent articles describe infection in older pigs and it is not uncommon to observe PCVD in late stage finishers (Palzer 2009). Under field conditions the timing of PCV2 virus infection is often unknown, therefore it is important that pigs are protected for the whole of the fattening period.

PCV2 virus is widespread, and infection in sows leads to varying antibody levels in blood and colostrum. Pigs can be vaccinated early in life against PCVD in the presence of MDA. The object of this study was to demonstrate the efficacy of Porcilis PCV in piglets with MDA against PCV2 virus, following a single dose of 2 ml at 3 weeks of age. At 25 weeks of age, vaccinated and control animals were challenged with wild type PCV2 virus to investigate the extent of protection.

Materials and Methods
Progeny of SPF sows with PCV2 antibodies (ranging from 7.1 to 11.4 ELISA log2 at farrowing) were studied. Piglets were assigned to different groups of 10 piglets, so that littermates were spread evenly over the groups, with equal numbers of males and females per group. At 3 weeks of age, Group 1 was vaccinated with 2 ml of Porcilis PCV and Group 2 with placebo. At 25 weeks of age, the pigs were challenged intranasally with a heterologous wild type PCV2 challenge virus strain I-12/11.

All animals were observed daily for clinical signs and weighed several times during the study. Three weeks post challenge all animals were necropsied. At post mortem, mesenteric and inguinal lymph nodes, tonsil and spleen were sampled for the determination of PCV2 antigen and nucleic acid. Serum samples were taken at vaccination, at 10 weeks of age, at challenge and weekly thereafter until necropsy. Fecal swabs were taken at challenge and every week thereafter. Statistical analysis of the serology employed Tukey’s multiple comparison. Q-PCR data was analyzed by ANOVA using a linear mixed model, assuming a constant correlation of the repeated measurements of a subject.

Results
No differences were found between the groups for clinical signs or bodyweight, either after vaccination or after challenge.

Serology: at the time of vaccination the average titer in the PCV vaccinated group was 7.2 log2 and in the controls 7.3 log2, both above the protective antibody level (Fort 2009). By the time of the challenge, the controls had no detectable antibodies, whereas the vaccinates had titers of at least 6.9 log2 (P<0.0001). After challenge, a clear antibody response was seen in the controls but hardly any reaction in the vaccinated pigs (see table 1).

Discussion
Porcilis PCV induces strong humoral and cellular immunity (Fort 2009, Martelli 2010 in press). Vaccination of MDA-positive piglets of 3 weeks of age with a single 2ml dose protects them from a heterologous challenge at 25 weeks of age. There was a significant reduction of virus shedding and PCV2 DNA load in lymphoid organs. The duration of immunity covering the whole fattening period, induced by a single dose, in the presence of MDA, is unique to Porcilis PCV. This feature has been confirmed by several field reports from different countries and forms part of the label claim for Porcilis PCV.

* wpc weeks post challenge

Q-PCR on serum, fecal samples and lymphoid tissues. At the time of challenge, none of the samples of either group contained detectable amounts of PCV2 DNA. After challenge, a significant reduction in the PCV2 load was found in serum, inguinal lymph nodes, spleen and tonsils of the vaccinates (P<0.05). No PCV2 DNA was detected in any of the feces samples from this group. However, PCV2 DNA was found in fecal swabs of the challenged control animals (P<0.0001). Similar findings in data generated under field conditions were reported by Toki (JSVSC 2008) and by Larsen (IPVS 2010).
Assessing the impact of maternally derived immunity on active immunization of pigs against PCV2

Angela Baysinger1 John Waddell2 Edgar Diaz1
1. Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA; 2. Sutton Veterinary Clinic, Sutton, NE, USA

Introduction
Porcine circovirus associated disease (PCVAD) is caused by porcine circovirus type 2 (PCV2). Most sows and gilts develop antibodies after natural exposure to or immunization against PCV2 that become passively acquired by their nursing offspring. The objective of this study was to assess potential maternal interference with active immunization when vaccinating weaned piglets around 3 weeks of age against PCV2.

Materials and Methods
Piglets were weighed and ear tagged within 24 hours of birth and weaned at approximately 3 weeks of age. All pigs were individually blood sampled for PCV2 IFA antibody measurement and classification as low (≤1:320) or high (≥1:640) titer just prior to vaccination at approximately 3 weeks of age (Day 0) based upon previously reported experiments. Four treatment groups were created balancing for pig weight and gender: low pig titer/non-vaccinated pigs (L-NV), high pig titer/non-vaccinated pigs (H-NV), low pig titer/vaccinated pigs (L-V), and high pig titer/vaccinated pigs (H-V). Vaccinated groups were intramuscularly injected with 1mL of Ingelvac CircoFLEX® (Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO). Body weights were individually recorded at pre-determined intervals and a subset of pigs were serially blood sampled for diagnostic serology. Pigs from all groups were commingled within nursery and finishing pens. Individual pig was the experimental unit with Day 0-128 average daily gain as the primary outcome of interest. The main effect of Day 0 pig PCV2 IFA titer and pig treatment were assessed using ANCOVA with the model including dam parity, pig gender, and day 0 pig weights as co-variates. Pairwise comparisons utilized Tukey HSD (JMP v8.0).

Results
Mortality rate did not differ between treatment groups, consistent with the classification of this flow as subclinically affected by PCVAD. Vaccination of pigs significantly increased D0-128 weight gain parameters compared to non-vaccinates regardless of pig PCV2 IFA titer status at the time of vaccination at 3 weeks of age (L-V vs L-NV; H-V vs H-NV; Table 1). D0-128 weight gain parameters did not differ among vaccinated groups from low or high PCV2 IFA titer groups of pigs (L-V vs H-V; Table 1).

Table 1. Least square means for performance data by main effect of pig PCV2 IFA (L≤1:320, H≥1:640) titer at 3 weeks of age and pig treatment (V=vaccinated; NV=non-vaccinated).

2 Means with different superscripts within a row differ significantly (Tukey HSD, P≤0.05).

Discussion
High levels of maternally derived PCV2 IFA antibodies (> 1:640 or >1:320) did not interfere with achieving significantly increased weight gain by active immunization of piglets with Ingelvac CircoFLEX at 3 weeks of age. Groups of pigs with subclinical PCVAD perform significantly better if vaccinated.

Impact of 1- OR 2-dose PCV2 vaccination regimens on wean-to-finish performance

Keith Erlandson1 Jeff Okones2 Roy Edler2 Justin Rustvold2 Edgar Diaz2
1. Iowa Select Farms, Iowa Falls, IA, USA; 2. Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA

Introduction
The objectives of this study were to compare wean-to-finish growth performance and efficiency in commercial pigs administered commercially available porcine circovirus type 2 (PCV2) vaccines used in either one or two dose vaccination regimens.

Materials and Methods
The study was conducted in a large production systems wean-to-finish research site. A randomized block design was used to allocate pigs to pens by gender and weight. Approximately 2000 pigs were weaned at an average of 21 days of age from a single PRRS negative sow source and placed in 77 pens across two barns over a 4 day period. There were six full and one partial block in one barn and five full and two partial blocks in the other barn. Each pen contained approximately 26 pigs. Six treatment groups consisted of 12 pens of non-vaccinated controls and 13 pens of 5 different vaccinated groups with pen as the experimental unit (Table 1). Two pigs per pen were serially blood sampled every 4 weeks for serologic monitoring of PCV2 viremia by quantitative PCR.

</tbody>
</table>

Performance data was analyzed in a blinded manner using a randomized design. When the ANOVA P value was less than 0.05 for ADG and FCR, Tukey’s HSD was used to discern differences between the vaccine treatments. The Chi square test was used to evaluate mortality rate.

Results
Natural exposure to PCV2 infection was confirmed by PCR. All vaccination regimens significantly reduced the incidence and magnitude of PCV2 viremia at 14, 18 and 22 weeks of age. All vaccination regimens except Suvaxyn 1 dose significantly improved the rate of day 0-178 average daily weight gain compared to non-vaccinated controls (P≤0.05, Table 2). Only Ingelvac CircoFLEX 1 dose significantly improved day 0-178 feed conversion efficiency compared to non-vaccinated controls (P≤0.05, Table 2). Day 0-178 mortality rate was not affected by treatment.

ab: means within a column differ significantly Tukey HSD P≤0.05.

Discussion
Ingelvac CircoFLEX administered as a single full dose to pigs at 3 weeks of age was the only vaccination regimen to significantly improve both rate of weight gain and feed conversion efficiency. Utilization of an effective single dose vaccine also maximizes time and labor utilization efficiency while imposing less stress on pigs.
Comparative efficacy of PCV2 and Mycoplasma vaccination regimens

Joel Nerem
Pipestone Veterinary Clinic, Pipestone, MN, USA

Introduction
The objective of this study was to compare the efficacy of various vaccination programs against PCV2 and Mycoplasma hyopneumoniae. The study was supported by Boehringer Ingelheim Vetmedica, Inc.

Materials and Methods
A 3200 sow farrow to wean facility and a downstream nursery/finishing site was used in the study. The system is PRRS virus positive, but stable (producing PRRS PCR negative weaned pigs) and is Mycoplasma hyopneumoniae (M hyo) positive. The off-site finishers had consistently suffered clinical porcine circovirus associated disease (PCVAD) losses with mortality rates of 10-15%. The system historically used a combined half dose of RespiSure One (Pfizer 1-dose M hyo vaccine) with a full dose of Circumvent (Intervet 2-dose PCV2 vaccine) at processing (3-5 days of age) and weaning (17-22 days of age). To reduce labor and stress on the pigs, they wanted to evaluate using a 1-dose vaccination program with the Ingelvac® CircoFLEX - MycoFLEX™ mixture, given either at weaning (~21 days of age) or processing (~5 days of age). They also wanted to evaluate the effectiveness of a split-dose program of 1/2 dose of the Ingelvac® CircoFLEX - MycoFLEX™ mixture at processing and at weaning.

Vaccinations, tagging and the first two weights were taken at the sow farm. At weaning, pigs were moved to an off-site 3 barn nursery-finishing site. Pigs were first housed in a power ventilated nursery for 40 days. From day 40 to day 150, pigs were housed in two curtain-sided finishing barns.

Five treatment groups (Table 1) were balanced for sow-of-origin parity with approximately 400 pigs assigned to each treatment group. Individual pig was the experimental unit. Pigs were ear tagged at processing and randomized by pen placement in nurseries and finishers with all five treatment groups represented in each pen. Final weighing occurred just prior to first pigs being sold to market. Average daily gain was evaluated along with mortality rate, culling rate and % prime marketed pigs.

</tbody>
</table>

Results
No differences were observed between treatment groups during the nursery phase. Clinical PCVAD was observed in finishing and was confirmed diagnostically. Comparisons between the M. hyo vaccines used could not be made because clinical and serologic results revealed no significant M. hyo exposure. The Ingelvac® CircoFLEX - MycoFLEX™ mixture administered at 3-5 days of age was not statistically different than controls for any parameter (Table 2). All other treatment groups produced better rate of gain, cull rates and % prime marketings than controls. Only Ingelvac® CircoFLEX - MycoFLEX™ given at weaning reduced mortality rate over controls.

Values in columns with different letters are significantly different at P ≤ 0.04 (Fisher’s exact test).

Discussion
Vaccination at 5 days of age was not successful. The only group that performed significantly better than controls for all 4 performance parameters was a single dose of Ingelvac® CircoFLEX - MycoFLEX™ mixture at weaning.
The importance of on-farm monitoring after sow vaccination (CIRCOVAC®) for successful control of porcine circovirus disease (PCVD)

Keiri Tokuyama1 M. Kagawa2 Y. Saito3 S. Ogino3
1. Merial Japan Ltd, Tokyo, Japan; 2. Kagawa Livestock Clinic, Gunma, Japan; 3. Nippon Zenyaku Kogyo Co., Ltd., Fukushima, Japan

Introduction

When vaccination against PCV2 is implemented, failure of PCVD control is often conceived as lack of vaccine efficacy. Since it is known that multiple pathogens are usually involved in PCVD (1), it is important to continuously monitor post-vaccination status for successful control. The objective of this study is to show the benefit of sow vaccination and on-farm monitoring practices.

Materials and methods

A 120 sow farrow-to-finish farm located in central Japan, was selected for the study. Sows were mass-vaccinated twice 4-week apart for PCV2 with CIRCOVAC (Merial) thereafter 2-4 weeks before parturition. Blood samples from sows and pigs were tested for PCV2 antibodies (IFA), PPRSV (ELISA), M. hyo (ELISA), and PCV2 viral load (RT-PCR). All clinical incidences, post-weaning mortality and days to market were recorded during the course of the study for approx. one year. Chi-test and Student-t test were used for statistical comparison of one year before and one year after vaccination.

Results and Discussion

Noticeable clinical signs were mainly due to diarrhea and/or digestive disorders during weaning, leading to increased mortality and runts. Although the mortality rate contained those losses, it stayed statistically lower than the previous year. Days to market were reduced by 10 days (Table 1).

*statistically significant (P<0.01)

One year after vaccination sows had markedly lower PCV2 viral load and higher antibody titers (Fig. 1a). In pigs, PCV2 DNA was detected before vaccination at 8-13 wks, but one year after vaccination viremia was detected at the finishing stage (17-22 wks) (Fig.1b). Despite viremia at 21-22 wks, no particular clinical signs were observed, and days to market were reduced by 10 days. Mortality in the finishing period was reduced to 2.0%.

As opposed to the pre-vaccination year, pigs seroconverted against PRRSV and M. hyo around mid-finishing in the year post vaccination. Both pathogens are known to negatively impact immune functions, and enhance PCV2 replication (2, 3). These co-factors may have played a role in the asymptomatic raise of PCV2 viremia in the late finishing stage. Mortality and growth improvements clearly indicate that PCVD was well controlled in this farm. The rise in M. hyo and PRRS ELISA titres indicate that continuous monitoring is necessary since farm epidemiology can change over time. Monitoring thus enables quick implementation of appropriate measures.

In terms of efficacy, cost and labor, sow vaccination is practically one of the most useful options when monitoring is carefully implemented as in the present study.

Willingness to approach behaviour in weaned piglets following vaccination with two different PCV2 vaccines in a Japanese commercial farm

Mali Miyashita1 Y Takahashi2 Takeshi Yamaguchi1 Yasuko Shimomura1
1. Boehringer Ingelheim Vetmedica Japan Co. Ltd., Tokyo, Japan; 2. Shokukanken Inc., Gunma, Japan

Introduction

Adapted from the animal observation section of the 2003 Swine Welfare Assurance Program (SWAP), willingness to approach observations have been used to evaluate pig behaviour after vaccination (1,2). The objective of this study was to compare the willingness to approach behaviour in pigs following vaccination with two different PCV2 piglet vaccines that are commercially available in Japan.

Materials and Methods

A 450 sow PRRS positive farm with a past history of PMWS located in Ibaraki, Japan, was selected for the study. A total of 871 weaned piglets aged 3 to 4 weeks, were included for observation. At weaning pigs were allocated to pens of approximately 20 pigs each. After an average acclimation time of 1 week, half of the pens (22) received 1ml of Ingelvac CircoFLEX (group A), while the other half received 2ml of Porcilis PCV (group B). Vaccines were administered according to manufacturer instructions. There was no difference in average weight, age or sex between vaccine groups. An adaptation of the animal observation section of the 2003 SWAP was utilized to evaluate willingness to approach behaviour (WTA) of piglets pre- and post vaccination. After entering the pen, sitting down and waiting a 15 second period, the blinded observer counted all pigs that approached and/or were in eye contact to him. These counted pigs divided by the total number of pigs in the pen resulted in the % willingness to approach (% WTA). The initial observation (baseline) was conducted at 4pm on the day prior to vaccination. On the following day, vaccination of pigs was completed by 10am, and WTA observations were conducted at 6 hours (4pm) post vaccination. The change in post vaccination % WTA was compared to the baseline for each vaccine group and between groups. The % WTA compared to baseline between groups was analyzed by the Pearson Chi-square test. Results were considered significant when P values were equal to or less than 0.05.

Results

Results are summarized in table 1. Six hours post vaccination, there was a statistically significant difference (p<0.0001) in the % WTA compared to baseline between groups (83% and 27% for groups A and B, respectively).

*Number of approaching pigs/Number of pigs observed

**Number of approaching pigs/Number of pigs that approached at baseline

Discussion and conclusion

Using the willingness to approach model, it was previously shown that Ingelvac CircoFLEX was not different to saline (2), for which reason a control group was not included in the study protocol. In this study pigs from group A showed more willingness to approach 6 hours post vaccination, compared to those of group B, indicating that depending on the type of PCV2 piglet vaccine used, differences can occur in the behaviour of piglets at 6 hours after vaccination. Willingness to approach observations utilize the natural behaviour of pigs by assessing their level of interest to a person in the pen, thus providing a certain indication as to the well-being of those pigs. Based on the results of this study, willingness to approach observations may provide a useful tool to objectively assess the potential welfare impacts of different vaccines on pigs.

Direct and indirect transmission of four Salmonella enterica serotypes in pigs

Julia Österberg; Susanna S. Lewerin; Per Wallgren
National Veterinary Institute, Uppsala, Sweden

Introduction
The Salmonella serotypes commonly detected in raw feed materials in Sweden often differ from the serotypes most often isolated from animals and humans. Why only few of the “feed-associated” serotypes seem to reach or spread within the animal population has not been sufficiently investigated. In the present study we have performed comparative examinations of two serotypes commonly isolated from pigs (S Typhimurium and S Derby) and two “feed associated” seotypes (S Yoruba and S Cuban) by studying their ability to infect pigs in a direct and indirect transmission situation aiming to investigate possible differences among serotypes.

Materials and Methods
In total, 48 ten-weeks-old pigs, deriving from a Swedish nucleus herd, were split into eight groups. Each group was housed in a separate room in a pen with solid concrete floor. Sawdust bedding covered half of the pen and the dung was cleared out twice daily.

Direct contact transmission (DT) was studied by mixing six pigs with two seeder pigs, aged 18 weeks, in each of four cleaned and disinfected pens. The two seeder pigs in each group had a well documented history of long-term faecal excretion of one of the four selected serotypes of Salmonella, as they had been inoculated with 10^9 colony forming units (cfu) of the serotype 8 weeks earlier (1, 2).

Indirect transmission (IT) was studied in six pigs in each of four pens were Salmonella infected pigs had previously been housed. The infected pigs had been inoculated with 10^9 cfu of the serotype eight weeks earlier and their faecal excretion of Salmonella had been monitored for eight weeks before the naive pigs replaced them in the unwashed pens (1, 2).

All pigs in the eight rooms were monitored for two weeks with respect to their faecal excretion of Salmonella and the presence of serum antibodies. In total, eight faecal samples and three serum samples were collected from each pig. In addition, eight tissue samples per pig were collected at necropsy.

Results
The results from culturing the faecal samples and the samples collected post mortem are shown in Figure 1.

Discussion and Conclusions
The rate of transmission was apparently low in both the direct and the indirect transmission situation, and no differences between the four serotypes could be concluded with respect to the faecal shedding of Salmonella. In contrast, a difference between serotypes was indicated by the results from the IT post mortem samples, as S Typhimurium was re-isolated from four pigs housed in the contaminated environment.

In conclusion, the overall low level of transmission of all four serotypes in both trials most probably reflected a low dose exposure. Pigs shedding Salmonella at detectable but low levels may not necessarily transmit the pathogen to its pen mates, not even in a solid floor environment. This high-lights the importance of hygienic measures, in order to keep the shedding and re-circulation of Salmonella spp. low in infected herds. However, isolation of S Typhimurium from especially the ileocecal lymph nodes can be expected even in herds with a very low load of S Typhimurium.

A review on Salmonella control in fattening pigs through the use of potassium diformate (KDF) - European case studies

Christian Lückstädt; Peter Theobald; Horst Auerbach
ADDCON, Bonn, Germany

Salmonella control has a high priority in European pork production. It is a significant cause of human Salmonellosis and causes major economic losses in the pork production chain, through reduced productivity, increased veterinary and hygiene control costs. Preventing the spread of salmonella to the consumer requires special control measures during slaughter and processing. The extra cost of these controls is increasingly being transferred back to the producer in the form of financial penalties or the loss of the market for contaminated pigs.

Gut health is increasingly being shown to be effective against intestinal pathogens, a strategy that has only really been made possible through the removal of antibiotic growth promoters in feed. Creating and maintaining a healthy intestinal environment has become essential to productivity and food safety programmes alike.

S. enteritica typhimurium is the predominant serotype found in pig carcasses in Europe, accounting for around 71% of cases. Several serotypes are resistant to antibiotics, putting increasing pressure on producers to prevent contamination. While salmonella cannot be eradicated in pig units, it can be controlled to minimise the risk to consumers. Biosecurity plays a significant role in salmonella control. In feed compounding, although heat treatment is effective in reducing contamination of feed leaving the feed mill, this effect does not persist during transport, storage and subsequent outfeeding. When conditions within the feed are less conducive to bacterial infection, salmonella contamination can be reduced. The next critical control point is within the pig's gut itself, where conditions for bacterial growth may once again be optimal. Salmonella growth requires warmth (35-37°C is optimal), a moisture content greater than 12% and a pH between 4.5 - 9.0. It is no coincidence that the pig gut can provide salmonella everything it needs to thrive.

While biosecurity and hygiene in the feed mill and on farm are essential, the acidification of feed ingredients or finished feeds with organic acids also offers considerable benefits to salmonella control. Feed acidification is not only effective within the feed; possibly its biggest benefit occurs within the pig itself. Research trials in the UK, France and Ireland with 0.6% potassium diformate (KDF) feed additive, showed significantly reduced salmonella count in the feed as well as in the gut of pigs. This effect is particularly well illustrated by data collected on 12 farms in Ireland (Lynch et al., 2007). The main objective of this investigation was to evaluate the efficacy of salmonella control measures on highly infected farms. Salmonella control has been compulsory under Irish law since 2002 and farm status is categorised by the percentage of positive pigs in a herd according to the Danish mix-ELISA test. Category 3 (>50% positive) farrow-to-finish farms and their associated fattening units were selected for the study. All the farms that were treated with KDF alone; or a combination of KDF with improved hygiene and biosecurity measures had notable improvements in both bacteriological and serological prevalence of Salmonella spp. All but one farm in which KDF was used ended the trial with a much improved salmonella status, with bacteriological prevalence also low on most farms. Using improved hygiene and biosecurity measures alone also improved salmonella status, but to a much lesser extent. The reduction in prevalence obtained by KDF alone, compared to the two farms which also implemented additional hygiene and biosecurity, demonstrates the additive's efficacy.

These findings are not unique, however. Studies by Dennis and Blanchard (2004) in the UK as well as most recently in France (Correge et al. 2010) concluded potassium diformate, to be an effective tool in a salmonella control strategy in commercial farms, reducing the percentage of salmonella positive pigs by 50% and in pork meat juice ELISA scores by 46%, respectively in grower finisher pigs. The UK trial also showed an improvement in daily gain of 7.7%, reduced mortality and a reduction in medicinal intervention compared to the rolling average for that unit. The economic benefit of implementing salmonella control was also evaluated.

Comparison of risk factors and bacteriological findings in the environment of pig herds with high or low Salmonella prevalence

Verena Gotter 1 Amely Ovelhey 3 Sarah Kösters 3 Thomas Blaha 1 Günter Klein 2
1. University of Veterinary Medicine Hannover, Field Station for Epidemiology, Bakum, Germany; 2. University of Veterinary Medicine Hannover, Institute for Food Quality and Food Safety, Hannover, Germany; 3. University of Veterinary Medicine Hannover, Department of Biometry, Epidemiology and Information Processing, Hannover, Germany

Introduction
With the introduction of a national, serological Salmonella monitoring-program in Germany in 2007, the knowledge of risk factors for Salmonella infections in pigs in conventional husbandry systems reached a new level of meaning for the veterinary practitioner. In order to help those of his clients whose herds have a high Salmonella prevalence, he must be able to devise a strategy using the multitude of risk factors mentioned in literature as basis. However, the importance of individual risk factors is highly debated even among the scientific community (1), with few results from various studies being generally accepted, one being that since Salmonella ssp. does not require an animal host to survive, the indirect transmission plays a significant part (2, 3).

The goal of this study was therefore to establish on a wide basis the validity and significance of known risk factors by comparing herds of high (category III) and low (category I) serological prevalence via questionnaire and to reinforce the findings with bacteriological samples from the environment of the animals. Following completion of the study the results are then to be published as guidelines for the veterinary practitioner.

Material and Methods
A 23 page questionnaire with six parts and five attachments was validated and sample sites were chosen as accordingly. In category I 67 herds were examined; in category III 103 herds. All herds were situated in an area of high pig herd density in northwestern Germany. Only a fraction of the asked questions is presented in this abstract:
1. Are the driving boards cleaned and disinfected before each fattening batch?
2. Are the loadings ramps cleaned and disinfected before each fattening batch?
3. Is the central hallway of the barn cleaned and disinfected before each fattening batch?

Samples were taken by swabbing the area in question with a sterile, BPW (buffered peptone water)-enriched tissue. The samples were examined via RT-PCR (real time polymerase chain reaction), after an 18 hour enrichment phase in BPW at 37°C at the Field Station for Epidemiology in Bakum.

Results
An excerpt of the results of the samples is presented in Table 1.

Discussion
These samples show that in herds in category III have about double the amount of positive samples (in percent) than herds in category I. This supports the belief that herds in category III indeed do have more Salmonella in the environment surrounding the pigs. These three exemplary risk factors may belong to the crucial group of risk factors, which must be considered when implementing a strategy against the Salmonella problem of a herd, as further results may show when the detailed inspection of all answers of the survey, cross-referenced with the sample results become available. This may also answer the critical question whether this discrepancy between the herds is due to the individual execution of cleaning and disinfection or to the existence of such procedures per se.

Does pre-slaughter stress affect pork safety risk?

Marcos H. Rostagno; Susan D. Eicher; Donald C. Lay, Jr.
USDA-ARS-LBRU, West Lafayette, IN, USA

Introduction
Food safety is a defining issue in the global pork market today, and Salmonella contamination is a major concern for the pork industry all over the world. Although much of the Salmonella contamination of pork occurs within abattoirs, infected pigs leaving the farm are considered as the original source of abattoir contaminations. According to Berends et al.(1996), live animals that carry Salmonella at the time of slaughter are 3-4 times more likely to produce positive carcasses. Furthermore, it is reasonable to assume that the extent of carcass contamination is also determined by the levels of Salmonella entering the abattoir in the intestinal tract of slaughtered pigs. Therefore, two experiments were designed to determine if common stressors occurring prior to slaughter affect the prevalence and levels of Salmonella in market weight pigs, and consequently, the associated pork safety risk.

Materials and Methods
Initially, a field study (i.e., under commercial conditions) was conducted to determine the effect of transportation from the production farm to the abattoir, and pre-slaughter lairage on the frequency of Salmonella shedding in market pigs. In this study, 5 Salmonella-positive finishing lots were used. From each lot, 30 pigs were randomly selected from Salmonella-positive pens, transported in a clean and disinfected livestock trailer for 1.5 hour, and subjected to 2 hours of pre-slaughter lairage. Individual fecal samples were collected immediately prior and after transportation, and after lairage. All samples were processed for the isolation and identification of Salmonella enterica. A follow up study was conducted under controlled conditions, with the objective of determining if feed withdrawal and transportation affect the levels of Salmonella in the intestinal tract of market-weight pigs. Three replicates with 20 market-weight pigs each (5 pigs/treatment) were conducted, including the following treatments; Control (no stress), feed withdrawal (12 h), transportation (1 h), and feed withdrawal (12 h) followed by transportation (1 h). Pigs were individually challenged with a Salmonella Typhimurium Nalidixic acid-resistant strain 3 days prior to the experiment, and euthanized immediately after the treatments for necropsy. All samples were processed for the isolation and enumeration of the challenge strain.

Results
In the first study, significant increase (P<0.05) of Salmonella shedding prevalence was observed from pre-transport (11.3%) to post-transport (20%), and from post-transport to post-lairage (42%). In the second study, feed withdrawal by itself or combined with transportation caused increased levels of Salmonella in the ileum (P<0.05), whereas only the combination of feed withdrawal and transportation caused increased levels of Salmonella in the cecum of market-weight pigs (P<0.05).

Discussion
Studies of the effects of pre-slaughter stressors on food safety risk in market pigs are scarce. Taken together, our studies show that a significant increase of Salmonella shedding and its levels in the intestinal tract of market pigs occurs between the production farms and the abattoirs. We have already shown that an increase of Salmonella prevalence occurs due to rapid infections during pre-slaughter lairage (Hurd et al.,2001; Rostagno et al.,2003). Besides of confirming this occurrence, these studies show that the process of moving market pigs from the production farm to the abattoir also contributes to increase pork safety risk. Although many can argue that transporting pigs from the farms to the abattoir is a process that cannot be avoided, it is important to keep our minds open to potential changes or modifications. For instance, transportation conditions can be manipulated to minimize stress, and/or the gastrointestinal microbial ecosystem can be made more resilient to changes (or stabilized) through the use of probiotics, prebiotics or other alternatives.

References
Introduction
Salmonella is considered as one of the most important foodborne pathogens that has potential implications for human health (1). To control Salmonella at the pre-harvest stage, the implementation of a surveillance and control program has been established in the different EU Member States. Since 2005, the Belgian Federal Agency for the Safety of the Food Chain (FASFC) implemented a National Salmonella surveillance and control program in pigs, the Salmonella Action Plan (SAP), which became compulsory by means of a Royal act in July 2007 (2). Since July 2007, Belgian pig farms can be assigned as Salmonella-risk farms, based on serological analysis of blood samples collected from the fattening pigs.

This study was conducted to evaluate the serological status of the sows on Salmonella risk farms compared to non-assigned farms.

Materials and methods
With a 4-month interval, every Belgian pig farm needs to collect blood samples from 12 fattening pigs for the National Aujeszky-disease monitoring program. All samples are analyzed using an indirect LPS-Salmonella ELISA (Idexx). Since July 2007, farms are identified as risk farms if the mean S/P-ratio, from 12 fattening pigs, is equal to or higher than 0.6 for 3 successive sampling events.

For this study blood samples (n = 1138) of sows were randomly collected on 100 different farrow-to-finish herds. To this end, 583 samples were obtained from 50 Salmonella risk farms, identified as farms with a mean S/P-ratio equal to or higher than 0.6 for 3 successive sampling events; and 555 samples were obtained from non-risk farms, identified as farms with a mean S/P-value lower than 0.2 for 3 successive sampling events.

A statistical analysis (Mann–Whitney–Wilcoxon test) was performed to compare the mean S/P ratio in both sow groups.

Results
The results show that the mean S/P ratio obtained from the sows of the Salmonella risk-farms (1.138 ± 0.026 SEM) was significantly higher (P < 0.0001) compared with the non-risk farms (0.702 ± 0.021 SEM). The mean S/P-ratio for the 1138 sows was 0.925 ± 0.018 SEM. In this study there was a presence of Salmonella antibodies in 98.7% of the sows. At a cut-off of S/P = 0.6 we found 63.6% of the sows to be positive.

Discussion and conclusions
Sows play an important role in the maintenance of Salmonella infections in farrow-to-finish herds (3). The increasing number of sows on a farrow-to-finish farm was recently identified as a risk factor associated with higher average S/P-values on a farm (4). In this study we could clearly show that the infection status of the sows plays a significant role in the assignment as a Salmonella risk farm in the Belgian Salmonella control program, which is based on sampling of fattening pigs. Control of Salmonella on farrow-to-finish herds is now almost only done by implementing measures in the fattening unit. It is clear that further studies are needed to evaluate intervention measures in the sow unit. Vaccination could be one of these intervention options.

In conclusion, it is clear that the role of the sows and their serological Salmonella status is a potential influencing factor for the assignment of Salmonella risk farms, which is principally based on sampling of fattening pigs.

Use of workshops and face-to-face interviews to teach smallholder pig farmers about how to prevent disease due to Taenia solium

Cate E. Dewey¹ Jared Wohlgemut¹ Florence Mutua² Mike Levy¹
1. University of Guelph, Guelph, ON, Canada; 2. International Livestock Research Institute, Nairobi, Kenya

Introduction
Neurocysticercosis is the major preventable cause of adult-onset epilepsy in developing countries. Epilepsy is caused by the neurocysticercosis form of Taenia solium. The life cycle includes the pig as an intermediate host having larval cysts (Cysticercus cellulosae) and the human as the definitive host, having adult tapeworms (taeniasis). Humans also act as intermediate hosts if they consume T. solium eggs.

The purpose was to describe changes in and retention of knowledge and changes in behaviours of pig farmers after providing workshops using the training of the trainers model followed by one-on-one farmer training.

Materials and Methods
A random sample of 282 pig farmers in the Busia and Kakamega Districts of Western Kenya were included in the study beginning in 2006. Each farm was visited 3 times at 4-7 month intervals. Data was collected from farmers in face-to-face interviews at each farm visit. The authors presented a one-day workshop about pig management, feeding, housing, and the lifecycle of Taenia solium and its association with epilepsy to government livestock, veterinary and public health officers (staff). Then, the staff taught this material during one-day farmer workshops. Three farms visits that were 5 months apart enabled researchers to conduct one-on-one training. Farmers were asked what management changes they made as a result of the research and workshops during 2008 & 2009 workshops.

Proportions of correct answers to questions regarding the lifecycle and prevention of disease due to T solium in people and pigs were compared amongst three groups of farmers based on training; those who attended workshops and those who were given one-on-one training. Acquisition of knowledge was compared within respondent from the 2nd to the 3rd farm visit using a McNemar’s chi-square test.

Results
Many farmers (51%) have seen tape worm segments in their own stool. Most farmers (89%) knew that if they saw these segments, they should seek medical treatment. However, few farmers knew how people became infected with the tapeworm. Male farmers were 9 times more likely to have seen a pig with cysts than female farmers.

Farmers were 3.7 times more likely to know how people become infected by T solium after the one-on-one training (60%) than before this training (50%). Farmers with at least a grade 8 education were more likely to understand the life cycle than farmers with less education. Farmers were more likely to tether their pigs 100% of the time after the workshop (51%) than before the workshop (34%) and still more likely after the one-on-one training (63%) (P<0.02). At the end of the study, 79% of farmers were keeping their pigs tethered 75% of the time. More than half (59%) of the farmers knew how to make the pork safe to eat if it was infected with cysts. This proportion was higher (66%) for those farmers who received the one-on-one training.

Discussion
Education is the primary method of reducing the prevalence of diseases due to Taenia solium in developing countries. Workshops and one-on-one training increased the level of knowledge and changed the behavior regarding confining pigs. The life cycle of T solium is difficult to understand. Farmers with a grade 8 education and those with individual training were most likely to understand the cycle and therefore know how to prevent the disease. Individual training is expensive but may be necessary to reduce the prevalence of epilepsy due to this disease.
Toxoplasma gondii Seroprevalence on U.S. swine operations in 2000 and 2006 and factors associated with changes in prevalence in 2006

Charles A. Haley¹ Eric Bush¹ Delores Hill²

1. USDA:APHIS:VS:CEAH:NAHMS, Fort Collins, CO, USA; 2. USDA:ARS: ANRI: Animal Parasitic Diseases Laboratory, BARC-East, Beltsville, MD, USA

Introduction.

Toxoplasma gondii is a protozoan parasite capable of infecting most warm blooded animals, potentially resulting in the disease toxoplasmosis. It is estimated that 60 million people in the U.S. are infected, although few demonstrate symptoms. Cats can serve as the host and shed oocysts in the feces for approximately 1-2 weeks. These oocysts then sporulate in 1-5 days following deposition. Swine, can be infected by ingesting material contaminated with the oocysts. It has been estimated that up to 25% of apparently healthy pigs in the United States have positive antibody titers. While few pigs display clinical signs, the parasite can persist in the edible tissues of pigs.

Our first objective was to compare sample and farm level prevalence of exposure to Toxoplasma (as measured by antibodies) in 2000 and 2006 from the National Animal Health Monitoring System’s (NAHMS) swine studies and associated herd factors. The second objective was to present factors associated with the number of positive Toxoplasma test results within farms sampled in the 2006 study.

Materials and Methods

Questionnaire data and blood samples were collected as part of the NAHMS Swine 2000 and 2006 studies. Producers participating in the NAHMS Swine 2000 and 2006 studies were able to submit up to 15 and 35 blood samples, respectively from finisher pigs to be tested for antibodies to Toxoplasma. In 2000, 5,718 samples were collected from 394 swine sites and tested using a modified agglutination test (MAT) test. In 2006, 6,238 samples were collected from 185 sites and tested using an enzyme linked immunosorbant assay (ELISA).

Results

Overall, 0.9% of grower/finisher pigs sampled were positive for Toxoplasma antibodies in 2000 and 2.7% in 2006. Smaller herds (<2K head) appeared to have more positive samples than medium (2-4.9 K head) and larger herds (5 K head plus) in both years. The number of finisher pigs housed in total confinement comprised a lower percentage of positives in 2000 compared with 2006.

The average within herd prevalence in positive (had at least one positive sample) and negative herds in 2000 was 1.8% of finishers overall and in positive herds was 23.5%. In 2006 the corresponding average within herd prevalence was 4.6% and 17.4%, respectively. Overall, 7.5% of sites were positive for Toxoplasma antibodies in 2000 and 26.8% of sites were positive in 2006. Similar to the sample level results, smaller herds appear to be affected more often in both years but the prevalence in confinement vs. not confined herds seemed to be different only in 2000.

For the 2006 samples we used a method of modeling called zero inflation to detect herd level practices associated with counts of positive samples. For farms that buried dead weaned pigs off site, the count of Toxoplasma positives was 7.2 times higher than when they were not buried off site. When a farm composted dead preweaned pigs on site the incidence rate of Toxoplasma positives went up 83 percent, while the use of traps, bait, poison, exterminator or some other method besides cats or dogs for rodent control on the farm reduced the prevalence of Toxoplasma by 63 percent.

Discussion

It is likely that since there was less sampling of finisher pigs in 2000, the incidence has not gone up so much as there wasn’t sufficient sampling in 2000 to find a difference. However, for 2000 and 2006 it would be possible to get estimates of true herd prevalence based on published test accuracies for the MAT and ELISA tests. The results of modeling suggest there is an unmeasured effect since one would expect that burying pigs off-site would decrease positive counts.

**Prevalence, detection and isolation of Toxoplasma gondii in swine tissue samples from a slaughterhouse in Bogota-Colombia**

Johanna M. Campos; Myriam A. Hortua; Barbara H. Zimmermann

Laboratorio de Bioquímica y Biología Molecular de Parasitos BBMP, Departamento de Ciencias Biológicas, Facultad de Ciencias, Universidad de los Andes, Bogota, Colombia

**Introduction**

Toxoplasmosis is a zoonotic disease caused by infection with the protozoan *Toxoplasma gondii*. Infections by this parasite are widely prevalent in humans and other warm-blooded animals in all continents. In humans, infection occurs either by consumption of uncooked meat containing cysts or ingesting or drinking contaminated food with sporulated oocysts. Studies have demonstrated that toxoplasmosis in pregnant women is generally related with uncooked meat consumption (Kapperud et al., 1996; Baril et al., 1999; Cook et al., 2000). It is important to study the prevalence of this protozoon in pork as it is a major source of infection. The seroprevalence in pigs was reported to be 29% worldwide. (Kim & Weiss, 2008)

To guarantee the destruction of the parasite, the meat must be properly cooked until it reaches a temperature of 67°C or must be frozen at freezing temperature lower than -10°C for a period of 48 hours. (Kijlstra & Jongert, 2008)

**Materials and Methods**

80 pig samples of tongue, heart and blood were collected in a slaughterhouse in Bogotá- Colombia.

DNA extraction of tissues samples of heart and tongue was performed by the method of salting out. The amplification of a 532 bp fragment of B1 gene was performed by nested PCR to evaluate the presence of the parasite (Boothroyd & Grigg 2001). For the isolation of native strains, subcutaneous inoculation of the processed material in CFW and Swiss mice was performed. Infection was assessed by analyses of mice sera by Western-blot technique using an anti-mouse IgG secondary antibody labeled with peroxidase.

Seroprevalence in pigs was assessed. The presence of antibodies against *T. gondii* and *Trichinella* in blood samples of pigs were analyzed using an ELISA kit (ID Screen toxoplasmosis indirect multi-species, and ID Screen Trichinella indirect), produced by ID VET innovative diagnosis (Montpellier- FRANCE).

**Results**

Analysis of the samples obtained by B1 gene amplification showed a 40% prevalence of *T. gondii* in pig tissue in 66 samples analyzed. Seroprevalence analysis showed 37% prevalence of antibodies against *T. gondii* in 80 swine serum samples, where 22 samples were positive by ELISA and PCR. Serum analysis for *Trichinella* gave negative in all cases.

The sera of mice infected with PCR positive swine samples were tested using Western blot to evaluate the possibility of infection. After 6 months only one mouse was Western blot positive, showing the presence of a native avirulent strain. This mouse serum showed reactivity to tachyzoite proteins of RH strain. The presence of cysts in brain were also detected in this mouse using PCR.

**Conclusions**

Using amplification of gene B1 it was possible to detect the presence of the parasite in 27 of the 66 samples from a slaughterhouse of Bogota, Colombia. This represents a 40% prevalence of *T. gondii* in swine tissue.

In the 80 samples analysed by the ELISA technique, the seroprevalence was 37%, coinciding with previous reported studies.

The tecnification of the production plants has allowed better control of some diseases transmitted by swine. Nevertheless the present Colombian legislation for the proper handling of swine is still too lax to control infection by certain mechanisms of control of *T. gondii*, for example the presence of cats in the production area.

According to the FAOSTAT Studies done in Colombia in 2005, the total consumption of pork and its derivatives corresponds to 10% of the total meat consumption. This, together with the high prevalence of *T. gondii* in the country, shows the urgent need for better methods of control.

Isolation of immunogenic glycopeptidolipids of *Mycobacterium avium* subsp. *hominissuis*

Henk J. Wisselink¹ Najlaa Abou¹ Conny B. van Solt¹ Lourens Heres² Peter Willemsen¹

1. Central Veterinary Institute of Wageningen UR, Lelystad, Netherlands; 2. VION Fresh Meat West, Boxtel, Netherlands

Introduction

*Mycobacterium avium* (MA) is an important pathogen in both animals and humans which belongs to the *M. avium* complex (MAC). Diagnosis of MA-infections in pigs is traditionally based on the detection of granulomatous lesions in lymph nodes seen by eye at slaughter. Since sensitivity and specificity of this approach is questioned (Komijn et al., 2007) we developed as an alternative a serodiagnostic ELISA assay on the basis of a polar lipid fraction from MA (Wisselink et al., 2009). We isolated glycopeptidolipids (GPLs) from *M. avium* subsp. *hominissuis* (MAH) and analyzed them for their suitability for serodiagnosis of MA infections in pigs.

Materials and Methods

MAH serotype 4 strain 17404 was grown at 37°C in Dorset Henry medium. Glycolipid antigens were extracted, analyzed by one and two dimensional thin layer chromatography (TLC) and further purified (Nishiuchi et al., 2004; Papa et al., 1993; Kitada et al., 2002). As reference, GPLs from a MAH serotype 4 strain were used (Kindly supplied by Y. Nishiuchi, Osaka, Japan). The immunogenicity of the GPLs was evaluated in ELISA tests using reference serum samples obtained from pigs held under experimental and field conditions.

Results

The TLC-pattern of GPLs from MAH strain 17404 and the reference GPL (Nishiuchi et al., 2004) showed both a Retention Factor (Rf) value of 0.42 (Fig. 1).

To evaluate the GPLs for their immunogenicity the cut-off value for negative and positive test results was calculated (Wisselink et al., 2009) which appeared to be 24.5 percentage positivity (PP). In all eight sera of pigs, experimentally infected with MA, high anti-GPL antibody titers were found. On the two infected farms 10.6 % (11/104) of the pigs tested serologically positive and on the five farms, free for an MA infection 3.3% (3/92) pigs (Fig. 2).

Fig. 1. One – dimensional (A) and two-dimensional TLC analysis (B and C). Reference GPLs from MAH serotype 4 (lane 1) and MAH serotype 4 strain 17404 (lane 2) had both a Rf value of 0.42. The purity of GPLs was examined by two-dimensional TLC (B: MAH strain 17404; C: reference GPL).

Discussion

Earlier we developed an ELISA test on the basis of polar lipids for serodiagnosis of MA infections in pigs. Here we show that purified GPLs can also be used as antigen in a serodiagnostic test because of its clear recognition by serum antibodies in experimentally infected pigs. For use under field conditions, the results of the GPL-ELISA indicate that MA-infected farms can be discriminated from MA-negative farms. Further work is needed to optimize and evaluate the GPL-ELISA for use in the field.

EU consumer reactions towards the vaccine method versus physical piglet castration with anesthesia: A quantitative cross-country study

Wim Verbeke; Filiep Vanhonacker
Ghent University, Gent, Belgium

Introduction
In most countries, rearing male piglets are castrated to avoid boar taint, an unpleasant odor that can be released during the cooking of pork from entire boars. In the European Union (EU), physical castration is as yet the most common practice. This method is increasingly criticized for its violation of piglet welfare, integrity and health. Alternative methods are being researched and evaluated in terms of practical and economic feasibility, production efficiency and animal welfare. One promising alternative pertains to the vaccination with Improvac (® registered trade mark of Pfizer). The vaccine stimulates the pig’s immune system to produce specific antibodies against the Gonadotropin-Releasing Factor (GnRF), hence inhibiting the production and accumulation of androstenone and skatole that cause boar taint. This so-called ‘vaccine method’ has been shown to improve production efficiency, and to be beneficial from an animal welfare and environmental perspective. The vaccine has received a marketing authorization of use in the European Union in March 2009. However, its successful introduction and adoption by stakeholders in pig supply chains is expected to depend among others on a favorable reception by consumers. Several qualitative, sensory or quantitative single-country studies have already been reported. The present study adds to this body of evidence from the EU consumer point of view towards piglet castration, through providing a large-scale quantitative cross-country approach, including the identification and profiling of cross-cultural pork market segments.

Material and Methods
A cross-sectional quantitative survey was conducted with representative consumer samples in Germany, France, the Netherlands and Belgium. In total, 4,031 pork consumers responded on an online interview. The data is weighted per country to reflect the demographics of pork consumers in terms of age, gender and education. Key questions pertained to the awareness and acceptance of the method of castration (measured on a 7-point scale from 1=‘completely unacceptable’ to 7=‘completely acceptable’), and the preference of the vaccine method relative to physical castration (measured on a 7-point scale from 1= ‘strongly prefer physical castration’; 4= ‘neutral’; 7= ‘strongly prefer the vaccine method’). Participants were informed about boar taint, physical castration with anesthesia, and the vaccine method after some introductory questions.

Results
Significantly higher acceptance scores were reported for the vaccine method (μ=5.38, SD=1.61) versus physical castration with anesthesia (μ=3.74, SD=1.74). Acceptance scores increased from Germany, over France and Belgium, to the Netherlands. About 70% preferred the vaccine method over physical castration with anesthesia; another 20% reported a neutral position. When informed about the two methods, 45% of the pork consumers intended to seek out pork produced using the vaccine method, while 33% indicated to intend avoiding pork produced using physical castration. Three distinct market segments were identified based on importance attached to pork taste, price, health, animal welfare and environmental issues. The largest segment (59.2%; relatively higher share of females and >55 years) reported a strong interest in ethical attributes and production method, along with interest in price, taste and health. Another segment (21.6%; relatively higher shares of heavy pork consumers, males, <35 years, lower income, Dutch) focused mainly on price. The third segment (19.2%; relatively higher shares of males, French and Germans) scored in between the previous segments on most attributes. The ethics oriented segment reported a lower confidence in the efficacy of physical castration, while the reported confidence levels that the vaccine method will avoid boar taint were similar across all segments. The two largest segments strongly rejected physical castration, while all three segments preferred the vaccine method to the same high degree.

Discussion
This cross-country study shows that uncertainties with respect to EU consumer acceptance of the vaccine method are void. A vast majority of pork consumers accept the vaccine method and strongly prefer this method over physical castration with anesthesia. The finding that confidence, acceptance and preference for the vaccine method do not differ between pork market segments indicates that the adoption of this method is unlikely to result in loss of any particular target market.

Effects of GnRH down-regulation using deslorelin (Suprelorin®) on sexual function in boars

Johannes Kauffold1 Hartmut Rohrmann2 Julia Boehm3 Axel Wehrend3
1. Department of Clinical Studies - New Bolton Center, School of Veterinary Medicine, University of Pennsylvania, Kennett Square, PA, USA; 2. Rohrmann Affiliation, Rövershagen, Germany; 3. Clinic for Obstetrics, Gynecology and Andrology of Large and Small Animals, Faculty of Veterinary Medicine, Justus-Liebig-University, Giessen, Germany

Introduction
Immunization against GnRH has been proven effective for boar taint removal [1], and long term treatment with GnRH analogues has been shown to down-regulate GnRH and to suppress GnRH dependent reproductive processes in several species [2]. This study was conducted to down-regulate GnRH in boars using Suprelorin® which is an implant that contains 4.7 mg of the GnRH analogue deslorelin, and to test the effects on sexual function.

Materials and Methods
Five boars had the implant inserted intramuscularly at the age of 5 weeks and the effects studied until market age at 26-27 weeks. Surgically castrated (n = 4) and intact boars (n = 3) served as controls. Parameters assessed included health, testes growth and libido. Boars were trained to mount the dummy at the age of 180 days, and if mounted, were collected 3-6 times for semen analysis. Animals were bled twice at the age of 26 and 27 weeks, and serum analyzed for the concentration of testosterone, estrone, estrone sulphate and estradiol 17β, respectively. All intact and implanted animals were surgically castrated at the end of the experiment and the testes as well as the epididymides subjected to histological evaluation.

Results
None of the boars that received the implant exhibited negative effects on general health or local reactions at the site of implant insertion. Four out of the 5 boars with the implant had only marginal testicular growth (Figure 1). These 4 boars did not show libido and did not mount, had low or undetectable concentrations of steroid hormones similar to what was observed in surgical castrates, and histological evidence of a ceased spermatogenesis. In the remaining fifth boar (#9), the testes started to grow around week 17 (Figure 1). Steroid hormone concentrations were as high as in intact boars or higher. This boar also showed libido and could be collected; however, semen quality was bad for the first three ejaculates but then improved, reaching normality with the sixth ejaculate at the age of 34 weeks.

Figure 1. Mean (± SD) testis length. Boars that received Suprelorin® had either marginal (n = 4; open squares) or distinct testis growth (boar #9; triangles). Non-treated intact boars (n = 3; diamonds) tripled their testis size. Their testes were bigger than of boars with the implant (except boar #9; P < 0.05–0.0001).

Discussion
This study has shown that, if five week old boars were treated with the implant Suprelorin® containing 4.7 mg of the GnRH analogue deslorelin in order to down-regulate GnRH, the testes only grow marginally and both the spermatogenesis as well as the steroidogenesis is inhibited. This is similar to what has been observed in male dogs [2]. Since these effects can last for an extended period up to the boars’ market age, GnRH down-regulation, as carried out in this study, may have potential for boar taint removal. However, since the effect does not seem to be sustained consistently in all boars, treatment may need to be refined.

Effects of Ractopamine Hydrochloride on growth performance of Barrows, entire boars and boars vaccinated with Improvac™

Glauber S. Machado1 Luiz G. Peroni3 Sheerin Mathur1 Vickie L. King1 John P. Crane1
1. Pfizer Animal Health, Kalamazoo, MI, USA; 2. Integriol Soluções em Produção Animal Ltda., Patos de Minas, MG, Brazil;
3. Perdigão Agroindustrial Ltda, Patos de Minas, MG, Brazil

Introduction

Ractopamine (RH) is a β-adrenoceptor agonist known to enhance weight gain, leanness and feed efficiency in both barrows and gilts (1,2). Barrows (physical castrates) are known to consume more feed, grow slower, and to have proportionally more fat compared to boars (3). An alternative to physical castration for the control of boar taint is vaccination against GnRF (also known as immunological castration) (4). Compared with barrows, boars that are raised with the use of vaccination are leaner and have better feed efficiency (5). The goal of the present study was to evaluate possible interactions between vaccination against GnRF and the use of ractopamine in finishing pigs.

Materials and methods

A total of 360 healthy crossbred Landrace x Large-White pigs from DanBred genetics were randomly allocated to one of six treatments, soon after birth. The study had a randomized complete block design with sub-sampling, with body weight being the blocking factor. Treatments were arranged in a 3x2 factorial design: T1 (barrows + saline), T2 (barrows + RH + saline), T3 (vaccinated boars), T4 (vaccinated boars + RH), T5 (boars + RH + saline) and T6 (boars + saline). Vaccination was performed using Improvac™ (Pfizer Animal Health) which was administered as two subcutaneous injections in the neck at 15 and 19 weeks of age. Day 0 was defined as the day when pigs were moved to the grower facility (approximately 9 weeks of age). Slaughter took place on Day 98 at approximately 23 weeks of age. The use of RH was in accordance with label recommendations, i.e., 5 ppm in-feed during the last 28 days before slaughter. All animals were fed ad-libitum and weighed at 9, 15, 19, 21 and 23 weeks of age. Feed disappearance was measured daily. Diets fed during the last 28 days had 18% Crude Protein (CP) and 1,0% total Lysine for treatments T2 to T6, while the diet used for T1 had 15% CP and 0,8% total Lysine.

Results

Following the second vaccination with Improvac, vaccinated animals showed higher feed intake (p<0,05). In this same period, T4 (Improvac + RH) had significantly higher daily gain than all other groups, being 18,6% higher than T2 (barrows + RH + saline) and 8,5% higher than T3 (Improvac only). During this period, the addition of RH to the diet improved feed conversion of vaccinated boars by 12,2%.

Analyzing the complete trial period (Day 0-98), entire boars were the most feed efficient (Table 1), but presented substantial incidence of boar taint at slaughter. Taking only vaccinated pigs and barrows (T1 to T4), the Improvac + RH group (T4) had significantly better feed efficiency than the others (p<0,05). The administration of RH to Improvac vaccinated boars (T4) improved feed conversion by 4,3% when compared to Improvac alone (p=0,018). The use of Improvac and RH together improved feed efficiency by 6,9% (p=0,0007) when compared to barrows given RH (T2).

Treatments that share the same letter are not significantly different from each other at alpha=0.05

Discussion/Conclusions

The addition of RH to the diet significantly improved feed efficiency of Improvac vaccinated pigs, when compared to pigs given Improvac alone. Besides that, the addition of RH during the last 28 days before slaughter produced similar qualitative effects in barrows, Improvac vaccinated pigs and entire boars, as described by a previous study (6). Comparing only the treatments which produced non-tainted meat, T4 (Improvac vaccinated boars + RH) resulted in the best feed efficiency.

Evaluation of the performance benefits from using Improvac™ in intact male pigs raised according to Canadian (Quebec) standards

Christian Klopfenstein1 Sheerin Mathur1 Vickie L. King1 Josee Daigneault1
1. Pfizer Animal Health, Kalamazoo, MI, USA; 2. Centre de développement du porc du Québec, Québec, QC, Canada

Introduction
Since the meat of boars is often tainted with an unpleasant odor, most countries of the world castrate pigs at a young age. However, as well as being a welfare concern, physical castration of young pigs impairs growth performance. Improvac is a novel immunological product which induces male pigs to develop antibodies to GnRF, consequently blocking testicular steroid synthesis and subsequent boar taint production prior to slaughter.1 Improvac is injected in the late stage of the grower-finisher period, and permits improved growth performance by retaining the advantages of intact males over most of the pig’s life.1-2 The objective of this study was to evaluate the production benefits of using Improvac in male pigs raised under Canadian (Quebec) standards.

Materials and Methods
Animals and trial design: Male pigs from 4 high health commercial farrowing units from 4 different genetic lines (one per farm) were blocked by litter and randomly allocated to 2 treatment groups: 1. 126 were physically castrated at 4 days of age; 2. 126 dosed with Improvac (the second 2 mL dose given at least 4 weeks after the first dose and at least 4 weeks before slaughter). After weaning at 22 days of age, pigs were transferred to the research unit. Treatment groups were not commingled. During the trial period, pigs were tended according to the guidelines and principles outlined by the Canadian Council on animal care.

Growth performance: Pigs were individually weighed on Days 0 (23 days of age), 41 (1st dose and transfer to grower-finisher), 71, 99 (3 days after 2nd dose in heavy pigs), 112 (2 days after 2nd dose in light pigs), and Days 123, 130, 137 and 144 (1st, 2nd, 3rd and 4th shipments to slaughter days). All pigs were fed ad libitum with feed rations meeting boar nutritional requirements. All the groups received the same rations during the same period. Feed consumption was recorded by pen.

Serology: Blood samples taken 1 day before second injection and 5 days before slaughter were assayed for anti-GnRF antibodies.

Behavior: Behavior assessment occurred 16–17 days post 2nd dose (aggression, mounting, physical appearance).

Carcass assessment: Carcass quality was assessed by measurement of hot carcass weight, carcass yield, back fat thickness, lean yield, loin eye area, leg, loin, shoulder and belly yields, 24 hour loin and leg pH, loin drip loss, ham yield and loin and leg Minolta color.

Statistical analysis: Data were analyzed using a general linear mixed model for repeated measures or for a single time point as appropriate.

Results

Growth performance: The mean live bodyweight at slaughter of Improvac pigs was significantly higher than for physically castrated pigs (P <0.05). Other growth data are given in Table 1.

Serology: The mean anti-GnRF antibody level at slaughter was significantly higher for the Improvac pigs than for the physically castrated pigs (P <0.05).

Behavior: None of the Improvac pigs showed any signs of boar behavior post 2nd dose.

Carcass assessment: Improvac pigs had significantly lower carcass and belly yields than physically castrated pigs (P <0.05). However, shoulder and ham yields were higher for the Improvac group (P <0.05). No significant differences were observed for any other parameter.

Discussion
The results indicate that male pigs injected with Improvac developed a strong immune response to GnRF. The Improvac pigs had significantly better growth (live bodyweight, average daily gain, feed conversion) than physically castrated pigs without any effect on carcass quality.

Conclusion
The use of Improvac can allow productivity benefits in intact male pigs raised under Canadian standards without affecting carcass quality.

Histomorphology of testes and epididymides of unvaccinated and Improvac® vaccinated slaughter boars

Friedrich Schmoll1, 3 Franz Schachinger2 Sabine Kölle2
1. Large Animal Clinic for Internal Medicine, Leipzig, Germany; 2. Institute of Anatomy, Histology and Embryology, VetmedUni, Vienna, Austria; 3. Institute for Veterinary Public Health, VetmedUni, Vienna, Austria

Introduction
Active immunization against gonadotropin-releasing factor using a GnRF analogue-protein conjugate, (Improvac®) is an alternative to surgical castration. Usually, vaccination is recommended twice, at least 4 weeks apart, with the second injection given 4–6 weeks before slaughter (1). Studies suggest that the immune response is temporary. In pigs kept longer than 7–8 weeks after the second dose, anti-GnRF antibodies may decline below effective levels, allowing return of testicular function and the risk of boar taint accumulation. Therefore, the timing of vaccination in the fattening period is of high practical relevance.

The objective of this study was to evaluate testes and epididymides size and morphology as well as boar taint in intact and Improvac vaccinated boars receiving the 2nd vaccination either 6 or 10 weeks prior to slaughter.

Materials and Methods
From a typical Austrian swine unit, 22 and 28 Improvac vaccinated males, receiving the 2nd vaccination 6 and 10 weeks prior to slaughter, respectively (2) were investigated. 17 intact boars were included as control animals. Testes and epididymides were collected at slaughter and measured (maximum length, width) using a calliper and all carcasses were organoleptically assessed (2). For histological evaluation, 1 × 1 cm pieces of testis and epididymidis were cut out, fixed, sectioned and stained with hematoxylin-eosin.

Results
Testes with and without adjacent epididymides were smallest in the group of the animals that were vaccinated 10 weeks before slaughter, followed by animals vaccinated 6 weeks before slaughter, and biggest in intact boars (table 1). Carcass weight and age of the animals at slaughter are shown in table 1.

In the epididymides of all vaccinated boars no sperm was visible. In the major part of the Ductus the stereocilia were completely eliminated. Whereas secretion was completely absent in boars vaccinated 6 weeks prior to slaughter, it was present in boars vaccinated 10 weeks before slaughter.

Discussion
Boar taint was completely eliminated in animals receiving the 2nd Improvac dose 6 weeks or 10 weeks prior to slaughter. Vaccination induced a complete inhibition of testicular function. However, the effects of vaccination seem to be reversible, since animals started to restore testicular and epidydimal function at week 10 after second vaccination.

**Introduction**

Electronic sow feeding (ESF) is a common feeding principle for group-housed gestating sows. With ESF it is possible to feed the sows individually and to check if the sows have been given their entire ration of feed. Studies have demonstrated that individual feeding of sows – particularly in the implantation period – is essential for satisfactory production results (1).

Pig houses with ESF often house large dynamic groups, which can make it difficult to supervise the individual animals. It is therefore necessary to have a tool that can provide the staff with information on sows with deviant behaviour, such as heat or disease.

**Materials and Methods**

In a one-year period in 5 production herds, data was compiled on the sows’ use of the feeding stations, heat and health problems and production data.

The pens were equipped with large nesting boxes with bedding and slatted floor in the activity area. The sows were transferred to group-housing after service. There were 65-80 sows per feeding station. Every 14 days, a technician from Pig Research Centre visited the herds.

**Results**

3.3 million observations/visits to the feeding stations were compiled corresponding to data from 18,300 cycles/sows.

- **Visits to the feeding station**
  Regardless of the sow’s age, the daily feed ration was eaten in one visit – typically the first. Gilts and young sows tended to have more visits to an empty feeder compared with older sows. This is most likely related to hierarchy.

- **Time of visit to feeding station**
  During the first 14 hours of the feed day, there was an even number of visits to the feeding stations. The sows had finished eating after approx. 19 hours. As the sows ate their feed ration, the frequency of unsuccessful visits to the feeding stations increased. Visits to the feeding station may have a facilitating effect on other sows in the group. Consequently, it must be expected that fewer unsuccessful visits reduce activity in the pen and thereby the risk of aggressive behaviour by the stations.

- **Choice of feeding station**
  Generally, the sows did not switch feeding stations from day to day in terms of feed visits. They stayed “loyal” to the feeding station they had chosen. In terms of unsuccessful visits, they were less “loyal” and used several feeding stations.

- **Number of sows per feeding station**
  More sows failed to eat their ration when there were more than 65 sows per feeding station.

- **Heat and health problems**
  A correlation was observed between changes in feeding time and heat. The sensitivity expressing the percentage of detected observations related to the “true” number of observations was 0.58-0.75. Unfortunately, the error rate (false alarms) was high, but can probably be reduced if surveillance was only made around expected heat.

The correlation between changes in feeding time and health problems only showed a low sensitivity, but can probably be improved by including information on sows’ temperature and movement patterns (2)(3).

**Discussion**

More knowledge on sows’ use of feeding stations coupled with more knowledge on sows’ movement patterns and the use of GPS systems will give pig producers greater opportunities for detecting sows with deviant behaviour.

Effects of losing body condition scores during lactating period on blood concentrations of glucose, urea nitrogen and non-esterified fatty acid in sows

Teera Rukkwamsuk; Supatee Kitkha; Pariwat Poolperm; Preeyaphan Udomprasert
Kasetsart University, Nakornpathom, Thailand

Introduction
The sows required higher energy during lactation for milk production. (1) At least 70% of energy requirement (2) and 90% of absorbed amino acids (3) needed for mammary growth and milk synthesis. Therefore, excessive mobilization of body reserved may occur if the sows inadequately intake nutrients, which resulting in poor lactation performance and infertility problems (4, 5)

Body condition scoring, body weight loss during lactation can be practically evaluated. It is interesting to investigate if the loss of body condition score (BCS) observed on a farm can be monitored by using blood metabolites. The aim of this study wanted to compare the concentration of glucose, non-esterified fatty acid (NEFA) and blood urea nitrogen (BUN) between the sows losing ≥ 1 point of condition score and the sows losing < 1 point of condition score.

Materials and Methods
The study was conducted in a 1,000 sows farm with an opened system and traditional 2 site production during May – July 2009. Individual sow was given a BCS on farrowing day and weaning day and then categorized into two groups, based on the difference of BCS at weaning and farrowing date, for BCS loss < 1 groups (group1) and BCS loss ≥ 1(group 2).

A total of 70 cross-bred sows with parity average of 2.8 were randomly selected. Blood samples were collected at 84 days of gestation, 2-3 days after farrowing and 1-2 days before weaning to evaluate the concentration of glucose, NEFA and BUN by using enzymatic spectrophotometry. Two-Sample t Test and correlation analysis were used for data analysis.

The gestation and lactation diet were formulated, based on broken rice, rice bran, soybean meal vitamin and mineral pre-mixes, to contain 14.02% CP, 3,075 Kcal/kg ME and 0.85% Lys. and 18.1% CP, 3,300 Kcal/kg ME and 1.12% Lys, respectively.

Results
The concentration of glucose and NEFA between the sows in group 1 and the sows in group 2 were not different. However, the concentration of BUN in group 1 was lower than those of group 2 (p = 0.004 and 0.030 respectively) (Table 1).

Table 1 Blood glucose, BUN and NEFA concentrations during pregnancy, weaning and farrowing between 2 different BCS loss during lactating groups (Mean ± SEM).

Discussion
BCS loss could reflect a negative energy balance condition of sows during lactation period. Sows in group1 had less BCS loss than sows in group 2, and had higher serum BUN during lactation. The increased BUN might be caused by increased protein intake (6). In this study, sows having less BCS loss may have higher feed intake, consequently enhanced metabolism of protein which led to increased BUN.

Prevalence of lameness in farrowing and weaned gilts and sows in Ontario commercial hog operations

Paisley Canning1, 2 Tim Blackwell2
1. Animal Health Laboratory, University of Guelph, Guelph, ON, Canada; 2. Veterinary Science and Policy, Ontario Ministry of Agriculture, Food and Rural Affairs, Elora, ON, Canada

Introduction
Lameness is a welfare and economic concern in hog production. Lame sows and gilts require treatment or removal from the herd. Early culling of sows is an economic cost for a hog producer. Lame sows are 1.7 times more likely than non-lame sows to be removed from a herd within 350 days of initial lameness assessment (Anil 2009). In 2007, American commercial herds participating in the PigCHAMP datashare program reported locomotor disorders including lameness and down sows as the reason for 14.5% of removals (Engblom 2009). Lame sows may also have poor reproductive performance including reduced number of pigs born alive compared to non-lame sows (Anil 2009). If lameness persists in a herd, it becomes a serious welfare issue and correcting it may require expensive modifications of housing areas. The prevalence and severity of lameness in gilts and sows has not been well documented. In the United Kingdom, the prevalence of abnormal gait in pregnant gilts and sows is 14.4% and 16.9% respectively but corresponding data for Ontario has not been collected (Kilbride 2009). To address this, the Ontario Ministry of Agriculture, Food and Rural Affairs has undertaken a surveillance project to determine the prevalence and severity of sow lameness on Ontario hog farms.

Materials and Methods
A scoring system was devised to score a sow or gilt’s gait based on three categories: no lameness, mildly lame and clearly lame. To apply this scoring method, as sows and gilts enter and exit the farrowing room(s), they are scored a 0 (no lameness), 1 (mildly lame) or 2 (clearly lame). The scoring system focuses on the gait of the sow or gilt and does not ask the evaluator to identify the cause of lameness, if observed in the animal. A lameness scoring video was created that provides a tutorial on using this 0, 1, 2 scoring system. The video is available from P. Canning (email address: canninp@gmail.com) and it helps standardize how producers score lameness on their farm. A survey form has been created for use with Episurveyor® on a Nokia 8086 and e71 cellular phones that asks producers to evaluate the soundness of sows and gilts as they move into and out of farrowing rooms each week, based on the 0, 1, 2 system. If a sow or gilt is scored mildly lame (1) and clearly lame (2), her ID tag number is recorded to track changes in her lameness score over the course of the study. Producers complete the survey on the cell phone and then send in the data to an internet-based server for analysis each week. Participants may also email, fax or mail in a paper copy of the lameness survey. On each farm, the study will continue for at least six months.

Results
Currently we are receiving weekly data from six hog operations in southwestern Ontario. Participants indicated that they found the 0, 1, 2 system and scoring video easy to understand and apply. Data has been collected on 1932 sows entering farrowing rooms and 1910 sows leaving the farrowing rooms. During the study period, 14 sows have died in the farrowing rooms for reasons unrelated to lameness. Below is a summary table of average prevalence data for enrolled herds.

</tr>
<tr>
<td>Score 2: clearly lame</td>
<td>0.49%</td>
<td>0.00% - 1.61%</td>
</tr>
</tbody>
</table>

Discussion
The prevalence of lameness in gilts and sows in the six study farms is low. All herds experience some level of mild lameness, and a lower prevalence of clearly lame females. Comparatively, prevalence of abnormal gait in the U.K. for gilts and sows is 14.4% and 16.9% respectively (Engblom 2009). Although the scoring method used in this study differs from the 0, 1, 2 system applied here, these results could indicate that in Ontario, lameness prevalence is comparatively low.

Production performance among lactating loose housed Norwegian hybrid sows: Feed consumption, weight loss, litter gain and the effect of extra water access

Signe Lovise Thingnes1,2 Ann Helen Gaustad1 Tore Framstad2
1. Norsvin, Hamar, Norway; 2. Norwegian School of Veterinary Science, Oslo, Norway

Introduction

Farrowing crates for lactating sows have been prohibited in Norway since 2003. The Norwegian Landrace/Yorkshire (LY) sow is a highly productive sow that performs well under loose housed conditions, but factors such as parity number and water access can influence this performance. Leibbrandt (1989) found that limiting the water access to lactating sows led to reduced feed intake and the catabolism of body reserves to maintain milk production. The objective of this trial was to investigate the effect of parity number and extra water access on the sows’ feed consumption, weight loss and production (in terms of litter gain) during lactation.

Materials and Methods

Data were obtained from 50 dry fed loose housed Norwegian LY sows from a commercial swine herd. Sows were fed using a pelleted lactation feed containing 9.86 MJ NE/kg feed and 8.26g Lysin/kg feed. 25 sows were placed in pens with access to water only through drinking nipples in the rear part of the pen; and 25 sows had water access in the trough in addition to the water nipples. Sows were randomly distributed to the pens, but first and second parity sows were evenly distributed between the two treatments. Within 12-36 hours after parturition (day 1) number of liveborn piglets was recorded along with litter weight and weight of the sow. Sow and litter were weighed again on day 19, and the day before weaning and day of weaning, respectively. Daily feed consumption of the sows was recorded, and piglets were given access to creep feed from week two. The data was analysed using Proc GLM in SAS 9.1 2003 edition. One sow was emitted from the study due to abortion. Fixed effects included parity number and water strategy. Length of lactation was used as a covariate. Weight loss was corrected for weight at day 1.

Results

The average weight on day 1 for 1st parity sows was 223.3 ± 21.5 kg, for 2nd parity sows 259.5 ± 22.0 kg and older sows 279.8 ± 24.4 kg. Average number of weaned piglets was 11.2 ± 1.0 for 1st parity, 11.9 ± 1.5 for 2nd parity and 11.7 ± 1.7 for older sows. Average length of lactation regardless of parity number and treatment was 31.7 days. Piglet mortality (not including still-births) was 8.2%.

Discussion

1st parity sows eat less (p<0.0001), loose more weight (p=0.02) and have a lower litter gain (p<0.0001) during lactation, than 2nd parity and elder sows. This suggests a lower feed intake capacity in gilts than elder sows, and that one should be cautious not to overexert the sows during their first parity. Water access in the feed trough could not be shown to significantly affect the feed consumption and weight loss of the sows, nor did it affect the litter gain, although a numerical trend was present at weaning. The lack of a statistical difference in litter gain could be due to the limited number of sows in this trial.

A tool to assess the economic impact of pleurisy in slaughter pigs
Henrike J. Jager1,2, TJ McKinley1, James L. Wood1, Gareth P. Pearce1, Susanna M. Williamson2, Nicholas Woodger2, Benjamin Strugnell3, Stanley H. Done3, Henrike Habernoll5, Alexander W. Tucker1

Introduction: Pleurisy is an easily detectable indicator of poor respiratory health in pigs at slaughter and is a common reason for carcase trimming and rejection. Although prevalence in the UK was estimated, at individual pig level, to be around 12.5% for the period 2005-2009, surveillance data shows that for the same period around 87% of all assessed slaughter consignments (18,648) were affected by pleurisy to some extent, with 38% of assessed batches recording pleurisy prevalence at >10% (BPEX Pig Health Scheme). Recent work by Wellenberg et al (2010) proposed a 4 Euros cost per finisher in batches experiencing at >10% prevalence, based on reduced daily live weight gain. Here we report the development of an economic tool for estimation of pleurisy associated costs based on average age at slaughter and post-trimming carcase weights. As part of the development we investigated the importance of recording pleurisy severity in addition to prevalence within the batch. Understanding the economic impact of pleurisy is essential to assist producers in justifying implementation of expensive disease control methods (e.g. all-in all-out production).

Materials and Methods: Correlation between pleurisy severity and individual carcase weight: 30 batches of slaughter pigs from grow to finish management systems were recruited over a 9 month period at a single abattoir and 40-50 pigs were assessed in each batch (a total of 1366 pigs). The presence and severity of pleurisy in each of the assessed pigs was scored as 0 (no pleurisy), 1 (visceral pleurisy), 2 (parietal pleurisy <25% of dorsolateral (DL) surface area, 3 (parietal pleurisy 25 – 50% of DL surface area), 4 (parietal pleurisy >50% of DL surface area). Mean post-trimming carcase weights were calculated for pigs affected by pleurisy of increasing severity using a multiple regression model (adjusted for the different mean weight in each batch using a zero-mean batch-level random effect).

Batch level correlation between pleurisy prevalence and on-farm performance: Eighty batches of slaughter pigs were recruited (a total of 96687 pigs in batches ranging from 198 – 4671 pigs). Three different integrators (each with different management systems) were represented including continuous flow (15 batches), wean to finish all-in all-out (35 batches) and grow to finish (30 batches). Performance data including average batch level post-trimming carcase weight (kg) and average batch level age at slaughter (days) were recorded. One consignment of each batch was randomly selected for pathology assessment at slaughter with 50 pigs being assessed for the prevalence of pleurisy in the representative consignment of each batch. We calculated the means and 95% confidence intervals for the effect of pleurisy prevalence on performance parameters using a multiple regression model including adjustments for an integrator-level random effect and different variance components for each integrator.

Results
Analysis of the impact of increasing severity of pleurisy on post-trimming carcase weights revealed that the main effect on carcase weight was whether a pig had any type of pleurisy rather than the severity of that pleurisy. For this reason, in the batch-level study, we focused only on pleurisy prevalence, and not severity. For the 80 batches studied, pleurisy prevalence ranged from 0% to 46%, batch mean post-trim carcase weights ranged from 71.8 – 83.1kg, and batch mean slaughter age ranged from 139 – 183d. Our model indicated that for each 1% increase in pleurisy at batch level there was a 0.07kg decrease in post-trim carcase weight (95% CI: 0.14 – 0.00 kg; p=0.04) and a 0.26d (95% CI: 0.09 – 0.44d; p=0.00) increase in mean slaughter age.

Discussion: We found that it was not necessary to record extensive information on the severity of pleurisy, beyond, simple prevalence, in order to detect a relationship between pleurisy and performance. This simple model of the impact of pleurisy on performance was based solely on UK data and different relationships might be found in other production contexts. However, based on prevailing price estimates in April 2009, it allowed us to estimate that for a pleurisy prevalence of 10% of a given batch the cost for every pig slaughtered in that batch was £2.26. At a 20% prevalence this cost increases to £4.52 per pig.

Prior colonization with an avirulent Haemophilus parasuis isolate prevents disease from a subsequent virulent challenge with a heterologous isolate

Susan L. Brockmeier; Crystal L. Loving; Michael A. Mullins; Karen B. Register; Tracy L. Nicholson
National Animal Disease Center, Ames, IA, USA

Introduction
Haemophilus parasuis causes Glasser’s disease in swine characterized by systemic invasion and bacteremia resulting in a polyserositis syndrome. H. parasuis can also cause pneumonia in swine. Disease patterns suggest that maternal antibody may protect pigs early, allowing them to be colonized without resulting disease while developing an active immune response. This is supported by studies examining the practice of exposing neonatal piglets to the predominant virulent strain on the farm as a method of prophylaxis. Reports have been mixed as to the degree of heterologous protection among strains. This may be due to relatedness of the strains, exposure to live bacteria on a mucosal surface versus bacterins given parenterally, and colonization status of the animal.

Materials and Methods
Pigs ranging in age from 5 to 10 weeks of age were obtained from an experimental barrier herd that has tested free of known swine pathogens. The pigs were distributed into 5 groups with 5 pigs per group and challenged intranasally with 10^6.5 CFU of 1 of 4 isolates of H. parasuis (29755, 12939, MN-H, and SW114), all of differing serotypes, or sham inoculated with PBS. If pigs showed signs of Glasser’s disease, they were euthanized and swabs of the respiratory tract and systemic sites were collected and cultured on Casman’s plates with added NAD. One week after challenge, a control pig was placed in with a healthy appearing survivor in 2 of the groups. Three weeks after challenge all surviving pigs were rechallenged with isolate 12939.

Results
Pigs challenged with 3 of the 4 H. parasuis strains developed signs of Glasser’s disease, including joint swelling and lameness, tremors, depression, and reluctance to move. All pigs challenged with isolate 12939 died peracutely or were euthanized due to signs of Glasser’s disease and 4 of the 5 pigs inoculated with isolates 29755 or MN-H were euthanized due to signs of Glasser’s disease between 2 and 5 days post infection. One isolate each from the 29755 and MN-H challenged groups and all pigs challenged with isolate SW114 remained healthy and showed no signs of disease throughout the experiment, but H. parasuis was isolated from nasal swabs of these pigs.

One week after challenge, one control pig was placed in with each of the survivors that had been challenged with isolate 29755 or MN-H to determine if the infected but healthy pig would transmit H. parasuis to the naïve pig and whether disease would result. Five and 7 days after placing the control pigs in with the MN-H and 29755 survivors, respectively, the contact pigs showed signs of Glasser’s disease and were euthanized and H. parasuis was isolated from systemic sites.

Three weeks after primary challenge, the 10 surviving pigs (3- control pigs, 5- SW114 pigs, 1- 29755 pig, and 1- MN-H pig) were all rechallenged intranasally with the 12939 isolate of H. parasuis. All control pigs were euthanized between 1 and 3 days post-challenge due to signs of Glasser’s disease. Gross pathology findings and culture results were similar to those obtained from the pigs originally challenged with this isolate. The 2 pigs previously inoculated with isolates 29755 or MN-H and the 5 pigs previously inoculated with SW114 remained healthy. These pigs were euthanized 10 days after secondary challenge, and no grossly visible lesions were noted. H. parasuis was isolated from the nasal cavity of 3 of these pigs and the lung of 1 of the pigs.

Discussion
Pigs from an experimental herd that is free from known swine pathogens were used in a study with several H. parasuis isolates in an effort to identify isolates of varying virulence. Three of the isolates caused systemic disease, with pigs showing signs of disease from 1 to 5 days post infection. One isolate, SW114, caused no observable clinical signs; however, H. parasuis was isolated from nasal swabs from these pigs indicating they were colonized. The MN-H and 29755 survivors were able to directly transmit H. parasuis to naïve pigs which became ill with signs of Glasser’s disease. The pigs colonized with SW114 were protected from challenge with a heterologous virulent strain. Thus, pigs within susceptible groups can remain healthy and serve as reservoirs for transmission, and heterologous protection using avirulent isolates is possible.

**Avirulent live Haemophilus parasuis vaccine induces cross-serotype immunity**

Russ Bey\(^1,2\) Jon Mahlberg\(^1\) Mark Titus\(^1\) Randy Simonson\(^1\) Doug Stine\(^1\) Simone Oliviera\(^2\)

1. Newport Laboratories, Worthington, MN, USA; 2. University of Minnesota, St. Paul, MN, USA

**Introduction**

*Haemophilus parasuis* is the causative agent of Glässer’s Disease, a primary problem for swine producers worldwide (1).

The National Animal Health Monitoring Service reports a sharp increased incidence of *H. parasuis* in U.S. swine herds from 2000-2006 (2). The incidence in nursery pigs has risen from 7.3% to 17.4%, and it has risen in grower/finisher pigs from 5.4% to 18.7%.

Fifteen serovars of *H. parasuis* have been defined. This diversity makes it difficult for the current commercial inactivated bacterins to provide cross-serotype protection. This lack of cross-serotype protection led to the development of an avirulent live culture vaccine that is able to induce cross immunity for multiple serotypes.

**Materials and Methods**

An avirulent live culture *H. parasuis* vaccine was developed and evaluated for efficacy in susceptible pigs. Pigs 17-21 days of age were divided into two groups. One group was immunized once with the avirulent live culture vaccine; the control group received a placebo. All animals were challenged with virulent serotype 5.

In a second study, three groups of susceptible pigs were vaccinated once with the live culture vaccine, while three other groups received a placebo. Animals were challenged with virulent *H. parasuis* serotype 4, 5, or 13.

In a third study, animals receiving oral antibiotic treatment (Carbadox or Denagard/chlortetracycline) were placed on the antibiotic seven days prior to vaccination. Two additional groups of pigs received either Draxxin or Excede one day prior to vaccination. Five weeks following vaccination, all animals were challenged with *H. parasuis* serotype 5.

In these studies, pigs were observed daily for mortality and clinical signs of disease. Average daily gain was also determined.

**Results**

In these studies a typical, highly lethal Glässer’s Disease was induced by experimental challenge of susceptible commercial pigs. A significant number (p< 0.05) of vaccinated animals were protected from death. Arthritis was significantly lower in vaccinated animals, as was the average total number of gross lesions. Seventy-five percent of animals receiving the placebo vaccine died.

The average daily gain in vaccinated animals ranged from 0.99 to 1.65 lbs/day, compared to -2.34 lbs/day for surviving controls. No vaccinated animals had a fever following challenge.

Antibiotic treatment did not interfere with the efficacy of the vaccine, as >90% of immunized animals were protected from death and lesions typical of *H. parasuis* infection. The mortality rate in those animals receiving the placebo was 80%.

**Discussion**

A significant number of commercial pigs given ParaSail (the first avirulent live culture *Haemophilus parasuis* vaccine) were protected against experimental infection with *H. parasuis* serotypes 4, 5, and 13. Immunized animals had reduced mortality and gross lesions as well as increased average daily gain compared to sham inoculated animals. These results suggest that the live vaccine expressed a wide variety of outer membrane proteins, which are thought to be required for the induction of cross-protective immunity (3,4).

Gene expression profiling in the lung of pigs with different susceptibilities to Glässer’s disease

Jamie M. Wilkinson1, 4 Carole A. Sargent2 Lucina Galina-Pantoja3, 5 Alexander W. Tucker1
1. Department of Veterinary Medicine, University of Cambridge, Cambridge, UK; 2. Department of Pathology, University of Cambridge, Cambridge, UK; 3. Pig Improvement Company, Hendersonville, TN, USA; 4. Department of Agricultural, Food, and Nutritional Science, University of Alberta, Edmonton, AB, Canada; 5. Pfizer Animal Health, New York, NY, USA

Introduction

Glässer’s disease is caused by the bacterium Haemophilus parasuis. Several commercial vaccines are available but none of these protects against all pathogenic strains. This is good justification to attempt the identification of genetic factors that affect susceptibility to this disease and utilize them in marker assisted selective breeding schemes. Previously, statistical differences in the severity of Glässer’s disease in the offspring of different boars were observed, indicating a genetic component to susceptibility1. This project used microarrays to look for gene expression differences in the lung tissue of animals exhibiting different susceptibilities to Glässer’s disease.

Materials and Methods

Offspring of 6 boars from a Landrace-Duroc breed cross were decontaminated, screened as free from H. parasuis, and reared without maternal colostrum in an isolation facility. Animals were inoculated at 21 days with a pathogenic strain of H. parasuis serovar 5 (strain 29755). Controls were mock-inoculated with saline. Pigs were scored for clinical signs of the disease by observation. Approximately equal numbers of pigs were euthanized at 24, 48 and 72 hours post inoculation. At necropsy, animals were scored for the severity of lesions at affected sites and lung tissue samples stored in RNA Later (Ambion). In total, samples were obtained from 129 inoculated and 29 control animals1. The scores were used to classify animals into different susceptibility categories, and pigs from the two categories which exhibited the largest difference in susceptibility (‘Fully Resistant’ (FR) and ‘Susceptible’) were chosen for gene expression profiling by microarray.

RNA was isolated from lung samples of individual ‘FR’ and ‘Susceptible’ animals (n = 6) at two different time-points (24 and 72 hours), and from pools of ‘Control’ animals matched for sire and time-point. This was reverse transcribed into cDNA and amplified using the SMART-PCR system (BD Biosciences). The products were labelled with fluorescent Cy-3 or Cy-5 conjugated nucleotides and hybridized to pig oligonucleotide arrays (Operon). Labelled cDNA from individual ‘FR’ or ‘Susceptible’ pigs was hybridized to a reference sample from the pool of mock-inoculated ‘Control’ animals. After hybridization, the arrays were washed to remove non-specific signal and scanned on an Axon A4100 scanner. Signal intensities were quantified using Bluefuse software and differentially expressed (DE) genes were identified using the programme ‘limma’.

Results

Lists of DE genes produced by the analysis were used to identify the subsets of genes that were differentially expressed in ‘FR’ compared to both ‘Control’ and ‘Susceptible’ animals (the ‘FR’ gene expression profile) and in ‘Susceptible’ compared to both ‘FR’ and ‘Control’ animals (the ‘Susceptible’ expression profile) at both time-points. These genes were of most interest as they were potentially regulated differently in response to H. parasuis in ‘FR’ and ‘Susceptible’ animals. The expression profile of the ‘FR’ pigs contained 21 and 22 genes at 24 and 72 hours respectively. The expression profile of the ‘Susceptible’ animals contained 58 and 347 genes respectively.

Discussion

‘FR’ animals at 24 hours exhibited an increased expression of genes encoding extracellular matrix components, possibly indicative of tissue repair following the successful early resolution of infection. The gene expression profile of ‘FR’ animals at 72 hours supported the hypothesis that higher levels of antibacterial activity could have been responsible for the ‘FR’ phenotype, possibly due to an increase in the production of innate ‘natural’ antibodies and decreased signalling by the immunoregulatory transcription factor peroxisome proliferator-activated gamma (PPAR-γ). The expression profile of ‘Susceptible’ animals at both time-points was characterized by an imbalance in signalling between pro and anti-inflammatory cytokines, with the pro-inflammatory cytokine genes resistin (RETN) and interleukin 1-beta (IL1B) particularly highly expressed. At 72 hours, a reduction in the expression of genes involved in antigen presentation by both MHC class I and II molecules was observed, which could have contributed to the inability of ‘Susceptible’ animals to clear infection. In conclusion, this study identified several candidate genes and pathways associated with susceptibility to H.parasuis infection.

The use of serum profiles for control of Haemophilus parasuis and Actinobacillus pleuropneumoniae

Irena Golinar Oven; Zdravko Valenčak
Veterinary Faculty, Ljubljana, Slovenia

**Introduction**

Glässer’s disease, caused by Haemophilus parasuis (HP), was once considered a sporadic disease of young pigs compromised by stress. Introduction of HP may result in systemic disease of high morbidity and mortality, affecting swine at any stage of production. HP is a contributor in the porcine respiratory disease complex (PRDC) as a predisposing agent, a secondary invader, or a primary pathogen involved in pneumonia (1).

Actinobacillus pleuropneumoniae (APP) is the etiological agent of pleuropneumonia in pigs and also the contributor in PRDC. It can cause pneumonia, clinical disease, or subclinical disease and causes losses from death, reduced production, and increased costs of medication or vaccination (2).

Treatment of PRDC varies with each individual production unit and system. Serology can gather information on which pathogens are circulating in a herd (3). Serum profile is testing groups of pigs at specified ages to detect when seroconversion to a pathogen is occurring in the unit. The most common method is to collect samples from several age groups on a single day. A less common but more accurate method is to follow individuals over time as they grow. The purpose of this study was to prepare serum profiles for HP and APP for one large farm.

**Materials and Methods**

39 serum samples from individual animals were tested on APP (ApxIV factor) and HP. Serum samples were taken at age of 2, 4, 6, 8, 11, 14, 17, 22 and 28 weeks. Pigs were raised in large Slovenian pig farm with 6000 breeding animals. For detection of specific antibodies against APP and HP commercial ELISA kits were used: The CHEKIT-APP-ApxIV ELISA test kit (IDEXX) and Haemophilus parasuis Antibody test kit (ELISA) Swinecheckâ HPS (Biovet).

**Results**

Colostral antibodies to HP were detected only in 5.1% at age 2 weeks. We detected antibodies in 25.6% at age 11 weeks, then prevalence increased to 94.7% at age 28 weeks (Figure 1). Antibodies to APP were detected in 100% till 4 weeks, then prevalence decreased to 53.8% at age 14 weeks, and then increased to 100% at age 22 and 28 weeks (Figure 2).

**Discussion**

Farm animals were not vaccinated against HP and APP. Colostral antibodies against HP were found only in 5.1% in 2 weeks old piglets. Circulating antibodies as consequence of natural infection were detected from 11 weeks (25.6% prevalence) to 28 weeks old pigs (94.7% prevalence). Colostral antibodies against APP persisted for about almost 8 weeks (94.8% prevalence). The lowest prevalence was detected in 14 weeks old pigs (53.8%), and the highest in 22 and 28 weeks old pigs (100%).

The results can enable the best time for vaccination which is 2-3 weeks before active antibodies appear. The best time for vaccination in this farm against HP is around 8-9 and against APP around 11-14 weeks of age.

Serum profile is a method which can help create an effective specific vaccination program on farm.

Porcine genetic markers for resistance to bacterial respiratory tract infections

Doris Hoeltig1 Gerald F. Gerlach2 Karl-Heinz Waldmann1 Fugato Consortium IRAS3 Fugato consortium RePoRI3
1. Clinic for Swine and Small Ruminants, Forensic Medicine and Ambulatory Service; University of Veterinary Medicine Hanover, Foundation, Hannover, Germany; 2. IVD GmbH, Hannover, Germany; 3. University of Veterinary Medicine Hanover, Foundation, Hannover, Germany

Introduction
Respiratory tract infections are of major importance for the pig industry. One possibility of limiting the spread of respiratory tract disease may be the breeding of pigs with increased resistance to respiratory tract pathogens. Therefore the FUGATO-IRAS project and the follow-up project RePoRI work on the identification of genetic markers responsible for an increased resistance towards Actinobacillus (A.) pleuropneumoniae infection.

Materials and Methods
Within IRAS 106 pigs of 4 breeding lines (German Landrace, Piétrain, Hampshire, Large White) were infected. The aerosol infection was performed using A. pleuropneumoniae serotype 7 strain AP76. Sampling (BALF, blood) and phenotyping were carried out twice (day 4 and day 20 post infection [p.inf.]). Pigs were euthanized immediately after the sampling, lung lesions were scored during necropsy by the Lung Lesions Score according to Hannan et al. (1), and lung tissue was taken. For additional phenotyping a Respiratory Health Score (2) was used. Acute phase proteins were determined (blood, BALF), glycoproteins (BALF) were analyzed via differential two-dimensional gel electrophoresis (2D-DIGE) and RNA expression was investigated using the Affymetrix GeneChip® porcine Genome Array. Additionally, a consumer study investigating the allele diversity within German pork was realised and SNPs for candidate genes, derived from known human genes, were detected and characterised.

The aim of the RePoRI-project (ongoing) is the validation of possible marker genes, the establishment of genetic markers and the modelling of the host reactions based on the IRAS results. To achieve these aims a QTL-analysis based on the F2 generation of a Hampshire (F0 male) -German Landrace (F0 female) cross, the development of a custom-buildt expression array (including candidate genes, selected ORFs of A. pleuropneumoniae and Mycoplasma hyopneumoniae) as well as pathway analysis using ConsensusPathDB and association studies by FAMHAP®-software are performed.

Results
Within IRAS there were 7 main results: 1) Severity of disease is highly dependent upon the innate immune system. 2) The Hampshire-line came out to be the most resistant and the German-Landrace-line to be the most susceptible. 3) The level of haptoglobin in blood plasma correlates with the course of disease. 4) The level of hyaluronidase in BALF increases after pathogen contact and therefore might be a possible health marker. 5) The combination of a high level of Fetuin A and a low level of Surfactant-D-protein in BALF correlates with the absence of lung lesions and therefore might a marker for breeding selection. 6) There is no depletion of allele diversity within the German pig population. 7) 1597 potential genetic markers could be detected.

Within RePoRI so far, 188 microsatellites were established and mapped and an average distance of 14,5 cM could be realised. One Pathway (Toll like receptors) of importance was detected, and within the FAMHAP®-Analysis of the genotypes there were significant differences (p<0,05) found for 7 marker loci (mainly focussing on Transferrin- and Interferon receptors) between pigs with mild and severe pleuropneumonia.

Discussion
Although these studies for experimental reasons are limited to interactions between pigs and A. pleuropneumoniae they might be an essential first step in the development of genetic markers for DNA-based breeding selection aimed at the increased resistance towards lung infections. The first candidate markers might be available for testing under production condition within the next two years. Before applying these markers for selection in breeding programmes a thorough investigation is required to avoid unwanted adverse effects on wanted traits.

Introduction

Respiratory diseases in swine are often caused by several pathogens and triggered by a multitude of other environmental and management factors1. Different kinds of lesions in the lung and the surrounding tissue lead to a multi-factorial syndrome with respiratory symptoms and poor growth described as Porcine Respiratory Disease Complex (PRDC). The aim of this study was to investigate the effects on health and performance of a tiamulin (Denagard®, Novartis Animal Health Inc.) treatment in nursery pigs suffering from PRDC.

Materials and Methods

The study was conducted at a farrow to finish farm. Piglets were vaccinated against PCV2 and Mycoplasma (M.) hyopneumoniae (two-shot). Respiratory symptoms occurred in the nursery between 8 and 12 weeks of age. 173 piglets at 9 weeks of age were randomly divided into two groups. Piglets of group TIA (n = 88) received 15 mg/kg/day tiamulin by water over 14 days. All animals of group CONT (n = 85) were left untreated. Both groups were housed in different pens within one room. All animals were weighed before treatment (day 0), at the last day of treatment (day 14) and on day 21. On day 0, 1, 2, 3, 5, 7, 9, 11, 13, 14, 15, 17, 19 and 21 a cough index was calculated for both groups. 30 piglets from each group served as sampling animals (SAs). Bronchoalveolar lavage fluid (BALF) was collected from the SAs on day 0, 14 and 21. BALF was used for bacteriological investigation (BI) of various lung pathogens and for PCR-testing to detect porcine mycoplasmas2.

Results and Discussion

In group TIA the amount of Haemophilus parasuis (HPS) isolated from BALF was significantly reduced on day 14 compared to day 0. In addition (in group TIA) the amount of α-haemolytic Streptococci was significantly reduced on day 14 compared to day 0 and M. hyorhinis was detected in significantly higher amounts on day 14 than on day 21. In group CONT only the amount of HPS was significantly higher on day 0 than on day 14 and day 21. At day 0 the amounts of all pathogenes mentioned above were higher in group TIA compared to group CONT. Actinobacillus pleuropneumoniae, M. hyosynoviae and/or β-haemolytic Streptococci were only isolated in the BI of a few SAs on day 0. All tested animals were free of those pathogens on day 14 and 21. The amount of other detected pathogenes including Pasteurella multocida and Bordetella bronchiseptica in BALF did not differ significantly between the three sampling days. The cough index measured in both groups showed an estimated decrease of 50 % after 6.1 days in group TIA and 25.9 days in group CONT, respectively. The decreasing rates differed significantly between the two groups.

The mean body weight did not differ significantly between groups on day 0 (TIA: 20.10 kg, CONT 19.22 kg). During the trial period (day 0-14/0-21) the average daily weight gain was significantly higher (p < 0.001) in group TIA (731/722 g/day) compared to group CONT (640/651 g/day).

The trial data verified the positive effect of tiamulin treatment on the health status and performance of nursery pigs suffering from PRDC. The lower pathogen burden after treatment correlated with a significantly faster reduction of the cough index and a significantly higher daily weight gain in group TIA. Treated and untreated animals were housed within one room. On one hand this might be an explanation why some positive effects could also be seen for the untreated animals (e.g. reduction of HPS). On the other hand this might have caused a constant reinfection of group TIA by the untreated animals (CONT) or other vectors, including the farmer.

Novel immunization protocols to induce systemic and respiratory antibody responses in weaned pigs

Marco A. Vega-López1 Gabriela Alvarado-Cesar2 Carmen Ramírez-Estudillo1 Roberto Martínez2 Alejandro Vargas3
1. CINVESTAV-IPN, Dept. Infectomics and Molecular Pathogenesis, México, DF, Mexico; 2. FES-Cuautitlán-UNAM, Edo. de México, Mexico; 3. CEIEEP-UNAM, Jilotepec, MEX, Mexico

Introduction
Respiratory infections are an important problem in pig industry, especially at weaning, when passive maternal immunity decays and immune maturation is still incomplete (1-2). Vaccination is a successful strategy to prevent and control these maladies; however, intramuscular administration induces solid systemic immune response but poor mucosal protection. Mucosal vaccination has no practical use since it requires high doses of antigen, bacterial toxins as adjuvants or multiple doses (3). Thus, the design of effective mucosal immunization strategies is of paramount importance to control respiratory and mucosal diseases in the young pig.

Aims
To develop novel strategies of immunization to induce systemic and mucosal immune response in weaned pigs.

Material and methods
A total of 20 four weeks-old weaned, conventionally reared healthy pigs, from an experimental farm (CEIEPP-UNAM), free of zoonotic diseases and with no vaccination protocols running, compiling with academic and federal regulations of animal care, were divided in four groups of five animals each. Animals were immunized with ovalbumin (OVA, Sigma, USA) three times, 10 days apart, by different routes as follows: subcutaneous (SC)/transcutaneous (TC)/IC (8 mg/pig each time); SC/TC/intranasal (IN) and SC/SC/IN. A SC group was inoculated with PBS and adjuvant (GIBCO) as control. Samples of serum, nasal secretion (NS) and saliva were taken on days 0, 10, 20, 27 and 57 after the first inoculation and specific anti-OVA IgG and IgA were measured by quantitative ELISA.

Results
Anti-OVA IgG: All immunization protocols induced serum response after the second inoculation, peaking at 27d (SC/TC/IN, P<0.05 & SC/TC/TC, P<0.01, Figure 1A). No IgG anti-OVA was detected in NS and saliva. Anti-OVA IgA: Again all protocols induced significant IgA response in serum after the 2nd immunization, peaking at 27d (P<0.01). The SC/TC/IN group kept significance until day 57 (P<0.001, Figure 1B). In NS the response was evident after the 3rd immunization in groups SC/TC/TC (P<0.023) and SC/SC/IN (P<0.037) and maintained differences to control until 57d (Figure 1C). All protocols induced immune response in saliva after the 2nd inoculation, with peaks at 27d in groups SC/SC/IN and SC/TC/IN (P<0.001), which kept the response until 57d (P<0.03) (Figure 1D).

Discussion
It has been reported that systemic and local immunization with live modified vaccines induces immune response in serum and mucosae (4). However, using inactivated vaccines the mucosal immune response is less successful (5). Our results show that using a combination of parenteral (SC/TC) and mucosal (IN) immunization, systemic and local specific IgG and IgA are effectively induced in weaned pigs, even when a poorly immunogenic protein is used (OVA). IN and TC immunizations were effective only with previous parenteral sensibilization (SC), suggesting that circulating memory cells are able to migrate to mucosal sites after a local challenge. These immunization protocols may provide an effective way to induce integral (systemic/mucosal) immune response in young animals to prevent diseases.

M. hyorhinis vaccine prevents mycoplasmal lesion and disease

Jung-Ah Lee1 Min-A Hwang1 Sang-Won Lee2 Jang-Hyuck Han3 Eun-Haeng Cho3 Sang-Shin Park4 Seung-Yong Park1 Chang-Seon Song1 In-Soo Choi1 Joong-Bok Lee1

Introduction

Porcine mycoplasmal pneumonia is one of well-known respiratory diseases. Mycoplasma hyorhinis is easily isolated in the upper respiratory tract and tonsil of swine unlike Mycoplasma hyopneumoniae. The ability of M. hyorhinis to cause pneumonia is unclear (1), but the pig with M. hyorhinis is simultaneously infected with porcine reproductive and respiratory syndrome virus (PRRSV). In previous study, we could find that M. hyorhinis may potentiate PRRSV-induced pneumonia in vivo. The aim of this study was to see if mycoplasmal lesion is prevented by vaccination to M. hyorhinis.

Materials and Methods

Sixteen weaned pigs free of M. hyorhinis, PRRSV and M. hyopneumoniae antibodies were randomly divided into 3 groups as shown in Table 1. 3 X 10^10 CCU of M. hyorhinis was immersed in the mixtures of oil and water with a ratio of 50:50.

Pigs in group A were intramuscularly vaccinated with M. hyorhinis vaccine. Pigs in groups B and C were received with saline. After 4 weeks, 1010 CCU/ml of the M. hyorhinis was administered through trans-trachea to pigs of groups A and B. Clinical signs of the infected pigs were observed for 4 weeks after vaccination. Sera were collected weekly. Antibody response was measured by ELISA. Animals were sacrificed 4 weeks after challenge and the macroscopic lung lesions were evaluated as described in previous study (2). We performed Mann-Whitney U test and Fisher's exact test to show the statistical differences of clinical signs and macroscopic lung lesions, and antibody responses between groups A and B by using SAS 9.2 software package (SAS Institute Inc, Cary, NC).

Results and Discussion

All pigs in group A and C showed neither any clinical signs nor mortality, but pigs in group B showed significant symptoms of respiratory disease including dyspnea, cough, fever and rough hair coat (Table 2).

Especially one of pigs in group B died of pneumonia showing typical mycoplasmal lesion on the lung, and we found more serious macroscopic lung lesions in group B than group A.

* p < 0.01, ** p < 0.001 for differences between A and B by Mann-Whitney U test

No pigs in group A developed glanuroma tissue and fever on the site of vaccination for the entire experiment period. Five pigs in group B did not develop antibodies until the end of this study, whereas only one pig showed immune response at 2 weeks after challenge and then its antibody disappeared 1 week later. However, pigs in group A showed antibody response at 2 weeks after vaccination. Those antibody titers were increased until 6 weeks after vaccination and then reached flat till end of the experiment. We found statistically significant differences from 7 weeks between groups A and B.

Figure 1. Immune responses after vaccination to M. hyorhinis

The results indicated that mycoplasma vaccine may be used to prevent mycoplasmal lesion and disease.

**Regional evaluations for PRRS in market swine**

James D. McKean

Iowa State University, Ames, IA, USA

---

**Introduction**

PRRS eradication is a future USA pork industry goal. One consideration is the prevalence and distribution of infected animals in at-risk populations. This study from Midwestern (9) and non-Midwestern (3) market swine abattoirs assists understanding of area prevalence of PRRS generally and for defined sized producers within the population. This information refines the scope of epidemiological diverse populations for PRRS. An observed difference between regions or herd sizes relative to PRRS exposure potential offers the opportunity to consider appropriate control/eradication strategies in larger groups than individual hers/sites. Two time periods were utilized to determine whether a seasonal effect on PRRS antibodies could be observed.

**Materials and Methods**

Each group of 10 or more swine (lot) at daily harvest on one shift in 12 cooperating abattoirs was sampled by USDA-APHIS-VS employees. As a convenience sample, 50-75 gm pieces of diaphragm (crus) of five carcasses per lot were obtained after evisceration, placed in whirl-pak bags and identified with lot number, date and plant number. In two shift plants, sampling rotated with each two week pay period to assure that over time most producers submitting to each plant were tested. Cooperating plants supplied lot identification, number per lot coupled to ownership information (name, mailing address and zip code) for lots daily. Such information enabled characterization of ownership and production size. A 12 week evaluation period was chosen for each sampling period to assure that low volume producers would submit multiple lots. All sampling was completed from November 2007 to October 2008. Meat juice samples were tested for each lot.

**Results**

A total of 24,890 samples from 4978 lots were tested in the two time periods of fall-early winter and winter-spring timeframes. By aggregating number of infected lots and their source characteristics it was possible to develop information about distribution and prevalence of PRRS antibodies within the general population and for selected subpopulations. Estimated annual herd production, and geographic area differences were observed for PRRS antibody prevalence. As herd size increased, irrespective of geographic location, the percentage of positive lots increased (Table 1). Plants that obtained pigs from swine-dense production areas (Midwest =9) and North Carolina (1) had substantially higher prevalence than plants (2) drawing from less dense areas (Table 2).

**Discussion**

Antibodies to PRRS are common in market swine throughout the USA. There is general acceptance that higher swine density areas results in higher prevalence for PRRS. The results outlined in this large survey would indicate an inability to demonstrate seasonality in PRRS prevalence, but show differences in annual production/producer and in regional catchment. Rates of antibody prevalence increased with each production size category over the same period confirming the impression that increased system size maintains PRRS infections. Group categories above 2001-4000 are likely to be multi-site production systems.

Use of oral fluid samples to detect PRRSV infection in individual boars

Apisit Kittawornrat1 Mark J. Engle2 Jeremy F. Johnson1 Wayne A. Chittick1 John R. Prickett1 Trevor J. Schwartz1 Daniel J. Whitney1 Chris W. Olsen1 Kent J. Schwartz1 Chong Wang4, 3 Jeffrey J. Zimmerman1

1. Iowa State University, Ames, IA, USA; 2. PIC North America, Endersonville, TN, USA; 3. Department of Statistics, Iowa State University, Ames, IA, USA; 4. Department of Veterinary Diagnostic and Production Animal Medicine, Iowa State University, Ames, IA, USA

Introduction

Previously, we described the use of pen-based oral fluids to monitor PRRSV and/or PCV2 infections in wean-to-finish populations.1,2 The purpose of the present study was to evaluate the use of oral fluids for the detection of PRRSV infection in individually-housed boars.

Materials and Methods

The study was conducted using 72 boars ranging from 6 months to 3.6 years of age. Boar were under the ownership of PIC North America (Hendersonville, TN USA) and housing, study procedures, and protocols were approved and supervised by the PIC USA Health Assurance and Welfare department. Boars were assigned in equal numbers (n=24) to three treatment trials (I, II, III). Boars in Trial I were vaccinated intramuscularly (IM) once with 2 ml of MLV (RespPRRS®, Boehringer Ingelheim Vetmedica, Inc. St.Joseph, MO 64506). Boars in Trial II were inoculated IM with 2 ml of a Type 1 PRRSV. Boars in Trial III were inoculated IM with 2 ml of PRRSV strain MN-184.

Following exposure to PRRSV, boars were monitored for 21 days. Oral fluid samples were collected daily using 5/8”, 3-strand, 100% cotton rope (Web Rigging Supply, Inc., Lake Barrington, IL 60010). Serum samples were collected from all boars on DPI -7, 0, 7, 14, 21. In addition, serum samples were collected from 4 randomly selected boars in each trial on DPIs 3, 5, 10, 17. Additional data collected on a daily basis included ambient temperature (maximum and minimum) in the facility and clinical observations. Serum and oral fluid were assayed for PRRSV RNA at Iowa State University (Ames, IA USA) using nucleic acid extraction and PCR protocols specifically optimized for porcine oral fluids.

All statistical analyses were performed using SAS® Version 9.2 (SAS® Institute Inc., Cary, North Carolina, USA). Serum and oral fluids results for real-time qRT-PCR were analyzed using a repeated measures analysis of variance (ANOVA) model run with the GLIMMIX procedure in SAS.

Results

The analysis showed that PRRSV infection affected the volume of oral fluid samples collected from individual boars (p = 0.0032), but did not impact the success rate for oral fluid sample collection. That is, boars continued to provide oral fluid samples even during acute PRRSV infection, although less volume was collected.

Oral fluid samples were qRT-PCR-positive from DPI 1 to DPI 21. Positive serum samples were detected from DPI 3 (first collection) to DPI 21. Overall, 92 % of the results were in agreement, i.e., 218 serum samples and 238 oral fluid samples were PCR positive.

The concentration of virus in serum and oral fluid samples followed similar patterns over time, with oral fluid containing less virus than serum before 14 DPI and equivalent levels of virus from 14 to 21 DPI. Boar age did not have a significant effect on the quantity of virus present in oral fluid samples, but the concentration of virus in both oral fluids and serum was affected both by the virus strain (p = 0.0001) and DPI (p= 0.0001).

Discussion

The data reported herein provide evidence that oral fluid samples are equivalent or superior to serum samples for the detection of acute PRRSV infection by qRT-PCR. The use of oral fluid samples offers a significant improvement in the ease, timeliness, and cost of disease surveillance in commercial swine populations.

**Histopathological findings in fetuses positive on porcine reproductive and respiratory syndrome by PCR or immunohistochemistry**

Dinko Novosel1 Tomasz Stadejek2 Katarzyna Chrabos2 Zoran Lipej1 Besi Roic’1 Andreja Jungic’1

1. Croatian Veterinary Institute, Zagreb, Croatia; 2. National Veterinary Institute, Pulawy, Poland

**Introduction** Porcine reproductive and respiratory syndrome virus (PRRSV) can cause reproductive disorder in naïve dams infected in the third trimester of pregnancy. Severity of gross and microscopic lesions in fetuses depends on the virus properties and the age of the fetus [1]. Segmental, a perivascular and transmural haemorrhages and multiple edemas with necrotic arteritis of umbilical cord together with lesions in myocardium, lungs, brain and liver usually can be seen [2, 3] but are infrequent. Detection of PRRSV in fetal tissue is usually done by RT-PCR [1]. Immunohistochemestical (IHC) detection of PRRSV antigen in fetal thymus can be also used [1, 4, 5]. The aim of this study was to describe gross and microscopic lesion in fetuses from cases of abortion attributed to PRRSV and to evaluate the incidence of PRRSV detection by PCR and IHC.

**Material and methods** For this study 83 fetuses from 8 large pig production units with significant reproductive losses, aborted in late gestation were used. Every fetus came from different sow. In all of the farms presence of PRRSV was previously detected by serology, PCR and immunohistochemistry. During post-mortem examination, samples of brain, thymus, heart, lungs, liver, spleen, kidney, intestines, lymphnodes and umbilical cord (if present) were collected and fixed in 10% buffer formalin for histopathological examination and IHC. For PCR detection samples of lungs, spleen and liver were stored in -70°C. All tissue sections were stained with hematoxilin and eosin and were analysed by IHC with anti-PRRSV monoclonal antibodies (Ingenasa®) according to previously described protocol [4]. For detection of PRRSV RT nested -PCR specific for ORF 7 was used on total RNA extracted from pooled homogenate of lung, liver and spleen as previously described [6].

**Results** PRRSV was detected by PCR in only 6 (7.23%) fetuses. The IHC detected PRRSV only in thymus of 19 (23.89%) fetuses. Three fetuses (3.61%) were PRRSV positive in both methods of detection. Altogether, 22 (26.51%) fetuses were positive in at least one of the methods while 61 (73.49%) were negative. Viral antigen in thymus was detected in follicular area in triangular selections is crucial for diagnosis of PRRSV in fetuses by PCR and IHC.

**Discussion** We were able to identify presence of PRRSV infection in only 26.51% of aborted fetuses from 5 Croatian pig production units where PRRSV circulation was previously shown. In three farms no evidence of PRRSV in aborted fetuses was found. Most frequent lesion found in PRRSV infected fetuses was edema and haemorrhages of umbilical cord, lymphocytic hepatitis and liver hyperaemia. All other lesions were equally frequent found in PRRSV positive and negative or even more in negative fetuses so it can’t be considered as PRRSV related lesions. There is a clear discrepancy between the results obtained with the two PRRSV detection methods. This could be attributed to the fact that for PCR and IHC different tissues were used. Thymus that appeared to be the only organ where PRRSV antigen was found by IHC, was not used for PCR. This study indicates that the tissue selection is crucial for diagnosis of PRRSV in fetuses by PCR and IHC.

Field trial of the specificity of an ELISA test for PRRS (IDEXX HERDCHEK\textsuperscript{R} PRRS 2XR) high specificity confirmed, but varying behaviour according to the age of the animals

Vincent Auvigne\textsuperscript{1} Jean-Louis Pinsard\textsuperscript{2} Hervé Gourgues\textsuperscript{3}

1. Ekipaj, Pozuelo de Alarcón, Spain; 2. Bio Chêne Vert, Chateaubourg, France; 3. IDEXX Laboratories, Cergy Pontoise, France

Introduction
The laboratory diagnosis of the Porcine Respiratory and Reproductive Syndrome (PRRS) is mainly based on the use of serological ELISA tests and PCR diagnostics. The aim of this study was to assess the specificity of a commercial ELISA test. In particular, the specificity of the test is compared in two different subpopulations: adult breeding sows and young pigs.

Materials and methods
The study takes into account a set of results carried out on French pig farms that are considered free of the PRRSV and with a low risk of contamination (areas with a low pig density or air filtration system). The farms are tested at least three times a year.

The IDEXX HerdChek\textsuperscript{R} PRRS 2XR is an indirect Elisa test for the detection of antibodies against the European and American strains of the PRRSV in the serum of pigs. Samples with an S/P ratio of 0.4 or more are positive. Those of less than 0.4 are negative. Only the first results were included in the study, before carrying out any confirmatory tests.

All farms with a positive result were checked to confirm that the farm was indeed considered as free from the disease, and to check if at least one subsequent negative result allowed excluding the hypothesis of a recent contamination.

Results
Test results carried out between December 2007 and March 2009 were taken into account. 641 adult animals (breeding sows) and 1017 young stock (between 80 and 150 days of age) were included in the study.

Specificity was significantly higher in young stock than in the adults (Chi\textsuperscript{2}, p < 0.02, Table 1). Analysis of the S/P ratio distributions of adult and young pigs showed a difference between the two sub-populations (Figure 1). They differed in the average (Mann & Whitney test, p < 0.001) and in the standard deviation. The percentage of borderline-negative results (S/P between 0.2 and 0.4) was higher in adult pigs.

</tr>
</tbody>
</table>

False positive results ranged from values very close to the limit (5 out of 16 with S/P < 0.45) to clearly positive values (5 out of 16 false with S/P > 1).

Discussion
The main difficulty of specificity studies in the absence of a reference tests is to deal with a disease-free study population. In this study, the combination of a history of controls and a low risk of contamination allowed affirming that the positive test results were false positives.

The observed values of specificity are high and confirm existing data obtained with a smaller sample (1). These specificity values are higher than those obtained with other tests in national control programmes in a disease-free environment (2). The specificity of a test should be put in balance with its sensitivity, as no test is 100% specific.

The difference in specificity between the two sub-populations (young stock and adult animals) studied is an original result. To our knowledge, this is the first time it has been described in the context of PRRS. One hypothesis to explain this difference between the two age groups is the existence of “immunological background noise”, which increases with age due to the accumulation of non-specific antigenic stimulation. It is surprising to note that this lesser specificity of adult animals is not due to an increase of the S/P ratio but to their variability. It would be interesting to have equivalent data for other pathological agents of pigs in order to determine whether this is a systematic phenomenon or only linked to PRRS.

Use of stillborn (pre-colostral) piglets as a sample source to assess viral circulation in PRRSv positive sow herds

Dale Polson1 Brent Carmichael2 Montserrat Torremorell3 Greg Hartsook1

1. Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA; 2. Iowa State University, Ames, IA, USA; 3. University of Minnesota, St Paul, MN, USA

Introduction

Production of PRRS virus (PRRSv) negative weaned pigs and elimination of virus from breeding herds has been successful using methods like herd closure, mass vaccination and roll-over.1-5 When gestating breeding animals become infected, PRRSv can subsequently infect their fetuses.5 Weaning age piglet monitoring is a relatively common procedure used to detect virus circulation in the breeding herd, but this procedure alone is incapable of distinguishing farrowing area circulation of virus from gestational circulation where susceptible sub-populations of gestating animals may exist.

The objectives of this observational study were to develop and evaluate a procedure of monitoring stillborn piglets to detect gestational virus circulation. The combination of weaning age piglet monitoring and stillborn fetal piglet monitoring would support greater opportunities to detect and resolve sources of virus circulation within PRRSv-positive breeding herds.

Materials and Methods

PRRSv elimination projects utilizing herd closure and mass vaccination were conducted on three previously naïve sow farms that became infected with PRRS virus.

Ten to twenty stillborn fetuses and 60 weaning age piglets from each farm were sampled monthly, and all samples were individually tested by PRRS rtPCR. Selected stillborn fetuses were processed as follows: [1] swab both axillary spaces and place in a tube containing 1mL saline, [2] clean axillary spaces with disposable disinfectant wipes and dry with paper towel, [3] using a new scalpel cut open both axillary spaces, [4] squeeze thorax hard so blood pools in axillary spaces, [5] use a disposable syringe to collect pooled blood, [6] transfer blood to serum separator tube, [7] open the thorax and check lungs for inflation, [8] incise stomach and check for milk. A fetus was considered acceptable for sampling if it had a wet umbilical cord, non-inflated lungs and no evidence of milk in the stomach.

Results

Serum and swab results from stillborn piglets from the three sow farms are shown in Table 1. Of the samples collected from 126 stillborn fetuses, 20.6% (26) of sera and 31.0% (39) of skin swab samples tested PCR positive. Interestingly, the percent of PCR positive stillborn serum samples declined over time at a similar rate as those of weaning age piglets (Table 2).

Discussion

The axillary space was targeted for swabbing because of all the external surfaces on a stillborn piglet, the axillary space represents the cleanest skin surface to assess whether viral RNA acquired before or during parturition might be present on the exterior of a stillborn piglet.

As a herd’s immunity develops following whole herd mass-vaccination, the level of in-utero infection would be expected to decline, fall to and remain at zero as long as new wild type virus introduction is prevented. If proper piglet management procedures are followed in the farrowing area,7 the level and likelihood of new infection among and within farrowing rooms should also fall to and remain at zero.

The stillborn piglet sampling/testing procedure potentially complements PCR-testing of weaning age piglets to detect and pinpoint PRRSv circulation in the breeding herd.

Evaluation of a methodology for collection and PRRSV detection at swine herd level

Catherine Charreyre1 Andrea Delvecchio1 Valérie Cozette1 Thaïs Vila1 Mathieu Chevalier2 François Joisel1

Introduction
PRRS virus is usually detected in individual pig serum, but it is often difficult to do at the herd level because of cost and the labour. Researchers have recently developed a new methodology (1,2,3): the objective of this study was to compare this new method of detection of the virus in oral fluid (OF) with the classical detection of PRRSV in serum.

Material and Methods
Animals: 3 replicates of 10 commercial pigs, housed in 3 separate pens, in strict isolation.

Experimental design: at 12 weeks of age (Day 0) each pig received a 4 mL intranasal injection of the PRRSV challenge suspension.

Serum and OF samples collected at Day 0 were used to qualify the extraction method and the qRT-PCR test and to confirm the absence of PRRSV.

OF and blood were collected from each animal at D0 (PRRSV challenge) and at D3, 7, 10, 14, and 21. A cotton rope (“Sanicorde”) tied up to each pen partition for 30 minutes was used to collect OF Pigs actively sought out and chewed the rope (2). The Sanicorde were wrung, OF were harvested and stored at -80°C until use.

Lab investigations: Serum and OF samples collected at Day 0 were used to qualify the extraction method and the qRT-PCR test and to confirm the absence of PRRSV.

OF and blood samples were performed with QIAamp® Viral RNA kit (Qiagen). OF samples were centrifuged to remove debris and PRRS virus load was evaluated by the qRT-PCR technique.

Statistical methods: McNemar’s test for concordance between viremia and oral virus results; Binomial probability distribution to assess the minimum number of OF samples to detect at least 1 positive sample.

Results
All blood and OF samples collected prior to virus inoculation up to Day 0 and all case control tested negative.

Comparison showed that the levels of virus in serum and OF samples in different groups followed a similar pattern, with OF consistently containing a lower detectable concentration of virus (Figure 1).

Comparing the proportion of negative or positive results in OF and blood samples in the 3 groups, each as a whole, the correlation was significant (p = 0.025) with 72% of concordant responses between blood and OF.

Figure 1: Average detection by qRT-PCR (maximum number of amplification cycles i.e. 40 - first detection amplification cycle = 40-CT) of PRRSV in serum and OF

Ten of the 15 OF samples collected were found positive (67%). Thus, we calculated the probability of having at least one positive sample (detection of PRRS virus in OF with Sanicorde) for a number of samples from 2 to 6, and a ‘true’ percentage of positive pigs from 50% to 80%.

With a 70%-prevalence of positive pigs in a group, 3 sequential OF samples collected each 3 to 7 day, are necessary to obtain at least 1 positive result with 95% chance of success (Table 1).

Discussion and Conclusion
The qRT-PCR test we used was designed for blood tests; it had not been fully optimized for PRRSV detection in OF and requires improvements. However our results confirmed that the collection of OF samples could be a useful and cheaper methodology to detect and monitor PRRSV infection at herd level. The results of this method have to be confirmed in the field.

A comparison of individual versus pooled sample testing on pool-level and case-level PRRS virus PCR detection sensitivity and specificity

Dale Polson1 Greg Hartsook1 Brent Carmichael2
1. Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA; 2. Iowa State University, Ames, IA, USA

Introduction
The time it takes to begin producing porcine reproductive and respiratory syndrome virus (PRRSv)-negative groups of weaned pigs following the new introduction of a non-resident PRRSv and related onset of a clinical reproductive PRRS outbreak in swine breeding herds has become an important means by which to assess the effectiveness of PRRS interventions applied to breeding herds. The measure “time-to-negative-pigs” (TTNP) is typically described as the number of weeks between the start of an intervention protocol (e.g., herd closure to new replacement introductions and/or mass vaccination) and the first “consistent” production of PCR-tested negative groups of weaned pigs. For estimating TTNP, the key measurement components are: sampling frame (e.g., piglets within 1 week or less of weaning), sample selection (e.g., smallest barrow from gilt litters, one piglet per litter), sampling method (jugular venipuncture, ear notch), sample type (e.g., blood-to-serum, swab-to-saline), sample size, sampling interval, sample pooling (e.g., pooling of N individual samples), shipping materials and method, PCR assay, laboratory procedures, and the number of consecutive tested-negative samplings.

The objective of this study was to assess the effect of sample pooling of 5:1 and 10:1 on PCR detection sensitivity and specificity at both the pool and case levels when estimating TTNP.

Materials and Methods
Two 5,000 sow PRRS-naïve breeding herds became exposed and infected with a wild-type PRRSv. A sampling-pooling-PCR testing evaluation was conducted on both farms. Sixty (60) due-to-wean piglets were periodically sampled and tested by PRRSv PCR – initially per month, then, when the individual sample-level PCR prevalence was first noted to be approximately 30% and less, 60 piglets were sampled per week until zero individual PCR positives were detected for at least six consecutive weeks. Due-to-wean piglet selection targeted the smallest barrow suckling a gilt or youngest sow.1

PRRSv PCR testing was done on all individual samples collected as well as on pools composed of 5 and 10 individual samples. All pooling was done in the testing laboratory under a hood using special precautions to prevent cross-contamination. Where a pool contained one or more tested PCR-positive individual samples, the true state of the pools was defined as positive. Conversely, where a pool contained all tested PCR-negative individual samples, the true state of the pool was defined as negative. PCR detection sensitivity (Se) and specificity (Sp) were evaluated at both the pool-level and case-level. The Se and Sp of the tested pool sizes were compared to the individual sample PCR testing results of the samples making up the pools.

Results
The results show a comparable estimated pool-level sensitivity for pools of 5 (84.5%, 95%CI = 73.5% - 91.6%, n=274) and pools of 10 (82.0%, 95%CI = 68.1% - 91.0%, n=137) – a 15.5% and 18.0% relative reduction in sensitivity for samples pooled 5:1 and 10:1, respectively, as compared to the PCR testing results of the individual samples making up the pools. However, both the pools of 5 and 10 had 100% sensitivity and 100% specificity at the case-level.

At the pool level the specificity estimates were 99.0% for pools of 5 and 97.7% for pools of 10. It is notable that all four “pool individuals-negative but pool-positive” (InPp) results occurred in the first two sets of cases pooled, and in every instance the InPp pool was preceded by a pool that contained one or more positive individual samples. After the pooling process was reviewed and adjustments made, no further occurrences of InPp were detected. This indicates the importance of the pooling process in obtaining accurate pool-level results.

Discussion
Based on these data, individual sample pooling up to 10:1 can offer comparable pool-level and case-level detection Se to that of pooling 5:1 and can further reduce testing costs when estimating TTNP.

Infection dynamics of Porcine Reproductive and Respiratory Syndrome Virus (PRRSV) in vaccinated and non-vaccinated pigs

Helle H. Jessen¹ Charlotte K. Hjulsager² Jens P. Nielsen³ Helle Stege¹ Lars E. Larsen² Anders Elvstrøm⁴

Introduction

Piglets from a PRRSV (EU type) seropositive stable sow herd were seronegative at weaning, but became infected with PRRSV EU after transfer to the finishing units located at the same site. To control PRRSV among the finishing pigs, vaccination with a modified live virus PRRSV EU vaccine (Intervac PRRS) all pigs prior to transfer to the finishing stables were initiated from October 2008. In July 2009 it was decided to terminate vaccination of pigs at transfer. The aim of this study was to investigate if non-vaccinated pigs could be inserted in an empty and clean stable without being infected despite the presence of vaccinated pigs in neighboring rooms.

Materials and methods

The study was performed as an intervention study with two groups of pigs including 58 vaccinated and 20 non-vaccinated Danish Landrace, Yorkshire and Duroc crossbreeds. All pigs were identified with ear tags. The vaccinated pigs were 8 weeks of age at the time of vaccination. Blood samples and nasal swabs were taken 0, 1, 2, 3, 8 and 13 weeks after vaccination. The non-vaccinated pigs varied from 5 to 10 weeks of age at transfer to the finishing stable and were sampled 0, 5 and 10 weeks after transfer. Non-vaccinated pigs were transferred to a clean and disinfected stable three weeks after the vaccinated pigs were vaccinated. There was no physical contact between the two groups, that were separated by walls and a door that was kept closed during the study. All blood samples were examined for antibodies against the US and EU PRRSV types by a differentiating blocking ELISA (4) and for the EU PRRSV type by IPMA (1). A ratio (OD%eu/OD%us) was calculated if ELISA EU or ELISA US were positive (cut off: OD% ≤ 44). IPMA EU detected antibodies in four dilutions (1:50; 1:250; 1:1250; 1:6250). Serum samples and nasal swabs from vaccinated pigs were examined for PRRSV RNA by real time RT-PCR (3) and the ORF5 and ORF7 were sequenced from selected positive samples.

Results

None of the tested non-vaccinated pigs seroconverted to PRRSV after transfer to the fattening unit despite the simultaneous occurrence of viraemia in vaccinated pigs housed in a neighboring room. All vaccinated pigs were seronegative at the time of vaccination. After vaccination they developed an immune response, which resulted in 85.5 % pigs with IPMA EU titers ≥ 1250, indicating an acute infection. No clinical symptoms were observed at this time. The mean ELISA ratio in week 13 was 0.6 indicating a previous PRRSV EU infection.

Discussion

The lack of transmission of PRRSV EU from vaccinated to non-infected pigs in neighboring rooms, is of importance for herd eradication programs in which PRRSV vaccination is carried out in order to reduce clinical effect. Until 8 weeks after vaccination, the vaccine induced an immune response comparable to a natural infection as previously described (2, 5). Virus was not detected in serum beyond week 3 after vaccination, and virus was not detected in nasal swabs at any time. Thus, it seems to be safe to mingle pigs 8 weeks after vaccination which is routinely used in Denmark. To our surprise, the IPMA EU titers markedly increased 13 weeks after vaccination indicating acute (re)infection. Although serum and nasal swabs were PCR-negative, this may be due to either an infection with a wild type virus or reactivation of the vaccine virus. Further studies are needed to elucidate if this is a general features in pigs vaccinated with live PRRSV vaccines.

Serological, virological and productive monitoring to control PRRSV infection in an endemically infected breeding herd in North-Eastern Italy

Giacomo Bortoletto 1,2 Marco Martini 2 Stefano Nardelli 1 Michele Drigo 1
1. Istituto Zooprofilattico Sperimentale Venezie, Legnaro (PD), Italy;
2. Dept. Public Health, Comparative Pathology and Veterinary Hygiene, Padua University, Legnaro, Italy

Introduction

In Italy PRRSV infection is widespread and circulation of several viral strains occurs. In breeding herds the key to break virus circulation is to expose replacement animals to the farm specific PRRSV strain to induce a good immune response prior to their introduction into the herd. Therefore, a rigorous bio-security policy is needed to avoid the incoming of new strains into an infected farm (Pesente et al. 2006).

The aim of this study was to monitor the serological, virological and productive trends of an endemically PRRSV infected breeding herd where the control of the infection was based on the implementation of an effective acclimatization program accompanied by strict bio-security measures.

Materials and Methods

The study was carried out in a 1500 sows farrow-to-wean farm, infected by PRRSV since 1995. As farmers decided not to vaccinate for PRRSV, an acclimatization program was improved over time. 52 3-week-old PRRSV negative gilts were introduced into the farm every month and at once exposed to PRRSV through the contact with weaned pigs, used as donor sources of virus. During the last 3 months of acclimatization viremic pigs were turned over every 2 weeks and taken away one month prior to the introduction of gilts into the stimulation unit. The aim of the program is to fertilize 8-month-old gilts after they become immune but no longer viremic.

For 24 consecutive months, from April 2007 to March 2009, sera samples were collected from 1185 gilts at the end of acclimatization. In the same period, 5 cross-sectional surveys were carried out almost seasonally, on a total of 607 pigs. Between October and November 2008 a PRRS outbreak occurred in the farm and thoracic fluid was collected from some aborted fetuses. PRRSV RNA was extracted from both sera and thoracic fluid samples, analyzed by RT-PCR, purified and sequenced in ORF7 region. Sera samples from gilts were also checked for the presence of a specific PRRSV immunity by an ELISA commercial kit. Performance Trend Analysis (PTA) was obtained using farm database, and analyzed statistically using Chi-square test for count data and one sample T-Test for continuous variables.

Results

After a first period of low efficacy of the acclimatization program, especially in July and November 2007, both prevalence of seropositive gilts and mean s/p ratio increased in the subsequent months (Fig.1). This trend may be the consequence of seasonality and of a better management of the viremic pigs used as virus donors. The 100% virus positivity in pools from 3 groups of gilts during cold season together with the virological results of the 5 cross-sectional surveys (ranging from 2/16 positive pools in July 2008 to 23/23 in February 2009) confirms that season plays a key role in the viral circulation.

The outbreak consisted in a reproductive failure with 27 abortions and in a significant fall of the productive performance: number of farrowings, farrowing rate, piglets weaned, piglets weaned/sow/year, total born/litter, liveborn/litter, piglets weaned/litter. The comparison of these parameters before and after the outbreak didn’t show significant differences, demonstrating that in a well acclimatization system the return to normality can be achieved rapidly. Phylogenetic analysis assessed the presence of a single homologous PRRSV variant on the farm and revealed the incoming of a new strain (9,4-10,8% of nucleotide p-distance) causing the outbreak and no longer detected in the following surveys.

Discussion

This study confirms that an acclimatization program may be able to maintain the circulation in not reproductive units of a unique viral strain over time and that it may be able to restore promptly herd stability after an outbreak. Phylogenetic analysis is more and more often a useful tool to help farmers and veterinarians to understand the causes of the failures and to apply successful control measures.

IntraUterine Growth Retardation (IUGR): morphological and behavioral description
Eric Chevaux1 Audrey Sacy1 Yannig Le Treut1 Guy-Pierre Martineau2
1. LALLEMAND SAS, Blagnac, France; 2. Veterinary School of Toulouse, Toulouse, France

Introduction
Over the past 15 years, selection of hyperprolific sows has actually increased litter size but also increased heterogeneity of piglets' weight at birth. However, piglet's weight at birth by itself is not discriminating enough to predict the whole animal's productive life (Litten et al., 2003). Immaturity corresponds to piglets with intrauterine growth retardation (IUGR) after 114 gestational days, which present all the characteristics of runt piglets. The goal of this study was to determine a set of simple morphological criteria, backed-up by anatomical data, in order to allow the rapid identification of immature piglets in the farm.

Materials and Methods
924 piglets (837 born alive, 87 stillbirth and 29 mummified) from 67 Topigs sows (Great Yorkshire /Large White type) and N-line (Dutch Landrace), were monitored at birth in a French herd for birth and weaning weight, vitality score within the first 15 seconds of life (Baxter et al., 2008), and qualitative morphological signs of maturity including head morphology (on lateral and dorso-ventral observations, Figure 1), head/body, and behavior (after a pre-study performed by Sacy (2008)).

Figure 1: Dorso-ventral characteristics of normal (left), intermediate (middle) and IUGR (right) piglets

Piglets dead within 2 days post-farrowing (IUGR=147, control=282), including stillborn piglets, were necropsied and their vital organs weighed (brain, liver, heart and lungs). The brain is the first vital organ to attain maturity, while other organs such as liver mature later. Therefore, the brain/liver ratio is a good indicator of a piglet development stage. The higher the ratio, the more immature the piglet (Town et al., 2005):

Brain/Lungs, Brain/Liver, and Brain/heart ratio: all ratios are highly significantly different between IUGR and control. Moreover, there is a correlation between the brain/lungs ratio criteria and morphological criteria of immaturity (Figure 2). Similar results were obtained with other vital organs such as heart: 5.21±1.95 vs. 3.15±0.85 (r=-0.677, p<0.001).

Behaviour: immature piglets exhibit typical behavioral criteria: they are usually found isolated from the other piglets, lying on their side, they have difficulties to suckle and are usually found where the farmer left them previously. They represented 11% of the live born piglets and it went up to 25% for older sows (parity>5).

Figure 2: Relationship between true stillborn piglets weight and their brain/lungs ratio (r=-0.701, p<0.001)

Results and discussion
Morphology: IUGR piglets are generally lighter than the more mature ones (71 % of IUGR piglets <0.9 kg vs 2 % of the mature ones p<0.001), but some light weight piglets exhibit the morphological traits of mature piglets.

Growth and mortality: Survival rates of IUGR piglets in maternity was lower than for mature piglets (62% vs. 89%, p<0.01). At weaning (3 weeks), IUGR piglets (n=54) have a lower live weight compared to control (n=642), 4.7 ±0.9 kg vs 5.7 ±1.2 kg, p<0.01.

Conclusion
Until now, IUGR assessment was based on anatomic criteria (Town et al., 2005). This study combines morphological and behavioral criteria that reflect piglets immaturity at birth, all criteria being validated by anatomical data.

From a producer point of view, quickly identification of immature piglets is essential.

However, it would be of interest to pursue this work with other genetic lines as the morphologic piglets criteria for immaturity might differ (according to the prolificacy).

Abortion in group housed sows with electronic feeders

Bas Kolpa², 1 Wikke Kuller 1 Rick Janssen 3 Theo Geudeke 4

Introduction
In the Netherlands, group housing of gestating sows will be obligatory from 2013 onwards. In 2008, a Dutch farm expanded from 280 to 450 sows and converted to group housing with electronic sow feeding. In the first 6 months of the new housing system, 59 animals aborted between 50 days until the end of gestation. The number of piglets weaned per sow per year dropped from 29 to 26.4 mainly caused by the abortions.

Material and methods
From 50 days of gestation onwards, 192 sows were housed in one group with four electronic sow feeders. Sows were customarily vaccinated for PRRS, E.coli, Erissypelas, influenza and PPV. During the outbreak, different diagnostic examinations were performed (table) and a variety of experts visited the farm.

In the feeding stations, a feed data recorder was installed that made it possible to analyze feeding data.

Results
The animals that aborted were sometimes slightly inert but appeared clinically healthy. There were no signs of aggression. No influence of parity was found. The samples that were examined showed no (increase of) antibody concentration. Aborted fetuses within a sow were all in one stage of development. Litter size of the other sows was not affected. Feed data analysis showed that several animals frequently visited the feeder for a very short time, but probably were not provided with feed. Further investigation showed that sometimes the feeders had a random reset and had a mechanical malfunction. After adjustment of the feeders no more abortions were observed.

Discussion
Low feed intake is a risk factor during the first weeks of gestation (1). However, in this case abortion occurred later on. Since the sows were fed using electronic sow feeders, one would not expect a high risk of feed competition like in group housing systems with trough or floor feeding. (1). But due to the malfunctioning of the feeders, the feed intake of some sows could have been very low, which might affect pregnancy. Valuable information on real feed intake can be obtained by data recording systems that some manufacturers provide. Veterinarians should use this information.

Another aspect of this case is the effect of stress. The detrimental effect of stress on (re)productivity of sows is hard to establish in experimental settings (2). However, stress has an effect on the hypothalamic–pituitary–adrenocortical axis and therefore probably on the maintenance of pregnancy (2). The fact that the feeders quite often randomly malfunctioned probably resulted in a lot of agitation and thus in (long term) highly unpredictable stress. Examination of sow behaviour could have given a clue.

Effects of zearalenone (ZEA) exposure of gilts during late gestation and lactation on metabolism and carry-over to piglets

Johannes Kauffold1, Katharina Stephan2, Dina Knauf3, Frank F Bartol4, Martin Waehner2

1. Department of Clinical Studies - New Bolton Center, School of Veterinary Medicine, University of Pennsylvania, Kennett Square, PA, USA; 2. Anhalt University of Applied Sciences, Bernburg, Germany; 3. Clinic for Obstetrics, Gynecology and Andrology of Large and Small Animals, Faculty of Veterinary Medicine, Justus-Liebig-University, Giessen, Germany; 4. Departments of Anatomy, Physiology and Pharmacology, College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

ZEA is a mycotoxin that binds to the estrogen receptor and exerts estrogen-like effects. Pigs are highly sensitive to ZEA [1] and can exhibit reproductive disorders if consume it. There is indication that ZEA is carried over to piglets in utero and through colostrum/milk, and may cause hyperestrogenism [2]. However, neither of both routes of carry-over has been conclusively demonstrated. This study therefore focused on the metabolism and carry-over of ZEA to piglets when fed to late pregnant and lactating gilts.

Materials and Methods

Gilts (n = 32) were hormonally synchronized for estrus and ovulation, artificially inseminated and tested positive for pregnancy. They were fed crystalline ZEA (Sigma-Aldrich, Germany) from day 101 of gestation until days 20/21 of lactation in a concentration of either 1.500 μg/kg feed/day (n = 7; EXP-H) or 250 μg/kg feed/day (n = 9; EXP-L), while eight gilts served as controls, respectively (CON-H, CON-L). For application, ZEA was dissolved in ethanol and injected into muffins that were individually fed to the gilts. CON animals received blank muffins. Prior to first colostrum uptake, female piglets were cross-fostered from the respective EXP to CON animals and vice versa, to obtain piglets that were differentially exposed to ZEA: in utero only (IU), through colostrum/milk only (MI), in utero and through colostrum/milk (IU & MI), none (CON). Group size was 11–13 piglets, respectively. Colostrum/milk was collected four times in weekly intervals. First collection occurred after farrowing. Piglets were weaned on day 20/21 of lactation, then sacrificed and bile collected. Sows were sacrificed one day after weaning, and bile collected. All milk and bile samples were subjected to analysis for ZEA and its metabolites α- and β-zearalenol (ZOL) using HPLC and mass spectrometry.

Results

Median concentrations for both ZEA and α-ZOL in bile of CON-H and L groups were around 5 ng/ml and 2 ng/ml, respectively. Concentrations were > 250 x higher in bile of EXP-H and 30–100 x higher in EXP-L gilts for both mycotoxins. ZEA, but not α- and β-ZOL, was found in milk collected from EXP-H and L but also from the respective CON animals. Mean concentrations of ZEA (average of the values obtained with all milk samples) were higher for the EXP-H and L than for the CON-H and L group, respectively. In none of the piglets could β-ZOL be detected in bile. Almost all IU & MI and MI piglets belonging to both the H and L experiment were tested positive for ZEA and α-ZOL in bile. Only single piglets exposed to IU or belonging to CON were positive. Median concentrations of ZEA and α-ZOL were higher in IU & MI and MI than in IU and CON piglets in both experiments, respectively (P < 0.0001).

Discussion

Results confirm that ZEA and its metabolites accumulate in bile of pigs and that the concentrations in bile depend on the amount of ZEA consumed [3]. The fact that non-exposed animals also had ZEA in bile albeit in very low concentrations indicates constant back-ground exposure. Data show clearly that ZEA can be encountered in colostrum/milk of lactating gilts. The fact that piglets nursed to ZEA-exposed gilts were preferentially ZEA positive in bile regardless of whether they were exposed also in utero or not, clearly demonstrates that carry-over of ZEA through colostrum/milk occurs in the pig. A recent study has shown altered expression of morphoregulatory important genes in those piglets [4].

Risk factors associated with frequency of abortions

Nuno M. Rainho¹ Maria Aparicio¹ Miguel A. de Andrés¹ Joquin Morales¹ Rafael Pallás² Vicente Rodriguez-Estévez³ Carlos Piñeiro¹

1. PigCHAMP Pro Europa, Segovia, Spain; 2. Kubus SA, Las Rozas, Madrid, Spain; 3. Dpto. Producción Animal, Universidad de Córdoba, Córdoba, Spain

Introduction

Current swine production is everyday more linked to a proper analysis and monitoring to maintain competitiveness. Despite of the fact that every farm has to improve taking into account its own results, in many cases general standards can be useful to set a quick reference in order to help to define farm objectives and to compare performances through benchmarking processes. Literature has described references for most of the key indicators during the last decades, but some of the factors has not been recently updated or explained in depth including interactions between them. Those risk factors related to frequency of abortions through several years in a large herd population are presented.

Materials and Methods

The objectives of the present study were to investigate the relationship between the relative frequency of abortion (percentage, AP) and number of parity (NP), weaning to first mating interval (WSI), number of service (NS) and day of week for service (DW). The present study used more than 870,000 mating records corresponding to four years (from 2005 to 2008) of about 80,000 sows on 161 commercial farms from Spain, Portugal and Italy, monitored by PigCHAMP Pro Europa S.A. and registered with Pigchamp® software.

Each factor was categorized: four groups for NP: 1, 2, 3-6 and ≥7 parity; three groups for NS: first-serviced (FS), first-reserviced (FRS) and second-reserviced (SRS); four groups for WSI: ≤3, 4-7, 8-11 and ≥12; and two groups for DW: Weekday and Weekend. Data were analysed using the MIXED procedure of SAS (v 9.00).

Results

Mean value (± SEM) of AP was 0.78 ± 0.03%. The main effects studied resulted as follows: Regarding NP, mean AP in parities 1 and ≥6 was higher than those in parities 2 and 3-6 (P=0.0001), showing a quadratic effect that explains the higher risks in both gilts and old sows (figure 1). A lineal effect was found for WSI, when WSI≤7 was lower than those of WSI≥8 (P=0.0001); furthermore, AP depended on DW and it was higher for matings during the weekend: 0.70 vs. 1.05 % (P=0.0001). Finally the mean AP for NS increased with the number of oestrus repetition (figure 1), showing: 0.45, 2.87, 4 26% for FS, FRS, SRS respectively (P=0.0001). Through the time, only year 2006 showed a lower AP (0.68) being the other years quite stable (around 0.80 all of them). Therefore factors associated with a higher AP were being gilts or old sows (≥7th parity), a reservice occurrence, prolonged WSI and service during the weekend.

Some interactions between the main factors studied were found. The most interesting one is probably the one between WSI and DW; sows mated ≤3d after weaning showed no differences between weekday or weekend, while sows with normal WSI (4-7 d) showed a higher risk during weekends (0.63 vs 1.29, p<0.0001), while later mated sows served 8-11 d post weaning performed better in matings during the weekend (1.24 vs 0.75, p<0.0001).

Discussion

Classical risk factors influencing abortion and return to estrus are well known (e.g. Koketsu et al., 1997; Vargas et al., 2009). However these results add more information about the relative importance of some classical factors as NP, NS or WSI, and show a new factor as it is DW. Besides these results can be useful to define with more accuracy the objectives of every farm and to avoid those factors that are largely influencing poor performance in order to keep continuous improvement and competitiveness.

Anaemia in the hyperprolific sow: Effect of injectable iron administration and relation with fattening score

Vincent Auvigne¹ Hugues Perrin² Arlette Laval² Bénédicte Bertucat³ Valérie Normand⁴

¹. Ekipaj, Pozuelo de Alarcón, Spain; ². ENVN, Nantes, France; ³. Ceva Santé Animale, Libourne, France; ⁴. Porc.Spective, Pontivy, France

Introduction

Although anaemia in sows is less studied than in piglets, it can be supposed that it is a key factor of the sow’s health status. The aim of this study is to describe levels of anaemia observed in hyperprolific farms in France and to study the effect of injectable iron (GLEPTOSIL®) administration during gestation.

Materials and Methods

The study was carried out in 2009 in seven hyperprolific farms (13.8 to 15.6 born piglets/sow/year) with a high percentage of stillborn (> 8%) and/or manual assistance at farrowing (> 15%). Sows (n=510) were individually randomised into two groups (Gleptoferron and Control), 7 weeks prior to farrowing after stratification according to parity and the initial haemoglobin level. Sows from the Gleptoferron group received two injections of GLEPTOSIL® at 7 and 4 weeks before farrowing (10 ml per injection, i.e. a total of 4 g of gleptoferron).

The level of anaemia was assessed by haemoglobinaemia, measured with the Hemocue® Hb 201+ device. Kinetics was observed by measuring the levels at four stages of the reproductive cycle of each sow: seven and four weeks before farrowing, after farrowing (between 48h and 5 days) and on day 20 of lactation. Two measures of the backfat layer thickness (BFL) were carried out on each sow (four weeks before farrowing and at farrowing). Lme procedures (R 2.9.0) were used. Parity ranking and haemoglobin level at the start of the study were set as fixed effects, farm and batch as random effects.

Results

Haemoglobinaemia is linked to the parity rank and decreases all along the career of the sows. The average BFL decreases from the fourth litter onwards. Sows with high haemoglobinaemia levels are fatter (Figure 1). This relation is significant, even after adjustment for the parity (p=0.02). A positive effect of the gleptoferron injection is observed 3 weeks after the first injection. However, there is an interaction between “Treatment” and “Parity” (Table 1).

Discussion

The drop in haemoglobinaemia with an increasing parity rank was not reported in a similar study carried out 30 years ago (2). This newly discovered relation might be due to the dramatic increase in prolificacy over the past decades. The relation between haemoglobinaemia and BFL is significant even after adjustment for the rank of parity, what strengthens its biological significance. Though, the study does not allow establishing a causal link we favour the hypothesis of an insufficient nutritional intake for both the build-up of body reserves and for restoring the haemoglobinaemia. The injection of gleptoferron allows partial compensation of the anaemia. This partial efficacy of gleptoferron could be explained by an insufficient quantity of iron injected.

Sow Life® – demonstrating the quality of advisory teams and reducing sow mortality on Danish farms

Kaj Vestergaard; Lisbeth U. Hansen; Elisabeth O. Nielsen; Hanne Nissen; Gunner Sørensen; Flemming Thorup; Heine Kristensen; Merete Studnitz; Lene K. Bruun; Verner Ruby; Michael G. Christiansen
Pig Research Centre, Danish Agriculture & Food Council, Copenhagen, Denmark

Introduction

Sow mortality is generally neglected by pig advisers, despite the significant losses incurred. According to official reports submitted to the Danish Food Advisory Service by the Danish rendering plants, more than 156,000 sow carcasses were processed during 2009, indicating that Danish pig producers dispatched 14.4% of their sows to rendering plants. The economic output gained from reducing this number would be considerable for most herd managers in Denmark.

The reasons behind the high sow mortality have been investigated in Danish herds. The main purpose of Sow Life® was to gain an insight into the normal production strategy, to clarify the potential for improvements and then act upon this by establishing a one-year strategy for the herds.

Materials and Methods

A total of 17 farms with above average sow mortality were selected for the investigation. All farms recorded productivity levels electronically and had a herd manager who was willing to spend time together with an advisory team consisting of the herd veterinarian, a local pig production adviser and a specialist from the Pig Research Centre.

Over a 3-month period, data from each herd were analyzed, technical errors were corrected, and the advisory team together with the herd manager then decided on a strategy to reduce the sow mortality and thereby increase the economic output. The strategy included a fixed level for sow mortality. The production was closely monitored by the advisory team over the following 12 months. Minor changes to the strategy were made if necessary. If the goals of the strategy were achieved within the 12-month period, the herd manager and the advisory team would agree on new goals within the strategy.

Results and Discussion

As can be seen in Figure 1, it was possible to reduce sow mortality on all 17 farms. Figures on productivity are shown in Table 1. The three best farms increased their output by additional €59 - €121 per year sow. Three farms were unable to increase the output by reducing sow mortality, one suffered from problems in recruiting reliable personnel and the other two were put up for sale due to financial problems.

When dealing with an issue such as sow mortality, it is important to agree on a specific goal and on how to achieve it. Despite different limits for sow welfare, 14 out of 17 farms achieved economic success through the planning process together with the advisory team.

The Sow Life® investigation has shown that by reducing sow mortality on Danish farms the herd managers would increase the output per year sow.
Reduction of total airborne bacteria and MRSA with an air cleaning device in a pig fattening unit - first results

Jochen Schulz1 Richard Hölscher2 Endong Bao3 Jörg Hartung1
1. Institute for Animal Hygiene, Animal Welfare and Farm Animal Behaviour, University of Veterinary Medicine Hannover, Foundation, Hannover, Germany; 2. Hölscher + Leuschner Company, Emsbüren, Germany; 3. College of Veterinary Medicine, Nanjing Agricultural University, Nanjing, China

Introduction
The air in modern pig fattening units contains large numbers of bacteria [1]. They give cause for concern threefold: firstly, high concentrations of airborne bacteria can impair the respiratory health of the animals. Secondly, the health of animal caretakers can be compromised by these air pollutants, and thirdly harmful bacteria can be transmitted via the exhaust air to neighboring animal houses and residential dwellings where they are supposed to cause infections and contaminations in animal and man [2]. Of particular interest are possible MRSA (methicillin resistant Staphylococcus aureus) emissions from piggeries. Therefore it seems useful to reduce the concentrations of airborne bacteria already in the animal house air.

This paper reports about experiments with a new air cleaning device in order to reduce the bacterial load incl. MRSA in the air of a commercial pig fattening unit.

Materials and Methods
The air cleaner consists of an air washer with an integrated UV (ultraviolet) irradiator (prototype developed by Hölscher & Leuschner Comp., Emsbüren, Germany). The device was placed in the center of an animal house with 600 fattening pigs. For the investigations the air flow through the system was adjusted to approx. 7000 m³ • h⁻¹. To warm up the UV lamps the system was started 10 min before each sampling. Two samplings (no. 1 and 2) were conducted in the 8th week, one in the 9th (no. 3) and one (no. 4) in the 10th week of the same fattening period. Airborne bacteria were sampled isokinetically and simultaneously using three impingers in the untreated air directly in front of the air cleaner and three impingers in the treated air behind the outlet of the system. Total airborne bacterial concentrations and airborne MRSA concentrations were determined as described by [3].

Results
In all samples a clear reduction of the total airborne bacteria concentrations were observed (about one log or average reduction rate and standard deviation of 93 ± 2% (Table 1). Similar and even better results are achieved for MRSA which are reduced by nearly two log or 98 ± 2% on average (Table 2).

<td>3.1 x 10⁶ ± 6.6 x 10⁴</td>
<td>1.2 x 10⁴ ± 2.0 x 10³</td>
</tr>
</tbody>
</table>

Discussion
The results demonstrate that the used air cleaning device is able to reduce the general bacterial load in the air of a commercial piggery significantly by 93% or about one log and MRSA by 98% or nearly two log. This air treatment technique offers the possibility to decrease bacterial loads in pig house air and bacterial emissions from pig farms. This would be beneficial for the health of the animals, the work force and the neighborhood.

Conclusions
The presented air cleaning device has obviously the potential to reduce the bacterial load in the air of piggeries significantly. Further investigations are necessary to confirm the results and to clarify the respective retention efficiency of the washer and the UV radiation unit.

Introduction
A livehaul accident scene is never an easy sight, however a timely and organized response can improve a bad situation to better for the industry. Twenty-seven percent of all livehaul accidents involve swine, 80 percent of which involve market animals. The number of trailers carrying livestock in North America, makes a small percentage of accidents appear to occur frequently. For example, the 3 main pork processing plants in North Carolina and Virginia receive 72,000 market trucks per year. The yearly estimated number of livehaul accidents in NC and VA is 24, which is only 0.03%. This paper outlines steps that should be followed when responding to a livestock accident. It is not a complete manual, but we have highlighted important areas based on principles of incident command, training documents and personal experiences.

Responsibilities of Responders - 1) Safety of the driver, all personnel and the general public; 2) the welfare and humane treatment of animals; 3) protection of property and 4) ensure a positive public perception of the industry.

Basics of Incident Command - 1) One person in command; 2) teamwork is necessary; 3) chain of command must be respected; 4) communication

Responders - Most emergency responders have little to no experience with handling livestock. Many transporters have little experience handling stressed livestock. Many livestock handlers have little to no experience in extraction. This requires teamwork, organization and a specially trained crew.

Local Responder Assistance - Law enforcement is responsible for public safety, traffic and crowd management. Fire departments are responsible for securing scene and vehicles, extrication if needed and water to cool animals. All others should be requested to leave the scene.

First on Scene - 1) Establish communication, exchange information with authorities, 2) establish lead person; 3) move loose animals off of the road; 4) provide assessment of scene to response team.

Rescue - It may take up to 2 hours before the actual extraction occurs, however response to the accident must occur prior to 2 hours. The average response time and clean up is 6 hours. Set up containment area and corral loose animals. Once containment area is set up, proper equipment and adequate responders are available, begin extraction of the animals inside the trailer, not before! Animals are loaded onto a transfer trailer in accordance with standard loading procedures and downer policy. All animals must be accounted for prior to leaving the accident scene. Sort boards and rattle paddles are used when loading animals. Electric prods are discouraged. Care should be taken when loading animals, take your time, show patience, composure, and use publicly accepted terminology.

Extrication - Rescue team should take ample time to assess accident scene and determine the best route/method of extrication. It must be determined if the trailer is stable to begin extrication, or a method of stabilization is determined. Never compromise the safety of the responders. Nearly 84% of trailers roll onto the right hand side, making extraction more difficult. When trailers roll on their side, floor space is cut in half at best. Be sure to stagger work load to prevent exhaustion, accidents, injury.

Euthanasia - Safety comes first! One person, primarily a veterinarian or trained professional, is assigned all euthanasia duties for the incident. Injured animals outside the trailer are euthanized as soon as possible. Injured animals inside the trailer are euthanized as soon as they are safely accessible. Euthanize animals out of sight of the general public. Law enforcement should not be involved with euthanasia. Dead animals should be removed from the working area and covered.

Post Accident - Lead person should assess property damage, cleanup needs, removal of damaged vehicles and inspection of scene after completion. Response team completes accident reports and reviews incident and media response for recommendations on continued improvement. We learn something new every time and try to be prepared for any situation.

Summary - Ability to comply with the above processes leads to an improved accident scene, improved response time, minimal expense and a positive perception to an otherwise negative event. More information on training can be found at www.livestockhandling.net

Introduction - Porcine circovirus Type 2 (PCV2) in growing pigs is associated with severe systemic and respiratory disease leading to high mortality and decreased growth performance. Historically, vaccination for swine diseases has focused more on population immunity. However, the pathogenesis and epidemiology of PCV2 disease makes individual pig immunity important due in part to the ability of the virus to persist in the environment. Accordingly, any ability to measure and monitor compliance to PCV2 vaccination would be valuable for effectively controlling these diseases.

Compliance - Is defined as “the consistency and accuracy with which a patient follows the regimen prescribed by a physician or health professional.” Compliance has been associated with four key factors: 1) patient’s perceived susceptibility to the disease; 2) patient’s perceived severity of the disease; 3) patient’s belief that the benefits outweigh the costs; and 4) whether the patient receives “cues to action” or reinforcement of the regimen.1 The potential exists for non-compliance in any health or production protocol.2 The most detrimental type of non-compliance is complete neglect of the vaccination protocols where groups of pigs are left susceptible to disease. In most situations, compliance is based on employee adherence to the established protocols. Improving compliance is based on educating employees, monitoring the vaccination process and protocol reinforcement.

PCV2 vaccination protocol - Piglet vaccination protocols in this production system are based on vaccine efficacy, economic return and compliance. Circumvent® PCV, along with MycoSilencer® ONCE, is used on all farms, enabling sero-compliance monitoring. The first doses are given at weaning (21 days), when the entire farm staff is present. The second doses are given 21 days later, on the same day of the week, when the farm team is already in a “vaccination” mindset. Giving two vaccines requires multiple employees to be present, improving compliance by “witness motivation.” The farm manager is mandated to be involved in the vaccination process, improving compliance by visual supervision and accountability.

Vaccine inventory management - A monthly report allows systematic monitoring of vaccine inventory, minimizes wastage, improves management of the product and reduces system vaccination cost.

Serological compliance - The PCV2 Differential ELISA test available at the Iowa State University Veterinary Diagnostic Laboratory, Ames, IA, has been shown to be useful tool for compliance monitoring for the PCV2 vaccine used.3 Compliance is monitored monthly by testing 10, ten week-old nursery pigs; <7 positive samples would trigger the following actions: 1) detailed inventory accounting; 2) farm visit to review protocols; 3) additional serotesting to confirm previous results and to identify other non- or poorly vaccinated, “at risk” groups; and 4) personnel action such as a written warning.

Non-compliance examples - Monitoring of Farm A found 9/10 and 10/10 negative tests in subsequent months. Vaccine inventory review for the past 3 months discovered only 43% of required vaccine had been purchased. Farm visit revealed unacceptable practices by an employee. Manager was mandated to give all PCV2 vaccinations and subsequent testing returned to acceptable levels. Monitoring of Farm B found 10/10 pigs negative. Inventory report showed no issues. Farm investigation revealed the timing of second vaccination had drifted from 6 wks to 9 wks of age. Initial samples were collected only 2 days after the second dose and thus were negative.

Discussion - Overall compliance to health and production programs is a major concern in large integrated systems and the ability to measure, monitor and assign accountability to those programs, including vaccination protocols, is of considerable value. Our monitoring program has helped us identify several key areas of vaccine implementation that have improved compliance.

Accuracy of dosing pumps: influence of type and maintenance

Anne Hemonic; Isabelle Corrégé; Nicolas Berthelot
IFIP-Institut du porc, LeRheu, France

Introduction
Good practices when using medicines in farms are essential to get drug efficiency, to respect the maximum residue limits in meat and to prevent the development of antimicrobial resistance. In particular, water medication administered with a dosing pump requires a well-dissolved and homogeneous solution at drinkers (1), a good regulation of the flow at drinkers and a reliable equipment. The aim of this study was to evaluate the dosing accuracy at farm levels, according to type of pumps and maintenance.

Materials and Methods
Three equipments were compared:
• A hydraulic pump (HP1) used in a farm during 4 years without any maintenance.
• HP1 after maintenance procedure (HP2).
• An electric pump after maintenance procedure (EP).

Pumps were set up on an experimental pipe and tested with 9 combinations of 3 pressures (3, 1.5, 0.5 bars) and 3 water flows, matching farm values: 600 l/h simulated high fattening flows (10 drinkers set at 1 l/min and used simultaneously). 30 and 300 l/h simulated low and intermediate post-weaning flows (1 and 10 drinkers in use and set at 0.5 l/min).

The dosing rate of the pumps was set at 5%, as it is the most frequently used on French pig farms (2). EP was also set at 10% to check how it affected the accuracy.

During each test, after filling up the tank with water, the weights of the stock solution (W1) and of the water collected downstream (W2) were recorded every 10 kg (20 measures). For an expected dosing rate of 5%, the observed one was calculated as: ((initial W1 – final W1) x 105)/W2.

We compared average observed dosing rates, coefficients of variation (CV) and the percentage of the dosing rates, irrespective of the 5% margin error set by the manufacturer.

Results and discussion
At 300 and 600 l/h, HP1 had average dosing rates between 4.96 and 5.10% with CV below 3% (Table 1), which is quite correct. On the opposite, at 30 l/h, results lied between 1.52 and 3.75% and CV reached 69% at 3 bars. A hydraulic pump that has worked regularly without any maintenance will underdose at low flows, sometimes injecting less than one third of the expected volume.

HP2 was tested only at problem flow (30 l/h). Average dosing rates were between 5.17 and 5.27% with all CV below 3%. So, maintenance clearly improved dosage accuracy.

EP, set at 5%, had correct results at 30 and 300 l/h (CV < 5%) with minor overdosing (between 2 and 5%). But at 600 l/h, EP underdosed and injected only 60% of expected volume. When the pump was set at 10%, the trends were the same. So, with post-weaning flows, electric pump was less accurate than hydraulic pump, though still acceptable. However, EP was not suitable with high fattening flows.

Conclusion
The regular maintenance of the pumps is crucial to get correct dosage accuracy. It consists in rinsing out the system after each use and performing yearly maintenance work on the pump. Moreover, hydraulic pump is suitable with post-weaning and fattening flows. But, electric pump is accurate only with post-weaning flows. It would be of interest to reset the rhythm of the electric pulse in order to be more compatible with higher fattening flows and to avoid underdosing.

Vaccination against *Erysipelothrix rhusiopathiae* in outdoor swine production

Fredrik Engström

*Swedish Animal Health Service, Kristianstad, Sweden*

**Introduction**

Joint disease is painful for the pig and causes 30% of all condemnations at slaughter in Sweden. Most common reasons for joint disease are infectious arthritis and osteochondrosis. *Erysipelothrix rhusiopathiae* is one of the most common bacterial agents involved in swine arthritis especially in outdoor pig production (1, 2). In comparison with conventional pig production, outdoor pigs suffer 3 times more observations for arthritis at slaughter (3). Despite this there are relatively few producers of outdoor pigs that vaccinate their slaughter pigs against erysipelas. The aim of this study was to investigate the effect of vaccinating outdoor slaughter pigs against erysipelas on the number of infectious arthritis seen at slaughter.

**Materials and Methods**

The trial was conducted as a prospective cohort study with vaccinated and control groups within 6 herds. Litters were split in half and groups were matched for gender and weight. In all, 903 pigs were given 2 ml of Erysorb vet® s.c. at 8 and 11 w of age and 905 unvaccinated pigs served as controls. Pigs were identified by ear tags and when slaughtered by tattooings. Those with acute arthritis were put to death and autopsied. Registrations for joint disease (infectious arthritis and osteochondrosis/arthrosis) were done at meat inspection. All data were collected from the abattoir and analysed by chi-square analysis.

**Results**

The pigs were slaughtered at two different abattoirs, 1200 and 598 pigs respectively. 10 pigs were put to death and autopsied due to acute arthritis.

Data from abattoirs and autopsy combined: Out of 903 vaccinated pigs, 33 (3.7%) were registered for arthritis, and 27 pigs (3.0%) for osteochondrosis/arthrosis. 3 pigs were culled due to arthritis. Of the 905 non vaccinated pigs, 57 (6.3%) were registered for arthritis, and 17 pigs (1.9%) for osteochondrosis/arthrosis. 10 pigs were culled due to arthritis. Over all, the prevalence of arthritis was significantly lower among vaccinated pigs compared to among non-vaccinated pigs (Table 1).

In farms A and E the differences in number of observations for arthritis between groups were statistically significant. Concerning the other farms differences between groups were numerical or none.

**Discussion**

There is doubt if vaccination has any major effect against chronic erysipelas (4). The relatively high number (33) of observations made for arthritis in the vaccinated group may be explained by arthritis due to other pathogens or chronic erysipelas in spite of vaccination. This study shows that vaccination against erysipelas in outdoor swine production significantly reduced the number of observations due to arthritis in pigs from some herds. Farmers that experience sudden onset of clinical joint disease and higher number of observations/culling due to arthritis at meat inspection are therefore advised to vaccinate against erysipelas.

Investigation of a case of PCV2 vaccine dilution and theft

Gail L. Cunningham¹  Mark Jacobson²  Ed Krol³

1. Boehringer Ingelheim Canada Ltd., Burlington, ON, Canada; 2. Warman Veterinary Services, Warman, SK, Canada; 3. College of Pharmacy & Nutrition University of Saskatchewan, Saskatoon, SK, Canada

Introduction

The use of pig vaccines to control porcine circovirus type 2 (PCV2) has proven to be both extremely effective in controlling disease and providing a return on investment to producers (1). This paper describes an unusual field case where clinical signs related to PCV2 infection were observed in a herd where pigs had seemingly been properly vaccinated with Ingelvac CircoFLEX®. The investigation, triggered by the manager of the farm, revealed that the vaccine was not at fault.

Case History

Two farm sites in Western Canada were involved in this case investigation: Farm 1, a 5200-sow, farrow-to-feeder (22 kg) system and Farm 2, a 1300-sow, farrow-to-finish operation. These farms were exporting 22 kg feeder hogs to the United States for finishing. Investigation: Farm 1, a 5200-sow, farrow-to-feeder (22 kg) system

The following is an outline of the events of the case during 2009.

May 13 - The manager of Farm 1 called the herd veterinarian and described irregularities in their Ingelvac CircoFLEX® vaccine on the farm. For several weeks, a number of vials out of an unusual case of vaccine stored in the barn had the stoppers punctured as if they had been put on an automatic syringe. However, the punctured vials were just as full as those that appeared unopened. The vaccine in the punctured vials was also lighter in color than bottles that had an intact stopper but the change was subtle. Dilution of the vaccine was considered at the time but discounted as a probability.

May 22 - The herd veterinarian received information from the producer that the US feeding operations were seeing pigs with PCV2-associated disease in the feeders from the flow of pigs from Farm 1. Mortality was up to 7.5% in some groups. Boehringer Ingelheim, the vaccine manufacturer was contacted at that time to evaluate the integrity of the potentially altered vaccine from Barn 1.

June 1 – 8000 doses of Ingelvac CircoFLEX® are discovered missing from Barn 1. All vaccine is locked up in the main office and not put in the barn after this theft.

June 13 - The office in Barn 1 has a break-in but no materials were missing. No Ingelvac CircoFLEX® was in the barn at the time. The veterinarian was then made aware that 2400 doses of Ingelvac CircoFLEX® and 1200 doses of Ingelvac MycoFLEX® had also gone missing from Farm 2.

July 22 – One vial of potentially altered vaccine from Barn 1 and an unopened vial of the same serial number of Ingelvac CircoFLEX® were submitted by Boehringer Ingelheim to the College of Pharmacy and Nutrition at the University of Saskatchewan for evaluation.

Materials and Methods

The vaccine samples were analyzed using an ultraviolet-visible (UV-Vis) spectrophotometric measurement (2). The measurement technique is considered acceptable for determining the relative concentration of a protein. This technique allowed for the determination of relative protein concentrations of the original and the potentially altered sample but not for information on whether other contaminants had been introduced.

The assay utilizes absorbance readings at 260 nm and 280 nm in the following equation: [Protein mg/mL] = (1.55 x A280)-(0.76 x A260), where “A” is the absorbance reading.

The unopened sample of the same serial number as the potentially altered vaccine was used to prepare 10 to 200 fold dilutions using phosphate buffer. A calibration curve was prepared with the diluted samples of the original, (y=1.5522x+0.013, r²=0.9655), and the assay was determined to be linear in the indicated concentration range. The potentially altered sample was handled in an identical manner and analyzed by UV-Vis with the protein concentration determined using the above equation. The analysis was carried out in triplicate.

Results and Discussion

The potentially altered sample fell below the level of the calibration curve and it was concluded this sample was at least 5 times less concentrated than the unopened original sample.

It is hypothesized that the tampered bottles had 80% of the vaccine removed and replaced with liquid to make them appear full. It is estimated that this went on for a minimum of 8 weeks with 500 doses per week removed if the dilution was consistent. Between the diluted vaccine and that stolen from the barn, more than $22 000CDN of product was stolen. The outcome of the dilution will never be fully known as the production system ceased operations shortly after this investigation.

Past investigations of cases of vaccine failure have been attributed to many causes including errors in shipping, storage, dosage and administration. Dilution may also now need to be considered when investigating perceived vaccine failure.

Storage and detection of African Swine Fever Virus DNA in clinical material collected on FTA cards

Jovita Fernández-Pinero; Carmina Gallardo; Ana Robles; Gómez Concepción; Alejandro Soler; Marisa Arias
Community Reference Laboratory for African Swine Fever, CISA-INIA, Madrid, Spain

Introduction
African Swine Fever (ASF) is a highly contagious disease that remains endemic in large parts of Sub-Saharan Africa and in Sardinia, producing great economic losses. In 2007, ASF emerged in the Caucasus for the first time, and has since spread to several countries in the region, being a major epidemic threat to neighbouring areas. As there is no vaccine available, rapid diagnosis of the disease is of utmost importance to contain its spread. Diagnosis is usually performed in equipped labs, although new tools for the on-site ASF virus (ASFV) detection are being developed. Key points of an accurate diagnosis include: appropriate collection and rapid convenient transport of suspicious samples to the lab, storage of samples in adequate conditions, and execution of suitable diagnostic techniques.

FTA cards (Whatman) are made of special filter paper that contains a chemically treated fiber matrix. It is described that once a biological sample is applied to the FTA card, chemicals rapidly lyse cells, inactivate proteins and stabilize the DNA. This kind of cards are described for the simple collection and storage of clinical samples at room temperature, allowing long-term stability and further detection of present DNA even for years (www.whatman.com).

Materials and Methods
Fresh EDTA-blood and serum samples collected at different days from experimentally ASFV infected pigs were applied to FTA cards. They were allowed to completely dry and subsequently stored at room temperature. Small disks were punched from sample area and put in a PCR plate well. Optimisation of the fast procedure for viral DNA purification on FTA cards was carried out to avoid cross contamination and to afterwards incorporate the PCR mix directly to the washed and dried disks. Conventional and real-time PCR were run according to SOPs established in the lab (www.asf-referencelab.info). For a comparative study of the system convenience, aliquots of fresh collected blood and serum samples were also processed as usually to determine the presence of ASFV DNA following the reference PCR SOPs.

Results
Most of blood and serum samples collected on FTA cards, from different ASFV experimental inoculations, were properly identified by both conventional and real-time PCR. Some higher Ct values were observed when compared real-time PCR results from fresh and FTA-card samples analysis.

Analysing daily collected samples, positive results were obtained in fresh blood and serum samples from 1st and 3rd day post-inoculation (dpi), respectively. Samples collected on FTA cards were ASFV positive from 2nd dpi in blood and 3rd dpi in serum after three years of room temperature storage.

Two ASFV positive EDTA-blood and serum samples were serially diluted in negative porcine blood and sera, respectively, and analysed for sensitivity studies, being detected as positive until 10^-4 and 10^-3, respectively. When FTA cards impregnated with these samples were analysed, 10^-3 (real-time PCR) or 10^-4 (conventional PCR) was the detection limit for blood sample, whereas 10^-1 was the lowest positive dilution for sera.

Discussion
When clinical signs appear in ASFV infected animals and urgency for a rapid diagnosis is needed, the viraemia titre is sufficiently high to be detected by using FTA cards. The advantages of simple collection, transport and storage at room temperature, together with the non-infectious basis of samples collected on FTA cards, the easy treatment procedure and the potential combination with newly developed pen-side tests, show FTA cards as a possible convenient way to make real the ASFV DNA detection in basic/regional labs as a first line tool for the rapid on site diagnosis.

African swine fever: a high risk again

Lina Mur1 Beatriz Martinez-Lopez1 Marta Martinez-Aviles1,2 Jose Manuel Sanchez-Vizcaino1
1. VISAVET, Animal Health Department, University Complutense, Madrid, Spain;
2. Animal Health Research Centre. CISA-INIA, Valdeolmos, Madrid, Spain

Introduction
African swine fever (ASF) is one of the most important diseases of swine, due to the rapid and fatal spread causing great implications in international trade of swine products and animals (1). Since the eradication of the disease from the Iberian Peninsula in 1995, ASF has been restricted to Sub-Saharan countries and Sardinia (Italy). However, in the last decade, the epidemiology and distribution of the disease changed with the increased number of outbreaks in African countries, and the new affected areas in the European continent (Russian Federation and Caucasian countries).

The closeness of the European Union (EU) with these new affected territories and the high probability of Russian Federation to become endemic due to the presence of infected wild boars and the huge volume of unauthorized trade and transport in the area (2), convert ASF as a potential risk for EU.

In order to prevent the potential entrance and the negative impact of ASF within the EU borders, a risk assessment is necessary to detect the potential risk factors and to update the current surveillance and control programmes. This risk assessment will consider the following ways for the potential introduction of ASF in the EU: legal trade (live animals and products), illegal trade, wild animals, vectors and fomites. The study presented analyzes the risk of introduction of ASF in the EU by legal trade of live animals.

Materials and Methods
The presented model is a stochastic model to quantify the risk of introduction of ASF in EU by the legal trade of live pigs, adapted from the model used by Martinez et al. (3) to quantify the risk of introduction of Classical Swine Fever in Spain. The probability of having an outbreak of ASF in the EU by legal trade of an infected animal was estimated per month, country of origin of pigs, and destination country.

The input distributions were fitted using @Risk v5.5 (Paladise Corp.), and the model was run 10,000 times using a Monte Carlo approach with @Risk software on Microsoft Excel®. The results obtained were mapped using the software ArcGIS 9.2 (ESRI®).

Results
The results of the model indicate that the mean risk of introduction of ASFV in the EU is 5.07x10^-4, 95%IP (1.46x10^-5, 1.85x10^-3) which corresponds (if conditions remain constant), to approximately one outbreak in 1972 years. This risk is mainly concentrated in the countries of Slovenia, France and Belgium and in the month of May. The non-EU countries that mean a higher risk for the introduction of ASF in EU are Albania and Belarus.

Discussion
Results from this study show that imports of live pigs do not represent a high risk for the introduction of ASFV in the EU. This result is consistent with previous epidemiological studies of the disease that identify contaminated garbage from airports and ports, as the main route for the introduction of ASFV in free areas (4). The other pathways of introduction such as illegal trade, wild boars, ticks and fomites have to be considered in further analyses in order to obtain a complete and useful risk assessment to prevent the introduction of ASF in the EU.

This work has been financed by the European Community’s research project ASFRISK (FP7 KBBE-2007-1-3-05).

Swine fever virus, a major health constraint to productivity of pig in Congo

Tshibwabwa P. Nkambua
1. Laboratoire Veterinaire de Kinshasa, Kinshasa, Democratic Republic of the Congo; 2. Eau pour Tous, Kinshasa, Democratic Republic of the Congo

Porcine production represents an important component of the Congolese livestock production system, providing 12% of the value of livestock products consumed at the farm level and 48% of the cash income generated. Democratic Republic of Congo is third in Africa and seventh in the world in terms of pig population. The country has, however, benefited little from this enormous resource owing to a multitude of problems, disease being the most important. Disease alone accounts for mortalities of 30% in Congolese pig population. One of the diseases appears to be the African swine fever virus (ASFV). The ASFV is the main DNA arbovirus and the sole member of the family Asfarviridae. The pathogenesis of ASFV is characterized by a low infectious dose, lifelong infection, efficient transmission to pigs, and low mortality until after the first ovipositor. It causes a lethal, hemorrhagic disease in domestic pigs. Productivity losses attributable to the African swine fever virus are often substantial. A loss of US$ 101.8 million is reported annually due to ASFV.

In a country confronted with challenges of an ever-rising human population and food shortage, such enormous losses caused by the swine fever virus are unacceptable. Therefore, swine fever virus control should receive special attention in poverty reduction strategies through improved productivity of livestock if the present and future challenges of food shortage are to be addressed.

This conference reviews extensive evidence demonstrating that swine fever virus is a major constraint to productivity of pig in Congo. It also discusses epidemiology and ecology of major swine fever virus in the country and suggests strategies for improved control in various agro-ecological zones and production system.
Introduction
Classical swine fever virus (CSFV) is an enveloped positive-stranded RNA virus in the genus Pestivirus of the Flaviviridae family. It is the causative agent of classical swine fever (CSF), a highly contagious disease in pigs. Major envelope glycoprotein E2 is exposed on the outer surface of the virion and induces neutralizing antibodies during infection. Four antigenic domains, A to D, were identified at the N-terminus of E2 and formed two independent structural units; one composes of domain B and C and the other contains the domain A and D (1). Although CSFVs consist of a unique serotype, they can be differentiated by different patterns of reactivity with CSFV-specific monoclonal antibodies (mAbs) (2). The objective of this study was to further analyze the antigenic differences among various CSFV subgroups.

Materials and Methods
Three CSFV strains were used in this study, including a subgroup 2.1 virus (TD/96/TWN), a subgroup 3.4 virus (94.4/IL/94/TWN), and a subgroup 1.1 vaccine strain (LPC/AHRI). Several truncated and site-mutated E2 proteins of three CSFV strains were expressed using baculovirus system and tested for their reactions to a panel of mAbs against different epitopes and strains of CSFV. The reactivity was detected by indirect fluorescent assay (IFA).

Results
The antigenicities of E2 glycoproteins of different CSFV genotype subgroups can be distinguished by their variable reaction patterns between expressed B/C domains of E2 and a panel of mAbs. The mAbs against B/C domains were able to differentiate field viruses TD/96/TWN and 94.4/IL/94/TWN from the vaccine virus LPC/AHRI. The smallest integral antigenic unit of the B/C domains was mapped to the N-terminal 90 residues between amino acids 690 and 779 (Table 1). Site-directed mutagenesis further showed that the residues 693C, 737C, 771L, 772L, 773F and D774 were critical for the reactivity of E2 protein with mAbs (Table 2). The D/A domains of various CSFVs were relatively conserved and recognized by all mAbs against the A domain.

Discussion
Our study indicated that each of the four conserved residues, 771L, 772L, 773F and D774 is important in maintaining the structural integrity of the B/C domains. Mutation of either 693C or 737C abrogated the reaction with mAb, indicating that the disulfide bond between 693C and 737C is essential for correct folding of E2 protein. Taken together, the reactivity of the epitope on B/C domains with mAbs depends on both the disulfide bond and the motif 771LLFD774 located at 34 amino acids downstream of the disulfide bond; the epitope is thus believed to be conformational and discontinuous.

Introduction

Classical swine fever virus (CSFV) is the causative agent of one of the most devastating porcine viral diseases; classical swine fever (CSF). There is a current need for efficient and safer marker vaccines to assist in the control of future CSF outbreaks (1). Multimerization is a nature-mimicking strategy of antigen presentation. Indeed, pigs vaccinated with a dendrimeric peptide against foot-and-mouth disease virus, did not develop significant clinical signs upon challenge and inhibited replication and excretion of virus (2).

Here, we describe the design and construction of three dendrimeric peptide, that integrates B (three different epitopes from E2 protein) and T (from NS2-3 protein) cell epitopes, and their capability to induce T cellular and neutralizing humoral immune responses against CSFV challenge in domestic pigs.

Material and methods

The dendrimeric peptides were synthetized by Stepwise Solid Phase Peptide Synthesis on a Rink Amide ChemMatrix resin using standard Fmoc chemistry, P1: 4B (aa 694-712), 1T (1446-1460), P2: 4B (aa712-728), 1T and P3:4B (aa829-842), 1T. To evaluate the immune response induced by the dendrimeric peptides, four groups of six domestic pig were placed in four different section of the BSL3 animal house from CRESA (24 pigs in total). Three of these groups were inoculated twice, at day 0 and at day 21, by intramuscular injection (i.m.) with 1.4 mg of P1, P2 and P3, respectively. Peptides were emulsified with Montanide ISA V206 adjuvant (Seppic). The fourth group of animals was used as the control (non-vaccinated pigs).

Ten days after the last immunization, all pigs were challenged with 105 DICT50 of CSFV (strain Margarita) (3). The clinical signs of disease were scored daily and pigs were bled weekly to follow the specific neutralising antibody induction by neutralisation peroxidase-linked assay. Peptide specific antibodies were detected by indirect ELISA. E2 specific antibodies were detected using ELISA (IDEXX). Evaluation of the interferon gamma-producing cells was performed as described (4). The presence of CSFV RNA in serum was analyzed using the Q RT-PCR real time assay (5).

Results

Immunization of pigs with dendrimeric peptides induced dendrimer-specific antibodies in the three groups of immunized pigs, mainly in those that received dendrimer P1. These dendrimer-specific antibodies not recognize the E2 CSFV protein in ELISA, and were not neutralizing. On the other hand, the three dendrimeric constructions were able to induce IFN gamma-producing cells in immunized pigs after two doses, being the higher response also observed with dendrimer P1. After viral challenge, non vaccinated pigs developed fever and severe clinical signs of CSF from day 3 pi. Contrary, immunized groups showed lower score values, mainly in pigs immunized with dendrimer P1 in two animals of this group. Induction of ELISA antibodies against E2 protein and neutralizing antibodies, as well as a decrease in viral charge at 13 dpi were observed. On the other hand, the highest values of IFN gamma-producing cells in these animals was observed at 13 dpi.

Discussion

Multimerization of peptides, such as that provided by dendrimeric constructs, has been recognized as an effective tool for enhancing peptide immunogenicity (2). In this work, we report that immunization of pigs with dendrimers P1, P2 and P3 induces non-neutralizing peptide-specific antibodies, as well as IFN gamma-producing cells, the latter probably due to the NS2-3 T cell epitope included in their formulation). With the three dendrimers, a significant lower score of CSF clinical signs after viral challenge was observed compared to that of naive animals. Interestingly, two of the animals immunized with dendrimer P1 developed neutralizing antibodies and showed the highest values of IFN gamma-producing cells after CSFV challenge, suggesting that dendrimer P1 can induce efficient T cell and humoral responses that correlated with protection against CSFV.

Classical Swine Fever vaccination: study of compatibility of mass vaccination in a sow herd and piglet vaccination

Eric Brunier1 Rawat Chantong2 Susichol Sittinuntn2 T Sisom2 Achinee Runcharoen3

Introduction:
Classical Swine Fever (CSF) is a contagious infectious disease affecting swine classified in the A list of the OIE (International Office for Epizootics). Ceva Santé Animale has developed a live attenuated vaccine, COGLAPEST®, containing the Thiverval strain. This strain allows the vaccination of the sows during the gestation period 2 to 6 six weeks before farrow in order to enrich the colostrum with maternally derived antibodies (MDA). The timing for the piglet vaccination depends on the MDA level. The objective of this trial was to study whether, in mass vaccination conditions, a unique vaccination program can be defined for the piglets whenever the sows are vaccinated during the gestation.

Material and method
In a farrow to finish farm of 3000 sows in Thailand, three batches of 70 sows each have been constituted. The first batch has been vaccinated with COGLAPEST® (2 ml intramuscularly) 100 days, the second batch 63 days, and the third batch 20 days before farrowing.
Different samples have been done: blood sample on the sows at farrowing and their five first born piglets at 14 days of age; colostrum after farrowing. The CSF antibody levels have been measured in all this samples by serumneutralization.

Results:
At farrowing, there was no significant difference among the three groups of sows concerning their serum VN titers (table 1). A significant difference existed between the groups vaccinated 63 or 100 days before gestation for the colostrum as well as for the piglets serum VN titers. The group vaccinated 63 days before gestation had the highest level of VN antibodies both in the colostrum and in the piglets serum.

Concerning the sows of first and second parity, there was no significant difference among the groups.

Discussion and conclusion:
The sow antibody level at farrowing is significantly higher when the vaccination is done at 63 days before farrowing compared with a vaccination done at 100 days as well as at 20 days before farrowing.
Studies done on piglets show the highest level of antibodies usually appears 50 days after vaccination (M. Launais et al.). It could be hence interesting to compare the vaccination of sows at 63 days and at 42 days before farrowing to define the best moment for the vaccination of piglets. The antibody level in piglets however is homogeneous enough in this trial to define a unique vaccination program for the piglets at 4 and 7 weeks of age (figure 1).

This trial shows that the mass vaccination against CSF with COGLAPEST® is a possible practice that allows a common vaccination program for all the piglets.

Introduction
The genus Bocavirus consists of three members; bovine parvo-virus, canine minute virus and human bocavirus. Recently a novel porcine bocavirus-like virus was identified in pigs in Sweden (PBo-likeV)1.

Recent research in our laboratories has isolated and identified 2 antigenically distinct novel bocavirus-like viruses in pigs (SwBoV1 and SwBoV2) from farms in Northern Ireland with clinical postweaning multisystemic wasting syndrome. Purification of the viruses followed by molecular cloning methods allowed partial sequencing of the two viruses.

Materials and Methods
Tissue and faeces isolates were grown up in primary pig kidney. Isolates that exhibited a cytopathic effect (CPE) were screened for a range of common viruses using PCR. Several PCR negative isolates were sucrose purified and put through a 1.16 g/ml CsCl density gradient. An in-house antigen capture ELISA was developed and used to determine the virus-containing fractions. These were subject to electron microscopy (EM). DNA was isolated from the fractions using phenol/chloroform extraction and was electrophoresed on agarose. Bands were excised, purified, restricted with HAE III and cloned into TOPO TA vector. After transformation into E. coli and overnight growth on agar, colonies were grown in broth and plasmids were purified and sequenced with M13 primers. BLAST analysis was used to compare the sequences to GenBank. PCR primers were designed against the viral sequences and were used to produce amplicons spanning the clones. These were sequenced as before. Assembled sequences were analysed in NCBI ORF finder for the presence of putative open reading frames. Nucleic acid and translated putative protein sequences were BLAST analysed and compared to known bocavirus sequences using Clustal W. Phylogenetic trees were produced from SWBoV sequences and those of known bocavirus sequences from GenBank using Mega 4. An antiswine-FITC conjugate was used to screen 370 swine sera using virus infected coverslips. Monoclonal antibodies (MAbs) were produced for each of the SwBoVs.

Results
Two bocavirus-like viruses were isolated using virus culture. Small particles of about 20nm could be seen by EM. After molecular characterisation they were found to be related to the genus bocavirus and were designated SwBoV1 and SwBoV2. Currently 5082 bps (SwBoV1) and 4215 bps (SwBoV2) have been sequenced. ORF analysis predicted 3 putative ORFs (1 partial ORF for SwBoV2) with protein similarity corresponding to the NS1, NP1 and VP1/2 proteins of known bocaviruses. SwBoVs 1 and 2 share 84% homology to each other and 39-49% homology with the other known bocaviruses, as determined by Clustal W analysis. Phylogeny of the partial DNA sequences grouped the SwBoVs with the other animal bocavirus and that they were distinct from PBo-likeV (Fig. 1). Serological analysis showed that 32 and 33 out of 370 sera tested were +ve for SwBoV1 and 2 respectively. MAbs for the two SwBoVs do not cross-react.

Discussion
Two novel, antigenically distinct swine bocaviruses were isolated and partially characterised. These were related to the other known bocaviruses and distinct from another known bocavirus, PBo-likeV from Sweden1. The prevalence, clinico-pathological significance, epidemiology and genetic diversity of SwBoV within the swine population are currently being investigated.

Laboratorio Avi-Mex, S. A. de C. V., Mexico City, DF, Mexico

Introduction
Blue Eye Disease (BED) was reported at the beginning of the 80’s in farms near La Piedad Michoacan, Mexico, characterized for affecting pigs of different ages, generating nervous signs and high mortality in piglets, corneal opacity and reproductive alterations in adult animals (Stephano et al/1981). The first molecular characterization was done by Moreno et al (1986) and named LPMV, this is considered as the prototype of the genus Rubulavirus (Santos et al, 2004). The objective of our study was to determine and compare the genetic sequence of 13 field isolates, but also to compare them with genetic information obtained from GenBank.

Materials and Methods
Viruses. 13 isolates obtained from 2000 to 2007 from 4 mexican states. The sequence for 7 viruses was gathered from GenBank (http://www.ncbi.nlm.nih.gov/) (see table 1).

Propagation. PK 15 cell monolayers were infected with each isolate and incubated at 37°C for viral replication.

Identification by RT PCR. Amplification and transformation of genetic material (RNA) was done by RT PCR in order to obtain cDNA. From cDNA, the amplified fragment (HN) was visualized in agarose gel. Cortes et al (unpublished data).

Sequencing. The amplified fragment was purified and sequenced according to Cortes et al (unpublished data). The obtained results were compared utilizing the Vector NTI Advance program (Invitrogen Corp 2007) in order to align and generate a dendogram.

Results of viral presence were confirmed by Hemmaglutination Inhibition test (HI) and by RT PCR.

Results and discussion
Genetic homology is shown in table 2. The 13 field samples showed a high homology when compared against LPMV (ranging from 97.9% to 100%) and from 98.0% to 100% for the 7 sequences obtained from GenBank. The consensus of the 20 sequenced data showed a high homology (98.94 to 100%) when compared against the original LPMV sequence (21st sequence shown in the dendogram).

We could also detect the formation of 6 groups (clusters) among the isolates (figure 1). It is important to mention that individual genetic differences found in some of the 20 analyzed sequences are equal or higher than 2%, when compared against the original sequence of LPMV, showing differing from previous report by Berg et al (1997), who reported differences of less than 2% comparing the same HN fragment.

Although we found differences up to 2.1%, these differences are not expressed as in vivo antigenic changes (Echeveste et al (2009), similar to what is usually found when compared to other Paramixoviridae virus such as Newcastle disease virus (Anónimo, ANECA 2000).

Figure 1. Dendogram.

LPMV is considered the original sequence and thus used as comparative.

Introduction
Blue Eye Disease (BED) is caused by a Rubulavirus, characterized for producing nervous disorders in suckling pigs and reproductive problems in adult pigs. Serological diagnose is made through tests that quantify neutralizing or hemagglutinant antibodies (VN or HI tests), or based in a S/P relation (ELISA). The objective of this study was to compare the 3 diagnostic tests for BED.

Materials and Methods
Samples: Twenty three vaccinated animal sera, 17 negative sera from a BED free farm, along with 212 field sera.

Virus Neutralization (VN) Test: It was conducted according to Burleson et al. (2002), the samples were diluted, added to monolayer cell cultures and incubated at 37.0 C.

Hemmaglutination Inhibition Test (HI): Samples were inactivated and adsorbed in kaolin; bovine erythrocytes were applied according to the technique described by Ramirez et al. (1996). Samples with a titer equal or higher than 1:16 were considered as positive.

Sera for ELISA were diluted 1:200 and tested according to the instruction of the kit developed by Aranda et al. (unpublished data). Samples were considered positive when the s/p was equal or higher than 0.4.

All results were analyzed by descriptive statistics.

Results
Samples derived from vaccinated animals: On regards to sensitivity, VN test detected 22 samples as positive with a sensitivity of 95.65%, while ELISA test detected less than 74%. On regards to specificity, VN and HI resulted 100% negative with the negative samples while ELISA only 82.35%, as shown in Table 1.

Field samples: VN test detected the highest percentage of positivity (71.70%) compared to ELISA and HI tests, both with less than 47%, as shown in Table 2.

Discussion:
In this study, VN showed the highest sensitivity in positive samples obtained from vaccinated animals, followed by ELISA and HI tests. This data agrees with previous reports. Hernandez et al (1992) obtained similar results with VN test from vaccinated animals in a disease free zone. Aranda et al (2006) found 77% sensitivity in vaccinated animals at 30 days post vaccination using the ELISA test. Hernandez et al (1998) found that the HI test detects lower antibody levels compared to VN using sera derived from BED challenged pigs. Gonzalez et al (2002) using field sera samples were able to detect a higher number of positive samples using the ELISA test (58.18%) compared to HI test (55.49%).

Conclusions.
All serologic tests are important and have diagnostic applications. It’s of capital importance to consider false positive or false negative results that every test can produce and this is why it’s necessary to evaluate and compare results of samples using different tests. Not only sensitivity and specificity must rule our selection criteria, also other parameters such as Positive and Negative Predictive Values and Total Efficacy of the test in order to choose the one that best suits our requirements.

**Efficacy of three different Modified Live Aujeszky’s Disease vaccines under Asian field conditions**

Ming Yong¹ Philip Lehrbach² David Y. Ping-Cheng³ Wang Yao-Horng⁴

1. Pfizer Animal Health (Asia Pacific), Shanghai, China; 2. Pfizer Animal Health, Melbourne, VIC, Australia; 3. Animal Technology Institute, Taipei, Taiwan; 4. College of Health Sciences, Yuanpei University, Hsinchu, Taiwan

**Introduction**

There is no official effort to eradicate Aujeszky’s Disease (AD) in Asia but modified live vaccines are successfully used to control clinical disease. In recent years, due to the increased pressure of PRDC and the emergence of PCV2, there is renewed interest in looking at the efficacy of AD vaccines under field conditions in Asia. The objective of this trial was to evaluate the efficacy of three commercially available AD vaccines.

**Material and Methods**

The trial was conducted in a commercial farm in Taiwan. 300 healthy piglets were randomly selected, ear tagged and assigned into 6 groups (see Table 1). Ten pigs were selected randomly from each group and transferred to the holding facility for laboratory challenge. Three commercial vaccines were used in the study: Suvaxyn Aujeszky IN/IM; Suvaxyn Aujeszky NIA 783 and Suvaxyn PRV gpI (3 groups, including with Suvaxyn O/W as diluent). The dose volume for all vaccines was 2 mLs. IN vaccination was done by the procedure described for administering the challenge virus.

All pigs were challenged with a local virulent strain (TNL) of AD at 28 days post-vaccination. Challenge dosage was 10⁵ TCID⁵₀ in a 2 mL volume. Each animal was challenged with 1 mL of inoculum per nostril administered over a 30 second period. Mortality, clinical signs, serology and body weight were monitored.

**Results and Discussion**

Mortality and Clinical signs. Vaccinated groups survived the severe challenge (> 80%) while only one unvaccinated pig survived (Figure 1). Unvaccinated pigs developed high fever (>40o C) second day post challenge and showed respiratory (sneezing, dyspnoea, conjunctivitis) and nervous clinical signs (convulsion and paralysis). Post mortem findings were consistent with AD. Only mild fever was detected in a few of the vaccinated pigs and subsided quickly. The growth rate of the vaccinated and challenged pigs was not severely affected by the challenge and was comparable to vaccinated and unvaccinated unchallenged pigs on the farm, which remained seronegative (gE antibody negative). In contrast, pigs challenged with virulent field strain of ADV seroconverted (gE antibody positive) 2 to 3 weeks post-challenge.

**Figure 1. Survival curve of vaccinated and unvaccinated control pigs after virulent AD challenge**

Serology All vaccinated groups showed a strong antibody response to AD 4 weeks post vaccination, with Suvaxyn Aujeszky NIA 783 stimulating the highest. Suvaxyn PRVgpI in Suvaxyn O/W diluent induced a higher response than the same vaccine in water.

**Figure 2. SN titres following AD challenge**

Despite the use of a very virulent challenge strain all 3 commercial vaccines were effective in reducing or preventing clinical signs, mortality and other production losses associated with AD.

Introduction
Torque teno virus (TTV) is a non-enveloped virus with circular single-stranded DNA genome belonging to the floating genus Anellovirus. TTV was discovered in humans and later identified in other species including pigs.

In pigs, two different genogroups have been described, genogroup 1 (TTV1) and genogroup 2 (TTV2). Swine TTV infection is ubiquitous and species-specific (1). However, its potential role on disease occurrence is yet to be defined. TTV infection has been associated with pigs affected by postweaning multisystemic wasting syndrome (PMWS) (1,2) and linked with development of a porcine dermatitis and nephropathy syndrome (PDNS)-like condition in pigs co-infected with TTV1 and porcine reproductive and respiratory syndrome virus (PRRSV) (3). Faecal-oral transmission route is considered the most common route of TTV dissemination but vertical transmission route may play an important role (4).

In the present work, a prospective study was designed to assess the prevalence of both swine TTVs in cases of abortions. Healthy foetuses collected from pregnant sows at slaughterhouse were used as age-matched controls.

Material and Methods
A total of 98 abortions cases from 22 different Spanish farms and 55 foetuses collected from pregnant sows (from 14 farms) at slaughterhouse were studied. Foetal age was estimated and foetuses collected were classified according first (A) or second half of gestation (B).

All foetuses were necropsied and relevant tissues were collected, pooled and submitted to DNA extraction. In order to evaluate the presence of TTV1 and TTV2, samples were analyzed by a specific polymerase chain reaction (PCR). Contingency tables were used to compare prevalence of TTV1 and TTV2 in different samples and association between gestation stage and TTV infection.

Results
Results on TTV prevalence are summarized in table 1. There were no statistically significant differences when comparing prevalence of swine TTVs by type of sample or by gestation stage.

Table 1. Prevalence of swine TTV1 and TTV2 in foetuses coming from abortions and from slaughtered sows with no reproductive problems. Foetuses were classified as from first (A) and second half (B) of gestation.

Discussion
The present work represents the first description of swine TTV infection in pig foetuses at different stages of gestation. Results obtained confirm that vertical transmission is an important route of TTVs dissemination in swine. In addition, data obtained suggest that swine TTV infection is commonly present in aborted foetuses and foetuses collected from slaughtered sows. However, TTVs should not apparently be considered as infectious agents responsible for abortion occurrence.

**Torque teno sus virus 1 and 2 viral loads in postweaning multisystemic wasting syndrome (PMWS) affected and non-affected pigs**

Mario Aramouni; Marina Sibila; Gerard E. Martin-Valls; David Nieto; Martí Cortey; Joaquim Segalés; Tuija Kekarainen  
CReSA/UAB, Bellaterra (Barcelona), Spain

**Introduction**

Torque teno virus (TTV) is a small, non-enveloped virus with a circular single-stranded DNA genome, belonging to the family Anelloviridae, genus Iotatorquevirus and widely distributed in different animal species and humans. In swine, two genetically distinct genogroups have been identified, Torque teno sus virus 1 (TTV1) and 2 (TTV2). No clear-cut pathogenic role of TTVs has been demonstrated so far. However, it has been shown that TTV2 prevalence is higher in postweaning multisystemic wasting syndrome (PMWS) affected pigs, and TTV1 has been linked to PMWS and a porcine dermatitis and nephropathy syndrome (PDNS)-like condition (1,2,3). Nevertheless, the TTV viral load in diseased animals has not been investigated. Therefore, the aim of the present study was to quantify TTV1 and TTV2 viral load in serum of PMWS-affected and healthy animals using a newly developed quantitative PCR (qPCR) method.

**Materials and methods**

Serum samples of sixty animals ranging from 11 to 21 weeks of age included in a previous study on Porcine circovirus type 2 (PCV2) (5) were analyzed by TTV1 and TTV2 qPCRs. From them, 29 pigs were diagnosed as PMWS by histopathology and PCV2 in situ hybridization (ISH) (4), and 31 were healthy, age-matched animals.

A qPCR assay was developed using TTV1 and TTV2 D-Lux primers technology (Invitrogen). Standard curves were generated using ten-fold serial dilution (10^8 - 10^0 genomic equivalents) of purified TTV1 and TTV2 whole genome plasmids. Serum samples as well as standard dilutions were run in triplicates. The average log10 copies of TTV1, TTV2 and PCV2 per ml of serum were compared globally, and between healthy and PMWS pigs, using Mann-Whitney’s U and Kruskal-Wallis test. Significance was set at P<0.05. PCV2 viral load was obtained from data generated in the abovementioned study (5).

**Results**

PCV2 log10 copies/ml from the previous published work (5) as well as TTV1 and TTV2 log10 DNA copies/ml of serum in PMWS and healthy pigs are represented in figure 1. TTV2 DNA was detected and quantified in all the PMWS affected animals but not in all healthy animals. TTV1 was detected in most but not all the animals of both groups. In general, TTV1 viral loads in serum were similar in healthy and PMWS animals, with values comparable to TTV2 viral loads in healthy animals. On the contrary, PMWS animals had significantly higher (p<0.05) TTV2 viral load than healthy animals. PCV2 viral load in healthy animals was significantly lower than TTV2 loads. No significant differences were found between PCV2 and TTV2 loads in PMWS animals.

**Discussion**

Results from this study showed that TTV2 and TTV1 were highly prevalent among studied pigs. Moreover, the fact that TTV2 loads in serum were higher in PMWS affected than in healthy pigs would support the previously suggested association between TTV2 and PMWS (1). On the contrary, this relation was not observed for TTV1. However, results obtained in this study encourage further studies on the role of TTVs in pig diseases or disease triggering.

**Figure 1:** TTV1 and TTV2 log10 copies/ml of serum in PMWS and healthy pigs. PCV2 viral loads of studied animals are from Grau-Roma et al.

Simulation of the economic impact of Lawsonia intracellularis infection

Patricia K. Holyoake1 Alison Collins2 Bruce Mullan3
1. Wagga Wagga Agricultural Institute, Wagga Wagga, NSW, Australia; 2. Elizabeth Macarthur Agricultural Institute, Menangle, NSW, Australia; 3. Department of Agriculture and Food, South Perth, WA, Australia

Introduction
Proliferative enteropathy (PE) is an enteric disease of pigs caused by the obligate intracellular bacterium Lawsonia intracellularis. Results of economic modelling conducted using the AUSPIG decision support system in 1996 estimated that PE cost pork producers up to $7.00 per pig, with most of the cost attributed to using antibiotics in the pig diets to treat and control PE.2-3 This model did not take into account the economic impact of subclinical PE in a herd, and the potential for reduced antibiotic costs through the use of vaccine (Enterisol® Ileitis, Boehringer Ingelheim) to aid in the control of disease. This paper reports on recent simulations on the economic impact of L intracellularis infection.

Materials and Methods
Growth and carcass data were from an experiment where 36 entire male pigs (18 challenged, 18 controls) were challenged at 63 days of age with $5.85 \times 10^9$ L intracellularis bacteria. Feed intake was measured on 2 consecutive days every week from 2 weeks before inoculation until 6 weeks after. Pigs were weighed each week from the day they arrived until slaughter at 106 days of age. Carcass composition data, including P2 backfat were sourced from CT scans conducted on pigs at 52, 85 and 106 days of age. Data on PE treatment and control costs were from 5 L. intracellularis-infected farms of varying health status. The AUSPIG simulations were based on a 1000-sow farm with commercial Large White X Landrace genotype. Three infection categories (controls (non-challenged), sub-clinically and clinically-affected) were modelled. It was assumed that pigs were sold at a constant liveweight (approximately 104 kg). The impact of infection at the herd level was modelled by altering the proportion of control, subclinical and clinical pigs in three simulations and including 50% females and 50% castrates. These proportions were based on results of a recent serological survey, where an average of 84.2% of pigs within herds in Australia had antibodies to L. intracellularis.4 The “subclinical” simulation included 20% control and 80% subclinical pigs. The “clinical” simulation included 10% control, 74% subclinical, 16% clinical and an increase in grower pig mortality of 0.5%.

Results
The growth performance of pigs for the three infection herd categories is presented in Table 1. Profit (net revenue) in the control, non-infected herd was modelled at $25.31AUD per pig. Subclinical L. intracellularis infection reduced net revenue by $8.33AUD, whilst clinical infection reduced net revenue by $13.00AUD, relative to the non-infected “herd”. The cost of controlling PE was $2.70AUD per pig.

Discussion
We used the AUSPIG decision support system to estimate the economic impact of L. intracellularis infection. This is similar to a previous estimate of subclinical PE costs.5 The impact of infection on growth and P2 backfat greatly outweighed the PE control costs. Costs will vary among herds depending on the proportion of pigs infected, disease severity, treatment/control costs and effects on farm flow. Research is currently underway to refine the results of these simulations, including the growth response of pigs to vaccination/medication.

Reduced muscle growth in pigs sub-clinically affected with proliferative enteropathy

Alison M. Collins¹ Shayne Fell¹ Jolien van Straaten² Nadine Bolsius²

¹. Elizabeth Macarthur Agricultural Institute, Narellan, NSW, Australia; ². University of Utrecht, Utrecht, Netherlands

Introduction
Pigs clinically affected with proliferative enteropathy (PE) suffer diarrhoea, reduced growth and poor feed efficiency, which can cost Australian producers as much as A$7 per pig¹. These costs do not include changes to body composition such as muscle growth. The impact of sub-clinical PE is difficult to estimate because many producers are unaware of the problem. In this study we examined the impact of sub-clinical PE in real time on body composition, muscle growth and P2 backfat depth.

Materials and Methods
Thirty six male hybrid weaner pigs (Large White x Landrace) were randomly allocated at 13.8 ± 1.0kg into 2 treatments: pigs infected with L.intracellularis, and a cohort of uninfected pigs. Pigs were housed in individual pens, with strict quarantine between treatments (separate rooms). Serology and faecal PCR monitoring of pigs prior to challenge indicated that all pigs were naïve to L.intracellularis. At 9 weeks of age, one group of 18 pigs was orally challenged with 5.9 x 10⁹ viable L.intracellularis extracted from a PE-affected mucosa, and the control group was inoculated with phosphate buffered saline. The consistency of pig’s faeces was scored daily as either normal or diarrhoeic. Blood collected at 0, 28 and 38 days post inoculation (pi) was tested for L.intracellularis-specific IgG using an indirect fluorescent antibody test (IFAT). Faeces collected twice per week from 0 to 35 days pi was tested for L.intracellularis DNA by a conventional PCR. The body composition of pigs was determined at 14 days pre-inoculation and 21 and 42 days pi, using a Picker spiral CT scanner (Model PQ2000). Pigs were anaesthetized and cross-sectional images of the whole pig in 10mm sections (reconstructed in 3 dimensions) were analysed to calculate tissue volumes of bone, muscle, fat, skin and water using described CT densities². Muscle growth was defined as the difference in muscle volume divided by the number of days between CT scans. Tissue volumes were converted into a mass, using described tissue densities and calculated as a proportion of the total mass of the pig³. The P2 backfat was measured from the 42 days pi CT image².

Results
L.intracellularis infection was demonstrated by faecal PCR and IFAT between 14 and 42 days pi in all pigs challenged with L.intracellularis. The majority of infected pigs (>80%) were sub-clinically affected, but pigs inoculated with L.intracellularis had a significantly higher probability of diarrhoea than control pigs between day 22 and 26 pi. L.intracellularis infection did not significantly alter the mean tissue weights or proportion of tissue types. However, L.intracellularis infection did significantly reduce the muscle growth in the late infection period.

The totals of CT tissue weights were accurate compared with the actual body weights of the pigs (±1%). Muscle growth was highly correlated with feed intake and weight gains of pigs (r>0.80) and with the absence of diarrhoea (r>0.72) throughout the trial. L.intracellularis infection did not significantly alter the P2 backfat depth.

Discussion
While sub-clinical PE did not affect body composition or P2 backfat depth, it did reduce muscle growth in experimentally challenged pigs. Animal genetics, gender, diet and pig weight all play a significant role in muscle growth. However, L.intracellularis-specific changes to the digestive and absorptive capacity of the intestine may also explain changes in muscle growth. Reduced amino acid absorption³ and reduced digestive enzyme activity⁴ have been described in pigs with PE.

Intestinal absorption and histomorphometry of Syrian hamsters (Mesocricetus auratus) experimentally infected with Lawsonia intracellularis

Fabio A. Vannucci1 Elizabeth L. Borges2 Juliana S. Oliveira1 Roberto M. Guedes1
1. Universidade Federal de Minas Gerais, Veterinary School, Belo Horizonte, MG, Brazil; 2. Universidade Federal de Minas Gerais, Institute of Biological Science, Belo Horizonte, MG, Brazil

Introduction

L. intracellularis is an obligate intracellular bacterium and causative agent of porcine proliferative enteropathy (PPE) (1). PE has been experimentally reproduced in pigs and hamsters, and similar lesions have been observed in both species (2). So far, the physiopathological mechanisms responsible for diarrhea in PE are unclear (3). The aim of this study was to experimentally reproduce PE in hamsters (M. auratus), evaluate the intestinal absorption and histomorphometric changes in infected animals.

Materials and Methods

Sixty Syrian hamsters were divided into two groups, inoculated (n=30) and control (n=30). The inoculum was prepared from segments of porcine intestines with PE lesions (1). Each hamster was intragastrically inoculated with 1.0 mL of inoculum using a gavage. On day 26 p.i., all animals were submitted to surgical procedures for evaluation of intestinal absorption. Two cannulae were introduced in the small intestine and Tyrode solution containing twice the concentration of glucose, Na+, K+ and Cl was infused. Intestinal absorption was calculated by the difference among influx and efflux content for each 10-min interval. Gross and histological lesions were evaluated and one section was stained by IHC (1). The amount of positive antigen labeled in the sections was graded according to Table 1. Additionally, intact and well oriented intestinal villi were selected for morphometric evaluation.

Results

IHC results are summarized in Table 1. Five control and two inoculated hamsters died during the surgical procedure. Furthermore, three animals had no demonstrated positive antigen labeling and were excluded from the statistical analysis. The relevant results of intestinal absorption are demonstrated in Figure 1. There was no difference of villous height or crypt depth between groups. However, the infected group demonstrated positive correlation (p<0.02) between the intensity of positive antigen label by IHC stain and crypt depth.

Discussion

This study described experimental reproduction of PE in hamsters which had significant reduction of intestinal absorption of glucose and electrolytes (K+ and Cl-). We believe these findings are relevant for the understanding of L. intracellularis pathogenesis. The poor intestinal absorption seems to be the main explanation for the lower performance of hamsters and pigs naturally affected with subclinical or clinical PE. Therefore, malabsorptive diarrhea appears to be the main process involved in physiopathology of PE diarrhea.

Table 1: Intensity of positive antigen label of L. intracellularis, in hamsters experimentally infected.

An alternative protocol for cultivation of *Lawsonia intracellularis*

**Fabio Vannucci¹ Suphot Wattanaphansak ² Connie Gebhart¹**

1. University of Minnesota, Saint Paul, MN, USA; 2. Chulalongkorn University, Pathumwan, Thailand

**Introduction**

*Lawsonia intracellularis* is an obligate intracellular bacterium and causative agent of porcine proliferative enteropathy (PPE). The isolation and growth of *L. intracellularis* in monolayers has been described using a specific incubator (Tri-gas) with 83.2% nitrogen, 8.8% carbon dioxide and 8% oxygen and a temperature of 37°C (2). This requirement has limited the maintenance of this microorganism in vitro to only a few research institutes. The aim of this study was to describe an alternative protocol for cultivation of *L. intracellularis* in cell monolayers providing necessary growth conditions without Tri-gas incubators.

**Materials and Methods**

The *L. intracellularis* isolate PHE/MN1-00 previously isolated from a pig with the hemorrhagic form of PPE was used for evaluating growth under two different environmental conditions. The strain was grown in murine fibroblast-like McCoy cells, maintained in a cell culture system and stored at -72°C until use, as described previously (1). The frozen bacteria were thawed and grown in cell culture for three continuous passages in specific conditions, which are described below, in order to allow the bacteria to recover from the frozen stage. The infection was monitored during every passage using immunoperoxidase staining with polyclonal antibody specific for *L. intracellularis* (1). After three passages, two 16-well tissue culture plates with one-day-old McCoy cells were infected with bacterial suspensions containing approximately 3.4 x 10⁷ *L. intracellularis* organisms/ml. The method for quantification was performed by direct count as previously described (1). One plate was placed in an anaerobic jar and the air was evacuated by vacuum pump to 500 mm Hg and replaced with pure hydrogen. The plate was then incubated at 37°C in a Tri-gas incubator for five days (2). The other plate was placed in a plastic bag (Original Space Bag®) and hermetically closed. The air inside the bag was then removed by vacuum pump to 100 mm Hg. Afterward, the bag was inflated through a cuff connected to a gas cylinder containing 10% hydrogen, 10% carbon dioxide, and 80% nitrogen. Finally, the bag was incubated in a conventional 37°C incubator for five days. Every 24 hours, the gas inside the bag was replaced. Carbon dioxide and oxygen percentages was monitored in both protocols using CO₂ and O₂ indicators (FYRITE® Gas Analyzer) at the initiation of incubation and every 24 hours during the five days of incubation.

**Results**

After five days, the McCoy cell monolayers in both plates were heavily infected by *L. intracellularis* demonstrating the success of the alternative incubation protocol. The infection rate was quantified by direct counting of the number of heavily infected cells after immunoperoxidase staining (1,3). Four wells were counted for each incubation protocol. The average rate of infection of the monolayer was 78.9% (+1.3) in the Tri-gas incubator and 76.7% (+2.6%) in the bag incubation. The CO₂ level measured between 11-12% in the Tri-gas incubator and 7.0-7.5% in the bag. The O₂ level was 9.0% in the Tri-gas incubator in all measurements and ranged from 5.0 to 5.5% in the bag.

**Discussion**

Incubation in the bag provided environmental conditions for *L. intracellularis* to infect and multiply in the cells, similar to the published protocol (2). Based on these preliminary results, we believe this approach can be used for static cultivation of bacteria without requiring a Tri-gas incubator. This fact creates aoption for in vitro studies and gives an opportunity to engage more research institutes in this area. Other isolates of *L. intracellularis* have been cultivated with this approach with the results being analyzed. In addition, studies using various conditions for growth and incubation in the bags are being conducted.

Effect of diarrhea on average daily weight gain in grower–finisher pigs

Markku Johansen1 Anders Stockmarr1 Charlotte S. Kristensen1 Poul Baekbo1 Jens Peter Nielsen2 Helle Stege2 Ken S. Pedersen2
1. Technical University of Denmark, Copenhagen, Denmark; 2. University of Copenhagen, Copenhagen, Denmark;
3. Pig Research Centre, Danish Agriculture & Food Council, Kjellerup, Denmark

Introduction
Diarrhea is an economically important disease, in grower-finishers. Pigs with diarrhea may have impaired growth and feed conversion. The objective of this study was to estimate the effect of diarrhea on the average daily weight gain in grower-finisher pigs in 5 herds with diarrhea.

Materials and Methods
A prospective cohort study was carried out in five grower-finisher herds with a history of diarrhea and seroconversion to Lawsonia intracellularis and PCV2 virus in the pigs. The herds were selected by convenience. In each herd 60 pigs from four pens were individually ear tagged. The pigs were weighed at the beginning of the study and at the end of the six-week observation period. A total of 298 pigs, all approximately 12 weeks old, were included in the study during the first week in the grower-finisher barn. No routine flock medication against diarrhea was used in the observation period. Faecal samples from each pig were collected in week 1, 3, 5 and 7 during the observation period and scored visually. A faecal score was assessed on 0-3 scale (normal=3, loose=2, fluid=1, fluid+discoloration=0). Diarrhea was defined as faecal score ≤ 1.

The impact of diarrhea on average daily weight gain was estimated in a linear regression model with average daily weight gain (ADWG) as a dependent variable. Diarrhea at least once, diarrhea more than once, and start weight were included as systematic effects. The herd and pen were included as random effects. The analysis was carried out using the SAS®-system, version 9.13, using Proc Mixed.

Results
The proportion of pigs with diarrhea in the observation period ranged from 3-28 % in the five herds. A total of 9.7 % of the pigs had diarrhea on one or more occasions during the six-week observation period. The proportion of pigs having diarrhea on one occasion was 7.4 % while 2 3 % had diarrhea on two or more occasions. The variation in prevalence during the observation period is shown in Figure 1. A total of 26 pigs had missing observations. The statistical analysis including 272 pigs showed a significant interaction between start weight and diarrhea on one or more occasions. (P<0.05). This means that the effect of diarrhea increases as the start weight increases. There was an additional effect of diarrhea more than once (p<0.0001). The start weight (P<0.0001), and squared start weight (P<0.0001) had significant effects on the average daily gain. The results are shown in Figure 2.

Discussion
It should be kept in mind that this study was based on a small number of herds and that most of the pigs with diarrhea originated from one herd only (fig 1).

Antimicrobial susceptibility of Belgian Brachyspira hyodysenteriae isolates

Philip Vyt

Medic Lab, Diagnostic Laboratory, Aalst, Belgium

Introduction
Swine dysentery, a muco-hemorrhagic colitis caused by Brachyspira hyodysenteriae, is responsible for substantial economic losses in affected herds. The prevalence of B. hyodysenteriae in Belgium has increased the last ten years. Until 2004, isolates were characterized as susceptible to pleuromutilins. Since the appearance of pleuromutilin-resistant strains elimination attempts at farm level have become compromised. Susceptibility testing prior to the start of treatment protocols is now inevitable. The present study summarizes the antimicrobial susceptibility of B. hyodysenteriae isolates during 2008 and 2009.

Materials and methods
Sixty and 58 isolates of B. hyodysenteriae were collected for susceptibility testing in 2008 and 2009 respectively. Isolates were recovered from 49 and 52 different farms in 2008 and 2009. The strains were isolated on modified Trypticase Soy Agar (TSJ-BJ) with 5% sheep blood from feces or colon contents submitted for diagnostic purposes. Susceptibility was determined using the agar dilution technique against valnemulin, tiamulin, tylvalosin, lincomycin and doxycycline as described earlier. The tested concentrations (μg/ml) ranged in two-fold dilutions from 0.015 to 2 for valnemulin, 0.03 to 16 for tiamulin, 0.25 to 32 for tylvalosin, 2 to 128 for lincomycin and 0.062 to 16 for doxycycline.

Results
Table 1 outlines the results of 101 isolates from different farms. Similar results were obtained in 2008 and 2009. A high proportion of isolates with decreased susceptibility was observed for pleuromutilins: 40-45% had MIC for valnemulin >= 2 μg/ml; 45 – 50% had MIC >=1 for tiamulin. Results for both molecules were similar: a high MIC for tiamulin coincided with a high MIC for valnemulin. Forty isolates (40%) had decreased susceptibility for both pleuromutilins. Only three isolates had a lower MIC for tiamulin compared to valnemulin, once with more than a two-fold dilution.

For tylvalosin, MIC50 was 32 μg/ml. Two-third of the isolates was categorized as susceptible for this molecule (<32 μg/ml). In the case of lincomycin, 15 to 18% of the isolates were considered susceptible. Twenty-eight isolates showed decreased susceptibility for both tylvalosin and lincomycin. Seventeen isolates, resistant to both pleuromutilins, had an MIC for tylvalosin of <=32 μg/ml. All four antimicrobials were considered ineffective in 21 isolates. Considering doxycycline, 61% had an MIC<= 4μg/ml and were considered susceptible.

For the 17 farms from which two or more isolates were tested, susceptibility patterns of the isolates were within one dilution for all antimicrobials.

Discussion
The present data show the widespread distribution of decreased susceptibility to pleuromutilins in Belgian B. hyodysenteriae isolates. The decrease in susceptibility to both valnemulin and tiamulin reflects the problems on farm when treating animals infected with these strains (P. Vyt, personal observations). On those farms a complete susceptibility panel to all antibiotics may reveal other treatment options. Although limited sensitivity data was available for tylvalosin, recent B. hyodysenteriae isolates from Spain4 had lower MIC values than in Belgium. Doxycycline, based on a limited number of isolates, could be used in affected farms. These data demonstrate that in nearly half the cases with pleuromutilin resistance tylvalosin could be an alternative treatment.

Table 1: MIC50, MIC90 (μg/ml) and susceptibility of B. hyodysenteriae isolates for valnemulin (V), tiamulin (T), tylvalosin (A), lincomycin (L) and doxycycline (D)

**Comparison of three commercial vaccines for the control of Salmonella spp in pigs**

Juan M. Palacios¹ Rosalba Carreon² Celene Cruz²

1. Intervet Schering Plough AH, Huixquilucan, MEX, Mexico; 2. Veterinary Faculty UNAM, Mexico, DF, Mexico

**Introduction**

Salmonellosis is one of the most common infections in swine production, leading to important economic loss due to mortality, morbidity and the cost of non-specific treatment. Attenuated vaccines have been the main immunological basis for the control of these infectious diseases. In general, live attenuated vaccines induce a superior immunological response than the inactivated ones. Vaccination significantly reduces clinical signs, and the colonization and excretion of Salmonella sp. The available bacterin vaccines stimulate a strong humoral response providing protection against the septicemic phase1,2. The aim of this study was to investigate the effect of three different products on the shedding of Salmonella spp in feces, and on standard production parameters.

**Materials and Methods**

The study was carried out on a farm in Mexico operating a continuous production system. From weekly batches, pigs were randomly selected, individually identified and assigned to one of four treatment groups, each of 20 piglets: three vaccinated with different commercial vaccines, and an unvaccinated control group. Group 1: unvaccinated controls; Group 2: a modified vaccinea from S. cholerae suis strain SC-54, for intranasal use in a single dose at one day old; Group 3: modified vaccineb against S. cholerae suis, for oral administration in a single dose at three weeks of age; Group 4: a bacterinc vaccine against S. cholerae suis and S.typhimurium, for parenteral administration in two doses at 3 and 5 weeks of age.

Rectal swabs were taken 5, 10 and 21 days post-vaccination for bacteriological analysis. Serum samples were collected at 70, 109 and 154 days of age for the detection of S. cholerae suis antibodies by ELISA (HerdCheck™, Idexx, EE.UU). Pigs were weighed at birth, 21, 70, and 105 days old and when sold. Average daily weight gain (ADG) and feed efficiency were calculated for a series of growing periods. Data were evaluated by variance analysis with a Tuckey test using SPSS 15.0 statistics software.

**Results**

**Graph 1** shows S.cholerae suis fecal shedding after vaccination.

**Chart 1** shows the production parameters (ADG by period, and feed efficiency), morbidity (signs of digestive disturbance) and mortality.

**Discussion**

Shedding in Group 3 was less than in the control group throughout the cycle. Although all products led to reduced shedding, the single dose vaccine on the first day of age (Group 2) applied to an immature intestine in the presence of high MDA seemed to compromise the health of the piglets, evident from low weight gains during the sucking and growing phases, with severe morbidity and mortality.

The vaccine given at weaning (Group 3) produced the best performance with respect to ADG, morbidity, mortality and Salmonella sp shedding.

The use of a safe vaccine against Salmonella spp is a useful tool in the control of the disease. It helps reduce excretion and, together with biosecurity measures and good management, is the key to reducing damage and economic loss due to disease caused by Salmonella spp.

Vaccination to control Salmonella and improve weight gain in pigs

Vahab Farzan; Robert M. Friendship
University of Guelph, Guelph, ON, Canada

Introduction
Immunization appears to be one of the most promising approaches for control of Salmonella on swine farms (1). Salmonella Choleraesuis vaccines are commercially available (2-3), however S. Choleraesuis does not appear to be a common pathogen in Ontario swine herds any longer (4). On the other hand Salmonella Typhimurium var. Copenhagen has become the most frequent serovar recovered on Ontario swine farms (4). The objectives of the present study were i) to determine if an autogenous S. Typhimurium vaccine or a commercial live S. Choleraesuis vaccine can reduce the prevalence of Salmonella shedding in pigs, ii) to determine if Salmonella shedding is associated with weight gain in pigs.

Materials and methods
The trial was conducted on one farrow-to-finish pig operation with the history of salmonellosis. Nine cohorts of weaned pigs, with approximately 350 pigs in each group, were randomly assigned S. Typhimurium bacterin, S. Choleraesuis vaccine, or as the control group. A Salmonella Typhimurium var Copenhagen strain was used to prepare the autogenous vaccine. In each cohort, one pen was randomly selected in the nursery stage and 30 pigs were ear-tagged and weighed. The tagged pigs were weighed again when marketing. Pooled fecal samples were collected bi-weekly from manure found on the pen floor and cultured for Salmonella. A Generalized Linear Latent and Mixed Models was used to compare the presence of Salmonella in the pooled fecal samples collected from the pens in three groups. A mixed linear regression method was applied to compare the average daily gain in the vaccinated and the control pigs.

Results
The prevalence of Salmonella shedding in each group is shown in Figure 1. The odds of Salmonella shedding during finisher stage in S. Choleraesuis vaccinated pigs [OR=5.2 (1.8, 15.5)] and S. Typhimurium vaccinated pigs [OR=3.3 (1.1, 9.9)] was higher than in the control group. The S. Choleraesuis vaccinated pigs were more likely to shed Salmonella compared to pigs which were vaccinated with S. Typhimurium bacterin. The control pigs which had the lowest average of Salmonella shedding showed the best growth performance compared to the vaccinated groups (Table 1). In addition, the pigs from pens with a higher Salmonella recovery rate were deemed to have a lower average daily gain.

Discussion
The prevalence of Salmonella shedding was initially lower in the control group. Younger pigs are more likely to shed Salmonella than finisher pigs (5) and therefore our estimate of vaccine effectiveness may be biased because the decrease in shedding might be due to age. It is possible that vaccination was performed after pigs had been exposed and that efficacy might have been improved had the pigs been vaccinated sooner. At least one study suggests that it might be prudent to establish a vaccination strategy for pregnant sows to control Salmonella in their piglets (6). Another significant finding of this study is that pigs that appeared clinically healthy but were found to be shedding Salmonella grew slower than pigs not shedding Salmonella. This suggests that there is an economic cost to subclinical Salmonella infection and provides an economic incentive for producers to implement Salmonella control measures.

Clinical findings in outbreaks of acute diarrhea with indication of antibiotic treatment

Ken S. Pedersen1 Sven E. Jorsal2 Helle Stege1 Poul Baekbo3 Jens P. Nielsen1

1. University of Copenhagen, Frederiksberg, Denmark; 2. National Veterinary Institute, Technical University of Denmark, Frederiksberg, Denmark; 3. Pig Research Centre, Danish Agriculture and Food Council, Copenhagen, Denmark

Introduction

Gastrointestinal disease in weaners is the most common cause of antibiotic consumption in Danish pig production. Most antibiotics are used as recurring therapeutic batch medication of acute outbreaks of diarrhea. Clinical signs, pathology and microbiology of this type of outbreak have been poorly described. The objective of the current study was to estimate within-batch prevalence of clinical signs in outbreaks of acute treatment requiring diarrhea in pigs between 10 and 70 days post weaning. Results of the pathological and microbiological investigations are reported elsewhere in these proceedings.

Materials and Methods

A cross sectional study was conducted. Herds were selected by multistage sampling. All herds serviced by six specialized swine veterinarians from the same vet practice at Zealand and fulfilling the inclusion criteria were selected. The criteria were recurring therapeutic use of in-feed or in-water medication for diarrhea at room level in pigs between 10 and 70 days post weaning. Only herds with modern intensive production systems were selected. One outbreak of acute diarrhea was investigated in each herd. Farmers and herd veterinarians notified the authors at initiation of an outbreak of acute diarrhea in a nursery room, where treatment by in-feed or in-water medication at the room level was necessary in their opinion. All herds were visited the day following notification and the farmer was not allowed to medicate any pigs before the pigs were examined. If the pigs had received antibiotic batch medication within the last 7 days of the examination day, the outbreak was excluded from the study. A sample of 80 pigs in each herd was selected for clinical examination by systematic random sampling among all pigs in the nursery room where the outbreak of acute diarrhea occurred. The selected pigs were subjected to a clinical examination by the same observer. The observer’s diagnostic sensitivity and specificity for detection of diarrhea was estimated by fecal dry matter (DM%) determination for a subset of the examined pigs (n = 773). DM% ≤ 18.8 was considered as diarrhea (1).

Results

A total of 20 herds were examined during outbreaks of acute treatment requiring diarrhea in 2009. On average the pigs were 32 days post weaning (range: 12 to 63 days). Mean within batch prevalence of diarrhea (loose + watery) was 37% (range: 25% - 67%), Table 1. For detection of diarrhea the observer had a diagnostic sensitivity = 0.88 and specificity = 0.91.

Discussion

The prevalence of diarrhea was higher than expected. The observer’s diagnostic sensitivity and specificity gave an overestimated prevalence (true prevalence = 35%, analysis not shown). The 24 hours between notification and examination may have contributed to the higher than expected prevalence. The within-batch prevalence of other clinical signs than diarrhea was low. This may be due to the study of the early part of the outbreaks. The different within-batch prevalence of clinical signs between herds may be due to different treatment thresholds for the individual farmers. It may also be the result of different etiology showing different clinical behavior. Further analyses are planned to explore these aspects. The small sample of herds investigated in the current study only represents modern intensive production systems. However, the results do imply that more pigs have diarrhea at initiation of antibiotic batch medication than is commonly believed.

Intestinal pathology of acute diarrhea in weaners: A case control study in 20 Danish herds

Ken S. Pedersen1 Roberto M. Guedes2 Sven E. Jorsal3 Helle Stege1 Jens P. Nielsen1 Tim K. Jensen3
1. University of Copenhagen, Frederiksberg, Denmark; 2. Veterinary School, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 3. National Veterinary Institute, Technical University of Denmark, Frederiksberg, Denmark

Introduction
The most common cause of antibiotic consumption in Danish pig production is gastrointestinal disorders in weaners. The largest part of the consumption is used as recurring therapeutic batch medication of acute outbreaks of diarrhea. It is generally believed that proliferative enteropathy associated with Lawsonia intracellularis is the major cause of these outbreaks of diarrhea. The objective of the current study was to describe the gross pathology in outbreaks of acute treatment requiring diarrhea in pigs between 10 and 70 days post weaning. Results of clinical and microbiological investigations of these outbreaks are reported elsewhere in these proceedings.

Materials and Methods
A case control study was conducted. Herds were selected by multistage sampling. All herds serviced by six specialized swine veterinarians from the same vet practice at Zealand and fulfilling the inclusion criteria were selected. The criteria were recurring therapeutic use of in-feed or in-water medication for diarrhea at room level in pigs between 10 and 70 days post weaning. Only herds representing modern intensive production systems were selected. One outbreak of acute diarrhea was investigated in each herd. All herds were visited the day following notification from the farmer/veterinarian of an acute treatment requiring outbreak of diarrhea and the farmer was not allowed to medicate before the pigs were examined. If the pigs had received antibiotic batch medication within the last 7 days of the examination day, the outbreak was excluded from the study.

A sample of 80 pigs in each herd was selected by systematic random sampling among all pigs in the nursery room where the outbreak occurred. The selected pigs were subjected to a clinical examination and fecal samples were collected. Among the examined pigs a simple random sample of 8 pigs with diarrhea and 8 pigs without diarrhea was selected. The 16 pigs were killed and transported to DTU-VET for necropsy the following day. Fecal dry matter (DM%) was determined. DM% ≤ 18.8 was considered as diarrhea (1) and was used (if necessary) to reclassify the pigs as diarrheic (cases) or non-diarrheic (controls) in the statistical analysis.

Results
Twenty-four non-diarrheic and 12 diarrheic pigs (determined at clinical examination) were reclassified according to the DM% determination. Seven pigs were excluded from analysis. Results of the gross pathological examinations are displayed in Table 1. Discussion
Small intestinal lymph node hyperplasia, large intestinal mucosa hyperemia and proliferative enteropathy-like changes were found at low but significantly higher levels in pigs with diarrhea than those without. The low prevalence of proliferative enteropathy-like changes implies that the importance of Lawsonia intracellularis in relation to diarrhea could be much lower than previously believed. Interestingly, obvious signs of infectious enteritis were rare and most of the other intestinal changes were equally prevalent in pigs with or without diarrhea.

Further conclusion awaits results of histological and microbiological examinations.

Discussion
Small intestinal lymph node hyperplasia, large intestinal mucosa hyperemia and proliferative enteropathy-like changes were found at low but significantly higher levels in pigs with diarrhea than those without. The low prevalence of proliferative enteropathy-like changes implies that the importance of Lawsonia intracellularis in relation to diarrhea could be much lower than previously believed. Interestingly, obvious signs of infectious enteritis were rare and most of the other intestinal changes were equally prevalent in pigs with or without diarrhea.

Further conclusion awaits results of histological and microbiological examinations.

Validation of an animal-based welfare assessment tool for the New Zealand pork industry: a case-series of welfare conundrums

Eric J. Neumann; Ian W. Barugh; William F. Hall; Daan Vink
Massey University, Palmerston North, New Zealand

Introduction
An animal-based welfare assessment tool was developed to quantify welfare outcomes for pigs in NZ. The current 2005 New Zealand Code of Welfare (Pigs)\(^1\) was developed using traditional facility-based metrics that provides a means of collecting objective but indirect measures of the welfare of farmed pigs. As part of an ongoing effort to improve well-being of pigs, the pig industry in 2009 undertook a review of the current Code with the aim of developing an evaluation tool that would directly assess the well-being of the pigs. The tool combines both subjective and objective measures of welfare based on direct observations of the pigs. As the current Code is still in effect and represents the “minimum welfare standards”, the proposed animal-based standards have been linked to applicable parts of the Code by which a farm would judged by a competent authority. As both the proposed animal-based criteria and the existing facility-based criteria are visibly linked on the assessment tool, the assessor is able to conveniently judge the welfare of pigs using both systems concurrently. The animal-based welfare indicators include aspects of vocalisation, appearance, behaviour, mobility, and faecal consistency. Once the validation process has been completed by early 2010, a graduated approach to replacing the current Code with the new animal-based standard will be initiated.

Materials and Methods
Validation of the tool involved a one-day training session for the assessors. Following this, assessors visited farms having variable production practices, herd sizes, and housing systems in order to create a dataset suitable for an analysis of inter-rater reliability and repeatability. The tool allowed concurrent assessment of the farm based on the current welfare Code (PASS/FAIL grade on 20 facility-based standards – ie m²/metabolic bodyweight, number pigs /feeder space, water flow rate, gestation stall width, etc) and the proposed animal-based standards (use of a “traffic light” system of green, amber, and red).

Results
A total of 9 farms have been assessed and has included all stages production in both intensive and extensive production systems. The agreement between assessors was good but as all farms that have been assessed were in compliance with the current welfare regulations, statistical analysis of the data was uninformative.

Discussion
Analysis of the assessments demonstrated that, farms that appeared to have welfare issues were consistently identified by the assessors, and specific issues identified on farms by the assessors were similar.

Use of the animal-based standards (specifically, the ability to evaluate a situation with the traffic light scoring) was uniformly praised by assessors as they had the flexibility to interpret the welfare of a given situation in the context of the larger setting rather than having to singularly judge a pig or event as cause for PASS/FAIL of the entire farm. Examples of this included:

- Existence of a small proportion of gestation stalls 590mm wide (currently less than the codified minimum width of 600mm) could still be given a “green light” as the farmer managed this by housing only gilts in the narrow stalls.
- Occurrence of dramatic vocalization by sows when an assessor entered a barn of limit-fed gestating sows could be given a “green light” when viewed in light of the sows’ Pavlovian response to an anticipated feeding event.

However, use of the animal-based standards created several unanticipated conundrums for the assessors. Examples of this included:

- Reliance on the analogy that “good production levels must mean good welfare” had to be abandoned as its inverse (“poor production levels must mean poor welfare”) was not necessarily valid. This was apparent in the case of a small and inefficient producer (30 sows producing only 7 pigs per sow per year) who’s sows were fat, content, and in an enriched environment (sic broken down machinery, expansive wallows, and every-other-day waste-food feeding) would have failed the codified standards but received “green lights” across the board using the animal-based standards.
- In extensively housed sows, rock chewing was common on some farms. Assessors were unsure as to whether they should consider the behavior as stereotypic (“red light”) or was simply the sow making use of environmental enrichment provided by the farmer (“green light”).

Conclusion
It is unlikely that a purely animal-based or facility-based welfare assessment tool will accurately ascertain the true well-being of farmed pigs. A tool that uses a combination of these criteria is capable of identifying farms that compromise the welfare of pigs.

**Behavioural, clinical and clinical-chemical indices in pigs suffering from disease**

Gerald Reiner; Katrin Hübner; Hermann Willems

*Department of Veterinary Clinical Sciences, Justus-Liebig-University, Giessen, Germany*

**Introduction**

In assessing the quality of life of farm animals, the absence of disease has been given highest priority (e.g. Dawkins 2006). However, a disease-free state cannot always be ensured. Thus, infectious diseases are major causes for pain and suffering (Hart 1988, Algers, 2004). During infection, sickness and suffering refer to a coordinated set of behavioural and physiological changes, leading to the concept of sickness behaviour. Behavioural indices are rarely assessed in conjunction with clinical diagnostics in more than a qualitative manner. Knowledge of the effects of model diseases on behaviour and on relationships among clinical/clinical-chemical parameters and behavioural indices would permit a better understanding and assessment of animal suffering due to infectious disease. Therefore, the aim of this study was to describe the physiological and behavioural patterns and relationships in pigs before, and during the acute, subclinical and chronic stages of a model disease.

**Materials and Methods**

Based on a well defined model disease (*Sarcocystis miescheriana*), we have studied behavioural patterns (lying inactive [LYWA], activity during lying [ADLY], feeding [FEED], drinking [DRNK], rooting [ROOT], walking [WALK], and social interactions [SOCB] of pigs during stages of health (day 0, before infection), acute disease (day 14 post infection [p.i.]), subclinical disease (day 28 p.i.), and chronic disease (day 42 p.i.). Data were captured from video records of 139 F2 Meishan x Pietrain crossbred pigs between 09:30 a.m. to 11:30 a.m. The time interval for observation was chosen so as to overlap with the first activity peak in the morning and to avoid times of human intervention. Behavioural indices were correlated with a set of clinical-chemical parameters (red and white blood cells, serum enzymes, serum metabolites and electrolytes).

**Results**

Before infection, respective time fractions were 56% (LYWA), 21% (ADLY), 10% (FEED), 0.9% (DRNK), 6.3% (ROOT), 2% (WALK), and <1% (SOCB). This behavioural pattern changed distinctly during Sarcocysts—tosis. Overall activities were reduced from 44% (day 0) to 10% (day 14 p.i.), 34% (day 28 p.i.), and 20% (day 42 p.i.).

The development of different stages of disease was accompanied with distinct changes in clinical and clinical-chemical parameters. Deviation from the population’s “standard” activity (before infection) could be predicted with clinical-chemical parameters (e.g. alkaline phosphatase [AP]).

Behavioural activities were generally reduced, whenever clinical/clinical-chemical traits changed to pathological values. A multivariate regression model revealed five predictors to explain e.g. total activity. The model was statistically significant with $P < 0.0001$ and explained 32% of the pigs’ total variance for this indicator (correlation coefficient 0.564). AP was the most important predictor. A decrease of 100 IU/l was associated with a reduction in activity of 7.8% during the observation period. A 10% reduction in leukocytes or 10 mmol/l less serum sodium ions were each equivalent to a more than 5% increase in activity. Increases of 10 μmol/l in serum creatinine or 1000 IU/l in serum creatine kinase (CK) were associated with an increase in activity by another 1.4 and 5.1%, respectively.

**Discussion**

To date, most welfare research has been concerned with identifying effects of housing conditions on welfare. The present study substantiates the role of infectious diseases in animal welfare. Taking into account the high prevalence of infectious diseases, it surprises that there is still very little research published on how different common diseases affect an animals’ welfare (Algers, 2004). With more information about effects of defined model diseases on behaviour and on relationships among easily obtainable clinical/clinical-chemical parameters and behavioural indices, our understanding and assessment (eventually even under field conditions) of animal suffering due to infectious disease, even under subclinical conditions, might be decisively improved.

Impact of physical castration and anti-GnRH vaccination (Improvac®) of boars on feeding behaviour and body lesion scores in single- and mixed-sex group housed fattening pigs

Tatjana Schmidt¹ Mario Grodzycki² Marleen Paulick¹ Franziska Rau¹ Eberhard von Borell¹

1. Institute of Agricultural and Nutritional Sciences, Halle (Saale), Germany; 2. Pfizer Animal Health, Berlin, Germany

Introduction

Physical castration of male piglets is common practice in many countries for the control of boar taint. A vaccine against GnRH (Improvac) is licensed in Europe as an alternative to this painful procedure. Vaccinated pigs behave like entire males up to the second vaccination and may potentially exhibit aggressive behaviour towards each other (von Borell et al, 2009). In this study we analysed feeding duration and indirectly measured agonistic interactions by shoulder lesion scores (Turner et al, 2006) of physically castrated pigs (PC) and pigs vaccinated with Improvac (IC). We also examined if penning with females would affect these parameters in males.

Material and Methods

PC and IC males (Pig x[German LRxLW]) were either penned in single-sex groups of 10 (treatment T1 and T2) or mixed with females (5:5, T3 and T4). A total of 160 animals started the experiment in four replicate groups. 11 pigs were excluded due to health problems. Pigs were mixed after weaning at 4 wks of age and regrouped by weight at wk 11 for the start of the experiment (Vaccinations at 12 and 23 wks of age). An automatic single-space feeder (IVOG®) per pen recorded the feeding duration (FD, minutes per day) of each pig. Shoulder lesions (LS) were scored weekly ranging from scratches (scores 1-2), abrasions (3-4) to severe wounds (5-6) and compared in 4 phases (P1-4). Mixed linear models with repeated measures design were used for statistical analysis with fixed effects of treatment, pen and replicate for feeding data and an additional fixed effect of observer for lesion score data as well as Tukey’s HSD test (JMP®, SAS Institute).

Results

T1 showed a greater FD (Table 1) than T2 in wk 14 and than T2&T4 in wk 20. There was no treatment effect in either FD in wk 25 or LS (Table 2) in P4. LS were high for all treatments in P1 but decreased in P2-4 (except for T2). T2 showed higher LS than T1 in P2 and P3.

Discussion

Georgsson & Svendsen (2002) found that feeding time was lower in pig groups when high levels of competition occurred at the feeder. This could indicate that competition for feeder access reduced FD in IC groups in wk 14&20. However, FD was only significantly higher in single-sex, not in mixed-sex PC males compared with IC groups.

In P1, shortly after regrouping of pigs, the LS were high in all treatments. Higher LS in single-sex IC males in P2 & P3 indicate more agonistic interactions. In contrast, LS of mixed-sex IC groups were not greater than in the PC treatments suggesting less aggression in mixed-sex groups compared to IC single-sex groups. No differences occurred in FD and LS after effective castration of IC males. In all groups, mean LS were only marginally >2, indicating almost no severe injuries. Therefore, the results of this study suggest that the impact of increased aggression in the IC males does not seem to constitute a major welfare problem.

Free space utilisation of group housed sows

Fiona C. Rioja-Lang
Prairie Swine Centre, Saskatoon, SK, Canada

Introduction

With announcements by the largest producer/packers in both the USA and Canada that they will transition all of their production facilities to group housing for sows over the next ten years, all N. American producers are anticipating a change to group housing. This study investigates the implementation of walk-in/lock-in stalls in group housed sows. There is some concern regarding the degree to which sows use the free space areas in this system, and how to avoid excessive competition and aggression.

The objectives of this study were to compare two different pen configurations by determining the proportion and type (size/parity) of sows that are using the free space areas of the walk-in/lock-in stalls, and also how sows utilize the free space areas.

Methods

Eight groups of 25 sows (± 3; mean ± SD) were used in the study, and were housed in walk-in/lock-in stall gestation pens at the Prairie Swine Centre, Saskatoon. Each of the groups were exposed to one of two configurations of free space areas. The first is referred to as the ‘I-pen’ as it consisted of an alley (3.0m x 10.7m) with slatted flooring running between two lanes of 16 stalls on each side. Any additional stalls, surplus to the group number, were locked off for the purpose of the trial. The second pen configuration is referred to as the ‘T-pen’ as it consisted of an identical alley with an additional solid floor loafing area at one end (3.8m x 7.1m). Pigs were individually marked and photographs were taken from a mounted camera every 2 minutes over a 24hr period every week, for 11 weeks through gestation. Measurements recorded from the photographs include the percentage of time spent out of the stall over 24hrs, and also the location and position of sows in the free space areas.

Results

The majority of sows did use the free space areas although not on a regular basis or for extended periods of time. Older, heavier sows appeared to use the free space area significantly more than younger, small sows (P<0.0001).

Discussion

Although many sows did use the free space, it was at a much lower level than expected. This could be due to several possibilities, such as lower ranking animals feeling threatened by higher ranking sows, or larger sows utilizing the free space due crowding in the stalls. With the impending ban of gestation stalls it is important that we conduct adequate research to design the optimum group housing system which will facilitate positive social interactions and minimize levels of aggression and competition.

Future research is likely to involve methods for enticing the sows into the free space areas, including making the free space more comfortable to lie on with rubber mats, providing environmental enrichment, or possibly allowing sows access to the free area in different social groups i.e. young and old.

Introduction

Whereas several countries are still seeking for an effective and practicable solution for piglet castration without any analgesic treatment, CO₂/O₂ gas anesthesia during castration is already performed in the Netherlands.

This study appraises stress and pain of castration without any analgesic treatment and a potentially positive effect of CO₂ anesthesia by means of serum cortisol and plasma catecholamine measurements [1,3].

Materials and Methods

188 (n) three to five day old clinically healthy male piglets for cortisol (co) and 39 piglets for norepinephrine (ne) and epinephrine measurements were randomly assigned by weight to four treatment groups (tab. 1).

Table 1: Treatment groups

</tbody>
</table>

Inhalation anesthesia was introduced with a 70%CO₂:30%O₂ gas mixture using an anesthetic machine as in the Netherlands. After introduction time of 45sec, piglets were anesthetized for a maximum of 30sec during castration or immobilisation.

To evaluate postoperative castration pain, blood samples for cortisol were taken from each piglet before as well as 30min, 1, 4 and 24h after treatment. Due to the short half-value periods of epinephrine and norepinephrine, blood samples from those piglets were taken 15min before, immediately and 2min after treatment. Significant differences were tested with paired t-test.

Results and Discussion

Mean cortisol concentrations did not differ in basal values between the four treatment groups (Fig. 1). 30min after castration, mean cortisol concentrations of uncastrated groups I and III were significantly lower than mean concentrations of castrated groups II and IV. A significantly higher mean value was observed 1h after castration in group II than in groups I, III and IV. 4h after castration, cortisol levels of uncastrated groups I and III were still lower than of group II (p≤0.05).

In accordance with results from Schulz et al. (2007), immobilisation (group I) and castration (group II) caused a twofold increase of plasma norepinephrine concentrations to 4471 pg/ml and respectively 4871 pg/ml immediately after treatment (p≤0,001). In contrast, CO₂ anesthesia induced a significant and nearly 50-fold increase of mean norepinephrine levels in groups III and IV immediately after treatment, and levels were still elevated 2min after treatment. These results are confirmed by the results of epinephrine measurements.

Conclusion

Serum cortisol concentrations 1h after castration under CO₂ anesthesia indicate a small but significant analgesic impact by the use of CO₂. However, this effect was not detectable after 30min. In contrast, the analysis of plasma norepinephrine and epinephrine revealed a tremendous additional stress for piglets from both CO₂ groups independent from castration. Considering that the aim of anesthesia is to reduce pain and stress, and that the consumers’ demand for anesthesia during castration tends to increase animal welfare, CO₂ anesthesia cannot fulfil the requirements to the full extent.

Pre-emptive meloxicam for postoperative analgesia in piglets undergoing surgical castration

Alassane Keita; Eric Pagot
CTPA Zoopole développement, Ploufragan, France

Introduction
The welfare issues associated with surgical castration procedures in piglets is a growing concern within the public and European lawmakers. Castration of male piglets is a routine practice in most European countries, carried out to avoid boar tainting of meat (an unpleasant smell that sometimes arises when the meat of boars is heated). Current European directives make anaesthesia and prolonged analgesia only mandatory for castration of pigs over 7 days of age, the procedure being carried out by a veterinary surgeon. Countries like Norway or Switzerland have, however, already banned surgical castration without anaesthesia and other countries may follow. It has been demonstrated that surgical castration was followed by an increase of plasma cortisol and plasma adrenaline via the activation of the adrenal and sympathetic axes [1, 2]. This paper reports the outcome of a study having investigated the effect of a pre-operative intramuscular administration of meloxicam on postoperative stress and pain induced by surgical castration in piglets.

Material and methods
Overall 150 young (mean age of 5.1 + 1.3 (SD) days and mean body weight of 2.4 + 0.6 kg) healthy male piglets, coming from 3 different commercial farms, were included into the study. The piglets were ear-tagged and allocated at random within litters to groups to receive one of the following treatments between 10 and 30 minutes prior to surgical castration: a single intramuscular injection of 0.4 mg/kg meloxicam (i.e. 0.08 ml/kg of the product Metacam® 5 mg/ml solution for injection) or 0.08 ml/kg of a placebo (saline). Behavioural parameters (vocalisation, tremors, urine or faeces emission etc) were evaluated in blind conditions at time of castration up to 24h post-castration. Blood samples were collected from 30 subjects selected at random from each group at 30 minutes and at 24 hours post castration. In addition blood samples were taken from 30 non-castrated contemporary piglets to provide baseline values for the concentrations of the evaluated hormones.

The piglets were individually weighed at the start of the study and again at weaning. The criteria were: blood cortisol and ACTH concentrations at 30 minutes post castration, blood Haptoglobin concentration 24 h post castration, behavioural alterations up to 24 h post castration, weight gain between castration and weaning. ANOVA, Kruskal-Wallis and Pearson Chi-square tests were used to analyse the data with 5% as level of significance.

Results
The mean age and body weight before castration were similar in the two groups.

The mean blood ACTH concentration at 30 minutes post castration (fig. 1) was significantly (p = 0.007) lower in meloxicam (17 pg/ml) and non-castrated (18,1 pg/ml) groups than in the placebo one (35,8 pg/ml).

The mean blood cortisol concentration was significantly (p<0.001) lower in the non-castrated group (63 ng/ml) than in the meloxicam (206 ng/ml) and placebo (276 ng/ml) groups. The difference between meloxicam and placebo was also significant.

At both 2 and 4 hours post castration, the proportion of piglets showing no behavioural alterations was significantly (p<0.05) higher in the meloxicam group (83%) than in placebo one (68%).

No significant difference was observed between the mean blood Haptoglobin concentration and the weight gain of the two groups.

Conclusion and discussion
This study suggests that pre-emptive administration of meloxicam is able to produce an adequate postoperative analgesia after surgical castration of young piglet. Meloxicam can be proposed as a safe and effective solution to control stress and pain associated with routine castration in piglets.

Comparison of anaesthetic effects during piglet castration by using commercial inhalation systems with carbon dioxide and isoflurane

Karl-Heinz Waldmann¹ Maren Hoppe¹ Maria Steigmann¹ Arnim Andreae¹ Sabine Kaestner²

¹ Clinic for Swine and Small Ruminants, Hannover, Germany; ² Small Animal Clinic, University of Veterinary Medicine, Hannover, Germany

Introduction

The common practice of castration of piglets without any anaesthesia in the EU met with increasing criticism because of animal welfare reasons.

One of possible alternatives is the castration under general anaesthesia using anesthetic gases [1, 2]. In the last years inhalation systems were established for automation the narcosis process. The present study should demonstrate the quality and depth of narcosis and the degree of reduction piglets’ pain during castration under isoflurane- or carbon dioxide- anaesthesia. Furthermore the influence of NSAIDs on the anaesthesia and pain reactions was tested.

Material and methods

In the study exclusively healthy anatomically normal piglets at the age of one to seven days were used. All piglets had a body-weight between 1.5 and 2.5 kg.

Two kinds of commercial inhalation systems were tested; the first one used an isoflurane insufflation mixed with 30% oxygen, while the second one worked with a gas mixture of 70% carbon dioxide and 30% oxygen.

 Altogether 246 piglets in 18 groups were tested to compare the two different gas insufflations to traditionally not anesthetized piglets. Furthermore the influence of NSAIDs (Flunixine) in a common dosage was investigated. Each of the three anesthesia groups was split up in groups that were injected 60 minutes and 20 minutes before castration and a group without any NSAIDs. Additionally a sham group corresponding to every group existed, where the piglets were only handled in the same way without being castrated.

The most important method for recognizing the piglets’ pain was the electroencephalogram (EEG). Due to frequency analysis an EEG score expressed the depth of anesthesia, where a score of 3 or more represent an adequate narcosis. Furthermore an electrocardiogram (ECG) was recorded continually. The pulse and oxygen saturation of the blood were recorded at the beginning and after the insufflation. We used a score to define the vocalization, the movements and the reactions to the manipulations. The wound healing was observed for three weeks.

Results

As measured by EEG score about 90 % of the piglets of the carbon dioxide groups but only less than 40% of the piglets of the isoflurane groups did not show a sufficient narcosis. The treatment with NSAID had no influence on the depth of carbon dioxide narcosis. On the contrary NSAID influenced the depth of isoflurane narcosis significantly; the group without any flunixine treatment showed a lower EEG score (score 2.7) than the treated group (score 3.0). In this context the moment of flunixine application, 20 or 60 minutes before castration, was indiscriminative.

Movements of the piglets, measured with EEG, which are longer than two seconds can not be pronounced as an unconscious reaction but point at a conscious defense reaction to the pain. Between both anesthetic groups a significant difference could be recognized. The reactions to the emasculation were much greater in the carbon dioxide group than in the isoflurane group.

The ECG showed nearly no differences in pulse frequency and ECG waves between the status before and within the isoflurane anesthesia. In the contrary in many cases of carbon dioxide anesthesia a dramatic drop of pulse frequency from about 200-230/min before anesthesia to 20-40/min 30 sec after carbon dioxide insufflation could be measured. Additionally characteristic ECG changes probably point at hyperkalemia as a consequence of acidosis.

Conclusions

The first results of our study showed that an isoflurane narcosis can reduce most of the pain originated in castration. It induces a mostly deep enough anesthesia, while the depth can be enhanced by the application of NSAIDs.

Carbon dioxide anesthesia - especially with this inhalation system - did not induce a sufficient narcosis in most cases. The consciousness is reduced but not enough to lock out the awareness of pain.

Comparison of different analgesic treatments to reduce the pain associated with tail docking in pigs

Tiffanie A. Brooks¹ Mhairi A. Sutherland² Brittany L. Davis¹ John J. McGlone¹

1. Texas Tech University, Lubbock, TX, USA; 2. Ruakura Research Centre, Hamilton, New Zealand

Introduction
Tail biting is a behavioural problem occurring in pigs that is a welfare problem and of economic concern for producers. Tail biting can not only affect the welfare of the pigs being bitten directly, but the procedure of tail docking as a means to control tail biting can cause acute pain which is also an animal welfare issue. Exactly what causes tail biting behaviour to break out among pigs remains elusive, but this behaviour has been attributed to an array of factors including the environment, nutrition, group size, genetics and lack of substrates. Tail docking is routinely used on farms in the US as a solution to this problem. The objective of this study was to evaluate the effectiveness of different analgesics to reduce the pain induced distress caused by tail docking in piglets.

Materials and Methods
At approximately 3 days of age, piglets were allocated to one of five treatment groups: 1) Sham tail docking (CON); 2) Tail docking using conventional cutting with side-cutting pliers (CUT); 3) Tail docking plus local anaesthetic administered immediately prior to tail docking (LA); 4) Tail docking plus topical anaesthetic applied to the wound after cutting (TOP); 5) Tail docking conducted while the piglets were anesthetized with carbon dioxide (100% CO2 gas) using conventional cutting with side-cutting pliers (CO2).

Prior to (baseline), and 30, 60, and 120 min after tail docking, piglets (10 pigs/treatment) were held in a supine position and blood was collected for a complete blood count and cortisol analysis. Piglet behaviour (10 pigs/treatment) was recorded using live observations for 60 min prior and 120 min after tail docking. Behaviours and postures measured included lying-alone, lying-touching the sow or other piglets, nursing/massaging, standing, sitting, walking and pain-like behaviours and postures (e.g. hunching, scooting, and tail jamming).

Data were subjected to analysis of variance using the mixed model procedure of SAS version 9.1 (SAS Inst., Inc., Cary, NC).

Results
Leukocyte counts, differentials, and the neutrophil to lymphocyte ratio did not differ (P > 0.05) among treatments.

Cortisol was greater (P < 0.05) in CUT, LA, TOP, and CO2 compared with CON piglets 30 min after tail docking. Cortisol did not differ (P > 0.05) among CUT, LA, and CO2 piglets 30 min after tail docking. At 30 min, TOP piglets tended to have lower (P = 0.067) cortisol than CUT piglets. Cortisol did not differ (P > 0.05) among treatments at any other time point.

The percentage of time pigs spent performing nursing behaviour after tail docking tended to be greater (P = 0.062) in CO2 piglets compared with all other treatments. The percentage of time piglets spent lying alone was greater (P < 0.05) in CUT piglets compared with all other treatments 91-120 min after tail docking.

Discussion
Tail docking without analgesia caused increases in cortisol concentrations and performance of lying-alone behaviour, which may be indicative of pain. Cortisol concentrations tended to be reduced in piglets that had topical anaesthetic applied to the tail wound after tail docking, but not in piglets given local anaesthetic or carbon dioxide anaesthesia. Therefore, applying a topical anaesthetic to the tail wound may provide some relief from discomfort caused by tail docking in piglets.

Applying a topical anaesthetic to the tail wound immediately after tail docking may be an effective and easy way to reduce the pain caused by tail docking, but more research is needed to study the effectiveness of different analgesics that could be used to eliminate the pain caused by tail docking in piglets.

Periparturient analgesia: Does it improve neonatal survival and growth?

Glen Cassar; Rocio Amezcua; Robert M. Friendship
Ontario Veterinary College, Univ of Guelph, Guelph, ON, Canada

Introduction
There has been an increase in the public concern over the welfare of farmed animals in recent times. Pain control is an important component of animal welfare and in swine production there are many areas where pain control could be addressed. The process of farrowing is associated with pain and could be a welfare issue for the sow as well as affecting her ability to adequately nurse piglets, thus affecting performance. Farrowing intervention could be painful and could result in reproductive tract infections. In cattle, it is now common for analgesics to be administered around the time of parturition, and this practice is considered to improve milk production. Research findings suggest that the peri-parturient sow experiences discomfort, which causes her to change positions frequently, increasing the chance that she will crush her piglets. A major cause of pre-weaning mortality is due to maternal crushing of pigs. Pre-weaning mortality due to crushing has been estimated to be between 4.8 and 18 percent. Alleviating the sow’s pain might lead to a decrease in body position changes and a consequent decrease in crushing, addressing both a welfare and economic issue. Reduced restlessness in the peri-parturient period could result in uninterrupted nursing by piglets and consequently improved weight gain. Ketoprofen, (Anafen, Merial Canada Inc) an injectable non-steroidal anti-inflammatory analgesic, is approved for use in swine in Canada.

The objective of the study was to evaluate the effect of analgesia to the sow at farrowing on piglet mortality and performance.

Materials and Methods
A total of 223 sows were randomly assigned to the following treatment groups.
- a. Sows allowed to farrow with no analgesia (n=105).
- b. Sows treated with ketoprofen on the day before farrowing and on the day of farrowing (n=118).

Anafen dosage was 1.5 ml per 50 kg bodyweight. All piglets were ear notched for identification and weighed on the day of birth and again at 21 days of age to determine average daily weight gain (ADG). The number of stillborn piglets (SB) as well as preweaning mortality (PWM) were recorded.

Results and Discussion:
There was no difference in ADG, SB or PWM between the two groups. Table 1 shows the means for these parameters.

Based on the results in this trial there does not appear to be an economic incentive for producers to use analgesia routinely at farrowing. Possibly, if analgesia had been used only in the case of gilt farrowings or in the case of dystocia, a difference might have been observed.

References
Introduction

The well-being of swine has become a relevant issue because the quality of life of pigs seems to be associated with the food production and meat quality (2). The heavy selection aimed to obtain individuals with elevated reproductive and productive performances has often conducted farm animals to a poor state of health and welfare (3). The aim of this work is to study the effects of the environmental enrichment on the normal and abnormal behaviors and hematological parameters in a commercial line of pigs.

Materials and methods

In the present study, rearing pigs housed in a commercial farm either in Standard or Enriched pens were followed up over a period of eleven weeks. 28 hybrid pigs with initial average weight of 32.5 ± 2 kg were used in this study. The day of arrival at the farm, the animals were randomly assigned to two experimental groups. 14 individuals were housed in a physically enriched pen (‘Enriched group’) and 14 animals were housed in a conventional pen (‘Standard group’). The pens contained a total of about 50 individuals. The enriched pen contained 6 chains, 5 tough, non-toxic plastic balls with stones inside, two hemp ropes hung from the ceiling and 6 rubber hoses placed on the floor. Behavioural data and blood samples were collected on day of arrival of the animals (T.0), 24 hours later (T.1), and two weeks (T.2), six weeks (T.3) and eleven weeks (T.4) from the arrival. These samples were used to determine a range of haematological parameters. All statistical analyses were conducted using Statview 5.0 (SAS Institute Inc.).

Results

Results are shown in Table 1. Pigs from Enriched housing spent significantly less time in abnormal behaviours than the animals raised in Standard condition. Blood samples from Enriched group showed lower levels of white blood cells (WBC) than the Standard counterpart (Tab.1).

Discussion

Swine exposed to physical enrichments presented important and consistent reduction of abnormal behaviors. Furthermore, pigs housed in the enriched pen had a six times lower probability than those from standard condition to present skin body lesions. This study gives a clear indication that the presence of manipulative objects provides welfare advantages to the rearing pigs. Pigs from Enriched housing showed a significant higher level of neutrophils than those from the Standard pen, whereas the percentages of circulating eosinophils in the blood samples of the Enriched individuals were significantly lower compared with swine housed in the Standard pen, this fact may be reasonably ascribed to a different parasitic status on individual basis (1). Both lymphocyte and monocyte levels were markedly lower in Enriched than in Standard group. Interestingly, the animals from Enriched housing showed a progressive reduction of these white blood cells from Time 2 to Time 4, whereas swine housed in the Standard pen showed an increment between Time 2 and 3. This profile can be a consequence of ongoing bacterial infections in progress, such as enzootic subclinical pulmonitis typical of intensive pig farming systems. With regard to haematological measures, all parameters considered showed significantly lower levels in the samples from Enriched pen than in those from the Standard group, except the concentration of Red Blood Cells (RBC) that was not affected at all. However, the levels recorded fall all within the range reported in the literature in intensive farmed pigs and may be interpreted as small perturbation induced by the sub-clinical ongoing inflammatory processes above reported. A monitoring of selected behavioral parameters and profile progression overtime and skin lesion checks may be a use-friendly strategy of management in farms with elevated animal density and limited numbers of workers.

Challenge of pigs with natural immunity to H1 and H3 swine influenza virus with pandemic 2009 H1N1 influenza virus

Introduction

The emergence of the pandemic 2009 human H1N1 influenza A virus raised many questions about the implications for this virus in swine (1). One such question is, does prior exposure to influenza virus confer any protection against the new virus? This report describes a study to evaluate if natural exposure to swine influenza viruses confers protection against challenge with 2009 H1N1 virus.

Materials and methods

Conventionally raised pigs were purchased from a sow herd negative for swine influenza A virus. Due to purchasing and shipping logistics, the pigs had been weaned and transported to a nursery facility that was geographically separated from the sow farm. Within 7 days of arrival at NADC most of the pigs were seropositive by the Avian Influenza MultiS-Screen ELISA (2) and virus was detected in the nasal swabs from a few pigs. Multiplex RT-PCR assays using four specific primers for H1 and H3, and N1 and N2 were performed (3). Twenty group 1 (G1) pigs were housed for 5 additional weeks (until approximately 10 weeks of age) at which time they were challenged with 2 x 10^6 TCID50 A/California/04/2009 H1N1 (CA09) by the intranasal route. Naïve-age-matched pigs (n=4 pigs) or group 2 (G2) were also inoculated with CA09. Nasal swabs were taken on 0, 3 and 5 days post infection (dpi) to evaluate nasal shedding. Postmortem samples including serum, bronchoalveolar lavage fluid (BALF), lung, trachea and nasal swabs were collected at necropsy at day 5 pi. Serologic assays included hemagglutination inhibition (HI) assay (4) and ELISA (2). HI assays were used to evaluate 0, 3 and 5 dpi serum samples against CA09 (H1N1), OH07 (H1N1), MN99 (H1N1), and TX98 (H3N2) viruses. Real-time PCR assays were performed for quantitation of nucleic acids in BALF of pandemic H1N1 influenza virus (5), and for PRRSV, PCV2 and Mycoplasma hyopneumoniae using in house assays (6).

Results and discussion

All pigs were negative for PRRSV, PCV2 and M. hyopneumoniae nucleic acids in BALF at necropsy. Genetic analysis of viruses isolated from nasal swabs and BALF samples from G1 pigs revealed the presence of simultaneous H1 and H3 virus infections prior to the start of the study at 5 weeks of age. After challenge with CA09, all naïve-challenged pigs (G2) had macroscopic lung lesions with an average lung involvement of 2.7%. The multifocal lesions appeared typical with well demarcated margins, purple in color. Nine of the 20 G1 pigs had detectable macroscopic lung lesions, but decreased in severity compared to the non-immune controls, with an average of 0.9%. The character of the G1 lung lesions was different compared to G2. The macroscopic lesions were purple-grey in color; involving the tips of the apical and cardiac lobes with less distinct margins. G1 pigs had no detectable virus titers in the lung or nasal swabs (0, 3 and 5 dpi). However, G2 pigs had CA09 viral titers in the lungs and nasal swabs with average titers of 10^{1.6} TCID_{50}/ml (3 dpi) and 10^{2.3} TCID_{50}/ml (5 dpi) in nasal swabs samples, and of 10^{3.7} TCID_{50}/ml BALF samples at 5 dpi. Real-time PCR for H1N1 pandemic virus in BALF (5 dpi) showed that 14/20 naturally immune pigs (G1) and 4/4 naïve-challenged (G2) were positive for viral RNA. Quantitatively G2 samples presented an average of 9 x 10^6 copies of viral RNA / microliter of template. In contrast, G1 had an average of 1.4 x 10^3 copies, indicating a low viral replication in the lungs or residual RNA from challenge, confirming the negative results of virus isolation from nasal swabs and BALF. HI titers using the challenge virus (CA09) were not significant for either group at 0 and 5 dpi. However, significant HI titers against the γ-cluster SIV OH07 were detected in G1 pigs at 0 dpi. H3N2 HI antibodies against TX98 were not detected in either group of pigs. These results indicate that pigs with natural immunity against γ-cluster SIV have significant protection against infection with 2009 pandemic H1N1.

Introduction
In April 2009, an outbreak of human influenza was reported due to a novel H1N1 virus. On June 11th, 2009, the World Health Organization declared a global human pandemic of H1N1 (pH1N1). On May 2nd, 2009, the first case of pH1N1 infection in swine was reported in a small herd in Alberta, Canada. Symptoms developed in swine after a barn worker had returned from Mexico with influenza-like illness. Epidemiologic evidence supported human to swine transmission (1, 2). Little was known about the pathogenicity of this novel virus in swine. The objective of this study was to describe the clinical progression and production impacts of second pH1N1 infection in a naturally infected sow herd.

Materials and Methods
On June 16th, pH1N1 was confirmed in two swine barn workers at a second farm in Alberta. Symptoms in swine began on June 19th. The herd was a high health breeding herd of 300 sows, free of all major pathogens including PRRS. Sows were routinely vaccinated for classical swine influenza H1N1 and H3N2 viruses (Flusure, Pfizer Animal Health, Kirkland, Quebec). The herd was well managed with excellent biosecurity and above average air quality. No new animals had been introduced since September 2008.

Clinical signs in swine and humans were recorded daily during the outbreak. Nasal swabs were taken from systematically selected swine on days -1, 11, 25, 53 after the onset of symptoms. All swine nasal swabs were screened by RT-PCR at the Food Safety and Animal Health Division laboratory in Edmonton. Initial samples were sent to National Centre for Foreign Animal Disease (NCFAD) in Winnipeg, Manitoba for confirmation and molecular characterization. Molecular characterization and comparison to human virus isolates was done at St. Jude Children’s Research Hospital, Memphis, Tennessee. Reproductive performance records, feed intake and carcass quality data were obtained.

Results
The first clinical signs were observed in swine on June 19th, seven days after contact with the first ill worker and four days after contact with the second affected worker. A non-productive cough with a moderate abdominal effort, mild to moderate depression, pyrexia and anorexia of 24-48 hours duration was observed in gestating sows. Most affected animals displayed anorexia and depression only. Animals previously affected completely recovered within 24-48 hours. By the second day, two percent (29/1450) of the herd was affected. Over the next seven days new cases were seen daily in gestating and lactating sows and gilts. No clinical signs were observed in piglets, weaned pigs or growing pigs. The proportion of the herd affected never exceeded two percent and declined to 0.5 percent by day eight. After day 36 no clinical signs were seen. The herd made a complete recovery with no associated mortality. Positive nasal swabs indicated asymptomatic shedding and infection was likely occurring in all classes of swine.

Some reproductive impact on individual sows and boars was recorded.

The only symptoms of respiratory disease prior to this outbreak were in three animals in December 2008. At that time nasal swabs and lung tissue were negative for influenza by PCR. No other symptoms of respiratory disease have been recorded in this herd since 2003.

Discussion
The mild clinical signs in this herd are in contrast to the more severe symptoms reported in the first case of pH1N1 in swine (1). The absence of other respiratory pathogens, air quality and vaccination likely contributed to the milder clinical picture. This infection could escape detection in a less rigorously observed herd, creating challenges for surveillance. Subsequent growth and reproductive performance was negatively impacted in spite of lack of clinical signs. PCR results indicate that be infection and viral shedding may occur in asymptomatic animals.

Molecular characterization of the virus indicates the same virus infected both the workers and swine. The chronology of symptoms in humans and swine supports human to swine transmission.

Introduction
Swine influenza A viruses (SIV) in the major swine producing regions of North America consist of multiple subtypes of endemic H1N1, H1N2, and H3N2 derived from swine, avian and human influenza viruses with a triple reassortant internal gene (TRIG) constellation.1 Genetic drift and reassortment has resulted in four H1 phylogenetic clusters designated as α, β, γ, and δ that co-circulate in U.S. swine.2 Control of SIV has relied on the use of commercially available or autogenous influenza vaccines in the U.S. swine industry. However, inactivated vaccines have demonstrated poor cross-protection against heterologous homosubtypic, or heterosubtypic SIV. The emergence of diverse genetic subtypes has increased the need for effective SIV vaccines with adequate cross-protection. In this report, we describe a vaccine-heterologous virus challenge model demonstrating enhanced lung lesions in pigs given inactivated δ-cluster H1N2 vaccine (human seasonal H1-lineage HA) challenged with heterologous pandemic 2009 A/H1N1 compared to non-vaccinated challenged pigs.

Materials and Methods
Twenty, three-week old conventional pigs free of SIV and PRRSV were randomly divided into two groups. The vaccinated and challenged (vax/challenge) group was vaccinated with 105.5 50% tissue culture infectious dose (TCID50) units of A/SW/MN/02011/08 (δ-cluster) inactivated by UV irradiation with the addition of a commercial adjuvant. Vaccine was administered intramuscularly at six and three weeks prior to challenge. Vax/challenge and non-vaccinated/challenged (non-vax/challenge) pigs were inoculated intratracheally with 2ml of 1x105 TCID50/ml A/California/04/2009 H1N1 (CA/09). Five pigs remained non-vaccinated, non-challenged controls. Pigs were observed daily for signs of clinical disease and fever. Serum samples were obtained at each vaccination, challenge and 5 days post-infection (dpi). Nasal swabs were taken on 0, 3, and 5 dpi to evaluate nasal virus shedding. All pigs were necropsied at 5 dpi. Lungs were removed and evaluated for the percentage of lesions typical of influenza virus infection in pigs. Each lung was lavaged with 50ml MEM to obtain bronchoalveolar lavage fluid (BALF).

Results
All pigs were free of influenza A virus and antibodies prior to vaccination. At 24 hours post-challenge, vax/challenge and non-vax/challenge pigs had significant (P<0.05) febrile responses compared to controls. At 72 hours post challenge, vax/challenge pigs had a significantly elevated (P<0.05) febrile response to infection that persisted to 5 dpi compared to non-vax/challenge pigs. Febrile responses in non-vax/challenge pigs returned to normal at 72 hours. Vax/challenge pigs had significantly higher (P<0.001) macroscopic pneumonia scores averaging 20.5 percent of the lung at 5 dpi compared to an average of 8.9 percent of the lung in non-vax/challenge pigs. Macroscopic lesions were absent in negative controls. At 3 dpi, 7/10 and 5/10 pigs in the vax/challenge and non-vax/challenge groups, respectively, were positive for nasal shedding. By 5 dpi, both groups had 9/10 pigs positive for virus in the nasal cavity. Virus levels at 5 dpi in nasal secretions were significantly less (P<0.001) in the vax/challenge group compared to non-vax/challenge pigs. Virus levels in the lung were not significantly different. Isolate specific hemagglutination inhibition (HI) titers developed only in pigs primed with the δ-cluster killed vaccine and no cross-reactivity between sera from vaccinated pigs and CA/09 antigens were detected prior to challenge. Neutralizing antibodies (NA) against the δ-cluster virus were detected prior to challenge in the sera from vaccinated pigs although NA responses were lacking against the CA/09 virus at the same time. Additional antibody assays are in progress.

Discussion
This study demonstrates an enhancement of pneumonia in vaccinated pigs challenged with a heterologous, homosubtypic virus, consistent with previous reports by our group.3 The enhanced pneumonia was significantly greater compared to pigs challenged with the same virus without previous vaccination or prior SIV specific antibodies. Therefore, it is speculated that the vaccine-induced immune response in the lung contributes to the enhanced pneumonia. In addition, virus replication in the nasal cavity and lung were lower in vax/challenge pigs in spite of the enhanced lung lesions. To date, this phenotype has been experimentally reproduced when pigs are administered an inactivated SIV H1 vaccine followed by heterologous homosubtypic challenge. This phenomenon has the potential to be realized in the U.S. swine population due to the exposure of genetically diverse H1 SIV currently circulating among swine vaccinated with inactivated heterologous virus vaccines.

Introduction
The first outbreak of infection with pandemic influenza A (H1N1) 2009 virus (H1N1/09 virus) in a Norwegian swine herd was recorded on 10th of October 2009. Until then the Norwegian pig population was considered free of swine influenza subtype H1N1 and H3N2, as documented by a serological surveillance program running since 1997 (1). This paper describes the results of a surveillance study in the Norwegian pig population from 10th of October to 31st of December 2009.

Materials and methods

Herds. To investigate the extent of the H1N1/09 virus outbreak in Norway in October 2009, the Norwegian Food Safety Authority initiated an increased surveillance targeted at the following categories:

- Herds where the pigs had been exposed to persons with verified H1N1/09 virus infection or to persons with influenza-like symptoms (ILI).
- Herds where pigs with ILI were observed.
- Herds with a history of contact with or close proximity to infected herds.
- Serological screening of nucleus and multiplier breeding herds.

Sampling and tests. Initially most herds were tested by nasal swabs from 20 pigs. Detection of H1N1/09 virus was done at the Norwegian National Veterinary Institute, by real-time RT-PCR to detect influenza A virus (2). Positive samples were tested by H1N1/09 virus specific real-time RT-PCR (3). In addition, samples were tested at the National Veterinary Institute, Technical University of Denmark, by a H1N1/09 virus specific real-time RT-PCR (4). Later, many herds, including the nucleus and multiplier herds, were tested serologically by an enzyme-linked immunosorbent assay (ELISA, ID Screen® Influenza A Antibody Competition test, IDVET) and haemagglutination inhibition (HI) test to detect antibodies against influenza A virus on at least 20 pigs per herd. In addition, a few tracheal and bronchial swabs from pneumonic lungs, from the slaughter house were tested by RT-PCR.

Diagnostic criteria. One PCR-positive sample or five samples positive for antibodies against influenza A virus was defined as sufficient to confirm a farm as positive. If less than five samples were positive for antibodies with the ELISA, the herd was re-tested. The farm is declared negative when the re-tested second samples were all negative.

Results

Of the 114 herds tested by nasal swabs, 54 herds were positive for H1N1/09 virus, and 55 of the herds tested by serology were positive for antibodies against H1N1/09 virus as confirmed by HI test (Table 1).

*Some herds were tested by both RT-PCR and serology.

Genome sequencing of the virus from one pig confirmed it as identical to the virus from a sick farm staff member at the same farm and that it is at least 99.8% similar to other pandemic viruses circulating in humans in Norway.

Discussion

The majority of the positive herds, especially among the herds tested first, had a history of contact between pigs and humans whom were diagnosed with pandemic influenza or people with ILI. This suggests infected humans to be the most likely source for transmission of H1N1/09 virus to positive pig herds. Ongoing studies will evaluate the risk factors for infection in pigs, and the hypothesis that humans transmitted H1N1/09 virus to pigs. The diversity of H1N1/09 virus in the Norwegian pig population will be studied by sequencing positive samples.

Towards risk-based surveillance for swine influenza virus

Barbara Wieland1, Alexander Mastin1, Dirk U. Pfeiffer1 The COSI Consortium2

1. Royal Veterinary College, Hatfield, UK; 2. Combating Swine Influenza Initiative consortium, Cambridge, UK

Introduction

Pigs are a significant reservoir of H1N1, H1N2 and H3N2 influenza viruses, strains of which are endemic in pigs worldwide. Swine influenza virus (SIV) can also contribute to substantial economic loss in pig production due to respiratory disease. In order to monitor the SIV strains present in the UK, a national swine influenza surveillance programme was implemented in 1991, since when avian-like swine H1N1 and H1N2 strains have been detected. The programme is based on passive surveillance and therefore the true proportion of farms in the UK exposed to the different SIV strains and the prevalence of subclinical infection is difficult to estimate. The emergence of the novel pandemic H1N1v strain in people in 2009 is also a substantial threat for the pig industry and infection studies have confirmed the susceptibility of pigs to the virus and the ability to transmit from pig to pig.

For the development of an effective active surveillance strategy to allow early detection of H1N1v in pigs and to inform preventive and control measures, the epidemiology of SIV in England needs to be better understood. The study presented here aimed to provide further key knowledge by investigating farm level risk factors for SIV infection in pigs.

Material and Methods

In 2008/09, 146 farrow-to-finish farms were enrolled in a cross-sectional study; the sample represented about 17% of the English pig herd. Of each farm serum samples of 20 animals of different age groups were tested for H1N1, H1N2 and H3N2 influenza viruses with haemagglutination inhibition (HI) assays. At the time of the farm visit, extensive data on herd management, herd health, reproduction management, production parameters and the farm environment was collected. Factor analysis was used to reduce the number of variables and to account for co-linearity in the dataset. To identify herd level risk factors, the identified risk factors were tested for association with SIV infection using univariate and multivariate logistic regression models.

Results

Fifty-nine % of tested farms had at least one growing pig with a HI titre of 1/40 or at least two animals with lower titres. Avian-like H1N1 was found to be the most common strain in England, followed by H1N2 and one farm tested positive for H3N2. Also 18% of farms tested positive for H1N1 and H1N2, which could either be cross-reaction or infection with both strains. H1N2 positive farms were found across the country. There was however, a significant cluster of H1N1 positive farms in the Northeast of the country with farms located within the cluster having a relative risk of H1N1 infection of 4.63. Risk factor analysis identified association of farm size, location, and biosecurity measures in place with increased risk of infection with SIV. Also SIV positive farms were more likely to be infected with other endemic pig pathogens and had poor respiratory scores in slaughterhouse monitoring programmes.

Discussion

In conclusion the findings of this study improve our understanding of the current swine influenza situation in England. The prevalence found is much higher than expected and highlights the importance of subclinical infection, respectively that the importance of SIV as a significant production disease has been underestimated in the past. The findings of the risk factor analysis provide insight in how spread of SIV in general, and spread of H1N1v in particular, can be prevented and will inform future surveillance activities.
Antigenic and genetic diversity of delta cluster swine influenza virus
H1N1 and H1N2 field isolates from the United States

Introduction
Currently, four clusters of H1 swine influenza viruses (SIV) are circulating in the North American swine population. The most recent endemic H1 cluster to emerge is the human-like, or delta cluster, of H1N1 and H1N2 viruses that were first reported in the eastern and western USA in 2003 and 2005.¹,² The delta cluster viruses, beta cluster viruses (reassortant-like H1) and gamma cluster viruses (H1N2-like) are currently co-circulating in the US swine population, while classic-like (alpha cluster) viruses are still occasionally isolated in the US and Canada.³,⁴

Materials and Methods
The hemagglutinin protein similarity of delta H1 viruses was determined by sequencing the HA1 portion of the gene then aligning with Clustal V. A neighbour-joining analysis was used to reconstruct phylogenetic trees with the DNASTAR computer program. The length of each pair of branches represents the distance between sequence pairs, while the units at the bottom of the tree indicate number of substitution events. To evaluate the association of genetic relatedness to antigenic cross-reactivity, SIV-negative pigs were vaccinated with two doses of monovalent, adjuvanted and inactivated vaccines prepared from different delta cluster viruses.⁵ Sera were tested for hemagglutination inhibition (HI) antibody titers to homologous and heterologous delta H1 viruses. The animal phase of these studies was conducted according to the guidelines of Pfizer Animal Health’s (PAH) Institutional Animal Care and Use Committee.

Results
There are genetic differences among contemporary delta H1 SIV (Figure 1). Viruses also differed in HI cross-reactivity to the homologous and heterologous viruses (Table 1).

Discussion
We previously reported strong HI cross-reactivity between delta H1 viruses originating from US swine herds in 2005-2007.³,⁴ The current results, evaluating additional H1 field isolates from 2008-2009, indicate both genetic and antigenic diversity among viruses within this cluster. These data are consistent with a recent report that also demonstrated diversity among delta cluster viruses.⁶ Although HI cross-reactivity and HA similarity may be predictors of variability, vaccination and challenge studies are the best predictors of vaccine cross-protection.

Introduction
Prior to the introduction of the 2009 pandemic H1N1 virus (1) from humans into pigs in the U.S., four phylogenetic clusters of the hemagglutinin (HA) gene from H1 swine influenza viruses (SIV) co-circulated. Viruses from the classical H1N1 SIV lineage evolved over time to form α-, β-, and γ-clusters. SIV with HA genes most similar to human seasonal H1 viruses emerged in 2003 to form the δ-cluster (2). All four HA cluster gene types can be found with neuraminidase genes of either N1 or N2 subtype. Limited information was available regarding the 6 genes that make up the triple reassortant internal gene (TRIG) cassette in contemporary H1 SIV. In addition, information regarding the antigenic relatedness of the H1 viruses and diagnostic reagent updates were in need due to the dynamic and variable nature of H1 SIV. We characterized 12 H1 isolates from 2008 by sequencing and phylogenetic analysis of all eight gene segments and by serologic cross-reactivity in the hemagglutination inhibition (HI) assay.

Materials and methods
Viruses. Swine influenza viruses isolated from outbreaks of respiratory disease in pigs were grown in Mardin-Darby Canine Kidney (MDCK) cells. Virus isolates were: A/SW/NC/02023/2008 H1N1, A/SW/OH/02026/2008 H1N1, A/SW/MO/02060/2008 H1N1, A/SW/IA/02096/2008 H1N1, A/SW/KY/02086/2008 H1N1, A/SW/MN/02011/2008 H1N2, A/SW/MN/02093/2008 H1N1, A/SW/MN/02053/2008 H1N1, A/SW/NE/02013/2008 H1N1, A/SW/NC/02084/2008 H1N1, A/SW/TX/01976/2008 H1N2, and A/SW/IA/02039/2008 H1N2.

Antigenic characterization. Four-week-old cross-bred pigs were obtained from a herd free of influenza virus and antibodies. Two pigs per virus were immunized with inactivated virus combined with commercial adjuvant by the intramuscular route. Two or three vaccinations were given approximately 2-3 weeks apart until homologous HI titers reached ≥ 1:80. HI assays were performed with turkey RBC’s using panels of homologous and heterologous viruses and anti-sera with standard techniques. Quantitative analyses of the antigenic properties of swine influenza A H1 viruses were performed using antigenic cartography, previously used for human and swine influenza A (H3N2) viruses (3-4) and 2009 pandemic H1N1 (1).

Genetic characterization. Each virus isolate was concentrated and semi-purified on a sucrose cushion followed by library preparation for de novo pyrosequencing on a Genome Sequencer FLX system following the manufacturer’s recommendations with modifications. Briefly, viral RNA was extracted, fragmented, reverse transcribed, and ligated to oligonucleotide adaptors containing multiplex identifier (MID) labels. Pools containing MID-labeled viral cDNA were used to prepare sequencing beads via Roche’s GS-FLX standard chemistry emulsion-based PCR. Prepared beads were loaded into the small 16 regions on a GS-FLX standard chemistry pico-titer plate and sequenced using the GS-FLX LR 70 standard chemistry. Sequencing reads were compared to an influenza database created from > 85,000 influenza sequences extracted from GenBank in Dec. 2008. Using the BLAST results, sequencing reads were filtered, influenza specific reads extracted, and extracted reads were assembled with the Roche GS De Novo Assembler (Newbler) version 2.0 application. Gene segments with large gaps were closed by traditional primer based sequencing using an ABI 3100 genetic analyzer. The sequences were analyzed using SeqMan (DNASTAR). Phylogenetic analyses were conducted using MEGA version 4.

Results
Based on genetic analysis, each of the four previously described phylogenetic clusters of H1 SIV was represented in the 2008 panel. Additionally, it was demonstrated that the δ-cluster HA diverged into sub-clusters δ-1 and δ-2. Serologic cross-reactivity paired with antigenic cartography demonstrated that the phylogenetic clusters are also divergent antigenically. The genes composing the TRIG were all North American in lineage, although genetic variation was apparent.

Discussion
In 2008, five genetic and antigenic clusters of H1 SIV co-circulated in the U.S. pig population with limited HI cross-reactivity between them. Genetic diversity was demonstrated in all gene segments, but most notably in the HA gene. Gene segments from the 2009 pandemic H1N1 formed clusters separate from North American swine lineage viruses, suggesting this virus was not present in U.S. pigs prior to 2009. The HA variability has important implications for diagnostic testing as well as vaccine development.

Introduction
Swine influenza is caused by type A influenza viruses. The three commonest swine influenza virus (SIV) subtypes are H1N1, H1N2 and H3N2 although other less frequent or sporadic subtypes can infect pig farms as well H4N6 [1]. In Spain, previous serological studies revealed high seroprevalences for H1N1, H1N2 and H3N2 viruses in sows [2] and fattening pigs [3]. Nevertheless, available information indicating risk factors for the introduction and spread of the infection in farms is very much scarce. The main objectives of the present study were to estimate the seroprevalence of H1N1, H1N2 and H3N2 subtypes in sows and fattening pigs and to explore the potential risk factors associated with seropositivity to SIV.

Material and methods
Between 2007 and 2009 a cross-sectional survey was carried out in swine farms of pig-producing regions of Spain. Sampling was designed to guarantee a 95% probability of detecting at least one positive animal for an assumed within-herd seroprevalence of 50%. As a result 100 swine farms located all over Spain were examined. Epidemiological data were gathered through on-farm interview of the farmer based on “closed-ended” questions. For each farm, blood samples were collected from 14 sows and 20 finishers, totaling 2,249 pigs for the whole survey.

Blood samples were analyzed by means of an indirect ELISA (CIVTEST Influenza, HIPRA) directed to detect antibodies against SIV nucleoprotein that was performed according to the manufacturer’s instructions. A hemagglutination inhibition (HI) test was standardized for H1N1 (A/swine/Neth/Best/96), H1N2 (strain A/swine/Gent/7625/99) and, H3N2 (strain A/swine/Neth/St.Oedenrode/96) according to procedures previously described [4]. IH titres ≥80 were considered as positive. SPSS 14.0 statistical program was used to explore risk factors associated with swine influenza using the method of generalized estimating equations [5] (GEE).

Results
By ELISA, all farms had at least one seropositive animal, and in total 1,435/2,249 animals yielded positive ELISA results (63.8%; IC95%: 61.8-65.8%). Seroprevalence of sows was 77.8% (IC95%: 75.5-79.9%) significantly higher (p<0.05) than seroprevalence in fattening pigs (40.9%; IC95%: 37.6-44.2%). Average seroprevalence in positive farms was 68.3%. A total of 1,231 animals (54.7%; IC95%: 52.7-56.8%) were positive in the HI test. Again, sows had a significantly higher (p<0.05) seroprevalence compared to fattening pigs (72.9%; IC95%: 70.6-76.3 against 24.7%; IC95%: 21.8-27.6). Table 1 summarizes the results obtained by individuals and age group. In the epidemiological analysis, four variables (open vs. solid partitions between pens, pig density, natural vs. forced ventilation and the percentage of replacement rate) were identified as risk factors.

Table 1

Discussion
This results shows that SIV is widespread in Spain. The high seroprevalence observed against H1N1 and H3N2 compared to H1N2 could be explained by a reduced ability to spread the latter. The higher seroprevalence observed in sows could be explained by the fact that these animals have a long lifespan. As a consequence, sows would have more chances to be exposed to SIV. The epidemiological analysis also show results obtained in GEE have shown that major contact between animals favor SIV circulation. Low air renewal enhances a major concentration of SIV in environment, which explains higher seroprevalence in farms without forced ventilation. Finally, an increasing % of replacement, could favor a higher number of susceptible animals to SIV infection.

Introduction

Pigs may act as "mixing vessels" and generate recombinant viruses of unknown pathogenicity for animals and humans, as reflected with the last human H1N1 influenza pandemic. One of the main problems to obtain efficient vaccines against flu is the high variability of the virus, limiting the protection to highly homologous viruses.

In an attempt to identify potential cross-reactive epitopes within the H1 haemagglutinin (HA), a conformational spectrum analysis was done using sequences available in the GenBank database. One highly conserved peptide of 34 amino acids mapped in the flanking region of the HA binding site from human A/South Carolina/1/18 (H1N1) (NF-34 peptide), was selected1. The objective of this study was to test the protective effect of the synthetic HA-peptide based vaccine in vivo.

Materials and Methods

A total of eight 8 week-old conventional crossbreed pigs seronegative against swine influenza viruses (SIV) were randomly divided into two groups (four pigs each). Each group was intramuscularly injected three times either with the NF-34 peptide (10-15 μg per dose) (referred to as G1) or with phosphate buffer saline (referred to as G2) two weeks apart. One month after last dose, pigs were intranasally inoculated with 106 tissue culture infectious doses 50% (TCID50) of the human H1N1 pandemic virus (A/Catalonia/63/2009 strain). Six days later, pigs were sacrificed. Serum and peripheral blood mononuclear cells (PBMCs) taken before each immunization, before challenge and at 6 days post-challenge (necropsy day) were used to detect specific humoral and cellular responses, respectively. Specific antibodies were detected using a peptide-based ELISA or by the haemagglutination inhibition assay, while cellular responses were determined by IFN γ-ELISPOT after overnight stimulation with either the NF-34 peptide or with inactivated virus. After challenge with pandemic H1N1 virus, pigs were sacrificed at day 6 post-challenge and viral loads checked by a real-time qRT-PCR in bronchoalveolar lavage (BAL).

Results

Pigs immunized with the NF-34 synthetic peptide developed peptide-specific antibodies. Also, G1 animals showed an antibody boost at day 6 post-challenge (lines in figure 1). Similarly, peptide-specific IFN γ-secreting cells were detected by ELISPOT before challenge, showing a clear boost by day 6 post-challenge (bars in figure 1). Specific T-cells did not only recognize the NF-34 peptide but also the inactivated pandemic virus (data not shown).

Discussion

Despite the haemagglutination inhibitory antibodies induced after vaccination were relatively weak (data not shown), 50% (2/4) of G1 pigs showed lower viral load in the BALs compared with G2 pigs (Figure 2).

Discussion

Current vaccines against influenza (including those against seasonal influenza in humans) are restricted to the predicted circulating strain at a given time in a specific world location. It is important to notice that even though only partial protection was afforded in the present pig model, this was obtained against one of the most divergent H1N1 strains, with an HA differing in 3 aminoacids from the peptide used to vaccinate. We suggest that this strategy could be appropriated to immunize against divergent strains by incorporating to the vaccine epitopes able to induce neutralizing antibodies enabling to obtain safe and efficacious subunit flu vaccines.

Human-like H1 (δ-cluster) swine influenza virus (SIV) can efficiently replicate, transmit, cause lung pathology and induce humoral immune responses in the swine host

Janice R. Ciacci-Zanella1, Amy L. Vincent1 Eraldo L. Zanella1, Susan Brockmeier1

Introduction

Genomic characterization of recently identified H1 influenza A viruses demonstrated the viruses were triple reassortants with an internal gene constellation similar to temporary U.S. swine influenza virus (SIV) but hemagglutinin (HA) and neuraminidase (NA) most similar to human seasonal influenza virus lineages (1, 2). The HA gene of these viruses form the δ-cluster in phylogenetic analyses of HA genes from North American SIV. PB1-F2 is an influenza A virus protein encoded on gene segment 2 and described to be a virulence factor in other host species, but its role in swine is currently unknown (3). The δ-cluster H1 SIV was demonstrated to contain segment 2 encoding PB1-F2 proteins with and without premature truncations (3). The objective of this work was to study the pathogenesis and transmission of δ-cluster H1 SIV in swine.

Materials and methods

Three δ-cluster H1 SIV grown in MDCK cells were used in this study. Two isolates, A/sw/MN/07002083/07 H1N1 (MN07) and A/sw/IL/00685/05 H1N1 (IL05), were chosen due the absence of the full-length coding sequence for PB1-F2, whereas A/sw/TX/01976/08 H1N2 (TX08) contains the full-length PB1-F2 sequence. Forty-nine pigs were divided in seven groups composed of 3 primary inoculated pig groups with each δ-cluster virus, three contact groups and one uninfected control group. Primary pigs (n=10) were infected intratracheally with SIV and naïve contact pigs (n=5) were co-mingled after 48 hours to be infected via natural transmission routes. Nasal swabs were taken on 0, 3, 5, 7 and 9 days post infection (dpi) or days post contact (dpc) to evaluate nasal shedding. Oral fluids were also collected on days 3-10, 14, 18 and 20 dpi as described previously (4). Postmortem samples including serum, bronchoalveolar lavage fluid (BALF), lung, trachea and nasal swabs were collected at necropsy at days 5 and 21. Non-challenged age-matched negative control pigs were necropsied at 5 dpi (n=5 pigs). Serologic assays included the hemagglutination inhibition (HI) (5) assay and the Avian Influenza MultiS-Screen ELISA (6). In addition to homologous HI assays, 21 dpi and 19 dpc serum were evaluated against the studied viruses (TX08, MN07 and IL05) as well as a previously generated H1 serum panel in heterologous HI assays. Real-time PCR assays were performed for detection of SIV (oral fluids) and of PRRSV, PCV2 and Mycoplasma hyopneumoniae nucleic acids in BALF using in house assays (3).

Results and discussion

All pigs were seronegative for specific antibodies to SIV by the HI assay and by ELISA prior to the start of the study. Pigs were also negative for PRRSV, PCV2 and M. hyopneumoniae nucleic acids in BALF at necropsy. All viruses induced SIV illness; however, clinical signs and macroscopic lesions induced by MN07 were reduced in severity as compared to TX08 group pigs in this study. MN07 infected pigs had lower virus titers in the lung and nasal swabs (day 5) than the TX08 and IL05 groups. However, on day 7 dpi all of the nasal swab samples from MN07 and IL05 inoculated pigs were negative. In comparison, the TX08 inoculated group had 80% of the pigs shedding virus in nasal swab samples on 7 dpi, with average titers of 101.2 TCID50/ml. In contrast to TX08, only contact pigs were still shedding on 7 dpc in MN07 (10%) and IL05 (20%) groups. These data demonstrate that all viruses were able to replicate and be shed, however TX08 was more efficient in nasal shedding with higher titers and an extended duration of shedding. Oral fluids samples also showed lower however longer viral titers for MN07 (4-9 dpi) and IL05 (3-8 dpi) in comparison to TX08. Pigs in this study mounted a more robust humoral response to MN07 and IL-05 δ-cluster H1N1 compared to the TX08. This was statistically significant for HI titers at days 14 and 21. Cross-HI using heterologous virus demonstrated little cross-reactivity between the TX08 anti-sera and the MN07 and IL05 δ-cluster H1 viruses. However, there was cross-reactivity between the MN07 virus and IL05 anti-sera. This is consistent with phylogenetic evidence of 2 sub-clusters of δ-H1 SIV. This study indicates that the δ-cluster H1 SIV can efficiently replicate, transmit, cause lung pathology and induce humoral immune responses in the swine host. However, the kinetics of virus replication, pathogenesis, as well as host humoral immune response differed between the 3 viruses. Two sub-clusters of the δ-cluster SIV appear to have emerged simultaneously with limited serologic cross-reactivity between them. What role (if any) the full-length PB1-F2 present in TX08 played in the higher nasal shedding of virus remains to be determined.

Selection of influenza vaccine strains and rapid method for producing antigenically homologous vaccine

DL Hank Harris¹ Marie Gramer² Ryan L. Vander Veen¹ Mark A. Mogler¹

1. Iowa State University, Ames, IA, USA; 2. University of Minnesota Veterinary Diagnostic Laboratory, St. Paul, MN, USA

Introduction

There are a wide variety of swine influenza viruses (SIV) occurring in the United States swine population. The subtypes and variants present include 4 clusters of H1 - alpha, beta, gamma (which includes the pandemic H1N1 virus) and H1 or delta, and one dominant H3N2 (cluster 4).¹ ² Traditionally, nucleotide sequences of the first 900 nucleotides (5’ end) of the hemagglutinin (HA) gene are utilized to classify subtypes of viruses; however, genetic similarity does not necessarily correlate with antigenic relatedness. When selecting vaccine strains used to prevent seasonal influenza in humans, a vaccine strain is updated when there is an antigenic difference between the vaccine strain and a newly emerged strain of greater than 2 units (4-fold dilution) in the hemagglutination-inhibition (HI) assay.³ We report here the results of preparing antisera in pigs to recombinant protein subunit HA antigens and determining the antigenic relatedness of field strains of SIV by HI assay.

Materials and Methods

Swine influenza virus negative pigs were vaccinated twice with adjuvant vaccine consisting of either recombinant H1 beta, delta, gamma, pandemic, or Cluster 4 H3 HA subunit proteins for the preparation of cluster-specific antiserum. Serum samples with reciprocal HI titers of 160-320 were used for further HI testing against field strains of SIV.

Results

Table 1 shows the HI results of 2 H1N1 beta viruses, A and B, from different farms. Hemagglutination inhibition titers are similar for Farm A and Harrisvaccine (HV) beta viruses (within 2 antigenic units of the homologous reaction). Although all antigens were genetically similar, HI titers for Farm B are >2 antigenic units different from the homologous titer. Table 2 shows the HI results of cluster 4 H3N2 antigens. Again, the HV, Farm C and Farm D antigens are genetically similar; however, in this case, there is little antigenic difference discernable by HI.

Table 1. Reciprocal HI titers for antisera 1 and 2 against viruses Harrisvaccine (HV) Beta 2009, Farm A 2007, and Farm B 2009. Percent nucleotide similarities to HV Beta 2009 virus are also shown. Homologous reactions are in bold.

Discussion

These antigenic results suggest that the HV beta vaccine would protect against a challenge with virus from Farm A but not Farm B, despite the high genetic similarity of the three viruses. Antigenic drift was detectable in H1 strains, but was limited in the H3 viruses evaluated in this study. The H3 viruses were both antigenically and genetically similar, suggesting that vaccination with the HV Cluster 4 H3N2 vaccine would provide cross-protection against isolates from Farm C or Farm D. These results demonstrate that genetic similarity is not the sole indicator of possible vaccine protection, and should be combined with antigenic analysis to determine if a vaccine will be protective against field isolates. Because HA genes can be rapidly exchanged for constructs used to produce recombinant HA protein subunits,⁴ vaccines for prevention of influenza can be created quickly to match the strain occurring in the farm of origin.

Prior swine influenza virus infection enhances pulmonary responses to secondary *Haemophilus parasuis* infection

Susan L. Brockmeier; Crystal L. Loving; Amy L. Vincent
National Animal Disease Center, Ames, IA, USA

**Introduction**

Swine Influenza virus (SIV) infection and associated complications are a leading cause of morbidity and mortality. It is appreciated that SIV is often complicated by secondary bacterial infection. Tracheal epithelial cells (TEC) and pulmonary cells respond to infection with proinflammatory cytokines for controlling pathogen spread; however, exacerbated responses can lead to immunopathology that may be detrimental to the host. The extent to which prior SIV infection alters host responses to secondary stimulation is poorly understood. *Haemophilus parasuis* is an important and common respiratory pathogen of pigs. The innate immune responses of the respiratory tract of pigs infected with SIV 5 days prior to secondary infection with *H. parasuis* were examined.

**Materials and Methods**

Groups of 4 pigs were infected with SIV and 5-days later infected with *H. parasuis* (SIV/Hps). Non-infected, SIV-only and *H. parasuis*-only groups were included as controls. Pigs were necropsied 1 day following *H. parasuis* inoculation. Pigs were inoculated intranasally with 2 X 10^6 CCID50 of SIV (A/SW/OH/511445/2007 H1N1) and 10^6 CFU of *H. parasuis* strain 12939. Nasal wash, tracheal wash and broncho-alveolar lavage (BAL) were performed and number of CFU of *H. parasuis* per ml of wash was determined. Levels of IL-8, IL-6, and IL-1 β in BAL fluid and tracheal wash were determined by ELISA. mRNA expression of the cytokine genes from tracheal epithelium and BAL cells were determined using real-time RT-PCR.

**Results and Discussion**

*H. parasuis* colonization was higher in the nose and lungs of SIV/Hps pigs compared to Hps-only pigs (Figure 1). These results indicate that influenza virus infection contributes enhanced bacterial colonization.

In SIV/Hps pigs, IL-8, IL-6 and IL-1 β protein levels were increased in the tracheal wash and BAL, and TEC and BAL cells IL-8, IL-6 and IL-1 β mRNA expression levels were significantly increased over SIV-only and Hps-only pigs (Figure 2).

These results support the hypothesis that prior influenza infection alters subsequent immune responses. In addition, the data provide evidence of a synergistic response to secondary bacterial stimulation in animals previously infected with influenza virus.
Introduction
For over two decades producers, veterinarians and researchers have spent, and continue to spend, impressive amounts of time communicating about porcine reproductive and respiratory (PRRS) virus. And yet the lack of standard clearly defined terminology, related to the virus as well as the PRRS virus status of herds continues to create confusion and inefficiency. The purpose of this paper is to provide a standard herd classification scheme describing the PRRS virus status of herds, and a set of related definitions that is consistent with the biology and ecology of PRRS virus.

Development was jointly undertaken by the American Association of Swine Veterinarians (AASV) and the United States Department of Agriculture (USDA) PRRS-CAP. A definitions committee chaired by Dr. Bob Morrison was formed to complete the task. The committee was composed of researchers and veterinarians from private practice, universities and industry as well as representatives from AASV and the National Pork Board (NPB) in the U.S.

Method for classification of herds
For breeding herds, with or without growing pigs on the same premises there are four categories, I to IV. Category II is further divided into two sub-categories (II-A and II-B). For premises with only growing pigs present there are two categories.

The herd classification is based upon the shedding and antibody status of the herd. The shedding status is classified as negative, unknown or positive. An unknown shedding status means that diagnostic evidence is available to confirm the sustained absence of viremia and there have been no clinical signs over a period of time. However, the possibility that virus may be present in other tissue of and shed from the tested animals or other animals in the herd cannot be ruled out with certainty and therefore the shedding status is unknown. The antibody status is classified as negative or positive.

Results - Classification of breeding herds
Category I ("positive unstable") breeding herds have a positive shedding and antibody status. It is the default category when a status has not been confirmed.

Category II ("positive stable") breeding herds have an unknown shedding and positive antibody status. An absence of clinical signs of PRRS in the breeding herd and confirmation of a sustained lack of viremia in piglets, and if present growing pigs, for a minimum of 90 days is required. The antibody status of the herd remains positive. The possibility that animals in category II herds may still be infected and later shed the virus cannot be ruled out. A distinction is made between category II herds that are not undergoing PRRS virus elimination (II-A) and those that are (II-B). An elimination procedure begins when the herd is closed to introduction of breeding replacements that are not negative. Confidence that the piglets and growing pigs in category II-B breeding herds are not shedding virus is higher than for II-B since additional steps are being taken to eliminate shedding.

Category III ("provisional negative") breeding herds have a negative shedding status and positive antibody status. Sustained introduction of negative breeding replacements without seroconversion to the PRRS virus is required. Entering negative breeding replacements that have been in contact with previously positive animals and remain seronegative by ELISA for a minimum of 60 days is strong enough evidence to confirm that the virus is no longer being shed in the herd. Some adult breeding animals in the herd may still have antibodies to the PRRS virus due to prior infections. If growing pigs are present, confirmation of a negative antibody status in that subpopulation is also required. Category III herds include those intentionally pursuing elimination via herd rollover by entering negative breeding replacements.

Category IV ("negative") breeding herds have a negative shedding and antibody status. For herds established negative by herd rollover, all previously infected animals have been removed from the herd or alternatively all adult breeding animals in the herd are seronegative by ELISA. If growing pigs are present, confirmation of a negative antibody status in that subpopulation is also required. As with category III herds, sustained introduction of negative breeding replacements that remain seronegative is required. It also includes new premises startups that were populated with negative breeding replacements or premises that were completely depopulated and repopulated with negative breeding replacements that have remained seronegative by ELISA.

Results - Classification of growing pig herds
Herd with growing pigs only are classified as either positive or negative. Positive herds have a positive shedding and antibody status. It is the default category when a negative status cannot be confirmed. Negative herds have a negative shedding and antibody status.

Discussion
A standard, universally accepted herd classification scheme and definitions related to PRRS virus are required to facilitate regional and national elimination efforts. Equally important, they will improve communications between researchers, veterinarians, producers, genetic companies and other industry vendors by decreasing the amount of time required to communicate and reducing miscommunications.
Modelling PRRSv control within a pyramidal network of pig movements

Catherine Belloc¹ Amandine Lurette² Matt Keeling³

1. INRA-ONIRIS Vet School, Nantes, France; 2. INRA, Montpellier, France; 3. University of Warwick, Coventry, UK

Introduction
Epidemiological models can help to improve pathogen control through the ex ante assessment of control measure efficacy at several scales. The pork primary production chain consists in pyramidal structures with herds having specific links between them, some being animal suppliers for others. Since animal movements are a key issue for pathogen spread, we elaborated a dynamic network model describing between-herd animal flows. We then tested by simulation the implementation of a control program combining both intra-herd control measures and restriction of animal movements depending on the sanitary status of herds for an important pathogen of pigs: the PRRSv.

Materials and Methods
A stochastic network model with a one-week discrete time step was elaborated based on data collected by a group of French producers over 12 months. 256 herds were included in the model (4 nucleus herds, 17 multiplier herds and 235 production herds). They were divided into four types: breeding (n=7), farrow-to-finish (n=176), post-weaning-finishing (n=5) and finishing ones (n=68). Animals concerned by between-herd movements were 8kg-piglets (n=346 movements during the study period), 25kg-piglets (n=371), reproductive gilts (n=2440). Herds were randomly categorized according to their PRRSv status (negative or infected). Nucleus herds were all negative and prevalence of herd infection was assumed to be 0.2 and 0.6 for multiplier and production herds respectively (Lebret, 2008). This status was evaluated every six months. To simulate the implementation of movement restrictions we generated two sub-networks based on most connected herds using Unicet software version 6: “restricted” (n= 127 herds) and “non-restricted” (n=129) sub-networks. In the “restricted” sub-network, the infectious status of herds was checked before each movement and a PRRSv negative herd can be supplied by negative herds only. Moreover, herds of this sub-network may implement control measures aiming at reducing the probability of within-herd PRRSv persistence. We assumed that these measures were of variable efficacy depending on their real implementation under field conditions: probability of persistence of PRRSv between two tests (assumed to be equal to 1 without measure) could be reduced to 0.95, 0.9 or 0.8.

Results
The numbers of infected herds observed after 520 weeks of control implementation for 100 simulations by scenario are presented in Figure 1. The restriction of movements taking into account the PRRSv status of herds leads to a slight decrease in the number of infected herds (mean values from 180.9 to 152.4). Additionally when movement restriction was combined with within-herd persistence reduction, the decrease was more important, leading to a negative status of all herds of the “restricted” network after 10 years if the persistence probability did not exceed 0.8.

Discussion
Few data are available about the influence of control measures (biosecurity/vaccination) on the evolution of herd status over time. This model is a tool that can be improved if parameters of viral persistence can be more precisely determined. To reach this objective, data are currently collected. In the same way, although animal movements are crucial for herd contamination, other ways of viral spread will be considered. Another perspective is to combine this model with another one representing the within-herd viral dynamic. This new combined model will allow us to assess control measures implemented at both herd and production chain levels.

McREBEL as a key component for the successful elimination of PRRS virus from very large swine breeding herds

Dale Polson1 Greg Hartsook1 Kate Dion2
1. Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA; 2. Iowa State University, Ames, IA, USA

Introduction
Successful elimination of PRRS virus (PRRSv) from large swine breeding herds using herd closure, mass vaccination and rollover has been previously described.1 While use of these methods have been shown to result in successful elimination of PRRS virus from very large breeding herds, consistent elimination success in very large breeding herds may also require use of other management methods that minimize opportunities for persistent circulation of virus among subpopulations of susceptible animals. An area within breeding herds that may be prone to persistent virus circulation is the farrowing area. A set of concurrently applied farrowing area management practices (McREBEL) have been previously described for use in breeding herds to reduce suckling piglet losses during clinical outbreaks of PRRS.2

The objective of this observational study was to describe two cases where the discontinuation of McREBEL led to a recurrence of farrowing area PRRS virus circulation and the subsequent resumption of McREBEL resulted in the disappearance of virus circulation, and ultimately virus elimination in both farms.

Materials and Methods
In April 2008 two PRRSv naive 5000 sow farrow to wean farms within the same production system and located 1.2km apart identified PRRSv positive serum samples collected from gilts, sows and piglets by PCR and ELISA. Both farms instituted a herd closure, mass vaccination and rollover protocol to eliminate the virus. Also, strict McREBEL management practices were implemented in an effort to control PRRSv circulation in the farrowing area of both farms.

To assess progress with virus elimination, intensive sampling and PCR testing of breeding animal, stillborn fetus and due-to-wean piglet sera was initiated. Sixty individual due-to-wean piglet samples from each farm were tested by PRRS PCR and the prevalence of positive samples was followed over time utilizing the method described by Cano et al.3 Initial sampling and testing was conducted monthly, then as prevalence decreased to below 20% a weekly sampling and testing frequency was initiated.

Results
Following initial herd closure and mass vaccinations, the percent of PCR positive piglets declined on both farms to 13.6% at Farm A and 3.3% at Farm B. During this time piglets throughout farrowing appeared healthy, exhibiting no detectable clinical signs of PRRS so farm personnel relaxed McREBEL practices. At the subsequent two monitoring periods, the percentage of PCR positive piglets on Farm B rose to 12.7% and 33.3%. For the same two periods at Farm A the percentage of positives declined to 6.8% then rose to 30%. Even though piglet health remained excellent, McREBEL practices were resumed on both farms due to the increase in PCR positives at Farm B. Following the resumption of McREBEL practices, the percentage of PCR positive piglets resumed a downward direction on both farms (Figure 1). McREBEL practices were continued thereafter until there were no detected PCR positive samples found in the sampled due-to-wean piglets on each farm for at least six consecutive weekly samplings.

Discussion
Individual piglet monitoring provided evidence that prematurely relaxing McREBEL protocols during PRRSv elimination can enable resumed farrowing area virus circulation among otherwise healthy appearing piglets and lead to an increase in PCR positive weaned piglets, thus extending the time to negative weaned pig interval.

Combining sow herd stabilization and nursery PRRS virus control methods to achieve improved nursery performance

Jose Angulo; John Kolb; Reid Philips
Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA

Introduction
Porcine Reproductive and Respiratory Syndrome Virus (PRRSv) is capable of causing severely negative biological and economic impact in nursery pigs. A recent analysis suggests a negative impact of US$3.35-$9.12/pig during the nursery phase. Nursery depopulation and PRRS modified live virus (MLV) vaccination of pigs are effective tools to minimize the clinical and economic impact of PRRSv infection. The objective of this study was to evaluate the impact of sow herd stabilization, nursery depopulation, and PRRS MLV pig vaccination on nursery performance.

Materials and Methods
The study was conducted in a 3,000 sow three-site production system. The sow herd stabilization program included loading the farm with its anticipated 170-day need for gilts, closing the sow herd for 170 days and mass vaccination of the sow herd with Ingelvac® PRRS MLV (BIVI) soon after herd closure. Pig interventions included PCV2 vaccination (Ingelvac CircoFLEX®, BIVI), Mycoplasma hyopneumoniae (Ingelvac MycoFLEX®, BIVI) and PRRS MLV vaccinations in the nursery. Blood sampling was conducted monthly on 30 piglets from poor quality litters (1 piglet sampled per litter) at the sow site, and 20 pigs at 10 weeks of age from hospital pens at the nursery site. Along with the pig vaccination process, the nursery site was depopulated and remained empty for 4 weeks. PRRS RT-PCR testing was conducted on these sera including RFLP and ORF5 sequencing on PCR positive samples to differentiate wild type and MLV virus. The first blood sampling was conducted one month before starting the interventions. Mortality rates and average daily gain were assessed with statistical process behavior charting using MINITAB 15 software. A process change was inserted at the time of nursery depopulation and the onset of pig PRRS vaccination, with 93 groups closeout data prior to and 77 groups closeout data charted after the interventions.

Results
Wild type PRRSv was detected in 17% (5/30) of pre-weaning pigs and 100% of nursery pigs (n=20) the month pre-intervention but was not detected in any pigs during the 9 months post-intervention. MLV PRRSv was detected in nursery but not pre-weaning pigs post-intervention. The mean nursery mortality rate decreased from 2.90% pre-intervention to 2.15% post-intervention (Figure 1). Mean average daily gain (ADG) increased from 0.822 pre-intervention to 0.936 lb/day post-intervention (Figure 2).

Discussion
Sow herd stabilization, nursery depopulation and on-going MLV PRRS vaccination of nursery pigs were successful at controlling wild type PRRSv.

Herd closure as a strategy to eradicate PRRSV not always a success in large sow herds

Giampietro Sandri1 Patrizia Pesente2 Davide Giovanardi2
1. Agricola Tre Valli, Quinto di Valpantena - Verona, Italy; 2. Laboratorio Tre Valli, S.Martino Buonalbergo, Italy

Introduction
Understanding the dynamics of PRRSv persistence is essential for the development of successful PRRS control and eradication programs1. Among these, “Herd Closure” - a months long closure of the sow herd - is considered to be one of the most successful. It relies on consistent natural exposure that should provide a “sterilizing immunity” to all breeding stock on the farm leading to the natural disappearance of the virus by replacement of positive animals over time2. We decided to use Herd Closure as initial strategy to eradicate PRRS from three large sow herds (site one) in northern Italy with some disappointing results.

Materials, methods and case description
Serum samples at different stages and places were tested for PRRSv antibodies by IDEXX PRRS Elisa. A conventional one step RT-PCR developed by Laboratorio Tre Valli was used for viral Rna detection. Sequencing in the ORF 7 region followed.

Farm M. (7.500 sows)
After experiencing a major PRRS outbreak during summer 2004 and instability throughout December of the same year, gilt replacement was finally discontinued in January 2005. The last group of gilts was introduced in mid January 2005 and the following were all diverted to outside projects. The first animals (pregnant gilts) were re-introduced on Dec.15 2005 leading to a total closure period of 11 months.

Farm SQ. (6.500 sows closed herd)
Major PRRS outbreak from October 2005 to January 2006. Internal gilt production was discontinued and off site nursery and rearing projects were started with purchased PRRS negative animals starting from March 15th 2006. A Wean & Removal3 program was started in September 2006. PRRS negative animals/ gilts were again introduced on March 1st 2007 leading to a complete herd closure time of 12 months.

Farm A. (4.500 sow)
A severe PRRS outbreak occurred in this herd starting in April-May 2008. It was soon decided to discontinue all gilt replacement in order to stabilize the herd and to prepare a possible future PRRS eradication project. The last 3 weeks old gilts were introduced on May 19th 2008 and soon were exposed (serum inoculated) – together with all the other gilts present in the nursery compartment – to the farm strain. After this point in time all replacement gilts were diverted to off site nursery, growing and breeding projects. The first group of PRRS negative pregnant gilts entered in this herd again on April 27th 2009 after a complete closure more than 11 months long.

Results
After closure Farm M. reached a reasonably good production level without significant clinical problem but was never able to produce again PRRS negative piglets. When PRRS neg. pregnant animals returned to farrow on farm a contingency plan allowed good segregation of that population but unfortunately PRRSv started to re-circulate causing clinical problems early in April ‘06. Farm S.Q. was more successful because stabilized reasonably soon and as early as July ‘06 was able to consistently produce groups of PRRS neg. piglets with the exception of a few batches in Dec.06 when a little re-circulation occurred. Thank to the intensive Wean & Removal program4 in place PRRS eradication was achieved anyhow. Also Farm A. reached a good stabilization after Herd Closure but was never able to produce again PRRS negative piglets. The PRRSv strains recovered from different nursery sites always showed an almost complete homology with the farm strain. Not long after the first pregnant gilts started to farrow on farm they showed some PRRS clinical signs. The PRRSv recovered showed over 99% homology with the previous one. In spite of Wean & Removal PRRS eradication did not succeed in this farm.

Conclusions
Herd Closure after a major PRRS outbreak is definitely a good measure to speed up the return to clinical stability. Although in a number of different occasions Herd Closure proved to be a successful PRRS eradication tool it was not the case in our experiences. Under the conditions described before, even after very long closure periods, the specific PRRS viruses were still present. Though we have no evidence that any single animal can carry PRRSv for such a long time (11 mo.), we think that large herds with a lot of buildings and compartments certainly provide a “favourable environment” for the virus to “survive and move around” and eventually start new outbreaks when large naïve populations are introduced again.

Clusters of biosecurity in Ontario sow herds and their geographical distribution

Zvonimir Poljak1 Cate Dewey1 Robert Friendship1 Rob Deardon2 Derald Holtkamp3
1. Department of Population Medicine, OVC, University of Guelph, Guelph, ON, Canada; 2. Department of Mathematics and Statistics, University of Guelph, Guelph, ON, Canada; 3. Department of Veterinary Diagnostics and Production Animal Medicine, Iowa State University, Ames, IA, USA

Introduction
Implementing good biosecurity has direct benefits at the herd level since it is critical in reducing the likelihood of introduction and spread of emerging or endemic animal pathogens. In addition, biosecurity standards are increasingly having an impact at the industry level. Management practices related to biosecurity could be used to define a subpopulation and provide a basis for compartmentalization (1), to assist in the design of risk-based surveillance (2), or as an aid in regional disease control and eradication strategies. Studying biosecurity, however, is not without challenges. Several approaches and resulting assessments have been previously reported. The aim of this work was to assess biosecurity practices in Ontario sow herds including the determination of best number of biosecurity classes, characteristics of these classes, and their geographical distribution and association with herd density.

Materials and Methods

Questionnaire: The questionnaire used for this study was a part of the PRRS (Porcine reproductive and respiratory syndrome) Risk Assessment for the Breeding Herd (version 2) developed elsewhere, owned by the American Association of Swine Veterinarians and used extensively across North America (3). Three evaluators were trained and performed personal interviews with owners and herd veterinarians of 161 sow herds in Ontario during the summer of 2007. Herds were selected conveniently through herd veterinarians. The original questionnaire contained 155 questions divided into internal and external risk sections and 24 questions related to the demographics of the site.

Selection of variables for multivariate analysis: Out of all questions available, only 24 categorical variables were included in the statistical analysis. Variables were included if they were indicative of the introduction of pathogens from external sources including replacement animals and semen, management options related to acclimation and isolation units, site policies related to visitors, tools, sanitation, and protocols related to transportation of animals, feed, and people. Variables related to density of pig herds as well as variables related to herd type and demographics were excluded from this initial classification step. All variables were categorical with 2 to 4 discrete levels.

Statistical analysis: Two classification methods were used to classify the data: (i) two-step hierarchical clustering (SPSS 17) and (ii) latent class analysis (SAS 9.2, proc lca). Both of these methods have advantages over other classification methods in that they use statistical criteria to determine the best number of sub-classes and because they can directly analyze nominal variables. Best number of classes was determined using both methods, examined descriptively and agreement was assessed using the kappa statistic. Generalized additive models using logistic regression (R, package mgcv) were then used to map each of the biosecurity groups by displaying expected risk on a 10x10 km grid of Ontario. In addition, multinomial logistic regression (Stata 10) was used to investigate the association between biosecurity groupings of sow herds and variables indicative of herd density obtained through the questionnaire.

Results

Three classes of biosecurity practices exist in Ontario sow herds. This number, determined using the two different methods and classification of herds was in almost perfect agreement (kappa=0.83). Best description of these three is: (i) “High” biosecurity sow herds, (ii) “Low to moderate” biosecurity sow herds, and (iii) “Closed” sow herds. Proportion of sow herds that were classified in the high biosecurity group was higher in areas of high swine herd density. This result was confirmed independently by regressing the biosecurity group classification against the number of swine herds within a 8 km radius from each site (Overall P=0.03). The probability of being a high biosecurity herd was lower than the probability of being a low biosecurity herd in areas of low pig-herd density. In contrast, the probability of being a high biosecurity herd was higher than the probability of being a low biosecurity herd if number of neighbouring herds was high.

Discussion

These results contribute to our understanding of the types of herds that currently exist in Ontario, and the identification of practices in each group that should be prioritized for further improvement. Another important finding was the association between high biosecurity and high density of pig herds. The establishment of a high biosecurity herd in a pig-dense area may be facilitated through two different processes: (i) necessity of protecting animal populations in a herd located in a pig dense area, (ii) available expertise typically present in such areas. However this finding could impact the design of regional disease control strategies and needs to be evaluated in other swine producing regions.

Introduction
There is a significant economic advantage to maintaining a PRRS negative herd, whether it is a boar stud, sow farm, nursery, or finish. As aerosol transmission of PRRS, Swine Influenza, and Mycoplasma diseases are being accepted as reality, any means to prevent aerosol transmission of these agents is of great interest. Our practice has taken an aggressive approach with our producers on air filtration systems. Six farms implemented filtration in 2005, five in 2006, eleven in 2007, and twelve in 2008, two in 2009, and two in 2010.

Materials and Methods
There are 21 boar studs, 12 sow farms, 3 research barns, and two finishing sites. Small and large farms have been filtered. Nine of the sow farms are over 2500 sows. The other three are 700 – 1200 sows. Six of the boar studs are air conditioned. Aerosol transmission of PRRS virus can be repeated experimentally and it is becoming widely accepted to be a common way that negative farms become re-infected. One challenge for implementation of air filtration is the number of filters needed to obtain adequate air flow through a barn during summer time ventilation. Fifteen of the filtered farms are partial filtered, where air is not filtered during the summer months when ventilation rates are high. Rather than using a true HEPA filter, we have utilized a filter with slightly lower efficiency, either the L9 or L6 filter from Camfil Farr. This is the same filter used successfully in experiments. The cost to filter a farm depends on the filter used (L9 is more restrictive so more filters are needed), and whether air enters the farm the same way year round or whether there is a different ventilation system for summer (i.e. tunnel ventilation) than for winter. In general, filters last about 3 years, and the cost per pig over a 10 year period ranges from $1.00 to $1.60 per pig in US$.

Results
The first boar studs in our practice were filtered in August 2005. Since implementation of air filtration, we have had four PRRS breaks on farms using partial filtration. Three were infected when the air was not being filtered, and one was when the air was filtered, but a significant amount of air was back drafting through non-operational fans. We have had two PRRS breaks on farms with 100% filtration, although we believe that was the result of a transportation biosecurity breach or the result of having a number of heavily damaged filters in use. We have had two Swine Influenza breaks on 100% filtered farms. We have not had any Mycoplasma hyopneumoniae breaks on any of the filtered farms, although most are vaccinated. An important consideration for us from the start has been that we shouldn’t expect to never have a PRRS break just because we installed air filtration. However, if we can reduce the incidence of PRRS breaks significantly, it would be good return on the investment. This has proven to be the case, in our experience. Most of the farms that have had a history of multiple PRRS breaks. I have been tracking the results of filter farms for the 5 years prior to, and after filtration and updating the results quarterly. The following table shows the results through 1st quarter 2010 for 38 Swine Vet Center client farms. The # of Farm Years indicates the number of years the farm was in existence in the five years prior to implementing filtration, since some farms were less than five years old at the time of filtration.

Discussion
Air filtration systems have been in place in our practice for nearly 5 years, in a wide variety of farms. For boar studs, filtration has become the standard. To date, filtration has reduced the annual break rate on 38 farms from 34% prior to filtration to 8% after filtration for partial filtered farms and to 4% for 100% filtered farms.

A PRRS vaccination strategy to create PRRS-negative growers/gilts in SPF herds (re)infected with PRRS

Geertjan van Groenland1 Toine Cruijsen2 Victor Geurts2
1. TOPIGS S&D, Helvoirt, Netherlands; 2. Intervet-Shering Plough, Boxmeer, Netherlands

Introduction:
PRRS infections still lead to severe economic losses in the pig industry (1). It is possible to create PRRS-negative farms by depopulation and repopulation with negative piglets and gilts from PRRS-free farms. Despite stringent hygienic procedures on these farms, it is difficult to keep them PRRS-free in pig dense countries like the Netherlands. Between Feb-2006 and May-2008, 5 farms in the Netherlands became PRRS-free by depopulation and repopulation with SPF-pigs or by introducing SPF pigs in a new farm, and all of them became infected after 6 to 22 months. The PRRS-infection-route could not always be identified. Therefore, farmers choose to produce PRRS-negative growers and gilts via a system of vaccination together with testing and optimization of biosecurity. Vaccination of piglets was ceased as soon as there could not be detected PRRS-fields virus anymore in the outflow (by serological and virological tests). A conventional boar-producing farm followed the same strategy. The chosen PRRS vaccine (Porcilis® PRRS) reduces vertical transmission and reduces virus circulation in the population following vaccination [Ro <1] (3, 4). Furthermore, to reduce the risk of transmission between pigs by needle injection, a needle-less vaccination system was used (IDAL®, intra dermal applicator of liquids, Intervet/Schering-Plough animal health). The vaccine had already been effective in eradicating PRRS from farms(5).

Materials and methods:
Step 1. Once PRRS infection had been diagnosed on SPF farms, a cross-section of sows, piglets, fatteners and breeding gilts were sampled in combination with pooled virus isolation or PCR in order to investigate the spread. All biosecurity measures were checked and optimized and all pigs older than 2-weeks were vaccinated (herd vaccination, i.e. all sows, gilts, piglets, growers, fatteners). Sows were vaccinated 2-4 times with intervals of 2-4 weeks, thereafter all sows/gilts were vaccinated in mid-gestation (day 60) and during lactation (day 6). After the initial herd vaccination piglet vaccination was started at 14-21 days of age. On farm 3, only (pregnant) gilts and boars were present that were vaccinated only once.

Step 2. After 3-6 months, again sows, breeding gilts, and pigs of 4, 10, 16, and 22-26 weeks of age were sampled for serological and virus isolation or PCR. When the tests for PRRS field virus were negative, piglet vaccination was ceased.

Step 3. Farms which had stopped piglet vaccination were monitored by the same sampling procedure as in Step 2, every 4 months.

Results:
Until now (February 2010), five out of six farms succeeded in producing PRRS negative gilts/growers/boars. Only one farm got re-infected during the trial, the isolated strain was an US-type PRRS strain. No vaccinations were added after this herd became re-infected (sow/gilts vaccination was continued) partly due to the fact that no clinical signs were seen after re-infection and the spread was limited (most cohorts were PRRS negative). From September on sera from 10-weeks-old pigs tested negative for PRRS.

Conclusion and discussion:
Via testing, adjustments to biosecurity and targeted vaccination, it was possible to create PRRS-negative pigs from SPF farms that were infected with PRRS. In a pig dense country as the Netherlands where the estimated introduction risk of PRRS is high, this system proved to be effective in controlling PRRS.

On all farms, except for farm 3, sow vaccination (day 6- day 60) was continued to minimize the risk of vertical transmission because viremic born piglets will further spread the infection through the herds.

Sequence analyses on farms helps to identify the likely routes of re-infection. Two such routes were discovered during this trial/survey: (i) an aerosol infection originating from a neighboring farm and (ii) via infected replacement gilts. Because almost all SPF-farms in the Netherlands became infected after depopulation/repopulation it seems that (i) either regional approach or (ii) air-filtration of incoming air will be necessary for farms in pig dense areas such as The Netherlands to remain PRRS-free(2).

In the meantime vaccination of sows and gilts, together with well-defined internal biosecurity can be used to produce PRRS-negative offspring in infected breeding farms as well as in farms that are “at risk”.

PRRS modified-live virus mass vaccination and its potential role in regional control programs

Jean P. Cano; Laura Batista; Enrique Mondaca; Reid Philips; Dale Polson
Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA

Introduction
Mass vaccination combined with unidirectional flow, herd closure and/or partial depopulation has been used successfully for porcine reproductive and respiratory syndrome (PRRS) control and eradication.\(^1\)\(^-\)\(^3\) However, the effects of therapeutic vaccination on the infection dynamics at a population level had not been studied. Two large scale experiments were conducted under commercial conditions in order to evaluate the effect of PRRS modified live virus (MLV) mass vaccination on wild-type virus transmission and pig response to a highly virulent heterologous challenge.\(^4\)\(^,\)\(^5\) In these studies, pigs were infected with a homologous\(^4\) or heterologous\(^5\) PRRS virus (PRRSv) isolate prior to therapeutic MLV vaccination. The model also simulated the introduction of a new highly virulent strain to pig populations with diverse “exposure backgrounds”\(^4\)\(^,\)\(^5\).

Materials and Methods
For the heterologous study, 80 PRRSv-naïve pigs per group (A-D) were inoculated intranasally (IN) with PRRSv MN 30-100. At 7 days post-inoculation (DPI), pigs were vaccinated IM with Ingelvac\(^\circledR\) PRRS MLV vaccine. Group E was designated as the negative control. Pigs in group F received only vaccine. To evaluate viral transmission, sentinel pigs were introduced periodically to each group and sacrificed-sampled 30 days later. To evaluate persistence, 10 pigs per group were sacrificed-sampled at different DPI. At 98 DPI, 10 pigs per group were transported to isolation facilities and inoculated IN with PRRSv MN 184. A naïve pig was introduced to each of the rooms with 5 inoculated pigs 3 days after the MN 184 challenge.

Results
Consistent with the homologous study, but in a more field relevant scenario, heterologous therapeutic vaccination:

- Avoided wild-type virus transmission to naïve-sentinel pigs after 97 DPI.
- Did not “displace” the wild-type virus from the population, or reduce the proportion of persistently infected pigs within 127 DPI.
- Did not reduce the viral load in lymphoid tissues of persistently infected pigs.

Previous exposure to PRRSv, including one dose of Ingelvac\(^\circledR\) PRRS MLV (group F), significantly reduced clinical signs and increased post-challenge weight gain, but infection or shedding of a highly virulent heterologous isolate was not prevented. Pigs in group E remained ELISA and PCR negative through the duration of the study.

Discussion
These results represent a detailed and controlled evaluation of the benefits and limitations of the use of PRRS MLV mass vaccination under controlled field conditions involving a large population of pigs. Therapeutic vaccine intervention prevented viral shedding to naïve pigs and significantly improved clinical protection against a highly virulent heterologous challenge. Therefore, therapeutic vaccination may be used in combination with other strategies to reduce duration of PRRSv transmission and to increase the resistance of pig herds under certain scenarios in the field. This is especially relevant in a regional control context, where reducing shedding from infected populations and increasing resistance of susceptible populations is crucial for success. Potential applications of PRRS MLV mass vaccination intervention in regional control programs include:

- sow-herd mass exposure prior to a herd closure strategy,
- gilt acclimation programs,
- reduction of susceptibility of PRRS naïve-pigs placed into high prevalence areas, and
- reduction of infectiousness (shedding of wild-type virus) of PRRS infected-pigs placed into low prevalence areas.

Further epidemiological investigations need to be conducted to better understand the benefits and limitations of PRRS MLV mass vaccination intervention on a regional scale.

Advancing PRRS area regional control in the state of Sonora, Mexico

Laura Batista1 Marcela Fernandez2 Jesus Miramontes2 Ramon Pliego2 Enrique Mondaca1

1. Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA; 2. Comite de Sanidad Porcina de Sonora, Sonora, SON, Mexico

Introduction
The global swine industry faces economically devastating diseases such as porcine reproductive and respiratory syndrome (PRRS)1, porcine circovirus associated diseases (PCVAD), and new variants of influenza. Consequently, veterinarians have developed different means for individual or groups of farms to control and possibly eradicate diseases. However, the risk of re-infection remains high even with the best current biosecurity practices.2 This has led to the consensus that more coordinated, or 'regional', approaches must be taken to combat PRRS and other emerging swine diseases, rather than isolated efforts on individual farms which are often frustrated by the reappearance of a disease. Therefore, the objective of this study was to establish a PRRS regional control program in the State of Sonora, Mexico to reduce the economic impact of this disease in the Sonoran swine industry.

Materials and Methods
In September 2008, producers from the state of Sonora in northwest Mexico decided to organize to implement a regional PRRS control program. The region of 182,554 sq km, included 74 independently owned production systems with various production structures (i.e. farrow to finish, three site, and multisite production) with a total of 134,000 sows. The program was divided into three phases: phase 1 (September 2008-March 2009), data collection, understanding of the state's production industry organization, mapping, clusters and working groups establishment; phase 2 (April -September 2009) estimation of PRRS prevalence and virus sequencing analysis, individual farm risk assessment using the AASV PADRAP tool3, establishment of the program's website, and monthly continuous education and communication meetings with producers and veterinarians; phase 3 (October 2009-September 2011), pig and transportation route planning and implementation of farm and region control strategies.

Results
As of October of 2009, phases 1 and 2 have been successfully completed. The state was divided into three geographical regions with a 95% state PRRS prevalence. Twenty three working groups, including 91 clusters, were established and sequencing information allowed the identification of 5 major PRRS virus families. One hundred and twenty four PADRAP evaluations were completed and individual and regional analyses were performed.

Discussion
Information collection is a cumbersome and sometimes frustrating task, however, without the completion of phases 1 and 2 it would have been very difficult to establish solid bases to design and implement farm and regional PRRS control strategies. Disease control programs rely on accurate epidemiologic surveillance, access to appropriate tools for diagnosis and control, and adequate financial and human resources. To date, we have identified 3 major components leading to the successful advancement of this program. One, producer and veterinarian leadership and involvement; 2, regular informational meetings with local producers and veterinarians addressing advances of the program, continuous education, issues related to confidentiality, access to data, etc.; and 3, the establishment of a producer-paid economic fund, in the case of Sonora a fee is paid per sacrificed animal, which allows the advancement of the program. If we are able to foster producers participation, set aside individual interests and use valid knowledge and understanding of pathogen transmission and how to prevent it, understand the impact of geographical location and implement effective rather than “psychological” biosecurity strategies, we can help our producers with the battle against PRRS virus and other economically important pathogens. Successful implementation of PRRS area regional control holds the potential to restore success and profitability to the swine industry of Sonora.

Cost of PRRS outbreak in a sow herd and economic analysis of control strategies

Zvonimir Poljak1 Isabelle Moreau2 Martin Misener3 Doug MacDougald3 Cate Dewey1
1. Department of Population medicine, OVC, University of Guelph, Guelph, ON, Canada; 2. Elanco Animal Health, Guelph, ON, Canada; 3. OSHAB, Stratford, ON, Canada

Introduction
Swine producers and veterinarians have several options to manage a herd when facing a PRRS outbreak. Some will allow the disease to follow its course while trying to address the clinical signs with individual or population treatments, others will use vaccination with commercial vaccines or expose all sows to PRRS virus recovered during the outbreak, while others will use tilmicosin in the immediate 4 weeks following the PRRS onset with or without virus exposure. The objective of this project was to evaluate production loses and economic efficiency of common intervention strategies.

Materials and Methods
Veterinarians in Ontario and Quebec (Canada) were asked to provide computer records from sow farms that experienced PRRS outbreaks since January 2004 and to fill a questionnaire with demographic, diagnostic and intervention data. Computer records were extracted and collapsed to weekly averages or counts, as appropriate. Temporal iterative multivariate scan statistics (SatScan 7.0) was used to determine onset and duration of outbreaks. This was confirmed with the questionnaire data. Weekly data were then summarized to three periods for each farm: (i) 6-months pre-outbreak, (ii) outbreak, (iii) 6 months post-outbreak. Proportional change in number of pigs weaned was calculated for each period, relative to pre-outbreak level. Cost of intervention was calculated from quantity of substances spend in the sow herd. Best fitting distributions were determined within each intervention category and stochastic partial budgeting model was constructed (@Risk 5.0). Proportion of sows that farrow per week and average number of pigs weaned per litter were estimated using random intercept linear model; intercept (mean) and residual standard deviation were used in the economic model to obtain a range of scenarios. Scenario evaluated was based on fixed herd size of 1000 sows, 36$CND for a weaned pig sales over a period of 6 months. At the extremes, in the best case a farm will lose as little as $29/sow/outbreak while the worst case, a farm will lose as much as $158/sow/outbreak when no treatment is selected. The farms under study that chose to do nothing still incurred additional expenses from increased number of individual treatment. These comfort treatments cost on average $2.60/sow/outbreak. In farms that chose to try a PRRSV exposure control strategy, the PRRS outbreak either was shorter in duration or fewer piglets were lost. This resulted in higher revenue from wean piglets sale. The farms that exposed sows to PRRS virus, showed $20 higher revenue/sow/outbreak on average, than farms that chose to do nothing, while farms that included tilmicosin in the gestation diet after the outbreak, showed an average of $55 higher revenue/sow/outbreak than farms that chose to do nothing. Total intervention expenses related to individual animal treatment on farms that chose to expose sows with the PRRS virus averaged $2.90/sow/outbreak while farms that chose Pulmotil showed total average medication expenses of $12.80/sow/outbreak. Herds applying late homologous exposure strategy were expected to have lower revenue than herds without any intervention in 35% of cases. Herds applying tilmicosin strategy, with or without homologous exposure, were expected to have lower revenue than herds without any intervention in 13% of cases.

Conclusions
Under conditions evaluated in this study, no-intervention strategy seemed to be the most costly approach of managing PRRS outbreak in a sow herd. Management of PRRS under alternative, and more costly strategies, was expected to yield higher revenues on average; although none of the strategies is better under all scenarios. Under ideal conditions, collection of data that could be used for economic analysis would be a part of every routine outbreak investigation in swine herds.
Efficacy of AMERVAC®-PRRS after heterologous challenge with a pathogenic Chinese-like PRRS virus

Merce Roca¹ Sergi Bruguera¹ Mariona Gimeno²,3 Ivan Diaz² Ivan Galindo²,3 Joaquim Segales²,3 Enric Mateu²,3 Natalia Bello¹ David Llopart¹ Jaime Maldonado¹ Ricard March¹

1. HIPRA, Amer (Girona), Spain; 2. Centre de Recerca en Sanitat Animal (CReSA), Bellaterra (Barcelona), Spain;
3. Departament de Sanitat i Anatomia Animals UAB, Bellaterra (Barcelona), Spain

Introduction
Throughout the second half of 2006, large-scale, devastating outbreaks of porcine reproductive and respiratory syndrome (PRRS) affected several provinces of China¹. That epidemic was linked to a hypervirulent genotype-II PRRS virus (PRRSV) harboring a distinctive deletion¹. Economic losses from those outbreaks result from deaths but also from loss weight and impaired performance. Control of such outbreaks proved difficult and those hypervirulent strains spread in Asia. At present, genotype I strains are also present in different countries of Asia. AMERVAC®-PRRS (a genotype-I vaccine) is being marketed in Asia for the prevention PRRS virus infections. Is feasible that some herds vaccinated with AMERVAC®-PRRS could confront the infection with a hypervirulent Asian strain. The present study was intended to determine if vaccination with AMERVAC®-PRRS could produce some beneficial effect on performance of pigs infected with the hypervirulent strain.

Material and Methods
Twenty-one 4-week-old, PRRSV-naïve pigs were randomly divided into three groups (G1 n=8, G2 n=8 and G3 n=5) and housed separately in isolation facilities (BSL3 at CReSA, Barcelona, Spain). Animals in G1 received intramuscularly (day 0) 2 ml of a European-type modified live PRRS vaccine (AMERVAC®-PRRS containing 10⁴.⁶ TCID₅₀/ml). G2 and G3 pigs remained unvaccinated. At day +32, pigs in G1 and G2 were intranasally inoculated with 2 ml of 1x10⁵ TCID₅₀/ml of the strain PRRSV21 that was isolated from a highly virulent case of PRRS in Asia and share 99% similarity in ORF5 with other highly virulent genotype-II Chinese PRRSV strains. Pigs in G3 remained uninfected along the trial. Weekly body weight (BW), average daily feed intake (ADFI) and clinical signs were assessed during the 21 days of the challenge phase of the study. Statistical analyses were done using a non-parametric Mann-Whitney test.

Results
After challenge, pigs in G2 suffered an evident respiratory distress starting the 5th day post-inoculation (dpi) and lasting in most animals until the end of the trial. In G2, two animals died before the end of the study (25%). In G1 pigs showed milder respiratory signs and suffered no losses. Regarding BW, groups were equal before the challenge but by 7 dpi animals in G2 showed a lower BW compared to G1 and G3 (p<0.05) and these differences remained statistically significant along the trial. Significant reduction in ADFI was recorded in G2 pigs from 7 dpi to the end of the study. ADFI differences were remarkably high at the end of the trial (G2=0.44; G1 = 1.57 and G3 = 1.97 kg/day/animal). Thus, on average, comparing G1 pigs with unvaccinated-challenged pigs, vaccine prevented mortality (0/8 vs. 2/8) and allowed 8.9 kg more of weight gain for the 21 days period examined.

Discussion
PRRS21 infection severely affected the growth performance of non-vaccinated pigs (G2), as expected from the virulent nature of that strain. In contrast, vaccinated pigs (G1) showed a better performance and lesser mortality indicating that vaccination with AMERVAC®-PRRS was able to keep productive performance in the challenge model. The present results suggest that under field conditions, this vaccination may provide beneficial effects in economic terms if a vaccinated herd should confront an infection with a hypervirulent genotype-II strain.

Health status in organic pig herds in Europe

Albert Sundrum1 Amke Goebel1 Davide Bochicchio2 Marianne Bonde3 Aude Bourgoin4 Gérald Cartaud4 Klaas Dietze1 Sabine Dippel5 Stefan Gunnarsson6 Lene Hegelund3 Christine Leeb5 Kristina Lindgren6 Armelle Prunier7 Sofia Wiberg8 1. University of Kassel, Witzenhausen, Germany; 2. C.R.A. SUI, Modena, Italy; 3. Aarhus University, Tjele, Denmark; 4. Inter Bio Bretagne, Rennes, France; 5. University of Natural Resources and Applied Life Sciences, Vienna, Austria; 6. Institute of Agricultural and Environmental Engineering, Uppsala, Sweden; 7. INRA Institut National de Recherches Agronomiques, Rennes, France; 8. Swedish University of Agricultural Sciences, Skara, Sweden

Introduction

Organic pig production is still a small-scale production, achieving, however, increased interest by consumers who are concerned about the conventional production method. The EU-Regulation (EEC-No. 1804/1999) on organic livestock production, now replaced by EEC-No 834/2007, was introduced to provide a framework ensuring living conditions for organic livestock to be better than those in conventional systems and to harmonize the rules across member states. Scientifically based information on how and to what degree the EU-Regulation contributes to the objective of a high status of pig health in organic farming is scarce. Further information is needed to assess whether consumer expectations in organic pig production in Europe are met.

Material and Methods

An epidemiological study was performed on 101 organic sow herds in 6 European countries (Denmark, Germany, Austria, Sweden, Italy and France). 13 to 20 farms per country were assessed. On-farm data included a comprehensive interview with the herd manager in relation to housing conditions, feeding regime, data acquisition, cleaning and disinfection measures, medicine usage, culling reasons, vaccina-tion protocols, etc. Recorded livestock data included: liveborn and stillborn piglets/farrowing, weaned pig-lets/sow/year, piglet losses/farrowing, losses of weaned piglets, litters/sow lifetime, and the prevalence of diseases according to the treatment records. Data from all countries were merged into one joint database and analysed statistically.

Results

Although dedicated to the same minimum standards, the farm structures were characterised by a huge heterogeneity. 67 farms were keeping their sows outdoors while 34 farms were indoors with outside runs. Group suckling was implemented on 52% of the farms. The degree of specialisation was comparably low. About 40% of the farms had another economically relevant livestock enterprise on the farm apart from keeping pigs. Farmers differed widely in their feeding regimes, in making use of phase feeding and diet calculations. Moreover, the farms varied in the cleaning management and in the implementation of disinfection measures. The study also revealed large differences in animal health management with respect to the use of quarantine, availability of hospital pens, presence of the farmer during farrowing, and regarding routine measures such as castration, teeth reduction, and iron supplementation of piglets. For 50% of the farms the abattoirs provided feedback of pathological findings for slaughtered sows, and 80% for fattening pigs. Huge differences were detected in the perception of the farmers with regard to health problems on their farm and with respect to the availability of laboratory results.

Mean mortality rates of piglets until and after weaning averaged 19.7 ± 9.7% and 4.9 ± 5.4% resp., showing clear differences between countries and farms. Mean values for the annual replacement rates of sows and litters per sow lifetime were 32.4 ± 14.3% and 6.3 ± 2.3 resp. According to the treatment records, metritis and mastitis appeared as the predominant diseases of the sows, nearly all treated with antibiotics, followed by cases of lameness and abscesses. In the case of suckling piglets, diarrhoea, arthritis and respiratory diseases were predominant. Also the weaned piglets suffered primarily from diarrhoea. Farms showed an incidence of 27.6 ± 34.3% of piglets treated with antibiotics against diarrhoea.

Conclusions

The results indicated that in general the status of animal health in organic pig herds was comparable to data found on conventional farms. Differences between farms appear to be greater than those between production methods. Obviously, the production method defined by standards does not provide a homogenous outcome with respect to the animal health status. Differences in management practices and in feedback and control mechanisms within the farm system might be the main reasons for substantial variation in the prevalence rates of diseases. Any improvements in organic pig production require the use of feedback mechanisms and a clear definition of the expected results with respect to the outcome of the farm system. Consequently, there is a need for a change in the paradigm from standard and resource oriented to a result and outcome oriented approach. The implementation of a monitoring system including on farm clinical assessment, abattoir data and review of treatment data, concepts to deal with potential problems (e.g. health planning strategies, HACCP protocols, etc.) and a definition of the expected results with respect to the output of the farm system might be a way forward for organic farming ensuring a high status of animal health and welfare.
**Pig management in rural villages of Busia and Kakamega District, Western Kenya**

Florence K. Mutua¹ Cate Dewey² Samuel Arimi³ Michael Levy² William Ogara³ Esther Schelling⁴

1. International Livestock Research Institute, Nairobi, Kenya; 2. University of Guelph, Guelph, ON, Canada; 3. University of Nairobi, Nairobi, Kenya; 4. Swiss Tropical Institute, Basel, Switzerland

**Introduction**

Intensive pig farming in many developing countries is thought to be stagnant (1). Most pigs in Kenya are exotic breeds raised on commercial piggeries (2, 3). Farmers in Western Kenya keep local pig breeds that are raised using traditional methods of tethering and free ranging (4). These breeds possess a number of advantages, among them good adaptation to prevailing conditions (5). Understanding how such pigs are managed aids in farm planning and decision making. Improved pig productivity will greatly enhance the income of resource-poor farmers. In this paper, we discuss pig management practices in two districts of Western Kenya. We also explore opportunities for improved local pig production while safeguarding human health.

**Materials and methods**

A total of 288 randomly selected pig farms were visited three times in the course of the study period (June 2006 to October 2008). We used questionnaires administered in face-to-face interviews to gather data on how farmers managed their pigs. Pigs were examined for Taenia solium cysts using the lingual palpation method. Data were analysed in Stata®.

**Results**

Most farms had no pig barn (73%; 209/288). These farmers said they lacked the skills to build the barn (11%; 23/209) and had no money to purchase construction materials (45%; 93/209). Kakamega farmers were more likely to construct pig barns than those in Busia (OR=5.4; CI 3.1-9.7). Tethering of pigs was more frequent than free ranging or confinement to barns during the planting (91%; 263/290), growing (90%; 263/290) and crop harvesting seasons (78%; 227/290). Prevalence of cysticercosis in pigs was 4% (52/1290). Average land size per farm was 2.33 (SD=2.01) acres. Pork was the second most preferred meat (31%; 91/288) after beef. Most families consumed pork (74%; 212/288), 40% (n=212) included families that consumed pork once a week. The mean number of pigs owned per farm was 4.6 (SD=3.4), 1.8 (SD=1.2) and 1.5 (SD=0.9) for the pre-weaned, growing and adult pig categories. Farmers in Busia had been keeping pigs for fewer years (6.3 SD=5.6) than those in Kakamega (11.4 SD=8.7) (P<0.05). Spraying (29%; 128/438), dipping (24%; 101/438) and deworming (26%; 116/438) were among the most frequent routine practices observed in Busia District.

**Discussion**

Improving pig management practices leads to improvements in farm performance and reduces costs in production. Failure to confine pigs is a risk factor for important zoonotic diseases such as T. solium (6). Small-holder farming is important in enhancing rural livelihoods; addressing issues related to pig feeding, tethering, marketing, disease and sow breeding will greatly promote pig farming in rural districts Western Kenya.

Health bonus after transition to 4- or 5-week batch management systems
Frédéric A. Vangroenweghe1 Leo Suls2 Ellen Van Driessche1 Tamara Vandersmissen3 Els Goyvaerts3 Frans Castryck1
1. DGZ-Vlaanderen, Torhout, Belgium; 2. Janssen Animal Health, Beerse, Belgium; 3. DGZ-Vlaanderen, Lier, Belgium

Introduction
Sow batch management systems (BMS) become more popular because of advantages in labour planning, batch size of piglets, strict all-in all-out practices and health management. The 4- and 5-week BMS have advantages compared to a 3-week BMS, especially with regard to general health (1). Weaning piglets at 3 weeks of age in large batches creates possibilities for a significant improvement of the general farm health status. However, exact data on a health bonus with these management systems are not available. Therefore, a field study (project 'Veepeiler-varken' funded by Sanitary Fund) was designed to measure the health bonus for pig farms when changing from a conventional 1-week management system to a 4- or 5-week group management.

Materials and Methods
Ten Flemish wean-to-finish pig farms, changing from a conventional 1-week management system to a 4- or 5-week BMS were included in the trial. The average farm size was 227 sows, with a minimum of 130 and a maximum of 500. Samples were collected before and 2 years after finishing transition to the BMS. The type of samples and the different analysis are described in Table 1.

** ELISA test on serum samples

The following ELISA-tests were used: PIA – Bioscreen Enterisol® Ileitis ELISA, PRRS – Idexx HerdChek PRRSv Ab test, M. hyopneumoniae – Idexx HerdChek M. hyopn. Ab testkit and A. pleuropneumoniae – Idexx Chekit – App – ApxIV ELISA.

Results
The results of the serological screening are presented in Table 2. The nasal swabs were all negative for Pasteurella multocida DNT on all herds screened. No clinical signs of atrophic rhinitis were present on these herds. All faecal samples were negative for Brachyspira hyodysenteriae. Nevertheless, minor pathogenic species of Brachyspira were detected, both before and after the transition.

Discussion and conclusions
Transition to BMS seems to postpone and or slow down the seroconversion for PIA, M. hyo and App. This allows the farmer to vaccinate the pigs before they come in contact with the pathogen. It also allows more time for the pigs to build up immunity. Weaning age, maternal protection and transmission of pathogens from the sows to the piglets determine the speed and level of horizontal transmission within the batch. The degree of separation of the batches from each other then determines the vertical transmission between the batches.

In conclusion, the results show a clear health bonus for pig herds when changing from a 1-week BMS to a 4- or 5-week BMS.

Practitioner Line - Economics
Economic impact of intensive consultancy on 35 Danish finisher farms

Elisabeth O. Nielsen; Lisbeth Jørgensen; Henriette Steinmetz
Pig Research Centre, Danish Agricultural & Food Council, Copenhagen, Denmark

Introduction
Variation in productivity among Danish finisher farms implies that improvements can be made on many farms. Although Danish pig producers normally receive veterinary advice on a monthly basis, specific consultancy on feeding and housing is rarely provided. Cooperation between veterinarians and agricultural advisers is effective in some areas – such cooperation and thereby coordinated intensive consultancy formed the core of a project called “Plus €3.3 per produced pig”. Our aim was to improve the productivity of finisher farms and thereby improve the economic output of the pig producer.

Materials and Methods
A total of 35 Danish finisher farms participated. Records of the productivity were required for participation. The intensive consultancy was carried out over a one-year period by a veterinarian and an agricultural adviser for each farmer. The project plan included three visits by both, and three single visits by the agricultural adviser and nine single visits by the veterinarian. The farmer paid for the intensive consultancy. Prior to the year of intensive consultancy, all farms were visited by a team from the Pig Research Centre (PRC) consisting of a specialist on feeding, a specialist on housing and ventilation and a veterinarian. This visit was part of the project, at no cost to the pig producer. The PRC team and the two local advisers drew up a detailed action plan for improved productivity for each farm. The purpose was to improve productivity (feed conversion, mortality, growth rate and slaughter weight). Only minor investments were suggested. The year of intensive consultancy was initiated when the pig producer had approved the plan of action. The consultancies were initiated during the year 2007 and ran to the end of 2008. The production results in the year of intensive consultancy were compared with those of the previous year.

Results
Twelve pig producers achieved an improvement in productivity of more than €3.3 per produced pig. The average economic improvement was €2.5 per produced pig. Increased consultancy and investments amounted to €0.9, resulting in a net improvement of €1.6 per produced pig. The farms produced between 2,000 pigs and 11,500 pigs per year. The action plan included between 10 and 31 separate actions: some involved changes of daily routine, while others needed to be addressed just once. On average, 71% of the separate actions in a plan were carried out. The plans were unique, though the following features were included in many of the plans: improving feed hygiene (especially in liquid feed systems), making the unit ready (clean, dry and warm) for new pigs, and putting more effort into the daily surveillance for diseased pigs or pigs in need of special attention. Eighteen out of 35 pig producers received four or more advisory visits from the agricultural adviser; the remaining seventeen pig producers received only two or three visits. All herds received a monthly visit from the veterinarian.

Discussion
The whole action plan had to be cost-effective. However, it was, for example, easier to convince producers of better feeding regimes than to improve the climate by better ventilation. The individual actions had to be simple and practical, and the personnel carrying them out had to recognize their importance. We did not achieve this in all cases, since on average only 71% of the separate actions were carried out. Half of the farmers chose to have only two or three agricultural consultancies, which may have resulted in poorer productivity results. A certain degree of cooperation between more veterinary and agricultural advisers was achieved. This will improve the quality of the veterinary and agricultural consultancy.
**Variation: an underestimated economic factor in pig production**

Dennis DiPietre, Matthias J. Adam

1. Boehringer Ingelheim Animal Health, Ingelheim am Rhein, Germany; 2. KnowledgeVentures, LLC, Columbia, MO, USA

**Introduction**

Modern swine production systems rarely undertake economic analysis using anything other than the arithmetic mean for production or economic performance metrics when needed in calculations. This is because modern systems are built and operated in such a way that collecting the data necessary to measure the variance of almost any metric is not practical in a commercial setting (e.g., measuring individual daily feed intake and weight gain for each animal in finishing) 1.

While farms measure and report their average feed efficiency, average daily gain, average market weight, cost of production etc., very few if any know the underlying variance of these distributions. For this reason, farms evaluate a host of economic decisions such as target market weight, the adoption of a new technology, vaccine and/or pharmaceutical, whether to replace aging equipment, etc. by comparing the average expected benefit per unit (head, kg, cwt) of production with the average additional cost per unit. A question arises as to how important the variance of the distribution generating the average is in making the correct decision.

**Materials and Methods**

To gain insight into this issue, a comprehensive simulation model was used to test the effect on net price received, total feed cost and return over feed cost associated with changes in the variance of pig weights at marketing. The weight and lean percent of ten thousand pigs randomly drawn from correlated distributions fit to annual marketing's of a large U.S. farm were used for the analysis. Average cost per ton (US) for each diet, wean-to-finish, was obtained from the producer and total feed cost per head was estimated from slaughter weight, a standard growth curve (ADG) and feed efficiency average curve (FCR) adjusted to match the historical closeout data of the farm (2.5 kg/kg as FCR, 774 g/day as ADG - Average feed cost/US ton W-F $180;base carcass price: $1.43/kg). The actual average live weight and standard deviation of live weights marketed by the farm over the test year were 122.4kg/12.28kg.

Different scenarios of reduction in variation of the weights at marketing from 5%, 10%, 20% & 30% were simulated (table 1 & 2). The change was carried out by reducing the distance to the mean by x% for each individual animal weight in the dataset so the reduction in variation was symmetrical to the mean. Estimated individual animal lean and yield percents were each adjusted to the new weights by a separate constant estimated by regression.

**Results**

**Table 1: Variance of the production metrics for each simulation (average remains identical)**

**Discussion**

The simulation model focuses on the slaughter weight as it is the most common source of individual data in pig production. Thereafter each individual pig can be assigned their individual metrics (FCR & ADG) based on the adapted standard curves.

Simulation suggests that the standard deviations of the distribution of FCR & ADG are important determinants of cost of production and therefore influence profitability. A reduction by 10% of the standard deviation of slaughter weights improves return over feed cost by $0.78/hd. In addition, reducing variance results in a higher optimal weight which has not been accounted here.

**Conclusion**

By only accounting for the mean and changes in the mean in economic calculations, producers are missing important economic impacts associated with treatments or strategies which affect the variance of marketing weights.

**References**

Introduction

Viremia results in immune system activation that leads to a re-direction of nutrients that may result in a decrease in ADG and/or an increase in feed-to-gain ratio. Subclinical infections with PCV2 are common. They are known to occur if vaccination does not prevent viral replication. These PCV2 subclinical infections do not require co-infections.

The objective of this paper is to describe the prevalence and production impact of viremia in pigs while comparing two commercial circovirus vaccines or a placebo under field conditions.

Materials and Methods

A PRRS- and M. hyopneumoniae-free system was used for the study. At weaning, pigs were randomly assigned to be vaccinated with a one dose commercial PCV2 vaccine (n=1026) (1D); a two dose commercial PCV2 vaccine (n=1020) (2D); or saline as a placebo (n=100) (control). Both PCV2 vaccines were used according to manufacturer’s label recommendations. Individual pig weights were collected when pigs were 3, 11 and 19 weeks of age and just prior to market at about 110 kg. Individual ADG was determined between each pair of weights. To determine extent of PCV2 viremia, blood was collected from a random sample of 122 pigs at 3, 9, 15, 19, and 23 weeks of age and during the final week of shipping to market. Serum was tested with a qPCR. The proportion of viremic pigs at each sampling point by treatment group was determined. Difference in proportions was determined with a chi-square test. ADG was compared by group and by viremia status using a multiple linear regression after controlling for weaning cohort and starting weight.

Results

Starting weights did not differ by group. More pigs in the 1D (47%) and control groups (85%) were viremic than in the 2D group (8%) (p<0.01). More control pigs (73%) were viremic on at least 2 samples than 2D pigs (0%) or 1D pigs (24%) (p<0.05). Pigs that were viremic more than once, tended to have a lower ADG (by 33.8 gm/d) than pigs that were never viremic (p=0.11). The proportion of viremic pigs remained at 3% to 4% for the entire grower-finisher phase for the 2D pigs. However, this proportion increased from 11% to 39% for the 1D pigs and from 53% to 63% for the control pigs from 15 to 19 weeks of age. The ADG in the 2D group was 42g / day higher than in the 1D group from 19 weeks to market age (p<0.01). The coefficient of variation of ADG in the 2D group (19%) was lower than that of the 1D group (28%) indicating that there was more variation in the growth of 1D group.

Implications and Conclusions

The proportion of viremic pigs was higher in the control group than in the vaccinated pigs. The pigs receiving the 2D vaccine maintained a low level of viremia throughout the finisher phase whereas the pigs in the 1D group exhibited a rising proportion of viremia toward the end of the finishing phase. This viremia was associated with a lower ADG and more variation in growth performance, particularly during the final phase of production. This is the least efficient time of growth, feed conversion and facility use. This variation extends the time for marketing. Hence, viremia contributes to the overall cost of production in the 1D group.

Introduction
Experimental infections, using several routes of virus inoculation in pregnant animals brought at parturition (1, 2, 3, 4), demonstrate the role of the PCV2 on reproductive pathology. It is known that in utero death of foetuses producing dead or mummiﬁed piglets at delivery infected with PCV2 can be assessed in tissues (1, 3, 5). In PCV2 associated reproductive pathology the presence of uterine or placental lesions are scanty documented. We developed an original experimental model of PCV2 infection by artiﬁcial insemination of conventional sows with PCV2 infected semen and in this paper we present and discuss the PCV2 tissue distribution and the associated lesions of the sow and foetuses after post-mortem samplings.

Material and Methods
The experimental design and the results of the in vivo investigation are contextually presented (6). Necropsy was performed on all the not pregnant (n=3) and pregnant (n=6) animals. Several tissues of the sows and of each foetus (heart, lung, liver, placenta and amniotic ﬂuid) were collected (Table 1) for real time-PCR, histology and immunohistochemistry (IHC). The corresponding uterine tract and the placenta were collected together with foetus sampling. Real time-PCR analyses were in accordance to the method by Olvera et al. (7). Samples for histology were stained with haematoxylin and eosin (H-E). IHC was performed using 1/100 PBS-diluted PCV2 antibody (Mab F217, by Dr. G. Allan (Belfast, UK)), as previously described (8) but using a streptavidin-biotin-peroxidase polymeric complex (SuperPicture kit peroxidase, Zymed® Lab).

Results
In the sows, at necropsy, the only lesions recorded included mild to moderate chronic ﬁbrous pleuritis and/or pericarditis. One animal showed enzootic pneumonia. One case of a mild sero-fibrinous peritonitis and two cases of white spotted liver and amniotic ﬂuid were observed (Table 1) for real time-PCR, histology and immunohistochemistry (IHC). The corresponding uterine tract and the placenta were collected together with foetus sampling. Real time-PCR analyses were in accordance to the method by Olvera et al. (7). Samples for histology were stained with haematoxylin and eosin (H-E). IHC was performed using 1/100 PBS-diluted PCV2 antibody (Mab F217, by Dr. G. Allan (Belfast, UK)), as previously described (8) but using a streptavidin-biotin-peroxidase polymeric complex (SuperPicture kit peroxidase, Zymed® Lab).

Discussion
The present investigation suggests the protective role of the anti-PCV2 antibodies in preventing foetal infection even in case of intrauterine route of infection. Sow n. 25, with the lowest anti-PCV2 titre (beginning of the experiment) (6) and viremia for two successive samplings, had also the highest number of positive foetuses and concordance with corresponding uterine tract positivity. Moreover, the results seem to demonstrate that PCV2 replicates also in chorionic epithelium where it was the possible cause of necrosis. As well as viral load in foetal tissues, also placenta lesions can account for foetus death. This study evidenced that not all foetuses are positive for PCV2, it should be recommended to send the whole litter to the lab for a correct diagnosis of PCV2-related reproductive failures.

A preliminary study of the association between Porcine Circovirus Type 2, *Lawsonia intracellularis* and diarrhoea in growing pigs

Patricia K. Holyoake\(^1\) Charlotte Hjulsager\(^2\) Lars E. Larsen\(^2\) Ken S. Pedersen\(^3\) Markku Johansen\(^4\) Helle Stege\(^3\) Beverley Orchard\(^1\) Marie Stahl\(^2\) Oystein Angen\(^2\) Jens P. Nielsen\(^3\)

**Introduction**

Porcine Circovirus Type 2 (PCV2) infection is endemic in pig herds in most countries. Initially, PCV2 was linked to post-weaning multi-systemic wasting syndrome (PMWS). More recently, other disease syndromes have been associated with PCV2, and PCV2 has been reported to cause lesions similar to those of *Lawsonia intracellularis* (*L. intracellularis*).\(^1\) Our hypothesis was that there is an association between the quantities of PCV2 in serum and faeces, *L. intracellularis* in the faeces and diarrhoea in grower (>10 weeks) pigs.

**Materials and Methods**

Forty grower pigs were selected on six farms in Denmark for a case-control study. Each pig was ear-tagged and assessed for faecal consistency (normal, loose, fluid). Approximately half of the pigs had loose or fluid faeces and were classed as “diarrhoeic”. Blood and faecal samples were collected from each pig and tested using real-time PCR specific for PCV2 (blood and faeces) and *L. intracellularis* (faeces only).\(^2,3\) The associations between diarrhoea (+/-) and serum and faecal PCV2 quantity (negative/low versus moderate/massive), and between diarrhoea and *L. intracellularis* bacterial quantity (negative/low versus moderate/massive) were analysed. The association between the quantity of PCV2 in blood and PCV2 in faeces, and between the quantity of PCV2 in faeces and *L. intracellularis* in faeces were analysed. All analyses were conducted using generalized linear mixed models, with farm as a random effect (Genstat 11th edition).

**Results**

Two farms had no pigs with moderate/massive PCV2 results in blood or faeces. One farm had no pigs with a negative/low faecal PCV2 result. Two farms had pigs with no moderate/massive *L. intracellularis* results. Pigs with diarrhoea were no more likely than pigs without diarrhoea to have moderate/massive quantities of PCV2 in blood or faeces (p>0.05). Pigs without diarrhoea were no more likely than pigs with diarrhoea to have negative/low quantities of PCV2 (p>0.05). Pigs with moderate/massive quantities of *L. intracellularis* had 1.91 times the odds (95%CI 1.04 3.49) of having diarrhoea than pigs without diarrhoea (p>0.05). The farms where no pigs had moderate/massive quantities of PCV2 and/or *L. intracellularis* were excluded from analyses of associations between the two pathogens. Pigs with moderate/massive quantities of PCV2 in serum had 14.4 times the odds (95%CI 1.08 191.6) of having moderate/massive quantities of PCV2 in faeces than pigs with low/negative PCV2 serum results (p<0.05). There were no significant (p>0.05) associations between PCV2 quantities in blood or faeces, and *L. intracellularis* quantities in faeces.

**Discussion**

These preliminary results suggest PCV2 was not associated with diarrhoea in pigs on the six farms studied Pigs with diarrhoea shed moderate/massive quantities of *L. intracellularis* in their faeces. There was no evidence of co-infection between PCV2 and *L. intracellularis*. PCV2 results for blood and faeces from the same pig suggested that either clinical sample may be tested with a similar result. As there was evidence of Brachyspira spp. infection in euthanized diarrhoeic pigs on all farms (data not shown)\(^4\), the interaction between *L. intracellularis* and Brachyspira spp. warrants investigation.

Maternal immunity towards Porcine circovirus type 2 (PCV2)

Per Wallgren\textsuperscript{1} Maria Persson\textsuperscript{1} Gunilla Blomqvist\textsuperscript{1} Caroline Fossum\textsuperscript{2}

Introduction
Postweaning Multisystemic Wasting Syndrome (PMWS) is associated to porcine circovirus type 2 (PCV2), and as neutralising antibodies prevent pigs from developing PMWS (1), transfer of maternal antibodies to PCV2 may protect the offspring from developing PMWS. We therefore scrutinised the maternal immunity to PCV2 in two herds diagnosed with PCV2, but not with PMWS.

Materials and Methods
The studies were carried out in a nucleus herd with 180 Yorkshire sows, and in an SPF herd established by caesareans in 1988 with 170 Landrace, Yorkshire and hybrid sows. (2). The SPF herd was infected by PCV2a in 1993, certainly through semen. The herd experienced a reproduction disorders for around six months following the introduction of PCV2 (3), but has stayed healthy since then. PCV2a was demonstrated in both herds prior to initiating the studies. Neither sows nor piglets were vaccinated against PCV2, and PMWS had not been diagnosed in any pig.

Six piglets from 4 litters in each herd were given an identity. Blood was collected from these piglets weekly from birth to 9 weeks of age. Presence of serum antibodies to PCV2 was analysed in two-fold dilutions with an IPMA-technique. The amounts of antibodies are presented as Log10-values.

Results
As seen in figure 1, piglets in both herds received maternal antibodies to PCV2 with a mean log10-titre of 3.8 ± 0.6. The titres decreased significantly in both herds, but the decrease was more pronounced in the SPF herd from 5 weeks and onwards. Four piglets from two litters in the conventional herd seroconverted at 6, 7, 7 and 9 weeks of age, whereas only one pig in the SPF herd seroconverted to PCV2 at the age of 9 weeks.

Discussion and Conclusions
The results showed that all piglets received a maternal transfer of antibodies to PCV2, and that the level of antibodies not was influenced by the rearing system. Nor was any influence of breed indicated since maximal levels of antibodies (Log10 = 4.3) was measured in offspring to both pure bred Landrace and Yorkshire sows.

In contrast, significant differences in antibody levels were recorded between litters belonging to the same farrowing batch within each herd, and the lowest levels of maternal antibodies was measured in the offspring to the 7th parity sow. In the conventional herd, piglets that received low amounts of antibodies commenced to seroconvert to PCV2 already at 6 weeks of age, indicating an active infection with PCV2. Such piglets may thus increase the PCV2 load concurrently to the decline of maternal immunity in other litters. Therefore sows that transfer a low maternal immunity may jeopardise the health status of a herd because piglets will meet the PCV2-infection at a younger age. The results obtained indicate that old sows may contribute to such risks, and vaccination of old sows may be of particular interest.

Postweaning multisystemic wasting syndrome (PMWS) age-shift presentation is not supported by an 11-year retrospective study in Spain

Joaquim Segales; Martí Cortey
Centre de Recerca en Sanitat Anima (CReSA), Bellaterra, Spain

Introduction

Postweaning multisystemic wasting syndrome (PMWS) was firstly diagnosed in Spain in 1997 (3). Since then, the number of disease diagnoses increased significantly, reaching a peak between years 2000-01 (2), and then decreased over time. After 2007, the number of PMWS diagnoses started increasing again, basically due to the advent of porcine circovirus type 2 (PCV2) vaccines in the market. Therefore, it seems that the number of PMWS diagnoses in a given period depends on several factors. Firstly, a diagnosis in front of a novel disease was needed (mainly between 1997 and 2001). Secondly, once the disease was known and no practical solutions did exist, the interest of laboratory diagnosis decreased (2002-2006). This latter situation was coupled with the evolution of severe disease outbreaks to a more enzootic, chronic form of the disease. However, with the abovementioned introduction of PCV2 vaccines, the interest of a precise diagnosis of PMWS raised again among veterinarians (2007 to date). In such framework, a general perception was that the initial acute disease largely died down over time and since then veterinarians and producers face with the chronic effects of PMWS. Such situation leaded to the opinion that PMWS resulting mortality occurred at older ages in the chronic form of the disease (3). Therefore, the objective of the present study was to assess if such PMWS age-shift presentation took place over the years in Spain.

Material and methods

A total of 650 pigs diagnosed as PMWS at the Pathology Diagnostic Service at the Universitat Autònoma de Barcelona (Spain) with an unequivocally known age were included in this study. These animals were diagnosed as PMWS based on the three internationally accepted case definition criteria (4) between 1998 and 2008. The number of pigs available per year was variable, ranging from 9 in 2006 and 134 in 1999. The average number of pigs per year was around 60. Different ages were measured in months and for statistical purposes, a single number was given for all age groups included (i.e, age 1 corresponded to pigs between 1 and <2 months of age, age 2 corresponded to animals between 2 and <3 months of age, and so on). Differences in the PMWS age presentation among years, and between the overall and yearly average age were tested by means of several chi-square and Kluskal-Wallis tests. Statistical significance level was set at p<0.05. Confidence intervals (95%) for every year are presented in Fig.1

Results

The youngest age recorded corresponded to 11 1-month-old piglets, while the oldest animals diagnosed as PMWS included 13 6-month-old pigs. More than 80% of the pigs fall between 2 and <4 months of age (532 out of 650 animals). Fig. 1 shows the evolution of the average age of pigs diagnosed as PMWS between 1998 and 2008. Significant differences in age presentation were overall obtained, mainly due to the average age in two years: younger pigs in 2001 and older pigs in 2005. However, the average age evolution between 1998 and 2008 did not significantly increase.

Fig. 1. Average age evolution of pigs diagnosed as PMWS between 1998 and 2008.

Discussion

With the emergence of new diseases, it is expected that initial severe outbreaks are followed by a more chronic, not as severe form of the clinical problem. Such situation has been described for PMWS. It has been claimed that the development of the so-called “herd immunity” has been the main reason for disease evolution as well as the assumed shift in age presentation (1). However, the present data do not fit with this general opinion, and points to a relatively constant average PMWS age presentation throughout time.

Identification of the receptor for F18+ E. coli: new perspectives towards development of a prophylactic treatment against F18+ E. coli infections in pigs

Annelies Coddens1 Susann Teneberg2 Eric Cox1
1. University of Ghent, Faculty of Veterinary Medicine, Lab of Immunology, Merelbeke, Belgium;
2. University of Gothenburg, Institute of Biomedicine, Department of Medical Biochemistry and Cell Biology, Gothenburg, Sweden

Introduction

F18-fimbriated Escherichia coli are associated with porcine post-weaning diarrhoea (PWD) and oedema disease. Adhesion of F18-fimbriated bacteria to the small intestine of susceptible pigs is a primary event in the infection process. However, the target cell receptor for F18+ E. coli (F18R) has remained unidentified. The objective of our study was to unravel the carbohydrate-binding specificity of F18-fimbriated E. coli and to examine whether these F18R molecules can inhibit the interaction between F18+ E. coli and the pig small intestine.

Materials and methods

To identify the F18R molecules, mixtures of glycosphingolipids (GSLs) isolated from pig intestines were separated on thin-layer plates, followed by a chromatogram binding assay with radio-labeled F18+ E. coli. In addition, the inhibitory capacity of the F18R molecules was assessed using an in vitro villous adhesion assay.

Results

We report that F18-fimbriated E. coli selectively interact with GSLs having blood group ABH determinants on type 1 core chains, and blood group A type 4 heptaglycosylceramide. F18-binding GSLs were isolated from the small intestinal epithelium of blood group O and A pigs, and characterized by mass spectrometry and proton NMR. The only GSL with F18 binding activity of the blood group O pig was an H type 1 pentaglycosylceramide (Fuc α2Gal β3GlcNAc β3Gal β4Glc β1Cer). In contrast, the blood group A pig had a number of F18-binding GSLs, with the A type 1 hexaglycosylceramide (GalNAc α3(Fuc α2)Gal β3GlcNAc β3Gal β4Glc β1Cer) being the predominant one.

The minimal binding epitope was identified as the blood group H type 1 determinant (Fuc α2Gal β3GlcNAc), while an optimal binding epitope was created by addition of the terminal a3-linked galactose or N-acetylgalactosamine of the blood group B type 1 determinant (Gal α3(Fuc α2)Gal β3GlcNAc) and the blood group A type 1 determinant (GalNAc α3(Fuc α2)Gal β3GlcNAc), respectively.

Using the in vitro villous adhesion assay, the inhibitory capacity of several blood group sugars on F18+ E. coli adhesion was examined. Strong inhibition of F18+ E. coli adherence was observed after pre-incubation of F18+ E. coli with 1 mg of the blood group H (52.4%, S.D. = 19.9), blood group A (72.9%, S.D. = 15.5) and blood group B sugar (86.8%, S.D. = 11.4), whereas the negative control sugar lacto-N-tetraose did not inhibit (-2.8%, S.D. = 12.4) the interaction of F18+ E. coli with the intestinal villi.

Discussion

A highly specific interaction of the F18-fimbriated bacteria with GSLs having blood group ABH determinants on type 1 core chains was demonstrated. In addition, we showed that F18R molecules could be used to inhibit the interaction of F18+ E. coli with the porcine intestinal epithelium using an in vitro assay. In our future work, in vivo experiments will be performed to investigate whether these F18R molecules, when supplemented in pig feed, could provide a safe and efficient anti-adhesive therapy against F18+ E. coli infections in pigs.

Effect of toltrazuril in *Isospora suis* oocyst excretion from naturally infected nursing piglets

Vasilis Skampardonis¹ ¹ ² ² Smaragda Sotiraki² Polychronis Kostoulas¹ Leonidas Leontides¹

¹ University of Thessaly, Karditsa, Greece; ² Veterinary Research Institute, National Agricultural Research Foundation, Thessaloniki, Greece

**Introduction**

Currently, farm control of *Isospora suis* infection depends almost completely on the early routine treatment of piglets with toltrazuril. Its efficacy has been demonstrated mostly in experimentally infected piglets (Mundt et al., 2003). In this field trial we simultaneously evaluated toltrazuril efficacy in reducing both the odds and the level of oocyst excretion, from the 6th day post-farrowing (pf) until weaning at 29 days pf.

**Materials and Methods**

The study was conducted in a commercial farrow-to-finish herd with 300 sows, farrowing weekly all year round. The farm had a history of clinical diarrhoea in piglets, but no anti-coccidial compounds had been used. Prior to the initiation of the study, the presence of *I. suis* parasitism on the farm was parasitologically confirmed. Twenty-five litters with a total of 246 piglets were randomly allocated to either the treated (13 litters-128 piglets) or the untreated (12 litters-118 piglets) group. Piglets in the former, on the 3rd day pf, were orally treated with toltrazuril (BAYCOX® 5%) at the dose rate of 20 mg per kg bw, whereas those in the latter litters received no treatment. At least half a gram of faeces was collected individually from the rectum of each piglet daily from 6- until 13-days-old and thereon, every second day until weaning (i.e., 15 samples/piglet). Oocyst excretion (expressed as oocysts per gram of faeces (OPG)) was recorded for all samples. Because OPG counts were semi-continuous data (Liu et al., 2008), to evaluate the effect of treatment on the longitudinal OPG counts we fitted a two-part model in the aML software. Presence or absence of oocyst excretion was the response variable in the first part of the model, while the natural logarithm of the non-zero OPG values was used in the second part. Treatment and time were included as covariates in the model. Random effects were incorporated in the model to account for the within litter and within piglet correlation of observations. We adjusted for the cross-equation correlation (pCEC) of the litter- and piglet-level random effects between the logistic and linear part of the model to capture the biologically plausible fact that higher rates of excretion may also have higher mean OPG counts. Subsequently, we quantified the litter- and piglet-level unexplained variation via estimation of variance partition coefficients (VPC)(Kostoulas et al., 2009).

**Results and Discussion**

Parameter estimates from the model are in the table. Treated piglets had 66.5 (95% C.I.:10-500, P<0.001) times lower odds of excretion than the untreated ones. The mean difference in the amount of OPG in any day between treated and untreated piglets was 55.5 (95% C.I.:6-518, P<0.001). Piglets with higher odds of excretion tended to excrete more oocysts ( pCEC=0.99, P<0.001). Litters with higher odds of excretion also tended to have more oocysts excreted ( pCEC=0.55, P<0.001). VPCs were 40 and 23% and 26 and 17% for the litter- and piglet-level variance for the logistic and linear part of the model, respectively.

Toltrazuril treatment reduced both the odds of excretion and the mean amount of excreted oocysts. Estimated VPCs revealed that the greater portion of unexplained heterogeneity of oocyst excretion lies at the litter-level, highlighting the need of studies to identify litter-level risk factors for *I. suis* control.

The effect of toltrazuril treatment on the odds and level of oocyst excretion (logistic and linear part of the model, respectively) adjusting for piglet’s age.

Evaluation of the colostrum phase in 10 French pig herds dealing with enzootic neonatal diarrhea

Thomas Gin¹ Eric Pagot² Guy-Pierre Martineau¹

1. National veterinary school, Toulouse, France; 2. CTPA, Ploufragan, France

Introduction

Enzootic neonatal diarrhea (END) is occurring in 15 to 20% of French farrow-to-finish pig farms1. Dealing with this issue, veterinarians have to work on the aggression side i.e. control of pathogens and on the defense side i.e. control of immunity. During the first weeks of life, piglet immunity is mainly provided by colostral antibodies and cells. In this paper, we focus on the colostrum phase in pig farms dealing with END.

Materials and Methods

The study was conducted in 10 French farrow-to-finish pig farms during 2006 and 2007. Selection of farms was performed according to their history of END for more than 6 months. For the purpose of this study, one of us (TG) spent 7 consecutive days on each farm, starting the first day of farrowing as all farms operate on batch farrowing system.

For sows farrowing from 7 am to 7 pm, colostrum were manually taken from cranial mammary glands before the 3rd piglet’s birth and kept at 5°C until laboratory analysis. For each farrowing, data were recorded: length of gestation (calculated from the first day of AI), parity and emergence of neonatal diarrhea (determined by a clinical examination 3 times a day and during 7 consecutive days). Clinical as well as laboratory investigations are also registered2. At the end of the investigation week, 4 whole litters were blood-sampled, 2 control litters and 2 litters with diarrhea. In each farm, we select those 4 litters on 3 criteria: litters for which the sow was sampled for colostrum, litters that were 4 to 6 days old and litters in which we had less than 4 cross-fostering piglets.

IgG dosages were performed at LDA22 (Ploufragan, Côtes d’Armor, France) using a Pig IgG ELISA Quantification Kit* (BETHYL Laboratories, inc. Montgomery, Texas, USA).

Results

Piglet’s sera from 16 “diarrhea litters” (n=178) and from 22 “control litters” (n=244) were collected for evaluation of IgG ([IgG] sera, mg/ml). The mean of [IgG] sera for “diarrhea litters” is 22.2 mg/ml (SE=0.84; CV=0.50) while the one for “control litters” is 24.8 mg/ml (SE=0.83; CV=0.52). There is no significant difference (p>0.05).

Colostrum (n=135) from mixed-parities and mixed-genetics sows were collected for evaluation of IgG ([IgG] colostrum, mg/ml). When data from the 10 herds are pooled, we found that the mean of [IgG] colostrum is 81.3 mg/ml (SE=2.5; CV=0.32). There is a significant difference (p=0.005) in the [IgG] colostrum between sows with “diarrhea litters” (41 sows, mean=70.8 mg/ml, SE=3.5) and sows with “control litters” (94 sows, mean=85.8 mg/ml, SE=3.1). There is also a significant difference (p=0.001) in the [IgG] colostrum between sows farrowing at 114 days (mean=72.6 mg/ml, SE=4.1) and sows farrowing at 116 days (mean=104.8 mg/ml, SE=6.7). Finally, there is no parity effect (p>0.05) regarding [IgG] colostrum. As expected, there is a good positive correlation (r²=0.73) between [IgG] colostrum and average [IgG] sera of the litter.

Discussion

In our study, the colostrum phase was evaluated indirectly by the [IgG] sera of piglets. Within the same litter, [IgG] sera are in the 2/1 to 3/1 scale. This variation is not limited to affected litters or in some special litters. It is of concern in all litters. How can we explain this very important variation of colostrum intake between piglets? Two studies3,4 found that piglet’s vitality, birth weight and birth order are factors explaining a part of colostrum intake variation between piglets.

In our study, the colostrum immune quality was evaluated by the [IgG] colostrum. First, we found a relationship between low [IgG] colostrum and occurrence of diarrhea in the litter. Then, neonatal diarrhea is generally more frequent in gilts like for neonatal E. coli diarrhea5. However, in our study, there is no parity effect (p>0.05) regarding [IgG] colostrum. Another study3 showed that parity rank explains only a small part of the colostrum yield variation. Finally, Devillers et al.3 show an impact of farrowing induction (probably by an indirect effect on gestation length) on colostrum yield variation. Our study tends to show the same impact on [IgG] colostrum but with the same confusion between gestation length and farrowing induction.

During the colostrum phase, a lot of changes occur for the sows and for the piglets. The regulation of these changes is called homeorhesis i.e. orchestrated changes for the priorities of a physiological state. A better understand of the colostrum phase is needed to improve the performance in farrowing units.

Neonatal diarrhoea in piglets from E. coli vaccinated sows in Sweden

Lennart Melin1 Per Wallgren1 Sigbrit Mattsson1 Michael Stampe2 Monika Löfstedt2

1. National Veterinary Institute (SVA), Uppsala, Sweden; 2. Swedish Animal Health Service, Skara, Sweden

Introduction

The importance of virulent E. coli in the pathogenesis of neonatal diarrhoea in piglets has been well established since the 1960’s. The development of vaccines and proper vaccination routines of sows combined with good hygiene standards have reduced the problems with neonatal diarrhoeas to a minimum. However, despite proper vaccination routines the incidence of neonatal diarrhoeas has increased during the last years in several countries. This syndrome have been suggested the name New Neonatal Porcine Diarrhoea (NNPD). The aim of the present study was to search for possible causes for such diarrhoeas in Sweden.

Materials and Methods

Faecal samples, collected by The Swedish Animal Health Service, were taken from pens with clinically manifested diarrhoea in piglets less than 3 days of age despite E. coli vaccinations of their sows. In total 17 samples from 6 herds were investigated (3 samples from 5 herds and 2 samples from 1 herd).

The following analyses were performed;

• Defining the 4 most abundant aerobic bacterial species in each pen sample.
• Presence of 9 virulence factors (F4, F5, F6, F18, F41, LT, STa, STb, VT2) by PCR in the two dominating E. coli isolates/pen.
• Presence of 75 virulence factors in the two dominating E. coli isolates/pen using a microarray kit (Identibac EC Array Tube).
• The coliform floras were biochemically fingerprinted to define eventual common clones (Pheneplate®) (1)
• Determination of the resistance pattern of the two dominating E. coli isolates from each herd (Vetmic®).
• Presence of Clostridium perfringens type A (CpA) and Clostridium perfringens type C (CpC) by anaerobic culturing and PCR.
• Presence of genes for enterotoxin (cpe) or beta2 toxin (cpb2) in isolated CpA by PCR (2).

Results

No unexpected bacterium was found in any sample. E. coli, Enterococcus spp. and CpA were found in abundance in all samples.

As for E. coli no common virulence factor was found. In fact, only one of all the isolates was diagnosed with a virulence factor (STb) by the PCR technique. The microarray did not reveal any common pattern among the E. coli isolates. In total 18 virulence factors of the 75 possible were found in a random pattern among the isolates. Furthermore, no common phenotypic clone of E. coli could be demonstrated neither between nor within herds. The resistance pattern of all tested isolates of E. coli was normal for Swedish conditions (3).

All isolated CpA had genes for cpb2 but no one had genes for cpe. CpC was not isolated from any sample.

Discussion

In an international perspective neonatal diarrhoea is associated to infection/overgrowth of E. coli, CpC, CpA, Salmonella or corona viruses such as TGEV and PED. Neither CpC nor Salmonella was found in the herds included in this trial and TGEV and PED have never been isolated in Sweden.

Piglets are born with a sterile gastrointestinal tract (GIT) and the low production of gastric acid (HCl) and pH dependent gastric proteases give almost free access for invading microbes to colonise the animals GIT. They are therefore dependent on the colostrum from the sow to be able to establish a normal gastrointestinal flora. To accomplish this sows are vaccinated against pathogenic E. coli 5-3 weeks prepartment.

Despite the well known importance of E. coli in neonatal diarrhoea, no common E. coli associated explanation to the diarrhoeas could be found in the study.

The role of CpA on the other hand is not all clear. The bacterium is ubiquitous in gut content and soil and part of the normal flora. The genetic ability to produce cpb2 may be a sign of pathogenicity (4), but the importance of cpb2 is still under discussion.

So far, our results have excluded a number of microbes as likely causes of the neonatal diarrhoeas recently diagnosed in these herds with E. coli vaccinated sows.

Considering that this phenomenon has been observed in several countries, efforts to define microbes associated to such diarrhoeas ought to be intensified.

The effect of *Saccharomyces cerevisiae* on the occurrence of enteropathogenic *E. coli* in weaned piglets

Jan Bernardy1 Dana Kumprechtova1 Pavel Alexa2 Eric Auclair3
1. University of Veterinary and Pharmaceutical Sciences, Brno, Czech Republic; 2. Veterinary Research Institute, Brno, Czech Republic; 3. Lesaffre Feed Additive, Marq en Baroeul, France

**Introduction**

Probiotics, including live yeast and lactic acid bacteria cultures, have been reported to improve performance of weaned piglets (1, 2). Piglets fed by milk replacer supplemented with *Saccharomyces cerevisiae* Sc 47 (SC) show an increased postweaning growth and reduced TNF-α expression in the intestinal and liver tissues, suggesting an important immunomodulatory role of the treatment (3).

E. van Heugen et al. evaluated the effects of SC supplementation on faecal microflora and assessed whether live yeast could replace antibiotics and growth-promoting effect of Zn and Cu in nursery pigs. They found variable responses, and determined the conditions under which a measurable response can be expected (4). The objective of the present study was to evaluate the effect of SC dietary supplementation on the presence of enterotoxigenic *E. coli* (ETEC) strains and *Clostridium perfringens* in faeces, general signs of diarrhea and performance of post-weaning piglets.

**Material and methods**

The experiment was conducted under field conditions at the farrow to finish unit with 600 sows, with farrowing, post-weaning and finishing departments placed in separate buildings. The trial included two batches of piglets, from weaning at 25 days of age to the end of the post-weaning period at approximately 80 days of age. The piglets were housed in rooms with pens (25 piglets per pen) and slatted floor. The first batch (SC treatment) received mash liquid feed supplemented with SC culture at 1000 ppm (Actisaf Sc47, Lesaffre Feed Additives, France). The second batch (Control) was fed the same mash liquid feed without SC supplementation. Each treatment included 200 piglets. From each treatment, 10 piglets were randomly selected, ear-tagged and subjected to closer monitoring. They were weighed and taken rectal swabs on weekly basis, starting 11 days (Day 1) after the weaning. All the piglets in each treatment were subjected to daily diarrhea scoring (score 1 – no diarrhea signs; score 2 - pasty faeces, active piglets; score 3 - watery faeces, active piglets; score 4 - severe diarrhea, apathy piglets. Each entire batch was weighed at the beginning and end of the post-weaning period. The culling and mortality rates were summarized after the departure of the experimental piglets for the finishing department.

**Results**

The diarrhoea in weaned piglets is mainly caused by ETEC, how the results confirmed. The pathogenic strains *E. coli* were found in two piglets on Day 14 in the control group O141:F18, VT2e+ and O149:F4, STa+, LT+. In SC group no pathogenic strains were found.

Piglets were diagnosed in 98,12% *Clostridium perfringens* positive in the first sampling and 100% positive in the later samples regardless of treatment.

**Discussion**

In contrast to our findings (5), some researchers (6) reported that the yeast strain in their studies did not seem to affect any of the microbial groups tested incl. *E. coli*.

The mash liquid diet supplemented with SC showed a tendency (p<0.05) to increase daily weight gain by 8 g as compared with the untreated Control group (Table 1). The SC dietary supplementation may have reduced pathogenic *E. coli* strains and diarrhea occurrence. The diarrhea scores of the SC group differed significantly from those of the Control on days of the trial 11 to 13 (Figure 1).

Factors associated with pre-weaning piglet mortality due to crushing

Leena Anil1 Sukumarannair S. Anil2 Sam K. Baidoo1 John Deen2 Mark E. Wilson3 Terry L. Ward3
1. University of Minnesota, Southern Research and Outreach Center, Waseca, MN, USA; 2. University of Minnesota, Veterinary Population Medicine, St Paul, MN, USA; 3. Zinpro Corporation, Eden Prairie, MN, USA

Introduction
The average preweaning piglet mortality in US herds in the first quarter of 2009 is reported to be 12.2%. It has been reported that one-fifth of all fetuses fully formed at the end of gestation die before weaning. Thus preweaning piglet mortality is an important cause for economic loss in swine production systems. Injuries and crushing due to the sow falling on the piglets while making postural changes constitute a major cause for preweaning piglet death. Claw lesions in pigs are putatively painful. Sows with severe claw lesions may be restricted in making the necessary postural adjustments while attempting to lie down within the limited space inside the farrowing crate. In pigs the support role is more important in the front limbs which are nearer to the center of gravity. Further, observation of a sow lying down also suggests more movements associated with front limbs than the hind limbs. It is important to understand the factors associated with piglet death due to crushing to minimize the loss of live born piglets. The objective of the present study was to analyze the association of preweaning piglet death due to crushing with factors such as claw lesions, parity of the sow and gestation housing system.

Material and methods
This study involving 611 parity records of sows housed in group pens with electronic sow feeders (ESF) and 399 parity records of sows housed in conventional gestation stalls was conducted at the University of Minnesota, Southern Research and Outreach Center at Waseca. The lesions in the claws of these sows were examined at mid-gestation using a mechanical restraint designed for the purpose in one, two or three consecutive parities. The total claw lesion scores for front and hind limbs were obtained by adding the lesion scores in different claw areas (side wall, heel, sole, heel-sole junction, and white line) of lateral and medial claws. Information on reasons for preweaning piglet mortality, parity of the sow and housing system were collected from the PigCHAMP database of the unit. The association of number of preweaning piglet mortalities due to crushing with the parity of the sow, claw lesions score in front and hind limbs, and gestation housing system was conducted (Proc genmod, SAS v. 9.1) analysis with sow as a repeated measure. For analysis, parity of the sow was categorized into parities 1 and 2, 3 to 5 and >5.

Results
In this study 24% of preweaning piglet mortality was found to be due to crushing. Analysis indicated significant association between number of preweaning piglet deaths and parity of the sow, claw lesions and housing system. Sows of parities 1 and 2 and parities 3 to 5 had 61 and 36% lower piglet death due to crushing respectively, compared to sows of parity >5 (P<0.05 for both). For every unit increase in claw lesion scores in front, the number of preweaning piglet death due to crushing increased by 8% (P<0.05). A higher hind limb claw lesion score was also associated with higher number of piglet death due to crushing, though this association was not significant (P>0.05). Sows housed in group pens had 39% less (P<0.05) piglet death due to crushing compared to sows housed in stalls during gestation.

Discussion
The positive association observed between parity and piglet death due to crushing could be due to the smaller litter size in younger parity sows. An increase in number of piglet deaths due to crushing being associated with an increase in front limb claw lesion score is interesting. This may be suggestive of restriction due to pain in making the necessary postural movements to avoid uncontrollable falling within the farrowing crate, thus leading to a higher number of piglets being crushed. A higher number of crushed piglets in stall-housed sows could be related to a lack of exercise and consequent decrease in muscle weight and bone strength of these sows.

Conclusion
This study indicated a positive association between higher preweaning piglet death due to crushing and factors such as higher parity, stall gestation housing system and higher claw lesion scores in front limbs of sows.

Claw lesion effects on piglets born alive of stall-housed sows in two sow herds

A. Da Silva; S.S. Anil; J. Deen; R.B. Morrison

University of Minnesota, Saint Paul, MN, USA

Introduction
The number of piglets born alive per litter directly influences the average number of piglets weaned per sow per year (1). The aim of the present study was to evaluate the association of the productivity of stall-housed sows in terms of low litter size (≤10 piglets) with claw lesions scores, also considering stillborn, mummies, parity and sow herd.

Materials and methods
The lesions of these sows were collected from a convenience sample of 343 stall-housed sows (parities 1 to 13) belonging to two sow herds (Herd A, n=145; Herd B, n=198; of 1500 sows each herd). These sows were scored for lesions in different claw areas (side wall, heel, including overgrown heels, white line, heel-sole junction, and overgrown toes and dew claws). The claws were examined while the sows were in a recumbent position as there was no mechanical restraint to facilitate lesion scoring. The total score for each claw area was obtained by adding the scores for that area in the claws of front and hind limbs. For analysis, parity was categorized into parities 1 and 2, 3 to 5 and >5. A multivariate logistic regression analysis was performed to assess the association of lesion scores of different claw areas, stillborn, mummies, parity and sow herd with number of piglets born alive (≤10 vs. >10) (Proc Logistic, SAS v 9.2).

Results
A total of 105 sows (30.6%, mean=6.9, standard deviation=2.8) had ≤10 piglets born alive. The number of sows that had >10 piglets born alive was 238 (69.4%, mean=13.2, standard deviation=2.16). The total lesion score for all claw areas ranged from 0 to 27 and only two sows had no lesions. White line lesions (odds ratio 1.151, range of lesions scores=0 to 10) and overgrown toes (odds ratio 1.154, range of lesions scores=0 to 10) were positively associated (P<0.05 for both) with the likelihood of having ≤10 piglets born alive. The likelihood of having ≤10 piglets born alive increased with an increase in the severity of lesions in other claw areas as well (heel-sole crack and side wall), though the associations were not statistically significant. The numbers of stillborn piglets were positively associated with the likelihood of having ≤10 piglets born alive (odds ratio 1.298, P<0.01). Parity, number of mummies and sow herd were not found to be associated with piglets born alive in this study.

Discussions
The small number of sows with no lesions is in agreement with a previous study which indicated a high number of stalled housed sows that had at least one claw lesion (2). White line lesions and overgrown toes were positively associated with the likelihood of having ≤10 piglets born alive; suggesting that productivity of sows can be negatively influenced by the development of severe claw lesions in sows. The results of this study are indicative of potential adverse effects of claw lesions on the productivity of sows. It is important to identify factors affecting sow productivity and to reduce early removal of sows due to low productivity.

Better colostrum distribution increases piglet survival in high prolific sows

Jan Jourquin1 Johan Biermann2 Rainier van Gelderen1 Lieve Goossens1
1. Janssen Animal Health, Beerse, Belgium; 2. DAP Helmond, Helmond, Netherlands

Introduction
Colostrum intake is critical for the survival of the piglet. During the first days, the colostrum provides the nutrients for homeostasis and growth. For a much longer period the colostrum immunoglobulin fraction passively protects the piglets from disease (1). Only during the first 24 to 48 hours of life, these colostrums IgG's can pass the piglets gut. The colostrum intake per kg body weight (BW) ranges between 210 to 370 gram, but the capacity of a piglet to ingest colostrum is exceeding 450 gram/kg BW (2). The total colostrum yield of sows varies between 1.91 and 5.31 kg (3). Because litter size does not affect colostrum yield (3), in hyper prolific sow breeds, a high variation in colostrums uptake is difficult to avoid.

The aim of this study was to investigate the impact of colostrum distribution on pre-weaning piglet survival in high prolific sows.

Materials and Methods
In a 1600 sow farm, the litters of 220 sows were included in the study. At 3 days of age, individual blood samples were retrieved from the docked tail of six randomly chosen litter mates. The IgG titre of the samples was measured with a DAS-ELISA test (Colostrum Quality Counter™). This IgG titre, determined after the phase of colostrums IgG passage through the gut, can be used as a measure of colostrum intake (4). Of each litter, the average IgG titre and the standard deviation was calculated. By dividing the standard deviation by the average, the coefficient of variance of piglet serum IgG (CV IgG) was calculated. This coefficient is a measure for variation in IgG intake within the litter, and therefore represents the variation of colostrum intake. During the lactation period piglet mortality in each litter was recorded. The statistical analysis was performed with the SAS® program. A Poisson regression model on the number of dead piglets per sow was used. The total number of piglets was included as covariate.

Results
The CV IgG amongst litter mates ranged from 18 to 208%, with an average of 55%. In Table 1, the impact of colostrum distribution on piglet mortality is shown. Sows with a CV IgG of less than 50% (average 36%) were compared to those with a CV IgG of more than 50% (average 76%). With the same average litter size, the mortality was found to be statistically significant lower in litters with a low CV IgG.

ab: difference with p-value of 0.0259

The mortality rate over all litters was highly correlated with the number of piglets with the sow (p < 0.0001).

Discussion
These results clearly demonstrate that an even distribution of the available colostrum amongst littermates has a positive impact on the pre-weaning survival rate. The high number of piglets born alive, often in combination with low birth weight and low vitality as seen in highly prolific sows, reduces the chances of equal colostrums uptake amongst littermates. This leads to piglet loss mainly in the first days after birth. The ability of the sow to give all her piglets equal drinking opportunity is therefore a key factor. Even with a good colostrum distribution, mortality increases with the litter size, demonstrating that an increasing number of piglets calls for a higher colostrum yield, an increasing number of functional teats and sufficient drinking space. On the other hand, piglet suckling might also be promoted by reducing or eliminating all stress related behavior during the colostrum intake phase enabling the sow to optimally nurse her offspring.

All measures that improve the transfer and equal distribution of the available colostrum to each piglet should be taken into account to improve piglet survival.

Effect of a softer surface in the farrowing crate on the behavior of lactating sows

A. Da Silva; S.S. Anil; J. Deen; S.K. Baidoo

University of Minnesota, Saint Paul, MN, USA

Introduction

Lameness in swine herds is a common problem. Activity levels and frequency of standing may be higher during lactation (1). However, lameness, being putatively painful, may influence the frequency and/or duration of postural behaviors of the sow during lactation. Limited ability to make postural changes could in turn affect the quantity of feed and water consumed by the sow. Inadequate water intake has been suggested to cause low milk production (2) and reduced weight gain/death of piglets. Similarly, low lactation feed intake can affect subsequent reproductive performance of the sow. The quality and type of the floor are important factors influencing sows’ standing and lying-down behavior (3). However, studies on the effect of floor type on lameness and its effects in behavior of sows are rare. The present study aims to explore the effect of providing rubber mats in farrowing crates as a measure to minimize the adverse effects of lameness on behavior.

Materials and methods

This study involved 70 lame and 70 non-lame gestating sows (gestation stall n=63 and group pens with ESF n=77) identified based on their ability to bear weight on all limbs without favoring any particular limb when they were moved from the gestation housing systems to farrowing rooms. Lameness in all the sows was assessed by the same person. Equal numbers of sows were randomly allocated to farrowing crates with cast iron floor or to crates with the cast iron floor covered with rubber mats (3cm thickness) on the posterior half. The behaviors of the sows while in the farrowing crates on day 3, 9 and 15 post-farrowing were recorded using cameras and a time-lapse VCR. The frequencies of behaviors (getting up, dog sitting, drinking water and eating) of lame and non-lame sows with and without rubber mats on these days were compared using separately models, controlling for the effect of housing system (Proc Genmod, SAS v 9.2).

Results

The frequencies of getting up, dog-sitting posture, drinking water and eating on day 3, 9 and 15 post-farrowing were (0-31, 2-48, 2-41, 0-29) respectively. The frequency of getting up was 3% lower and 15% higher (P<0.05 for both) in stall-housed sows on d3 and d15 post-farrowing. Lame sows got up 12% fewer times on d9 post-farrowing. These sows also tended to have (P=0.05) 16% lower frequency of getting up on d3. On d9 post-farrowing, the frequency of dog-sitting posture was 13% lower (P<0.05) in sows with rubber mat. Stall-housed sows adopted dog-sitting posture 16% and 44% more times (P<0.05 for both) on d9 and d15 post-farrowing. However, lame sows tended (P=0.08) to show this postural behavior less frequently than non-lame sows on d9. The frequency of drinking water tended to be lower for lame sows in comparison to non-lame sows (P=0.09) and higher for those sows housed in gestation stalls (P=0.08) on d3 post-farrowing. The frequency of drinking water was 14% lesser (P<0.05) among sows with rubber mats on d9 post-farrowing. Sows housed in stalls drank 39% more times (P<0.05) than the group-housed sows on d15 post-farrowing. The frequency of drinking water tended to be higher in both lame sows (P=0.07) and those housed in stalls (P=0.07) on d9 post-farrowing. The frequency of eating was 11% less (P<0.05) among lame sows on d9 post-farrowing and the frequency tended to be less (P=0.08) on d3 post-farrowing.

Discussions

In general, the results are indicative of the adverse effect of lameness on postural behavior and feed and water consumption during lactation. However, post-partum behavior of the sow and familiarity of stall-housed sows to postural changes in restricted space could have influenced the results.

Use of paper strips as nesting material in sows: effects on abnormal behaviours, salivary cortisol and productive data

Paolo Candotti; Daniele Zappulla; Ivonne Archetti; Sara Rota Nodari
Izslor, Brescia, Italy

Introduction
In both wild and domestic pigs nest building is a natural, inherited behaviour that begins 24 h before farrowing. Stalling in single barren farrowing crates inhibits this behaviour and represents a source of mental stress in sows (Lawrence A.B. et al., 1994). The aim of this study was to compare salivary cortisol, abnormal behaviours and productive data of the litters in sows kept in barren farrowing crates and in sows given paper strips.

Material and Methods
91 sows of a farrow to finish farm of Northern Italy were selected for the study. The sows of the treated group (n=36) were given 2kg of strips of paper at day 112 of gestation; the control group (n=55) were left without. Both groups were kept in traditional farrowing crates. Salivary cortisol was evaluated at day 101, 107, 112 and 113 of gestation and at day 1 and 28 of lactation. Abnormal behaviours were recorded at day 107, 112-115 of gestation and at the 1st day of lactation. Productive data of the litters were also recorded.

Results and Discussion
Results reported in figure 1 show less abnormal behaviours in treated sows compared to control sows. Particularly, the treatment was able to reduce oral stereotypes.

The salivary cortisol measured at day 101 of gestation was compared to the salivary cortisol measured at the other samplings time points. Treated sows showed a lower increase in cortisol compared to control sows. In figure 2 the average level at day 101 of gestation and the difference with this basal level at the other samplings is reported. These findings confirm previous reports (Jarvis et al., 2001) that showed a positive effect of environmental enrichment on animals’ cortisol.

Cross-reactivity and efficacy of a monovalent swine flu vaccine containing the pandemic H1N1 2009 virus

Ralf Dürrwald1 Michael Schlegel1 Hans-Joachim Selbitz1 Andi Krumbholz2 Roland Zell2
1. IDT Biologika GmbH, Dessau-Roßlau, Germany; 2. Universitätsklinikum Jena, Institut für Virologie und Antivirale Therapie, Jena, Germany

Introduction
Since its first emergence in the human population in spring 2009 (1) infections with the pandemic H1N1 virus (cH1N1v) have been reported in pigs and other animal species in several regions of the world (2, 3). The pandemic virus can be experimentally transmitted between pigs (4). Although vaccine strains of authorised swine flu vaccines are cross-reactive to cH1N1v (5) a swine vaccine containing cH1N1v may be superior to the available vaccines. In order to investigate this in more detail hyper immune sera, post infection sera and a monovalent vaccine containing cH1N1v were produced and investigated for efficacy.

Materials and Methods
Hyper immune sera were established using a fourfold vaccination of pigs with antigens of H1N1 vaccine strains and a strain of the pandemic H1N1 virus using Freund’s adjuvant. Blood samples were taken 14 days after last immunization. A vaccine containing the pandemic H1N1 virus was produced. Swine flu vaccines available in central Europe and the newly produced cH1N1v vaccine were administered to pigs. Blood was withdrawn 7 days after second administration.

Furthermore an experimental aerosol infection was carried out using the parental strain of the most recent avian-like H1N1 strain contained in a European swine flu vaccine. Ten days after infection, blood samples were taken. Sera were investigated applying a neutralization test and hemagglutination inhibition (HI).

Results
The investigation of hyper immune sera revealed that there is neutralizing activity between the pandemic H1N1 virus and avian-like H1N1 European vaccine strains (A/sw/Netherlands/25/80, A/sw/IDT/Re230/92, A/sw/Haselünne/IDT2617/07) as well as with the New Jersey/8/76 (Fort Dix reassortant) strain at low level. A hyper immune serum established against the pandemic H1N1 virus was produced. Swine flu vaccines available in central Europe and the newly produced cH1N1v vaccine were administered to pigs. Blood was withdrawn 7 days after second administration.

Furthermore an experimental aerosol infection was carried out using the parental strain of the most recent avian-like H1N1 strain contained in a European swine flu vaccine. Ten days after infection, blood samples were taken. Sera were investigated applying a neutralization test and hemagglutination inhibition (HI).

Discussion
It is concluded that despite the cross-reactivity between avian-like and classical swine H1N1 strains with the pandemic H1N1 virus of 2009 a vaccine consisting of cH1N1v is superior in terms of efficacy in comparison to vaccines already licensed.

Transmission dynamics of a H1N1 swine influenza virus in a population previously infected with the 2009 pandemic H1N1 strain

Anna Romagosa; Monserrat Torremorell; Marie Gramer; John Deen; Han S. Joo
University of Minnesota, St Paul, MN, USA

Introduction

Little is known about the transmission and spread of swine influenza virus (SIV) in pig populations previously infected with the 2009 pandemic H1N1 influenza strain. A transmission experiment was performed to assess the transmission pattern of a triple reassortant H1N1 virus in pigs previously infected with the 2009pH1N1 SIV strain.

Material and Methods

Two groups of ten 3-week-old pigs were placed in separate isolation rooms. The groups were designated as control (C) or previously infected (I). Pigs in the control group were neither vaccinated nor infected with SIV. Pigs in the I group had been naturally infected with the 2009pH1N1 SIV strain at about 4 weeks prior to the beginning of the study. These pigs were virus free and HI test positive (titers ≥ 1:40) against the 2009pH1N1 at the time the study started. However, they were HI negative against the challenge strain (A/Sw/IA/0239/04).

In a separate room 2 naïve pigs were challenged with the triple reassortant A/Sw/IA/0239/04 H1N1 which was genetically different from the 2009pH1N1. Twenty four hours post challenge the challenged pigs were confirmed positive by nasal swab PCR. At 48 h one challenged pig was moved into each of the treatment rooms and placed in direct contact with the pigs in group C and I. Transmission was evaluated by collecting nasal swabs from all pigs on a daily basis. Nasal swabs were tested individually by PCR until all pigs in each group tested positive or until 14 days post contact (DPC) when the study was terminated. Blood samples were also collected at the beginning and the end of the study.

Pigs were monitored daily and clinical scores based on coughing, sneezing, lethargy, fever, nasal discharge and dyspnea were calculated. At necropsy the percentage of macroscopic lung lesions was recorded and tissues from the trachea, lungs, nasal turbinate, tonsils and lymph nodes were collected for PCR, virus isolation and histopathology.

Results

The transmission results are shown in Figure 1. Influenza virus was detected by PCR in all pigs in the control group by 5 DPC and pigs remained positive until necropsy (8 DPC). In contrast influenza virus was detected by PCR in only one pig in group I at 1 DPC. Differences in transmission patterns between the groups were statistically significant at p<0.001.

Discussion

Results indicate differences in transmission and spread of SIV between groups. Although SIV could spread rapidly in a naïve population (control group), transmission in the previously infected group with the 2009pH1N1 was limited and infection could not become established. This study represents preliminary work to understand the dynamics of SIV transmission in the field as represented by populations with different immune status.

Introduction

The gene constellation of the 2009 pandemic H1N1 virus is a unique combination from swine influenza A viruses (SIV) of North American and Eurasian lineages, but prior to April 2009 had never before been identified in swine or other species (1). Although its hemagglutinin gene is related to North American H1 SIV, it is unknown if vaccines currently used in U.S. swine would cross-protect against infection with pandemic H1N1. The objective of this study was to evaluate the efficacy of inactivated vaccines prepared with U.S. swine influenza viruses as well as an experimental homologous vaccine to prevent infection and disease from 2009 pandemic H1N1.

Materials and methods

Sixty three-week-old cross-bred pigs were obtained from a herd free of SIV and porcine reproductive and respiratory syndrome virus (PRRSV). A/California/04/2009 H1N1 (CA/09) was propagated in Madin-Darby Canine Kidney (MDCK) cells for use in the study described below. Three inactivated vaccines (Vaccines A, B, and D) were selected based on serologic evidence of cross-reactivity in a previous study(2). Commercial vaccines were supplied by the manufacturers for use in the study and administered as per label. Vaccine A (FluSure® XP, Pfizer Animal Health, New York, NY) is a fully licensed trivalent commercial product containing cluster IV H3N2, γ-cluster H1N1, and δ-cluster H1N1 SIV as vaccine seed viruses. Vaccine B (MaxiVac Excell® 5.0, Intervet/Schering-Plough, Boxmeer, The Netherlands) is a pentavalent product containing clusters I and IV H3N2 and β-, γ-, and δ-cluster H1 SIV as vaccine seed viruses. Vaccine D (Newport Labs, Worthington, MN) is a bivalent autogenous vaccine containing β- and γ-cluster H1 SIV as vaccine seed viruses. A monovalent experimental vaccine (Vaccine E) was prepared from CA/09 at 8 HA units per 50 μL and 1 X 10⁶.₅ 50% tissue culture infectious dose (TCID₅₀) per mL with inactivation by ultraviolet irradiation and addition of a commercial adjuvant. Pigs (N=10 per group) were vaccinated with 2 mL of each vaccine by the intramuscular route at approximately 4 weeks of age, boosted at 7 weeks of age, and challenged at 10 weeks of age.

Nasal swabs were taken at 0, 3, and 5 days post infection (dpi). At necropsy, lungs were removed to estimate the percentage of macroscopic pneumonia. Each lung was lavaged to obtain bronchoalveolar fluid (BALF). Virus titers in BALF were determined by serial dilutions added to MDCK cells in 96-well plates, and virus from nasal swab samples were isolated on MDCK cells in 48-well plates and positive samples titrated in 96-well plates.

Hemagglutination inhibition (HI) assays were done to evaluate sero-conversion using challenge virus as well as a panel of North American H1 SIV isolates representing each phylogenetic cluster (3).

Results

All vaccines tested provided partial protection ranging from reduction of pneumonia lesions to significant reduction in virus replication in the lung and nose. Although the commercial multivalent vaccines demonstrated partial protection, none were able to prevent all nasal shedding or clinical disease. An experimental homologous 2009 H1N1 monovalent vaccine provided optimal protection with no virus detected from nose or lung at any time point in addition to amelioration of clinical disease. The CA/09 vaccine induced high HI titer against homologous 2009 H1N1 as well as cross-reacting HI antibodies against α-, β-, and γ-cluster H1N1 SIV. Commercial vaccines that induced γ-cluster HI antibodies demonstrated statistically significant reductions in virus titers.

Discussion

Based on cross-protection demonstrated with the vaccines evaluated in this study, the U.S. swine herd likely has significant immunity to 2009 H1N1 from prior vaccination or natural exposure, especially those demonstrating immunity against γ-cluster SIV. However, consideration should be given for use of homologous vaccines to best protect naïve swine herds and limit the potential transmission of 2009 H1N1 from herd to herd and from pigs to people.

Acknowledgments

We thank Michelle Harland, Brian Pottebaum and Jason Huegel for assistance with laboratory techniques and animal studies.

Efficacy of swine influenza virus vaccines produced using the alphavirus replicon system

Ryan L. Vander Veen1,2 Mark A. Mogler1,2 DL Hank Harris1,2
1. Iowa State University, Ames, IA, USA; 2. Harrisvaccines, Inc., Ames, IA, USA

Introduction
Swine influenza virus (SIV) continues to circulate among most U.S. swine herds. The recent outbreak of pandemic H1N1 in the human population and its subsequent confirmation in pigs has again highlighted the zoonotic potential of these viruses. Using alphavirus replicon technology, a recombinant pandemic H1N1 hemagglutinin (HA) subunit vaccine and a cluster 4 H3N2 replicon particle (RP) vaccine were developed and efficacy was determined in swine vaccination-challenge models.

Materials and Methods
Hemagglutinin genes derived from A/California/04/09 and a field strain of cluster 4 H3N2 were commercially synthesized and inserted into the alphavirus replicon system as previously described.1,2 The replicon system was utilized to express HA subunit \textit{in vitro} (pandemic H1N1) or to produce a replication-deficient particle that produces HA protein \textit{in vivo} (cluster 4 H3N2). Twenty pigs were randomized and divided equally among 4 groups. One group served as non-vaccinated controls, while the remaining 3 received varying doses (high, mid, low) of pandemic H1 subunit vaccine. Pigs were challenged intratracheally with remaining 3 received varying doses (high, mid, low) of pandemic H1 subunit vaccine. Pigs were challenged intratracheally with 1x10^7 TCID_{50} of A/California/04/2009 and necropsied 5 days post-challenge. The H3N2 study consisted of 50 animals, with 10 strict negative controls, 20 vaccinates and 20 non-vaccinates. The 20 RP vaccinated pigs received 2 doses of cluster 4 H3 RP vaccine. The 20 vaccinates and 20 non-vaccinates were challenged with 1x10^7 TCID_{50} of homologous H3N2 virus. Necropsy was performed 4 days post-challenge. In both studies, vaccinated pigs received the first dose of vaccine at 3-4 weeks of age, with booster vaccination given 3 weeks later.

Results

Pandemic H1N1 Study
All of the vaccinated groups developed positive (>1:40) mean homologous HI titers following two doses of HA subunit vaccine. At necropsy, lungs exhibited gross lesions typical of SIV. Lungs evaluated from the vaccinated groups had significantly lower gross lung lesions, as well as histopathological lesions. Live virus titration performed on post-challenge nasal swabs demonstrated that vaccinated pigs had reduced viral shedding when compared to non-vaccinated pigs. The group receiving the high dose HA subunit vaccine did not shed virus at a detectable level, while on days 3-5 post-challenge the low and mid dose vaccine groups demonstrated significantly reduced viral shedding when compared to the non-vaccinated controls. In addition to reduced lung lesions and viral shedding, all vaccinated groups demonstrated higher average daily gain than the non-vaccinated group following challenge.

Cluster 4 H3N2 Study
All vaccinated pigs developed robust homologous HI titers following two doses of SIV RP vaccine. At necropsy, lungs evaluated from vaccinated pigs exhibited significantly reduced gross lung lesions when compared to the non-vaccinated pigs. The non-vaccinated groups developed a febrile response 24 hours post-challenge, while the temperature of the vaccinated pigs was significantly lower at this time point. No live virus was detected in the broncho-alveolar lavage fluid (BALF) collected at necropsy in any of the vaccinated pigs, while all of the non-vaccinated pigs had detectable virus in the BALF samples. These results correlate with the reduced lung lesions observed in the vaccinated pigs. In addition, no live virus was detected from nasal swabs in any of the vaccinated pigs taken throughout the post-challenge period, while by days 3 and 4 post-challenge most of the non-vaccinated pigs had detectable live virus from nasal swab samples.

Discussion
These studies further demonstrate the applicability and efficacy of SIV vaccines produced utilizing the alphavirus replicon system. The pandemic H1N1 study demonstrated the rapidness with which this technology can be utilized to respond to emerging strains of influenza, as the pandemic vaccine was available in less than 2 months after the public announcement of infection in humans. This is much quicker than traditional methods of influenza vaccine preparation. The rapid exchange of HA influenza genes in this system enables us to produce different replicons which express the HA gene of all the different clusters currently circulating in the U.S. swine population,3 as well as respond quicker to observed antigenic drift among influenza isolates.

In vivo evaluation of vaccine efficacy against challenge with a contemporary field isolate from the alpha cluster of H1N1 swine influenza virus

Susan E. Detmer¹ Marie R. Gramer¹ Sheerin Mathur² Vicki J. Rapp-Gabrielson²

1. University of Minnesota, Department of Veterinary Population Medicine, St. Paul, MN, USA; 2. Pfizer Animal Health, VMRD, Kalamazoo, MI, USA

Introduction

Influenza A virus vaccines currently contain a mixture of field isolates that reflect the genetic and antigenic characteristics of the currently circulating strains. In order to continue to provide protection, these vaccines need to be regularly updated. For North American pigs, swine influenza is a year-round respiratory disease caused by H1N1, H1N2 and H3N2 subtypes and within the H1N1 subtype there are 4 clusters designated α (classical swine influenza), δ (human-like swine influenza), β and γ (reassortant swine influenza viruses). For Canadian pigs, most of the currently circulating influenza A viruses are in the SwH1 α cluster. Therefore, this study was conducted to evaluate the efficacy of a vaccine containing a γ H1N1 virus (Flusure XP™) in pigs challenged with a contemporary α cluster field isolate of Canadian swine origin.

Materials and Methods

The animal phase of this study was conducted in accordance with the approval of the Institutional Care and Use Committee of the University of Minnesota.

Vaccines and vaccination: Flusure XP™ was administered as per manufacturer label instructions. Three-week-old swine from a high-health herd free of influenza, Mycoplasma hyopneumoniae and PRRS virus were vaccinated 14 days apart with a 2 ml intramuscular dose and assigned to 2 treatment groups, and non-challenged pigs that were housed in 3 rooms in an isolation unit at the University of Minnesota as follows:

Table 1. Vaccination treatment groups.

Challenge and post-challenge procedures: Immediately prior to challenge, the no treatment pigs (*) in rooms 2 and 3 were removed for euthanasia and necropsy. Two weeks following the second vaccination, swine were inoculated 2 ml intratracheally and 2 ml intranasally with $10^{5.5}$ TCID₅₀/ml of influenza A/Swine/IL/02450/2008 (H1N1), an alpha-cluster H1 of Canadian swine origin. Swine were monitored daily for clinical signs and nasal swabs were taken for virus isolation on MDCK cells. On day 5 post-challenge, swine were euthanized for necropsy; bronchoalveolar lavage fluid (BALF) was collected, lungs were scored for gross lesions and lung samples were collected for histopathology and virus isolation. All samples negative by virus isolation were retested by real time RT-PCR.

Hemagglutination Inhibition (HI) Antibodies: Blood was collected 12 and 2 days before the first vaccine, 1 day before the second vaccine, at challenge and 5 days after challenge. All sera were assayed for hemagglutination inhibition (HI) titers against the homologous virus in each vaccine and against the challenge virus.

Statistical analysis: Gross lung scores, HI titers and virus titers were evaluated by a general linear repeated measures mixed model using SAS (SAS Institute, Cary, NC).

Results and Discussion

There were gross lesions present in the lungs of all pigs that were inoculated with the challenge virus. However, the challenge virus only produced mild clinical signs that included fever lasting 24-48 hours in a few pigs and rare coughing. The results of the nasal swab virus titers show that there was reduction in viral shedding for vaccinated swine compared to unvaccinated swine post-challenge. The virus titers for the BALF and lung samples were lower in the vaccinated swine than the unvaccinated swine. The vaccinated swine had HI titers > 40 for all vaccine viruses on challenge day and 5 days after challenge. All swine had an HI titer ≤ 40 for the challenge virus 5 days after challenge. These results indicate that vaccination with Flusure XP™ reduced virus isolation from nasal swabs, lungs and BALF in swine experimentally challenged with a SwH1 α cluster virus that is genetically similar to those currently circulating in Canadian swine.

Nanoliter real-time PCR: A new molecular platform for simultaneous detection of multiple pathogens

Wonil Kim² Leslie Bower¹ Karen Harmon¹ Kyoung-Jin Yoon¹

¹. Iowa State University, Ames, IA, USA; ². Chonbuk National University, Jeonju, Korea

Introduction

Many disease problems in swine production are often multifactorial, which can be a diagnostic challenge. A multiple pathogen detection system can be then of great help to accurate and rapid differential diagnosis, simultaneous surveillance for various infectious agents, and studying interactions among different pathogens involved in a disease complex (i.e., disease ecology). Although various multiplexing technologies have been developed and applied for these purposes, their applications have been somewhat limited due to the complexity of test development and maintenance: optimization of multiple assays in a multiplex system is very challenging; and addition of a new assay to the optimized system requires significant time and effort for additional validation. Therefore, a new detection system in which multiple individual assays can be optimized and run independently, yet simultaneously and economically, needs to be explored.

High-throughput nanoliter real-time PCR (OpenArray™, BioTrove) [1] uses conventional SYBR Green or TaqMan real-time PCR formats. For each sample the system can run real-time PCR assays for up to 64 different targets simultaneously as independent reactions in parallel. Each array slide can run 48 different samples at the same time. The system is also considered to be economical since the total reaction volume for each assay is only 33 nanoliters, which is nearly 1000 times less than that of conventional real-time PCR assay. The following study was conducted to evaluate its utility and feasibility for veterinary diagnostic use.

Materials and Methods

The nanoliter real-time PCR system was evaluated for multiple pathogen detection in comparison with individual TaqMan real-time PCR assays which had been routinely used by the Iowa State University Veterinary Diagnostic Laboratory (ISUVDL) for various bacterial, viral and protozoan agents of various species.

Primers and probes labelled with FAM or VIC for 28 real-time assays were prepared in a plate (i.e., array) for the nanoliter PCR. The system was then validated and optimized using 86 clinical samples archived from previous submissions to ISUVDL and known positive control for each of the target agents. All procedures were performed as per manufacturer’s recommended protocol.

Results

All of the 28 assays prepared in the nanoliter PCR simultaneously detected each target agent without generating false-positive results. Because preliminary evaluation revealed that the analytic sensitivity of the nanoliter PCR was 10-100 times lower than that of conventional TaqMan PCR assays, a universal extraction system was developed in this study to prepare concentrated RNA or DNA of viral, bacterial, and protozoan pathogens from various sample matrices such as serum, oral fluids, tissues, and feces. Combined with the universal extraction system, the nanoliter PCR showed sensitivity and specificity equivalent to the corresponding individual TaqMan PCR assays.

Discussion

The study demonstrated that a high-throughput nanoliter real-time PCR system can simultaneously detect multiple infectious agents in a variety of sample matrices. Since the system is based on PCR amplification, it can provide higher sensitivity as compared to a conventional microarray system which is based on hybridization, not to mention faster turnaround. For epidemiological or ecological research, substantial test cost saving can be expected with the nanoliter PCR system because of its capability for simultaneous detection of around 60 different pathogens in parallel, when compared to the cost incurred by all those individual real-time PCR assays. Overall the system appears to be a valuable tool for veterinary diagnostics and epidemiological or ecological research.

**Herd health surveillance pilot project in Ontario commercial hog operations**

**Paisley Canning1, 2 Tim Blackwell2**

1. Animal Health Laboratory, University of Guelph, Guelph, ON, Canada; 2. Veterinary Science and Policy, Ontario Ministry of Agriculture, Food and Rural Affairs, Elora, ON, Canada

**Introduction**

The American Veterinary Medical Association recently supported the establishment of a disease surveillance system for American swine operations (Snelson 2010). A comprehensive surveillance system of this type aims to detect emerging, zoonotic and food-borne diseases central to current public and animal health issues. Disease monitoring frequently only reflects reportable diseases and samples submitted to diagnostic labs. Certain subsets of swine producers in Ontario, however, do not typically utilize veterinary diagnostic services. Many of these producers also have limited access to modern means of communication such as a telephone or fax machine. Consequently, it is difficult to assess changes in mortality and to promptly identify disease outbreaks if they occur on these farms. This presents a challenge for potential national or provincial animal health surveillance systems. To address this, a pilot project was designed to assess the feasibility of a broad based surveillance system including conventional and low diagnostic service user farms.

**Materials and Methods**

Enrolled producers submit weekly mortality and morbidity data from all areas of their production system (including the breeding/gestation, farrowing, nursery, and grow/finish sections) using a mortality form. The recording form asks producers to record age of suckling pig deaths, number of piglets born alive, general comments, in addition to mortality rates in all applicable areas of production. Producers have the option to mail in hard copies of the form using provided postage paid envelopes or to use a Nokia 6086 or e71 cellular telephone to electronically submit the data. These phones operate an online surveillance software called Episurveyor® that allows users to create surveys accessible on the mobile phone. Producers record mortality data using this phone program and then send their completed weekly mortality forms to an internet database from the phone. Participants also fax their weekly submission to the OMAFRA office. Currently, 14 of 24 producers utilized diagnostic services at least once through their veterinarian in response to mortality and morbidity changes in their herd. Submission to AHL through this program increased after a meeting was held for each clinic where producers received farm specific mortality data reports and spoke with study coordinators about the project. Direct interactions between veterinarians, producers and study coordinators appeared to help with compliance and highlighted the benefits of regular sample submission and veterinary contact.

**Results**

This pilot project focuses on evaluating if this submission design and set of incentives is sufficient to generate regular reporting of disease events each week. Secondly, from a surveillance standpoint, mortality data is analyzed for abnormal fluctuations as opposed to absolute numbers. Nine farms submit their data on time each week. For the remaining herds, receipt of data lags by one to three weeks between its completion on farm and arrival at the OMAFRA office. Currently, 14 of 24 producers utilized diagnostic services at least once through their veterinarian in response to mortality and morbidity changes in their herd. Submission to AHL through this program increased after a meeting was held for each clinic where producers received farm specific mortality data reports and spoke with study coordinators about the project. Direct interactions between veterinarians, producers and study coordinators appeared to help with compliance and highlighted the benefits of regular sample submission and veterinary contact.

**Discussion**

Currently, this pilot project is still active on participating farms and has generated useful data on herd health status. Due to the importance of catching emerging or zoonotic diseases early, timely data submission is crucial but has been problematic with some farms on this study. The Episurveyor® program has been functioning well on farm and data downloading has been successful. Compliance does remain a challenge and highlights the need for incentives and demonstrating the benefits of regular data submission to participating veterinarians and producers. Although more accessible to study participants, mailing-in data creates a larger lag between recording and collection. This can hinder effective disease surveillance but helps generate broad based surveillance data. The surveillance project continues to operate and is due to be completed in July 2010. A second producer meeting is planned in the spring to hold discussions on the surveillance methods in use and on mortality issues for each herd.

Testicles of castrated piglets an anachronism - but a powerful sample for disease surveillance in sow herds

Jens Boettcher; Andreas Hensch; Armin Gangl; Britta Janowetz; Michaela Alex; Hermann Niemeyer; Gerd Wittkowski

Bavarian Animal Health Service, Poing, Germany

Introduction
Collecting blood from adult sows is laborious; time consuming and sometimes hazardous to the veterinarian and/or the sow. Alternative samples would be of benefit. Some authors proposed colostrums as an alternative material, however antibody level in colostrums declines rapidly after parturition and due to high fat content samples have to be processed in the lab. Meat juice is a suitable sample for serodiagnosis in slaughtered animals (e.g. Salmonella enterica, PRRSV, Trichinella spp.). Therefore pieces of meat (4 cm³) are submitted to vials. After freezing and thawing meat juice is collected. As a general rule antibody concentration in meat juice is 1/20 of that in blood. In the present study it was analysed if tissue fluid from testicles (TJ) of castrated piglets could serve as a sample to predict the dam’s seroreactivity.

Material & Methods
The following ELISAs (Dilution of TJ) were used: PRRSV (1/10), SIV H1N1 (1/10), Salmonella (1/2), Mycoplasma hyopneumoniae (Mhyo; 1/10) supplied by Idexx and PCV2 (1/20), PPV (1/40) supplied by Ingenasa. Except for the dilution of TJ tests were performed according to manufacturer’s instructions. Results were expressed as titre (PCV2) or relative S/P-value after subtraction of the optical density of the negative control (other tests).

Blood and testicles were collected from piglets within the first week of life (not necessarily the same animal!) and blood was collected from the dam. Mean reactivity of OD or geometric mean of titre per litter were calculated and compared with the dam’s value. Individual results were compared by kappa statistics. Finally, serological classification of herds based on testing TJ and dam’s blood was compared.

Results
For each test a positive correlation between serum samples of dams and mean TJ reactivity of the litter was observed. Data for the comparison TJ versus dam’s serum were summarized in the Table. Agreement of TJ with serum from piglets as determined by k-statistics was generally higher.

In the case of PRRSV, SIV and Mhyo 100% of the herds were correctly classified. Agreement between dam’s serum and TJ was moderate for PPV, PCV2 and Salmonella. In the case of these infections pairs of samples with borderline reactivity tended to be misclassified.

Discussions & Conclusions
TJ is an alternative sample for serology in sows. Although k-values were sometimes below 0.8 one has to consider that mean reactivity per litter was compared. Agreement for PRRSV, SIV and Mhyo on herd level was excellent. Thus TJ-testing is a powerful tool especially for surveillance of PRRSV, SIV and Mhyo in sow herds.

In the case of Salmonella the ELISA-cut-off for meatjuice/serum was validated for slaughterhouse pigs and not for sows. The observation that ELISA-reactivity of piglets from negative sows (serum) was below 20% might indicate the need for an age-related cut-off. Agreement was higher at a cut-off at 60% for sow serum and 40% for TJ. Comparison of sample materials in the case of PPV and PCV2 were complicated by high numbers of samples with borderline reactivity. This might be explained by vaccination (PPV) or frequent infection (PCV2). Application of ELISA tests for detection of protective antibodies (e.g. correlation with neutralizing antibodies) in the future might allow prediction of optimized time-points for vaccination of piglets.

Pig health Surveillance in The Netherlands 2004-2009
Hetty van Beers-Schreurs; Peter van der Wolf
GD-Animal Health Service, Deventer, Netherlands

Introduction
Surveillance of the health status of pigs is very important for Dutch Pig farmers and the Dutch Government. Five years ago the Dutch Ministry of Agriculture and the Dutch Livestock Board (PVV) built a surveillance system for pig health in The Netherlands. The AHS was asked to carry it out. The goals of this system are 1) watching trends and developments, 2) detecting outbreaks of notifiable diseases and 3) detecting unknown diseases/problems. This paper shows how it works.

Materials and Methods
The surveillance system consists of a helpdesk for veterinarians and farmers (telephone and website), pathology and laboratory service, and herd visits, combined with specific disease surveillance and data analysis (figure 1). Specific serological surveillance is done for Pseudo Rabies (PR), Classical Swine Fever (CSF), Swine Vesicular Disease (SVD), Salmonella, and Brucellosis in commercial pig farms and PR, CSF, SVD, CSF, Foot and Mouth Disease and Trichinella in wild boar.

Results
In the years 2004 – 2009 there were 11824 questions (75% by vets), 22706 autopsies and 696 herd visits.

The occurrence of the most common non-notifiable diseases has been determined, figure 2 e.g. shows the declining trend in the occurrence of weaning diarrhea (enterotoxicosis) in autopsies in weaned piglets. Many hundreds of thousands of samples have been tested for notifiable diseases and no outbreaks have been detected. Occasionally, serological positives have been found for PR(n=2) in wild boar (close to the German and Belgium border), and for CSF from CSF vaccinated wild boar (n=4). The PR and CSF virus have never been detected.

Special results were e.g. an outbreak of Talfan in weaned piglets, Porcine Ulcerative Dermatitis Syndrome in sows, progressive posterior paralysis in sows with unknown etiology, two (independent) pigs with lymphosarcoma, broken legs as a result of low phytase in mixed feed and piglet mortality as a result of lack of vitamin D in mixed feed.

Discussion
In the past years the system has shown that it is capable of detecting isolated incidents as well as surveillance of pig health in general. Specific parameters show a declining trend resulting in an improvement of overall pig health.

Of course such a system has its strengths and weaknesses. Strengths are the aggregation of different kinds of data. One of the weaknesses of the system is the dependency on practitioners and farmers to send in animals for autopsy or blood/faeces samples. In the next future attention will be paid to this “weakness”. Autopsies and analysis of samples are not for free. The Government and the Dutch Livestock Board pay part of it. The results of diagnostics will not only provide the veterinarians and farmers more appropriate information about the cause of the problem, it will also give some information about the health status of Dutch pigs. In the case outbreaks of known diseases or occurrence of new syndromes, the Government, the Board, practitioners and farmers will be informed immediately, in order to make the right decisions. Reports will be handed over every 3 months.
Evaluation of the Ontario Swine Veterinary-based Surveillance System (OSVS) - an update

Maria R. Amezcua1 David L. Pearl1 Robert M. Friendship1 W. Bruce McNab2
1. University of Guelph, Guelph, ON, Canada; 2. Ontario Ministry of Agriculture Food & Rural Affairs, Guelph, ON, Canada

Introduction

There is an increasing interest in obtaining farm level data through veterinarians for real time surveillance, due to the growing concern of emerging and re-emerging diseases in swine populations. Practicing veterinarians are often the first to detect the initial cases of novel infectious diseases. Consequently, we undertook a twelve-month pilot study to determine the feasibility of a veterinary-based surveillance system for Ontario (1). This pilot program was evaluated based on the level of compliance among practitioners, and the timeliness and quality of data submitted to the program. Practitioners continued to participate in the program and the OSVS performance during the second year is presented in this study.

Material and Methods

Seven veterinarians from five clinics recorded and transmitted data from July 1, 2007 to June 31, 2008 using either paper forms or a personal digital assistant (PDA). In the second year of the study (July 2008 to June 2009), three additional practitioners joined the program. In addition, during the second year, OSVS recording forms were harmonized with clinic’s recording forms and/or billing systems and technical personnel were involved in the transmission of the data.

The practitioners summarized the number of farm visits and calls according to the body systems affected and the manner in which production was affected. To estimate the level of compliance among practitioners, the OSVS calculated the weekly ratio of the OSVS submissions to submissions made by the same veterinarians to the AHL. Completeness of data was assessed by measuring the frequency of data entered for each of the form’s fields/elements. The coverage of the program was assessed by determining the proportion of farms visited by practitioners compared to the number of farms registered in the Canadian Agricultural Census of 2006 in each agricultural region of Ontario. Timeliness was evaluated by calculating the difference between the date when the practitioners recorded the case and the date when the information was transmitted to the program coordinator.

Results

For the pilot study, the average time to availability of data (TAD) was 22.1 days and the quality of compliance was variable among veterinarians and months. Timeliness improved by 8 days in the second year of the study. However, timeliness and compliance continued to be highly variable among veterinarians particularly during the summer. Over the course of the pilot study, a total of 1,610 records were sent to the OSVS. The completeness of fields in the form ranged from 55-99%. Actual estimates of morbidity and mortality for disease visits/calls were rarely recorded during the pilot study. A total of 2,226 records were sent to the program during the second year. The completeness of fields in the form in the second year ranged from 73%-100%. Over the course of the pilot study, almost 24% of swine farms in Ontario were visited. After the pilot study, an increase in coverage of 13.6% was observed.

Discussion

Our results showed that it is feasible to administer a swine veterinary-based surveillance system in Ontario that is acceptable to practitioners, and can produce useful surveillance data. The use of friendly recording systems adapted to each clinic’s management system and involving animal technicians in the regular transmission of clinicians’ data helped to improve timeliness. However, financial incentives may be needed to improve compliance and achieve a “real-time” surveillance system using practitioner data.

Methods to assess different aspects of a veterinary-based surveillance program must be established to determine which aspects of the program’s performance need improvement.

Profile and agreement of dam and piglet PCV2 IFA titers

Angela Baysinger; Edgar Diaz; Roy Edler
Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA

Introduction
Porcine circovirus associated disease (PCVAD) is caused by porcine circovirus type 2 (PCV2). Following natural exposure to or immunization against PCV2, Most sows and gilts develop antibodies that become passively acquired by their nursing offspring. The objective of this evaluation was to illustrate the immunological status of a sow herd, and to assess the correlation of dam and offspring IFA antibody titers.

Materials and Methods
A 4,200 sow, PRRS-negative farm was selected for this evaluation. This herd had a young parity structure with no dams older than parity 3. Typical of commercial production, dams had been PCV2-vaccinated as weanling gilts but never booster vaccinated. Two hundred and five gestating dams (sows and gilts) were blood sampled 2 weeks prior to scheduled farrowing. Sera were tested by immunofluorescent antibody (IFA) assay at Kansas State University. Based upon these results, dams were assigned to either low titer (≤160) or high titer (≥1280) groups. Dams with intermediate titers (320-640), and their associated litters, were excluded from the evaluation. Piglets were ear tagged within 24 hours of birth and the existing cross-fostering practices of the farm were allowed with the following restrictions: pigs could only be cross-fostered after 24 hours of age, and only to a dam of like-titer status (i.e. high-titer dam to high-titer dam or low-titer dam to low-titer dam). All pigs were individually blood sampled for PCV2 IFA antibody measurement and classification as low (≤1:320) or high (≥1:640) titer at approximately 3 weeks of age based upon previously reported experiments.1,2 A contingency table was constructed and dam titer-pig titer percent agreement and Kappa statistic were calculated.

Results
The titer distributions of all dams are illustrated in Figure 1, while pig titers from only the designated low and high titer dam categories are represented.

Dam and pig titers by designated low/high categories appear in Table 1. Percent agreement of low dam-low pig and high dam-high pig titers [(305 + 349)/921] was 71% with a Kappa3 of 0.42 (SE 0.03).

Discussion
There was moderate strength of agreement between low dam – low pig and high dam – high pig titers. Low titer pigs from high titer dams may be explained by insufficient passive transfer of maternal antibodies. High titer pigs from low titer dams are more difficult to explain. A likely contributing factor is the designated pig IFA titer limits being only a single dilution apart (320:640) and the inherent subjectivity of reading IFA results. It may also be possible that some of the piglet antibody measured was of active (pig) rather than passive (dam) origin. Another explanation could be a higher antibody concentration in colostrum than in sow serum and a high uptake of colostrum in the high titer pigs.

**Qualitative and quantitative distribution of PCV2 in wild boars and domestic pigs in Germany**

Gerald Reiner¹ Bastian Bronnert¹ Corinna Hohloch² Christina Fresen¹ Stephan von Berg¹ Manfred Reinacher² Hermann Willems¹

1. Department of Veterinary Clinical Sciences, Justus-Liebig-University, Giessen, Germany; 2. Institute for Veterinary Pathology, Giessen, Germany

**Introduction**

Porcine circovirus type 2 (PCV2) is considered the essential infectious agent of a series of diseases in swine that are now collectively termed porcine circovirus diseases (PCVD). Besides domestic pig production, PCV2 has also been detected in wild boars from several countries by serological studies, PCV2 antigen and DNA detection, indicating that PCV2 circulates at a high rate among the wild boar populations in Europe. PMWS reports in wild boars are scarce, however.

In domestic pigs, the high incidence of subclinical infection and the stability of the virus complicate diagnostics and appraisal of PCV2 infection and PCVD. Diagnostics and prognosis based just on serology or conventional PCR overestimate the risk of developing PCVD. However, several studies have provided evidence for the association between PCVD and the PCV2 load in serum or tissues of pigs (Brunborg et al., 2004; Olvera et al., 2004; Segales et al., 2005).

Neither the PMWS status nor the quantitative load of PCV2 has been documented comprehensively in wild boar populations. We hypothesize that the countrywide prevalence of PCV2-infected wild boars is high with low incidence of PCVD, and that the discrepancy between both is associated with low loads of PCV2.

**Materials and Methods**

Samples from different tissues of 531 wild boars from 46 different hunting grounds and of 308 apparently healthy and 40 wasting (rejected at slaughter) domestic pigs from 48 provenances located in the same greater areas as the wild boars were analyzed. PCV2-specific DNA was detected independently by nested PCR (nPCR) and by quantitative realtime PCR (qPCR). PCV2-specific tissue alterations were examined by histological (HE) and immunohistochemical (IHC) standard procedures. Pigs were classified as PCVAD-affected (moderate to severe lymphocyte depletion and granulomatous inflammation of the lymphoid tissue, and moderate to high amounts of PCV2 genome equivalents [at least 5x10⁶ copies of PCV2 DNA/μg extracted DNA in at least one of the tissues]), subclinically infected with PCV2 (no or only slight lymphoid lesions, and a lower amount of viral genome copies), and non-PCVD (no lymphoid lesions and negative in qPCR) (Segales et al., 2005). The threshold of 5x10⁶ PCV2 DNA copies per μg of extracted DNA corresponds to 10⁷ copies of other studies?? (e.g. Harding, 2008).

**Results**

The average prevalence for PCV2 infection, determined by nested PCR, was 63.1% in wild boars and 100% in domestic pigs (p<0.001). Only 45.4% of the wild boars, but 98.8% of the domestic pigs were tested positive for PCV2 by qPCR. Wild boar prevalence in different areas of the country varied significantly between 36.2% and 87.5%. PCV2 loads differed significantly (p<0.001) between wild boars and domestic pigs. The average viral load was 102.8 in tissues of wild boars and 104.2 in those of domestic pigs. None of the 349 wild boars did definitely show clinical symptoms of PCVAD, but one of them (0.3%) met the criteria for PCVD. Based on the same classification, 8.7% of the domestic pigs from 15 of the 48 provenances were found to be PCV2-affected. None of the wild boars and 7.1% of the domestic pigs had PCV2 loads above 5x10⁶ DNA copies per μg of DNA. The number of PCVD-affected and non-affected pigs did not differ between pigs slaughtered and wasting pigs that were rejected at slaughter.

**Discussion**

In conclusion, this is the first study that describes the nationwide distribution of PCV2 in wild boars and domestic pigs qualitatively and quantitatively. As the level of PCV2 load appears to be the critical step in the development of severe PCVD, qPCR proved to be well suited for the evaluation of PCV2 infection and PCVD in wild boar and domestic pig populations.

Detection of Porcine Circovirus 2 in Mammary and Other Tissues from Experimentally Infected Sows

Hwi Won Seo; Chan Hee Chae
Seoul National University, Seoul, Korea

Introduction
Porcine circovirus 2 (PCV2), a single stranded DNA virus within the family Circoviridae, is now recognized as the aetiological agent of post-weaning multisystemic wasting syndrome (PMWS) (Chae, 2004). The virus is shed in body fluids and has been isolated from oropharyngeal and nasal swabs, faeces, whole blood and serum taken from experimentally infected pigs. Recently, PCV shedding was detected by polymerase chain reaction (PCR) in colostrum and milk from experimentally infected sows (Ha et al., 2008). The aim of the present study was to extend these observations by utilizing immunohistochemistry (IHC) and in-situ hybridization (ISH) to determine the distribution of PCV2 in mammary tissue from experimentally infected sows.

Materials and Methods
Sows were randomly allocated to an infected (n = 6) or control group (n = 2). Each animal was housed separately within the facility. The viral inoculum used for infection contained the PCV2 strain SNUVR000470, at its third passage in PCV-free PK-15 cells. The six test animals were inoculated intra-nasally with 6 ml of tissue culture fluid containing 1.2 x 10^5 tissue culture infective doses 50% (TCID50)/ml of virus. The inoculation was performed on day 93 of gestation. The two control sows were administered uninfected cell culture supernatant. Three days after parturition, the sows were sedated by intravenous injection of sodium pentobarbital and then euthanized by electrocution. The superficial inguinal lymph nodes, mammary gland, lung, liver, kidney, spleen, tonsil and ileum were also collected at necropsy and fixed in 10% neutral-buffered formalin before processing. IHC was performed with a primary rabbit polyclonal anti-PCV2 antibody. ISH was performed with a PCR probe derived from the sequence of the open reading frame 2 (ORF2) of PCV2.

Results
PCV2 antigen and DNA were detected in the mammary tissue of all experimentally infected sows. Virus antigen was distributed throughout the mammary gland. Virus antigen and DNA was associated with cells with oval nuclei and abundant cytoplasm having morphological appearance consistent with macrophages. These cells were chiefly located within the lumina of the glandular tissue. The epithelial cells lining these glands did not contain DNA or antigen. Mammary tissue from control sows did not contain PCV2 DNA or antigen. Virus antigen and DNA were also detected in the lymph node, liver, spleen, tonsil and ileal Peyer’s patches from all experimentally infected sows.

Discussion
The results of this study confirm that the sows were successfully infected following intranasal inoculation with PCV2. The virus appeared to infect macrophage-like cells in the mammary gland of these sows. Although monocyte-macrophages may not be the primary target for PCV2 replication in vivo, the simultaneous detection of PCV2 protein and DNA reported here suggests that the virus infects and replicates within these cells. PCV2 has been shown previously to replicate within macrophages (Kim et al., 2003), and numerous macrophages may be found in the milk of sows.

PCV2 is known to replicate in the tonsil, entering the systemic circulation and the lymphoid organs such as lymph nodes and spleen (Kim et al., 2003). The virus is also present in circulating monocytes (Kim et al., 2003) suggesting that these cells act as vehicles for dissemination of the virus. We propose that these circulating monocytes may enter the mammary glandular tissue. Additional study is required to determine whether infectious PCV2 particles (as opposed to virus DNA) is present within the milk and whether any such virus may be shed directly within the milk whey or is contained within macrophages.

References

Introduction
All pig-producing countries from around the world report the presence of Postweaning multisystemic wasting syndrome (PMWS.) This syndrome is regarded as a major problem in pig production. In America, PCV2 has been recognized in Canada, United States and Brazil. In Europe, France, Austria, Germany, United Kingdom and Sweden have detected the disease. In Asia, Japan, Taiwan and China have reported the disease’s presence too (1,2,3.) Knowledge concerning the genetic sequences of PMWS has been very important in all these countries for establishing the homology level between the different isolations and for learning more about of the disease (4.) In Mexico, there is no report describing the genetic sequences and variations of the PCV2 virus present around the country. For this reason, the main objective was to describe the homology and genetic sequences of the PCV2 virus obtained from different regions of Mexico.

Material and Methods
10 samples from different regions of Mexico were analyzed. DNA was extracted and the PCR was performed to amplify a fragment of 506 pb of the ORF2. The PCR products were cloned into a commercial plasmid vector and afterwards sequenced with ABI automated DNA sequencer. The sequences were compiled and aligned with the published in the GENEBANK, and finally were analyzed with the Basic Genebee CLUSTAL W 1.83 program in order to obtain the phylogenetic tree.

Results
10 sequences were identified, the homologies of the Mexican PCV2 virus range between 89% and 99%. The majority of them are genotype “b” but the genotype “a” is also present. At the amino acids level, it ranges from 88% to 100%.

The phylogenetic analysis (Figure 1) shows that the Mexican PCV2s are divided into 3 principal clusters. The majority of the sequences are closely related with European PCV2s in the PCV2 group a; and the virus inside of PCV2 group b have relation with European, Asian and Canadian virus.

The analysis of the main changes between amino acid sequences shows that there are 20 changes in the capsid protein; the majority of these changes are in the domain region situated in the position from aa59 to aa91. Table 1 shows these changes in detail.

Table 1. Most frequent changes of amino acids in PCV2 sequences from Mexico. One interesting finding is that the sequence PCV2MXP-BC_SC is different in 8 amino acids when compared with the consensus sequences of the others samples that belong to genogroup b

Discussion
Since PMWS was described in Canada (1997) genetic analysis of PCV2 has been done in different countries in order to understand the genetic variations and its implications (4.) According to our knowledge, there is not any report in Mexico about the genetic variations of Mexican PCV2. Our results show that the Mexican PCV2 has genetic variations; two strains show a high variation. The percentage of the heterology found in this investigation is higher than other reports described in America.

It is very important to establish whether the sequences of the Mexican PCV2 virus have relation with the pathogenicity of the strains.

Heterologous expression of nuclear localization signal (NLS) truncated capsid protein of porcine circovirus type 2 (PCV2) in Escherichia coli and its potential of the specific antibodies induction

Suphattra Jittimanee; Roongtham Kedkovid; Komkrich Teankum; Sanipa Suradhat; Roongroje Thanawongnuwech
Chulalongkorn University, Bangkok, Thailand

Introduction
PCV2 has been recognized as a causative pathogen of porcine circovirus associated disease (PCVAD), which is currently an important disease in the swine industry. The PCV2 capsid protein is the preferred antigen in a variety of serological tests and vaccines due to the strong immunogenicity (1). In this study, the recombinant NLS truncated capsid (NTC) protein was produced using E. coli expression system to prepare a subunit vaccine and examine the immunological response using an indirect in-house ELISA.

Materials and Methods
The NTC DNA fragment of PCV2 Thai isolate (07NP2) was amplified using PCR, cloned into the pGEX-5x-3 plasmid (GE Healthcare) and transformed into the E. coli BL21. For expression, 2 liters of the recombinant E. coli was induced with 0.1 mM IPTG at 30 °C for 4 h (2). The bacteria was harvested and disrupted by sonication. The recombinant protein was purified using GST purification system (GE Healthcare). The expression of recombinant NTC protein was determined using SDS-PAGE and Western blot analysis. The concentration of the recombinant protein was measured using the Bradford assay.

To prepare a subunit vaccine, the purified recombinant protein was mixed with a commercial oil adjuvant. The vaccine efficacy was examined in the experimental pigs free from PCV2. Forty-five, 4-week-old pigs were allocated into 5 groups: group A (n=10) received a one-shot vaccination (5 μg/dose); group B (n=10) received a two-shot vaccination (5 μg/dose, 2-wks-interval); group C (n=10) received a one-shot vaccination (50 μg/dose); group D (n=10) received a two-shot vaccination (50μg/dose, 2-wks-interval). Group E (n=5) was given only an adjuvant. The sera were collected before the vaccination (0 dpv) as the baseline and at 7, 14, 21, 28 and 42 dpv. Antibodies against recombinant NTC protein were detected using an in-house indirect ELISA (Chulalongkorn University-Veterinary Diagnostic Laboratory, CU-VDL).

Results
The expression of recombinant NTC protein from recombinant BL21 resulted in the production of the approximately 40 kDa protein (Fig.1, lane 2 and 3). This protein also reacted with the rabbit anti-PCV2 antibody (Fig.1, lane 4). Results from the vaccine trial study revealed that the one-shot group received 50 μg of the protein (group C) showed an increasing mean O.D values compared with the control group (Fig. 2). However, when pigs were given a two-shot protocol, both the 5- and 50-μg/dose groups showed significantly increased mean O.D. (Fig. 2, B and D). After the second vaccination, the levels of antibodies in the two-shot vaccinated groups were significantly higher than those in the one-shot groups especially in the 50-μg/dose group (p < 0.05).

Discussion
The results showed that the recombinant NTC protein expressed in the E. coli system could react with anti-PCV2 antibody and also induce the specific antibody responses in the experimental pigs especially in the two shot vaccinations of both concentrations. Interestingly, the immune response was also detected in the one-shot protocol when given the high concentration of the protein indicating of dose dependent. Our subunit vaccine could be used as a potential vaccine candidate. However, field trial of this subunit vaccine is needed for the future study.

**Comparison between an in house developed ELISA for the detection of antibodies against PCV2 and the Synbiotics PCV2 ELISA**

Marc Martens; Alex Eggen; Hanny Swam

*Intervet/Schering-Plough Animal Health, Boxmeer, Netherlands*

**Introduction**

Porcine Circovirus type 2 (PCV2 infections) and its related Porcine Circovirus Disease (PCVD) is a major drawback in pig farms all over the world. Initially managerial measures were taken to reduce the impact. Last years the appearance of PCV- vaccines has been a milestone to really prevent the disease. Maternally derived antibodies (MDA) may interact with the take of the vaccine. (M Fort et al. Vaccine 2008, 2009) Also the moment of vaccination is critical: it should be weeks before the onset of infection. To be able to establish the optimum moment for vaccination it is of importance to have tools to measure antibodies against PCV2. Intervet Schering Plough Animal Health (ISPAH) developed an in house PCV2 antibody ELISA. Besides commercial ELISA manufacturers also produced ELISA kits for the determination of PCV2 antibodies. The use of all these different tests complicate the interpretation of articles and trials related to PCV2 infections and vaccination. ISPAH therefore compared its in house ELISA for the detection of antibodies against PCV2 with the commercial available ELISA test of Synbiotics which is widely used in the field.

**Materials and Methods**

77 serum samples of conventional sows that were known to have antibodies against PCV2 were tested in both tests in three independent runs. Besides 20 sera of known negative PCV2 animals were tested in both ELISA's. The selected commercial test is from Synbiotics SERELISA®PCV2 Ab Mono Blocking ELISA. The ISPAH in house ELISA has been developed in R&D of ISPAH and is not commercially available. Since the results of the inhouse ELISA are expressed in Log 2 titers also the Synbiotic results are expressed in Log2-titers for this comparison.

**Results**

In Figures 1 and 2 the mean results of the 77 sows in both ELISA's are presented. In both tests the sera show a regular increase of titer when sorted ascending, although the slope of the Synbiotics test is more flat compared to the inhouse test. The in house ELISA shows a range of 2-16 log 2. The titer range in the Synbiotics test was between 4 and 14 Log 2.

In the in house ELISA all negative sera had a titer of <2Log2. In the Synbiotics test this was <4Log2. (individual data not shown)

**Discussion**

Both the ISPHA in house ELISA as well as the Synbiotics PCV2 ELISA show a regular increase of titer when sorting ascending. and both can be used to establish the antibody level in pigs. The slope of the two test differ which is important to realize when interpreting serological data; From in house data it is known that a 5Log2 titer in the ISPAH inhouse PCV2 antibody ELISA represents a protective level i.e. above 5 Log2 pigs will be protected. Since the slope of the two tests differ probably higher titers in the Synbiotics test are needed for protection. From the ISPAH test it is known that high titers around 10-12 Log 2 at the moment of vaccination may lead to suboptimal vaccination results. It is to be expected that in the Synbiotics ELISA this can already be the case at a somewhat lower level.

Detection and Genetic Characterization of Porcine Circovirus Type 2 (PCV2) in Pigs from Colombia

Maria A. Rincón2 Jose D. Mogollón1 Victor Vera1 Jairo Jaime1 Gloria C. Ramirez1 Michael Murtaugh3 Juan Abrahante3
1. Universidad Nacional de Colombia, Bogota, Colombia; 2. Instituto Colombiano Agropecuario, Bogota, Colombia; 3. University of Minnesota, St Paul, NM, USA

Introduction
Porcine circoviruses (PCV), members of the family Circoviridae, are composed of non-enveloped viruses with a single-stranded circular DNA. Two genetically and antigenically different viruses, PCV1 and PCV2, can be distinguished. PCV1 is nonpathogenic, and PCV2 is associated with postweaning multisystem wasting syndrome (PMWS) (1).

In Colombia, clinical PMWS associated with PCV2 infection was first reported in 2006. The PCV2 antigen was detected in the 91.2% of the 34 farms examined by IHC (2). This study reports the presence of PCV2 in Colombian swine herds prior and after PMWS outbreaks from 2006 - 2009.

Materials and Methods
Tissue samples (lymph nodes, lung, spleen, and kidney) were collected from nine farms with historical records of PMWS during 2006 – 2009. The individual diagnosis of PMWS was confirmed for each case (3). Twenty serum samples collected from March 2004 to November 2005 from four farms located in three different regions were also included. The samples were stored at -80°C until use.

DNA extraction was carried out using the QIAamp® DNA Mini kit (Qiagen, USA) according to the manufacturer’s instructions. The capsid gene was amplified and sequenced from nucleotides 998 to 1757 using specific primers capFw 5’ CTT TTT TAT CAC TTC GTA ATG 3’ and capRw 5’ CGC ACT TCT TTC GTT TTC 3 (4). Amplicons were sequenced using an automatic sequencer (Applied Biosystems, Macrogen, Korea). Strain-specific sequence chromatograms generated using forward and reverse primers were assembled into individual contigs using SeqMan (DNASTAR).

Resulting partial ORF2 sequences were aligned in ClustalX. The alignments was imported into CLC Sequence viewer for visual inspection, and the first 30 bp and the last 20 bp of the full length ORF2 region were excluded. Phylogenetic trees were generated in CLC Sequence Viewer using the Unweighted Pair Group Method with Arithmetic mean (UPGMA) method.

Results and Discussion
Preliminary analysis of 14 tissue samples from the field cases and six serum samples from the retrospective survey were positive for PCV2 by PCR. The 20 sequences obtained could be divided into two main clusters supported by high confidence values that matched the two genotypes defined previously; PCV2b (n=15) and PCV2a (n=5). Interestingly, all of the PCV2a sequences but only one PCV2b sequence were found in serum collected during 2003-2005. All of the samples from 2006-2009 were PCV2b.

The detection of PCV2b genotype since 2006 may explain the PMWS epizootic occurrence in farms of several states of Colombia. Additional sequencing is underway to expand these findings and provide a more complete picture of the genotype distribution of PCV2 and his association with PMWS in Colombian swine herds.

Evidence of a genotypic shift in porcine circovirus type 2 (PCV2) from PCV2a to PCV2b after PMWS outbreaks in two Spanish farms

Introduction
PCV2 is considered to be the essential infectious agent of post-weaning multisystemic wasting syndrome (PMWS). Many studies have not found any relationship between PCV2 strains and the occurrence of disease (1-3). Nonetheless, a growing number of publications (4-8) reported a shift from PCV-2a to PCV-2b that may be related to the occurrence of PMWS outbreaks.

Based on the existing evidence at different country levels, the main objective of this study was to follow up the evolution of PCV-2 genotypes in two farms in Spain that undergone a PMWS episode, to examine the dynamics of PCV2 infection and its relationship with the appearance of PMWS at herd level.

Material and Methods
A total of 51 samples (serum and PCV2 isolates from the PMWS outbreak) from Farm 1, collected from 1995 to 2009, and 87 samples from Farm 2 (serum samples), collected from 1996 to 2003, were analyzed. PMWS outbreak suspicion and diagnosis were confirmed on May 2007 and March-April 2001 in farm 1 and 2, respectively. Both were small experimental farrow-to-finish (40-60 sows) operations, free from most of common swine pathogens, including porcine reproductive and respiratory syndrome virus. A fragment of 652 located between the Rep and the Cap protein of the PCV-2 genome was sequenced on all available samples.

Results
A sudden genotype PCV2a to PCV2b overturn was observed on Farm 1: 34/37 sequences were PCV2a before the PMWS outbreak in 2007, whereas all sequences after the outbreak were PCV2b (Figure 1). On Farm 2, the frequency of PCV2a decreased steadily from 1996 to 2003 and the frequency of PCV2b increased (Figure 1). The chi-square analyses performed on both farm datasets yielded significant results, statistically supporting the change of genotype from PCV2a to PCV2b in both herds at the time of PMWS occurrence.

Discussion
The genetic shift linked to PMWS epizootics has been described in several countries from Europe (5,7,8) and North-America (4,6). However, this is the first report of a PCV2 genotype shift associated with PMWS appearance at individual farm level. Overall, the putative higher virulence of PCV2b strains seems to be supported by the present data. Both studies related the occurrence of PMWS epizootics to high frequencies of PCV2b and lower frequencies of PCV2a.

Isolation and identification of Porcine Circovirus Type 2 (PCV2) from lymph node samples

Introduction
PCV2 is an icosahedral 17 nm circular shaped, naked virus with single stranded ambivalent DNA (Fenaux 2004). Virus Isolation (VI) is done mainly in PK 15 cell line and it is particularly tedious due to the fact that the virus requires cells in active mitosis that provide it with DNA polymerase, needed for the viral replication process (Tischer et al 1987). Its presence is demonstrated by Immunoperoxidase (IP), Immunofluorescence or Molecular Biology techniques since it does not produce citopathic effect.

Material and Method
Cell line: PK 15 PCV2 free cells were employed, with 24 hrs growth and sensitized with D – Glucosamine.

Samples: Lymph nodes gathered from animals of 3 different farms, showing signs compatible with PCVAD. These samples were tested as 9 macerates for VI and 3 pools for PCRqrt.

Viral Isolation, all macerates were filtered at 0.22 μm and used to infect PK 15 cell cultures with the after mentioned characteristics. Viral presence was confirmed by IP tests (NVRI, Pulaway: Poland 2007).

PCRqrt: genetic material extraction was performed from the pools; viral particles present were amplified and quantified using the protocol developed by Cortes et al (unpublished).

Results
VI: From the 9 macerates, 7 yielded positive and 2 negative by the IP test (Table 1).

PCRqrt: All 3 pools were positive with a viral load between $10^{2.0}$ and $10^{3.0}$ viral particles/mL (Table 2).

Discussion
In this case PCV2 could be isolated and identified by IP and by PCRqrt showing an 80 – 100% positive respectively. These results confirm viral presence in Mexico and agree with seroprevalence results presented by Ramirez et al (2008) where 97% of the tested sera were positive, for PCRqrt Hernandez et al (2008) reported viral loads from $10^{3.0}$ to $10^{7.0}$ vp/mL from tissues. Other investigators results are also confirmed Trujano et al (2001) and Ramirez et al (2004), who reported viral detection by in situ hybridization and by viral isolation.It is noticeable the relation among the viral particles detected by PCRqrt with the positive results in VI and the stained nuclei detected by IP, where the higher the number of positive samples, higher the viral load and also the higher number of stained nuclei.

**Introduction**

Porcine circovirus type 2 (PCV2) is the essential infectious agent of postweaning multisystemic wasting syndrome (PMWS). PMWS diagnosis is mainly established based on laboratorial criteria, including histopathology and detection of PCV2 in tissues (1). Therefore, the objective of the present abstract is to summarise the results of an international immunohistochemistry (IHC) ring trial performed in 18 different laboratories across the world.

**Materials and Methods**

The IHC ring trial was undertaken using 10, formalin-fixed, paraffin-embedded tissues, including lymph nodes (n=5), lung (n=3) and thymus (n=2) from pigs with and without PMWS. The referral laboratory (laboratory 1) submitted the 10 tissue sections in duplicate to each laboratory (two laboratories contributed twice to the results). Each laboratory performed the IHC stain and evaluated the results blindly using a scale of 0 (negative), 1+ (weak reactivity), 2+ (moderate reactivity), and 3+ (strong reactivity).

Secondly, a written survey detailing 28 technical aspects of the IHC assays were also sent to all participants. To analyse the results, two multiple correspondence analyses (MDS) were performed, one using the discrepancies of the ring trial a second one comparing differences among IHC technical details and results among laboratories.

**Results**

Sixteen out of 18 laboratories had a mean number of discrepant results between 0 and 1 among slides; such number was 2 or higher in the other two laboratories. Of all participant laboratories, only 14 sent the technique details survey completed. When the IHC result and IHC technique details were taken into account jointly, 12 out of the 14 submitting laboratories showed no significant differences among them.

**Discussion**

Overall, the present study indicates that most of the participant laboratories reported congruent results. Technical differences were not a major source of result disagreement.

Introduction
Necrotizing lymphadenitis is a pathological feature observed in about 2% of postweaning multisystemic wasting syndrome (PMWS)-affected pigs. The pathogenesis of the lesion has been linked to a Porcine circovirus type 2 (PCV2)-related apoptosis-induced mechanism (1), but no further studies have been focused on this topic. Therefore, the goal of this retrospective work was to gain further insights into PCV2-associated lymphoid necrosis pathogenesis in PMWS cases.

Materials and Methods
Three groups of animals were selected: PMWS-affected pigs with necrotizing lymphadenitis (group 1, n=5), PMWS-affected pigs without necrotizing lymphadenitis (group 2, n=5) and healthy pigs with no PMWS-related lesions (group 3, n=5). Investigations performed included immunohistochemistry (IHC) of cleaved caspase-3 (to detect apoptosis) and von Willebrand factor (vWF, to detect this glycoprotein, which is involved in haemostasis), special stain for fibrin (Mallory stain) and in situ hybridization (ISH) to detect PCV2 genome.

Results
Table 1 includes individual results of histopathological findings. Fibrin deposition detected by Mallory stain was significantly higher in PMWS-affected lymph nodes with necrosis compared to those with PMWS or normal lymph nodes. Lymph nodes from PMWS-affected pigs had significantly higher PCV2 amount than those of healthy pigs. Otherwise, no significant differences were observed between the two PMWS-affected groups in regards intensity, location or amount of PCV2 genome detected by ISH.

Discussion
Necrotizing lesions in lymph nodes of severely PMWS-affected pigs usually show multifocal to coalescent areas of coagulative necrosis (in some cases, affecting the whole parenchyma of the lymph node) together with vascular thrombosis (3). This latter fact has been confirmed in the present study by the presence of fibrin thrombi detected by the Mallory stain. Taking into account that vascular injury seems to be the primary determinant of a thrombotic response (2), the existence of marked thrombosis in PMWS-associated necrotizing lymphadenitis suggests certain extension of vascular damage in these pigs. Such damage evidence was supported by the high endothelium venule hypertrophy and the over-expression of vWF in subendothelial (collagen bound), cytoplasmic and intravascular (circulating) locations. Such findings would account for the increase of intravascular fibrin deposition and, consequently, thrombosis. Therefore, obtained results would point towards a vascular accident with thrombi development and the subsequent follicular necrosis as the cause of necrotizing lymphadenitis in PMWS affected pigs.

Clinical incidence and frequency of lesions associated to porcine circovirus type 2 in pigs of a farm in the state of Yucatan, Mexico

Jose L. Guillermo1 Jorge C. Rodriguez1 Marco A. Torres1 Monica Quintal2 Raquel Miranda1 Rafael Colin1
1. University of Yucatan, Merida, YUC, Mexico; 2. Patologia Animal, Merida, YUC, Mexico

Introduction

Serological studies have demonstrated that PCV2 is present in both affected and unaffected farms with postweaning multisystemic wasting syndrome (PMWS) with a seroprevalence nearly 100%. However, the incidence of PMWS on a farm is typically low, suggesting that PCV2 is not the only agent involved and that other factors are required for the presence of the PMWS; animals infected with PCV2 and parvovirus or PRRSV, immunosuppressive or immunostimulating agents, so that the incidence of PMWS is variable between regions and between farms. The objectives were to estimate the cumulative and true incidence, the lethality rates and the frequency of macroscopic and microscopic lesions of PMWS and porcine dermatitis nephropathy syndrome (PDNS) in pigs of a farm in the state of Yucatan, Mexico.

Materials and Methods

The studied population was divided in 2 groups. Monitored group consisted of a production batch of 235 pigs, which were observed from week 4 to 22 of age to determine the number of new cases compatible with the PMWS and PDNS that occurred weekly and the number of pigs that died of these syndromes. Sacrificed group was formed gradually during each of the visits to the farm in this group the frequency of lesions compatible with the PMWS and PDNS was estimated, for which, postmortem studies were performed in all discarded pigs between 4-22 weeks of age and with signs compatible with the syndromes studied. Necropsy was performed in animals of both groups monitored and sacrificed. The organs inspected were: lymph nodes, spleen, liver, tonsils, ileum, lungs, kidneys and skin. Samples of all organs were obtained for histopathological studies.

Results

14 pigs showed signs consistent with the syndromes mentioned, 7 with the PMWS and 7 with the PDNS. The cumulative incidence and incidence rate for both syndromes were 0.06 and 0.0034 respectively. 5 pigs died, lethality rates calculated for PMWS and PDNS were 0.4 and 0.3 respectively. Necropsy was performed at 80 pigs, 50 with signs compatible with PMWS and 30 with PDNS. The most frequent macroscopic lesions in the PMWS were Lungs: lesions compatible with interstitial pneumonia and suppurative bronchopneumonia 80%. Skin: eritematous macules and plaques with crusted center 63%. Kidney: nephromegaly with hemorrhage 87%. Lymph nodes: lymphadenomegaly and congestion 63% and Spleen: Splenomegaly 60%. There were no macroscopic lesions in liver, ileum and tonsils.

Discussion

The PMWS and PDNS affect the population studied; with a slow diffusion, high mortality and the organ most frequently affected by the both syndromes were the lymph nodes (100%).

**Type of lesions and patterns associated on porcine circovirus type 2 in organs of positive swine for immunohistochemistry**

Monica Quintal2 Jose L. Guillermo1 Jorge C. Rodriguez1 Marco A. Torres1 Raquel Miranda1 Rafael Colin1
1. University of Yucatan, Merida, YUC, Mexico; 2. Patologia Animal, Merida, YUC, Mexico

**Introduction**
Porcine Circovirus type 2 (PCV2) is an emerging disease of swine that has been associated in the development of other diseases. Currently there are various diagnostic tools and techniques available for the detection of PCV2; however, the immunohistochemistry (IHC) is considered the gold standard for the detection of this disease1.

The objectives of the present study were to demonstrate the existence of the PCV2 antigen by IHC, and to determine the distribution patterns of histopathological lesions suggestive to PCV2 in different organs and tissues.

**Materials and Methods**
An observational study was realized on a farm with semitechnified intensive production system and full breed cycle. The type of sampling was not probabilistic for convenience. Sample sizes were 22 pigs. Whereas a population of 1400 pigs, an estimated prevalence of 30%2, 3 and a confidence level of 99.5% using formula: \( n = \left[1 - (1 - p) \frac{1}{D}\right] \left[N - D/2\right] + 1 \) 64.

Post mortem studies were performed in discarded pigs between 4-22 weeks of age. The method of euthanasia was electrostunning established by the NOM -033-ZOO 1997. Organs of 22 pigs with macroscopic lesions suggestive to PCV2 were sampled. The organs studied were lymph nodes, spleen and tonsils, lung, kidney, liver, skin and ileum. The tissue sections were fixed for 24 hours in 10% formalin pH 7.4 processed by the standard method of embedding in paraffin, and stained with routine staining H & E, for subsequent microscopic observation. The PCV2 antigen was detected by IHC using the system avidin-biotin-peroxidase as described by Ramos-Vara5.

**Results**
The microscopic lesions suggestive to PCV2 on lymphoid organs were: histiocytic infiltrate 68% (15/22) on spleen, 63% (14/22) lymph node and 54% (12/22) tonsil, lymphoid depletion was observed 40% on lymph node, on 20% (4/22) spleen and tonsil. On epithelial organs the most common lesions were hepatitis lymphohistiocytic periportal, 77% (17/22) interstitial lymphoplasmacytic nephritis with giant cells 36% (8/22) membranoproliferative; glomerulonephritis 13% (3/22), on ileum lymphoplasmacytic enteritis 59% (13/22), depletion of mucosa associated lymphoid tissue (MALT) 22% (5/22) and multinucleated giant cell 4.5% (1/22); on skin lymphoplasmacytic histiocytic perivascular dermatitis 31% (7/22); necrotizing neutrophilic leukocytoclastic vasculitis 22% (5/22); on lungs lymphoplasmacytic histiocytic bronchitis and bronchiolitis 72% (16/22) and interstitial pneumonia 31% (7/22).

22 pigs evaluated by IHC technique, were positive, at least in one organ, where positive antigen-antibody reaction was detected on lymph node 98% (21/22), tonsils 98% (21/22), spleen 98% (21/22), lung 68% (15/22), ileum 68% (15/22), kidney 5% (1/22), and liver 4% (1/22). All skin samples resulted negative.

The frequency of IHC positive cases by stage of production were: on weaning stage 8 (36%) positive tissues of lymph nodes and spleen and 9 (41%) tissues of tonsils. On feeding stage 11 (50%) positive tissues of lymph nodes and spleen and 10 (45%) tissues of tonsils.

The grade of immunopositive observed in the lymphoid organs in weaning pigs were uniform for spleen, lymph nodes and tonsils, with ratings of mild, moderate and strong unlike feeding pigs where 27% (6/22) in the spleen, lymph nodes and tonsil, were strong grade.

The grade of immunopositive in epithelial organs were variable in ileums 27% (6/22) were moderate in the lungs 31% (7/22) were weak in the kidneys there were not difference 9% (2/22) for three categories and the liver with 4% (1/22) that corresponded to grade of strong immunopositive, skin tissues without positive reaction.

**Discussion**
The relevance of the present study has demonstrated that tissue samples from lymph node, spleen, tonsil, lung, liver, ileum, and kidney should be the collected for routine and specialized PCV2 analysis. This study is the first of its kind in Mexico.

Correlation between qPCR and virus isolation for the quantification of porcine circovirus type 2 in tissue samples from naturally infected pigs

Ann B. Cay1 DJ Lefebvre1, 2 Y Van der Stede 1 C Miry3 HJ Nauwynck2
1. CODA-CERVA-VAR, Brussels, Belgium; 2. Laboratory of Virology, Faculty of Veterinary Medicine, Ghent University, Merelbeke, Belgium; 3. DGZ, Animal Health Care Flanders, Torhout, Belgium

Introduction
Porcine circovirus type 2 (PCV2) is the causative agent of several diseases that are grouped as porcine circovirus(-associated) disease (PCV(A)D) (1). The diagnosis of PCVD is primarily based on the presence of high amounts of PCV2 antigen or nucleic acids associated with microscopic lesions in lymphoid tissues and/or the foetal/neonatal heart (1). For routine PCV2 quantification, immuno-histochemistry, immuno-fluorescence, antigen-capture ELISA, virus isolation (VI), in-situ hybridization (ISH) or quantitative PCR (qPCR) are used (1). The present study aims to define the correlation between qPCR and VI in tissues from naturally PCV2-infected pigs.

Materials and Methods
Thirty-one different tissue samples from weaners and growers that were suspected of PCVD based on clinical symptoms and historical findings, were collected and submitted to the regional laboratory for histopathological and virological analysis. Lymph nodes, spleen and/or lungs were homogenised and the tissue suspensions were titrated onto PK-15 cells. A titre of >=104.5 TCID50/g tissue correlates well with histopathological lesions and was considered to be suggestive for PCVD (2). Simultaneously, tissue suspensions were analyzed by an ORF2-based real-time qPCR developed in the CODA-CERVA-VAR laboratory (home-made realtime-qPCR) and modified from previously described techniques (3,4). A Pearson’s correlation coefficient with a 95% confidence interval was calculated on the log10 transformed values obtained in VI and RT-qPCR from all 32 samples.

Results
The Pearson correlation coefficient was between the log10 transformed values of VI and qRT-PCR was 0.72 [0.49-0.86] and can be considered as large (Fig1). The highest mean virus titre was found in the lymph nodes [4.5 ± 1.9], followed by the lungs [3.6 ± 2.3] and the spleen [3.0 ± 1.6]. The same pattern was observed for the qRT-PCR: highest mean viral load found in lymph nodes [8.5 ± 3.5], followed by the lungs [8.2 ± 2.9] and the spleen [7.6 ± 4.3]. However, the differences between the sample tissues were not statistically significant.

Discussion
Previously, it was shown that >=107 genome copies per 500 ng DNA is suggestive for PCVD and correlates well with the results of ISH (3,5). In this study, virus titres and the number of genome copies were both expressed per g tissue. We could correlate a PCVD-suspected virus titre of >=104.5 TCID50 with a viral load of >=1010 genome copies, suggesting that our newly developed high throughput qPCR may be a valid alternative for time consuming VI. Although no significant differences could be found between the different tissue samples, the highest virus titre and viral load was found in the lymph nodes, confirming previous results (3).

Conclusion
Based on the correlation between VI and qPCR and given that a titre of >= 104.5 TCID50/g tissue is suggestive for PCVD (2), we can conclude from this study that a viral load of >= 1010 genomes/g tissue can be suggestive for PCVD.

**Clinical case: porcine circovirus type 2 (PCV2) and mycotoxine presence in an abortion case**

V. Muller¹ Guillaume Perreu² Jean-Bernard Herin³ Thaïs Vila⁴ François Joisel⁴

1. Réseau Cristal, SELARL Müller, Bazouges, France; 2. MERIAL, Lyon, France; 3. Merial S.A.S., Ancenis, France; 4. Merial S.A.S., Lyon, France

**Introduction**

Porcine circovirus type 2 (PCV2) associated to reproductive disorders must be included in the differential diagnosis of the reproduction infectious causes (1).

The objective of this clinical case description is to show the implication of PCV2 in a series of repeated abortions and the impact of CIRCOVAC® vaccination on this issue.

**Case description**

This PRRS-free 200-sow farrowing farm is well managed. Buildings are complying with the new welfare EU norms « 2012 » with boars and gestating sows loose on straw. Since 2007, around 20 late abortion cases (3-4 weeks to 3-4 days before expected farrowing date) per year, independently of the parity were recorded. The number of mummified foetuses was variable and could reach 0.6 per litter. Weaned piglets were well-formed but showed heterogeneity among litters. Post-weaning and fattening site are located off site at a several-km distance from the maternity and did not experience any PMWS signs. Sow fertility was good (90%). All laboratory investigation aiming at the detection of other infectious agents possibly involved in the reproductive disorders remained negative.

Early 2009, 2 sows aborted without fever. A PCV2 quantitative PCR was performed on sera from and on the hearts and livers of their aborted foetuses. Sera of the sows and thoracic liquid of their aborted foetuse were also submitted for PCV2 ELISA (SERO-LISA® PCV2 Ab Synbiotics, Lyon, France).

Mycotoxin i.e. zearalenone (ZEA) and deoxynivalenol (DON) quantification in straw was performed by a certificated laboratory.

**Vaccination schedule**

Primovaccination against parvovirosis and erysipelas used to be performed systematically in quarantine followed by a booster during further lactations. After PCV2 diagnosis was confirmed, a vaccination with CIRCOVAC was carried out: 2 injections 3 weeks apart after pregnancy ultrasound check up due to practical sow containment aspects and a booster injection was administered 3 weeks before farrowing.

Abortions dramatically dropped down after primo-immunization from 3.6% to 1.3%.

**Results**

A high level of mycotoxines was revealed in the straw (see table 1) in 2007 and 2008. After gestating sow feed was supplemented with appropriate concentration of anti-mycotoxines additives, mycotoxines level dropped down to acceptable levels.

A reduction in abortion rate was observed as soon as the first batch was vaccinated, and then no abortion cases were noticed anymore.

## Discussion

Zearalenone is not known to be usually responsible for abortions even at as high doses as 50mg/kg of feed which were far to be reached in this case (2). PCV2 is now well known to be a possible abortion agent (3) and diagnosis got on the farm showed its involvement in several aborted foetuses organ pools. Consequently, PCV2 can be considered as highly suspected to be responsible for the abortions.

**Conclusion**

Altogether abortions occurring late in gestation, a positive PCV2 diagnosis in sows and their aborted foetuses, poor antibody titres in sow sera along with no other pathogens are in favour of PCV2 implication in these abortions. The additional observation showing that abortions sharply stopped after CIRCOVAC vaccination contributed to incriminate PCV2 as the etiologic agent in this abortion episode.

Genotype analysis of Chinese porcine circovirus type 2 in 2008-2009

Wenxiao Cui; Xin Guo; Xinna Ge; Hanchun Yang
China Agricultural University, Beijing, China

Introduction
Porcine circovirus type 2 (PCV2), a member of the Circoviridae family, is one of the most important pathogen affecting the swine industry worldwide. The genome of PCV2 is circular single stranded DNA with a size of 1767 or 1768 nucleotides (1, 2), which contains three major open reading frames (ORFs). The EU consortium proposes naming the three PCV2 genotypes as PCV-2a, PCV-2b and PCV-2c. Using this methodology, ORF2 sequences of PCV2 are assigned to different genotypes when the genetic distance between them is at least 0.035 (3). Our recent publication indicated that PCV2 strains in China could be divided into 5 major groups PCV-2a, PCV-2b, PCV-2d and PCV-2e. In this study, we analyzed the genetic variation and genotype of 54 Chinese PCV2 sequences collected between 2008 and 2009.

Materials and Methods
Fifty-five sequences of PCV2 were collected in 2008-2009 from 11 pig-producing areas of China. Total DNA was extracted directly from each clinical sample. PCR was performed to amplify the complete genome of PCV2. The PCR product was purified with a QIA quick PCR purification kit (Qiagen, Germany) and cloned into the pGEM-T easy Vector System (Promega, USA) according to manufacturer’s instructions. For each genomic DNA amplified, two clones from each of two independent amplifications were sequenced on both directions using the ABI Prism 3730 sequencer at Invitrogen (Beijing, China). The genomic homology analysis and comparison among the PCV2 sequences were performed using the Lasergene Package (DNASTAR Inc). The deduced amino acid sequences of the encoded capsid protein were aligned using the Clustal W method. Genotype determination was done by the criteria described previously (3).

Results
Sequence analysis. A total of 54 PCV2 sequences were obtained. Pairwise comparisons of PCV2 complete genomic sequence, ORF1 gene, ORF2 gene, ORF3 gene among 54 sequences exhibited that the nucleotide homology ranged from 94.7-100%, 96.7-100%, 90.0-100%, 95.9-100%, respectively and the ORF1, ORF2, ORF3 amino acid homology was 98.7-100%, 86.8-100%, 87.6-100% respectively.

Genotype analysis. Of the 54 Chinese PCV2 sequences in this study, 42 sequences belonged to genotype PCV-2d, 10 sequences were cluster in genotype PCV-2b, and 2 sequences were classified into genotype PCV-2e, indicating that genotype PCV-2d has become a dominating in China in 2008-2009.

Discussion
PCV-2d was firstly determined in China. This genotype of PCV2 has not been documented in other countries (4). ORF2 gene clustered in genotype PCV-2d encodes 234 amino acids, and the remaining genotypes encode 233 amino acids. Since the last codon of ORF2 gene (TGG) mutated to AAG, this resulted in the change of the reading frame and the addition of a lysine. In addition, the amino acid variations of ORF2 were found at three positions 89 (I/R to L), 90 (S to T) and 169 (S to R), which were unique for genotype PCV-2d. In our study, 42 sequences belonged to genotype PCV-2d, suggesting that genotype PCV-2d became dominating in China in recent two years. Therefore, much attention should be paid to the pathogenicity of this genotype to pigs.

Evaluation of a SYBR green real-time polymerase chain reaction assay for the quantification of porcine circovirus 2 genotype b in serum

Kwang Soo Lyoo; Seung W. Kang; Han Soo Joo
University of Minnesota, St. Paul, MN, USA

Introduction
Porcine circovirus 2 (PCV2) is identified as the major cause for post-weaning multi-systemic wasting syndrome (PMWS). The virus has now been classified into 2 genotypes of PCV2a and PCV2b. PCV2b genotype has been more frequently isolated from pigs with clinical PMWS1,2,3,4. Therefore, PCV2b has been suggested to be more pathogenic, although it is still debatable. The PCV2 genomic quantification test has become useful in the diagnosis of PMWS, because quantity of the viral genome in tissue samples from the affected pigs has been highly associated with the severity of PMWS. In this study, a SYBR green real-time PCR assay specific for PCV2b genotype was developed, and the results were compared to those by a nested PCR (nPCR). Although a PCV2 SYBR green real-time PCR assay was reported recently5, the assay was not aimed at differentiating between the two genotypes of PCV2.

Materials and Methods
Test sera were collected from 120 pigs in a Minnesota farm during severe clinical PMWS. A nPCR assay was conducted by the method as described previously4. For a PCV2b specific real-time PCR, the DNA fragment of 361 base-pair on ORF2 was subcloned into pGEM-T Easy vector, and the plasmid was transformed into JM109 cells. The copy number/μl was determined by the serially diluted plasmid. The real-time PCR assay was carried out using PerfeCTa SYBR Green SuperMix in a thermal cycler Mx3005P (Stratagene). All real-time PCR reactions were performed in triplicates in neighboring wells.

Results
The recombinant plasmid was constructed and the amount of input template copy numbers was calculated. The over range from 4.3x10^1 to 4.3x10^9 copies was obtained from the linear standard curve, which resulted in cycle threshold (Ct) values from 38.5 to 10.8 cycles and on the slope value of -3.49 (R^2). The dilution factor from the original serum sample to real-time PCR reaction was taken into consideration when PCV2b copy numbers were calculating. In a comparison between quantitative real-time PCR (qPCR) and nPCR, the real-time PCR was found to be 1,000 times more sensitive than the nPCR assay. A comparative result between the percentage of PCV2 viremic pigs by nPCR or qPCR, and the mean genomic copy number of PCV2b by qPCR using the same samples is shown in Table 1. Of the 120 sera, 79 (65.8%) and 13 (10.8%) were positive by the nPCR for PCV2b and PCV2a genotype, respectively, whereas 98 (82%) sera were detected as PCV2b positive by qPCR assay. The copy number of PCV2b DNA ranged 3.66 - 10.01 log10 in 1ml of the serum samples.

Discussion
Higher prevalence of PCV2b genotype in association with clinical PMWS initially led us to develop a quantitative real-time PCR assay specific for PCV2b genotype. Most published real-time PCR assays for PCV2 infection were aimed at quantification of PCV2 without differentiation between the two genotypes. Development of a multiplex real-time PCR assay was reported to differentiate the two genotypes. However, the present SYBR green real-time PCR was found to be simpler to perform and less expensive when compared to the probe type in the multiplex PCR. In conclusion, the present assay could be highly valuable for PMWS diagnosis, especially if PCV2b genotype is more important factor for clinical PMWS.

Epidemiologic observation of PCV2 genotype infection and seroprevalence during and after clinical outbreaks of PMWS in commercial farms

Kwang Soo Lyoo; Nam H. So; Han Soo Joo; Peter Davies
University of Minnesota, St. Paul, MN, USA

Introduction
Post-weaning multi-systemic wasting syndrome (PMWS) has been an economically important disease in the U.S. since early 2006. Commercial PCV2 vaccines have been widely used on pig farms to prevent the development of PMWS and to reduce the economic losses. It has been suggested that PCV2 viremia and the antibody responses are integral to the development of PMWS in pigs. In order to better understand these relationships, we compared the prevalence of the viremic pigs with PCV2a and 2b genotypes and PCV2 antibody titers during (2006) and after (2008) clinical PMWS outbreaks on commercial swine farms.

Materials and Methods
Five farms in Minnesota were selected based on the clinical histories of severe PMWS in 2006, and absence of clinical signs in 2008 following implementation of PCV2 vaccination. A total of 230 serum samples from pigs between 4 and 16 weeks age were collected from the 5 farms in 2006. In 2008, blood samples were collected from 322 pigs of the similar age groups at the same 5 farms. Differential nested PCR for PCV2 genotypes was performed to detect viremic pigs. PCV2 antibody titers were tested using both IFA and SN tests. The percentage of PCV2 viremic pigs, mean IFA and SN antibody levels were analyzed by parametric and non-parametric test, respectively, using SPSS software to test the differences during and after the clinical PMWS in the 5 farms.

Results
Across all 5 farms, the prevalence of PCV2a viremic pigs decreased from 11.1% in 2006 to 2.5% in 2008. Prevalence of PCV2b viremic pigs decreased markedly from 66.6% in 2006 to 11.0% in 2008. Mean viremic pigs for both genotypes were significantly lower in 2008 when compared to those in 2006. The mean IFA titer of the grow-finish pigs was significantly lower in 2008 (7.6 log2) than that in 2006 (10.7 log2) (Fig. 1). The mean SN titers for the nursery and grow-finish phases in 2008 were significantly higher than those in 2006 (P<0.001 and P<0.005, respectively) (Fig. 2).

Discussion
Both the prevalence and level of viremia were significantly higher during clinical outbreaks in 2006 than following vaccination in 2008. The changes were more marked for PCV2b than PCV2a genotype supporting a greater role of PCV2b in the clinical outbreaks. This observation was similar to the previous findings by others. The IFA antibody titers were higher during clinical PMWS in 2006 than in 2008 indicating evidence of PCV2 infection. In contrast, SN antibody titers were higher in 2008 in the absence of clinical disease suggesting a likely protection effect against clinical PMWS. The higher SN antibody levels in the nursery pigs could be due to high maternal antibody and/or recent PCV2 vaccination.

**Porcine Circovirus Type 2 (PCV2) In Utero Seroconversion, Early Viremia, And Serological Profile In Naturally Infected Piglets**

Priscilla Gerber; Flávia Garrócho; Zélia Lobato  
Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil

**Introduction**

Reproductive disorders associated with PCV2 are characterized by abortion, stillbirth and mummified foetuses, with symptoms varying according to gestational age at the time of infection. Although PCV2 in utero infection was well characterized, little is known about its occurrence in naturally infected pigs and its consequence the onset of porcine circovirus diseases (PCVD) in the postnatal period.

The aims of this study were to describe PCV2 peripartum infection and PCV2 serological profile in naturally infected piglets.

**Materials and Methods**

Twenty PCV2 sows vaccinated with CIRCOVAC (Merial) were studied. One hundred piglets (5 pigs/sow) were ear-tagged at birth. Colostrum, serum and piglets’ presuckle serum were collected at the day of parturition (DP). Milk samples were collected at day post-partum (DPP) 20. Serum samples were taken and piglets were weighed at DPP 1, 20, 42, 63, 84.

Colostrum and milk were evaluated for infectious PCV2[1], total (TA) and neutralising (NA) antibodies[2]. Serum samples were evaluated for PCV2 DNA[4], TA, NA, IgA and IgM anti-PCV2[3].

Non-normally distributed variables were analysed using the Mann–Whitney tests. Differences were considered significant when P<0.05.

**Results**

Sows had high levels of TA and NA in serum (11.63±1.32 log2; 9.51±1.01log2) and colostrum (12.32±0.00 log2). However, 11 out of 20 and 5 out of 20 colostrum and milk samples had infectious PCV2 (1.96±1.02 log10 TCID50/50μl and 0.30±0.58 log10 TCID50/50μl). PCV2 DNA was detected in serum of 17 out of 20 sows (2.02±0.89 PCV2 log10 copies/ml of serum) in DP.

Nine piglets were born with low levels of anti-PCV2 antibodies, ranging from 4.32 to 8.32 log2 TA titre. In DPP1, PCV2 DNA was detected in 29 piglets’serum samples, ranging from 2.00 to 3.97 PCV2 log10 copies/ml of serum. There was no difference between the weight of viremic and non-viremic piglets (Table 1). IgM anti-PCV2 levels started to increase at DPP42, followed to seroconversion to TA and NA and decline of IgM levels at DPP84.

**Discussion and Conclusions**

Piglets were born with anti-PCV2 antibodies, indicating PCV2 in utero transmission after the period of immunocompetence. This result suggests occurrence of vertical transmission even in farms where sows have high titres of anti-PCV2 antibodies and in absence of reproductive failure associated to PCV2 (data not shown).

Vaccination of sows could not prevent PCV2 shedding intocolostrum and sow viremia at DP even in the presence of high levels of PCV2 NA. PCV2 in utero transmission or early infection resulted in viremia in the first day of life of piglets. Even with the early PCV2 infection, piglets seropositive at birth and viremic at DPP1 had similar weight to non-viremic and seronegative piglets, maybe due to low PCV2 DNA levels found, and the absence of PCVD clinical signs.

Regardless of piglets’ early viremia, PCV2 IgM raised only at DPP42, suggesting that PCV2 was able to stimulate the immune system only after the passive antibodies decay at subprotector levels (Fig. 1). Seroconversion to PCV2 TA and NA at DPP84 coincides with the decline of IgM anti-PCV2 levels, apparently controlling PCV2 infection.

In conclusion, vertical transmission of PCV2 may occur generating viable piglets at birth without losses in growth rate. Sows vaccination may not prevent PCV2 viremia at parturition and virus shedding into colostrum.

Naturally porcine circovirus type 2 (PCV2) exposed pigs generate a specific antibody response able to neutralise different PCV2 isolates of different genotypes and geographic origins

Sherry Kurtz; Martí Cortey; Maria Fort; Marina Sibila; Joaquim Segales

Centre de Recerca en Sanitat Anima (CReSA), Bellaterra, Spain

Introduction

Porcine circovirus type 2 (PCV2) vaccines are able to induce a strong humoral immune response. Their neutralizing antibody response is apparently cross-protective against both predominant PCV2 genotypes (PCV2a and PCV2b) (2). Also, PCV2a infection protects against a subsequent PCV2b challenge, presumably through cross-neutralizing antibodies (NA) (5). It is also known that there are several epitopes (detected by monoclonal antibodies) in the PCV2 Cap protein that are shared between different genotypes, as well as PCV1 (4,6), which represents a putative basis for cross-neutralization. However, there were several strains for which there was little or no neutralization using the same antibody panel. This suggests the existence of antigenic variability between PCV2 genotypes. However, these studies describing antigenic variation have been done using monoclonal antibodies, which are specific for unique epitopes. Therefore, the objective of the present study was to further insight on PCV2 antibody neutralization by using a pig sera obtained from field studies to assess the level of antigenic variation by cross-neutralization amongst different isolates of PCV2. Viral isolates used were from different geographical regions.

Materials and Methods

Serum samples. A total of 82 sera were used for the present study. A first group of animals corresponded to PMWS affected pigs (n=20), which where found to be infected by PCV2b strains (3). A second group was composed of age-matched healthy pigs (n=17) from the same farms, and a proportion of them also infected with PCV2b strains. Finally, in order to get sera samples from animals that would have been exposed to PCV2 in the past, randomly sampled slaughter age pigs (n=45) were taken.

PCV2 neutralization test. Neutralization assays were carried out as described (1) using two PCV2a (Burgos and Stoon-1010) and two PCV2b (MO/S-06 and Sp-10-7-54-13) isolates. Burgos and Sp-10-7-54-13 strains were isolated from postweaning multisystemic wasting syndrome (PMWS) affected pigs in Spain, while Stoon-1010 and MO/S-06 were isolated from PMWS in Canada and United States, respectively.

Total PCV2 antibody test. An immunoperoxidase monolayer assay (IPMA) technique to detect antibodies to PCV2 (1) was also performed with all available sera and compared to the different neutralization values obtained.

Results

Most of the sera were able to neutralise the four PCV2 strains used in the test, even they differed in their antibody titre. Globally, PCV2a genotype strains used in the test originated significantly higher neutralising antibody titres when compared to those against the PCV2b genotype. No differences in NA titres were observed between PCV2 strains within the same genotype. In addition, NA titres detected in healthy and slaughterhouse animals were significantly higher compared to PMWS affected pigs. No statistical significant differences were detected in the neutralizing activity of sera obtained from either healthy, PMWS, or slaughterhouse pigs when tested to PCV2 strains of different geographical origin. Finally, there was no direct correlation between IPMA and neutralizing titres detected in any of the animal categories.

Discussion

The present study sought to examine the role of antigenic variability in the context of a natural infection. Pig sera of different animal categories were able to neutralize PCV2 strains from different genotypes and geographical regions. This point seems to be extremely important, since would explain the field evidence that PCV2 vaccines available in the market (all based on PCV2a strains) show efficacy in controlling PMWS independently of the causing genotype (2). However, the differences observed in the NA titres of the tested sera when either PCV2a or PCV2b strains were used as antigen in the test suggest the existence of antigenic variability among those strains.

Introduction
Porcine circovirus type 2 (PCV2) is considered to be essential but not sufficient for postweaning multisystemic wasting syndrome (PMWS) development. Thus, several co-infections have been suggested as triggers for disease development in the field (1). The aim of the present study was to gain further insights on infectious agents as potential risk factors for PMWS development.

Materials and Methods
Two longitudinal case-control studies in 13 PMWS-affected farms from Spain and Denmark were performed as previously described (2). Blood samples from pigs (approximately 100 per batch coming from 10 sows) were longitudinally collected throughout their productive life. Pigs showing PMWS-compatible clinical signs were bled and euthanized together with healthy age-matched pigs (ratio 2:1). PMWS was diagnosed and pigs were classified into three categories: i) PMWS cases; ii) wasted non-PMWS cases; iii) healthy pigs (2).

Serological analyses were performed in all collected serum samples to detect antibodies against Porcine reproductive and respiratory syndrome virus (PRRSV), Porcine parvovirus (PPV), Swine influenza virus (SIV) and Lawsonia intracellularis (Law) in both countries. Moreover, in Spain, antibodies against Mycoplasma hyopneumoniae, Aujeszky’s disease virus and Salmonella spp. were also assessed.

A Cox proportional hazards model was used to investigate the simultaneous effects of seroconversion and maternal immunity against the studied pathogens in each country. Data were analysed within a survival analysis framework, where development of PMWS was considered as death/failure. All analyses were carried out using the Splus® software package, version 6.1.

Results
The number of studied pigs and their pathological classification is displayed in table 1.

Results from survival analysis showed that, for the Danish dataset, seroconversion against Law and PPV had a protecting effect. For animals that seroconverted against Law, the protective effect increased with the level of maternal immunity against this pathogen. Maternal immunity against PPV gave a protective effect in Spanish dataset. Moreover, high levels of maternal immunity against PCV2 had a protecting effect in both countries.

Discussion
Maternal PCV2 antibodies in both Danish and Spanish data showed a protecting effect against PMWS development, which is in agreement with previous studies (3). This situation would support the interest of PCV2 vaccination in sows in order to transfer a higher load of PCV2 antibodies to the offspring.

The protective effect of maternal immunity against PPV is in agreement with previous works suggesting PPV as a co-infectious trigger (4). Besides, the fact that seroconversion against PPV and Law resulted protective for PMWS development could seem contradictory. However, the present analysis was based on antibody levels, and not on direct evidences of pathogen infection. Since it is known that PMWS affected pigs are immunocompromised (5), seroconversion may indicate a well-developed immune system, which in turn will make the animal less likely to develop PMWS.

Introduction

Traditional postweaning multisystemic wasting syndrome (PMWS) diagnosis requires the necropsy of suspicious animals and the access to histopathological expertise (1). One of the major differences between PMWS-affected and non-affected pigs is porcine circovirus type 2 (PCV2) load in serum and tissues (2,3,4). Consequently, real-time quantitative PCR (qPCR) has been proposed as a potential diagnostic alternative. However, sensitivity and/or specificity of qPCR on individual basis are relatively poor (5). The main objective of the present study was to analyze the applicability of qPCR to detect PCV2 loads in pooled serum samples, with the purpose of increasing the diagnostic capacity of the qPCR technique. A second objective was to develop an easy-to-use PMWS qPCR-based diagnostic recommendation at the herd level, without the need to perform post-mortem examinations.

Material and Methods

Firstly, a theoretical model based on two qPCR viral load thresholds (3,4) to discriminate between PMWS affected and non-affected pigs was validated with an experimental pooling study considering pools of 3, 5, 10 and 20 randomly selected individuals. Secondly, pool sensitivities (PSe) and pool specificities (PSp) were estimated by means of Monte Carlo simulations. Such pooling included sera from diseased pigs with a PMWS diagnosis (PMWS), diseased pigs without fulfilling the diagnosis of PMWS (wasted-non-PMWS) and healthy (healthy) animals. Using only the PMWS diagnosed individuals and the wasted-non-PMWS, a second pooling approach considering targeted sampling (animals showing clinical signs compatible with PMWS) was simulated as an option to increase sensitivity at herd level. If targeted sampling is used, the probability of detecting the disease would be theoretically increased. The PSe and PSp obtained previously were used to estimate the sensitivities and specificities at herd level (HSe and HSp) for both approaches. Finally, we evaluated the capability of the model to discriminate between PMWS-affected and non-affected farms using qPCR real and simulated pools.

Results

Several pools of 20 individuals did not report correct results in the experimental study, most probably caused by handling difficulties. Therefore, Monte Carlo simulations considered only pools of 3, 5 and 10 individuals. The best HSe and HSp estimations were obtained using a single pool of 10 individuals or two pools of 5 individuals under the random sampling scenario. Targeted sampling reported worst estimations than random sampling, mostly because wasted-non-PMWS individuals showed higher qPCR values than healthy ones, making in this case difficult the differentiation of truly affected and non-affected individuals. However, the model correctly discriminated and identified most of the PMWS-affected and PMWS-non-affected farms despite some false-positives and false-negatives were reported.

Discussion

Assuming that the qPCR data used (3,4) are representative of the field situation, present results suggest that sample pooling may be a suitable strategy for PMWS diagnosis. Sera pooling offers several advantages compared with classical PMWS diagnostic methods. First, it represents a cost saving strategy, since more individuals can be analyzed using the same fixed analysis expenses. Second, the use of qPCR is performed in an easy-to-get sample and, therefore, it does not require histopathological expertise, indispensable with a necropsy based method.

Results of one-shot Circovac® vaccination at 0.5 ml in piglets on weight and mortality parameters

Bernhard Heissenberger; Andrea Ladinig; Christiane Lang; Christiane Püschel; Mathias Ritzmann
Clinic for Swine, Vienna, Austria

Introduction

Since the first report in 1996 (1) porcine circovirus type 2 (PCV2) diseases had a major impact on the swine industry worldwide. Since June 2007 Circovac® (Merial, Lyon, France), an inactivated PCV2 vaccine for swine is centrally registered in Europe for protection of the offspring of vaccinated sows and gilts by passive immunization (2).

The objective of this field study was to evaluate the efficacy of Circovac® administered once to three week old piglets at a dosage of 0.5 ml intra-muscularly (i.m.).

Materials and Methods

The study was randomised, controlled, blinded and conducted on an Austrian 250-sow farrow-to-finish farm with severe problems especially during the fattening period caused by PCV2. In total 1105 piglets were included in this field trial. They were randomly allocated to the vaccination group, which received 0.5 ml Circovac® i.m. at weaning, or to the placebo treated control group. Control and vaccinated piglets stayed intermingled. The body weight was determined at birth, weaning (3rd week), the end of nursery (13th week), in the middle of the fattening period (21st week) and at the end of the fattening period (28th week).

Wasting animals were defined as animals whose body weight was at least 25 % lower than the average of the respective group. All animals were monitored for clinical symptoms and mortality was recorded during the whole study period.

Results

An important parameter of this study was the evaluation of average daily weight gain. A significant difference of the daily weight gain between both groups occurred during the entire fattening period in favor of the Circovac® vaccinated group (+41.43g/d; p<0.0001). The main viremia period on this farm occurred during the first half of fattening (from 13th to 21st week), when the difference in ADWG was most obvious (+64.83 g/day, p<0.0001), which is shown in figure 1. The number of wasting animals was reduced by 5.15 % (p<0.044) in the Circovac® vaccinated group during the first half of fattening (13th – 21st week), the period of main viremia. The mortality rate during the fattening period was significantly reduced (-7.4%) in the vaccinated group (p<0.0001). As expected the difference in mortality was highest during the main viremia period. (Figure 2).

Discussion

Compared to a placebo treated control group, Circovac® vaccinated animals showed significant improvements. Vaccination resulted in reduction of mortality rate, increase of daily weight gain and reduction of wasting animals during the course of the study and particularly during the main viremia period.

Analysis of occurrence of porcine circovirus type 2 (PCV2) in PMWS-like pigs from farms in Slovak Republic

Juraj Pistl; Tomas Csank; Michaela Vlasakova; Jana Pollakova; Anna Jackova; Stefan Vlček
University of Veterinary Medicine and Pharmacy, Košice, Slovak Republic

Introduction
Circoviruses are small DNA viruses, which infect number of animal species. The most important circovirus in swine is porcine circovirus type 2 (PCV2), whereas, the most frequent clinical form of circovirus infection is the post-weaning multisystemic wasting syndrome (PMWS). The disease has been reported in most of the European countries (Segalés, 2007). Hitherto, the epidemiological situation of PMWS in Slovakia was not well understood and the country held unknown PMWS status (Segalés, 2007). Any official data about PCV2 detection and surveillance were missing. On this background, the research was focused on the detection and isolation of PCV2 from pigs with PMWS-like symptoms based on generally accepted scientific criteria (biological and moleculo-genetic methods), and prevalence of specific antibodies.

Materials and Methods
86 post-weaning (42-50 days old, body weight 7.2–9.4 kg) Landrace and Slovak Large White pigs suffering from PMWS-like clinical symptoms were selected from twelve pig farms from different regions of Slovakia. More than 40% morbidity and up to 15% mortality in weanlings was observed in the farms with wasting and respiratory disorders. Immunohistochemistry allowed us to prove PCV2 in cryosections of lymph nodes. Immunoperoxidase test (IPMA) was used to confirm PCV2 in cell culture PK-15 (Sanchez et al., 2001). A 263bp fragment from the ORF2 genome region was amplified using primers CF8 and CR8 (LaRochelle et al., 1999). Nucleotide sequences of PCV2 amplified fragments were analyzed by BLASTn analysis to find out similar sequences in GenBank. IgM and IgG specific PCV2 antibodies were detected by ELISA (Ingezin circovirus IgM/IgG, Ingenasa, Spain).

Results
All investigated pigs were clinically characterized by severe growth retardation, emaciation and marked spine. 52 weanling pigs (60.5%) were PCV2 positive. Massive occurrence of PCV2 infected cells was particularly seen in inguinal lymph nodes. PCV2 virus positive macrophages were located mainly in medullar cords along with paratrabecular sinuses of lymph nodes. The similarity search in BLASTn showed 100% sequence matches with Austrian AUT5 PCV2 strain (Accession number AY424405.1) and some Chinese strains as well. Based on the ratio of positivity/negativity, the coefficient of infection rate in individual farm was calculated. In four farms from twelve the coefficient of infection rate was 1.0, which indicates high prevalence of PCV2. In other farms coefficient was between 0.40 – 0.71, which indices actual risk of PMWS. A zero coefficient was present in only one farm. These results show high prevalence of PCV2 with occurrence of PMWS in pig farms of Slovakia. Prevalence of specific PCV2 antibodies in animals tested was 50.5%. In 51.5% of samples both IgM+IgG antibodies were detected. 13.2% of samples showed presence of IgM, while 35.3% samples had IgG antibodies.

Discussion
In the Central Europe the diagnosis of PMWS and detection of PCV2 was reported first time in Hungary (Kiss et al., 2000). Later the disease was reported in Austria (Schmoll et al, 2002), Czech Republic (Celer jr and Carasová, 2002) and Poland (Stadejek et al., 2006). The first detection and isolation of PCV2 from PMWS animals in Slovakia based on the generally accepted diagnostic criteria (Sorden, 2000) was published in 2009 (Pistl et al., 2009). Present study was focused to provide data on the evidence of PCV2 in PMWS-like pigs from other Central European country – Slovakia. Our work demonstrates the evidence of PCV2 in the PMWS-like affected pigs, determined on the basis of highly suggestive clinical and pathological symptoms, antigenic and genetic methods that clear the epidemiological situation of PCV2 in the pig farms of Slovakia.

Presence of viral pathogens in cases of porcine respiratory diseases complex (PRDC) in central Italy

Stefano Petrini; Marta Paniccià; Valentina Silenzi; Sara Briscolini; Chiara Magistrali; Giovanni Filippini; Marco Sensi; Stefano Gavaudan; Francesca Ciuti; Manfredo Fortunati; Giovanni Pezzotti
Istituto Zooprofilattico Sperimentale dell’Umbria e delle Marche, Perugia, Italy

Introduction
Porcine respiratory disease complex (PRDC) in pigs is one of the most relevant health concern for swine production today. As with respiratory disease in humans and other species, this complex in swine is often the result of the combined action of primary and opportunistic infectious agents. Primary agents in pigs include viral agents (1-2-3), like European type of Porcine Reproductive and Respiratory Syndrome Virus (PRRSV-EU), Porcine Circovirus type 2 (PCV2), Swine Influenza Virus (SIV) and Suid herpesvirus type 1 (SuHV-1). The objective of the present work was investigate the presence of these major viral infection agents in cases of PRDC in central Italy (Umbria and Marche Regions).

Materials and Methods
A total of 527 pigs with PRDC were observed between years 2007 and 2009, originating from 58 herds were no vaccination against the above mentioned viral agents was adopted. There was no epidemiological relation between these herds; however, a common clinical history was reported, with animals showing severe symptoms of respiratory disorder, high mortality and increased number of culled pigs. Morbidity ranged from 30% to 70%, with an average mortality of 4% to 6%. Necropsy was carried out at the Istituto Zooprofilattico Sperimentale dell’Umbria e delle Marche where different organs (lung, kidney, liver, spleen, palatine tonsil, lymph node, small intestine, uterus, ovary, abortion) were collected for histology and virus isolation using NSK cell culture. In particular the presence of PRRSV-EU, PCV2, SIV, SuHV-1 was evaluated.

Results
Most of the animal examined appeared in poor body conditions. Macroscopic lesions were essentially observed in the apical lobes of the lungs, showing pneumonitis, bronchial and bronchial necrosis, purulent bronchopneumonia, pulmonary haemorrhages and fibrous/fibrinous pleuritis. In the palatine tonsils petechial haemorrhages were observed while the bronchial lymph nodes appeared enlarged and pale. Histology confirmed the presence of the lesions in the lungs, palatine tonsils and the lymphoid tissues were giant multinucleate cells, peribronchial mononuclear infiltrates, fibrous bronchiolitis, granulomatous inflammation, coagulative necrosis and haemorrhages were found. No significant lesions were observed in other organs. Viral pathogens detected from the samples are summarized in Table 1.

N.I., Not isolated; N.D., Not determined

Discussion
The present study has contributed to clarify the role of the major viral agents in the occurrence of PRDC in pigs in the farms of central Italy. In particular, PCV2 was the most frequent agent, found in 55.97% of the cases followed by PRRSV in 39.65% of the animals. Only in few cases (2.46%) an association between these two viruses was found. Significant differences have been therefore observed in respect to other geographical areas, such as Spain (5), where PCV2 has been found in lower percentages (39.2%) or Korea (3) where, instead a frequent (55%) co-infection of PCV2 and PRRSV has been described. No positive samples for SIV or SuHV-1 were recorded, demonstrating a minor epidemiological role of these agents in the epidemiology of respiratory disorders in this area. Also in respect to this, different situations have been described in Spain, where SIV occurred in 4.1% of the cases and SuHV-1 in 1.4% and in Korea, where 13.3% of the samples from resulted positive to SIV.

Free piglets. An unusual feature of disease pathogenesis is a delayed onset of clinical disease following virus challenge and the subsequent rapid decline in the health of diseased piglets. Here we report evidence for development of antinuclear antibodies (ANA) in sera of germ-free pigs infected with PCV2.

Materials and Methods

A conserved amino acid sequence based on the published capsid protein sequence of PCV2a was used to make a synthetic peptide and to immunize rabbits for PCV2-specific antiserum production.

A series of animal studies were conducted with germ-free piglets derived aseptically from crossbred sows by cesarean section. Piglets were housed in sterile, stainless-steel pentub isolators (4 pigs/isolator) and fed a commercially-available pasteurized milk diet. Each pig within an isolator received the same treatment, either PCV2 or a sham inoculation at about 7-10 days of age. In comparative viral pathogenesis studies, different groups of pigs were similarly challenged with swine influenza virus.

ANA were measured by two independent methods: 1) a fluorescent microscope slide-based indirect immunofluorescence assay (IFA) (SCIMEDX HEP2 ANA IFA, Denville, NJ) and an ANA ELISA (QUANTA Lite ANA, INOVA Diagnostics, Inc., San Diego, CA) modified by using an anti-swine IgG secondary antibody (KPL, Inc., Gaithersburg, MD).

Results

To investigate PCV2 replication in tissue culture, a conserved peptide of the PCV2 nucleocapsid was produced to make polyclonal antisera in a rabbit. Initial testing with this antiserum revealed significant background staining of a porcine kidney cell line (PK-15) used to propagate PCV2 in our laboratory. The staining was most prominent in the nuclear region of PK-15 cells and was present regardless of the PCV2 infection status of the cells, suggesting the antiserum was recognizing nuclear antigens unrelated to PCV2. This led us to investigate the presence of ANA in piglet sera from prior germ-free isolator studies with PCV2 and other viruses.

Thirty-eight pigs used in 3 separate studies were found to be free of ANA on the day of inoculation with virus. In these studies, 21 of 38 piglets infected with PCV2 isolates developed detectable ANA of the IgG isotype based on the Hep-2 IFA ANA test. Most piglets that developed ANA did so by 18-25 dpi with PCV2. In contrast, 7 piglets infected in 2 separate studies with a swine influenza virus remained free of detectable ANA. To confirm these semiquantitative findings, a subset of samples from one germ-free study were tested by an ELISA that collectively detects total ANA against chromatin (dsDNA and histones), Sm/RNP, SS-A, SS-B, Scl-70, centromere and PCNA, as well as antibodies against cytoplasmic antigens such as Jo-1, mitochondria (M-2) and ribosomal-P protein. ELISA results demonstrated development of increasing levels of ANA over the course of a study in 9 of 12 piglets infected with PCV2 but not in 4 of 4 control virus-free piglets.

Discussion

Antinuclear antibodies are directed against normal nuclear antigens and are detected in sera of patients with autoimmune disease. Development of ANA in piglets infected with PCV2 preceded onset of clinical disease but not all pigs with ANA died. Finding ANA and a PCV2 capsid peptide that induced antibodies cross-reactive with porcine nuclear antigens suggests an autoimmune component to the pathogenesis of PCV2-induced disease in the germ-free pig model.

A study on the presence and DNA loads of porcine circovirus type 2 (PCV2) in feces samples

Gerard J. Wellenberg; Frits Bouwkamp
Animal Health Service, Deventer, Netherlands

Introduction
Up till now, there is hardly any information on the role of porcine circovirus type 2 (PCV2) in the development of diarrhea (enteritis), or in differences in PCV2 DNA loads in feces collected from pigs with and without enteritis. This study was performed to examine the presence and PCV2 DNA loads in feces from pigs with and without diarrhea (enteritis).

Materials and Methods
Feces samples from 51 pigs (n=46 farms) with diarrhea (enteritis) and from 11 pigs (n=11 farms) without diarrhea were examined for PCV2 DNA loads by quantitative PCR. Feces samples from pigs with diarrhea were also analyzed for the presence of Lawsonia intracellularis, Brachyspira hyodysenteriae and B. pilosicoli by PCR, E. coli, Salmonella spp by bacterial cultivation, coccidia and/or other parasites by microscopical examinations. The Student t-test and the one-sided Proportion test were used for statistical analyses.

Results
PCV2 DNA was detected in 23 (45%) of the 51 feces samples from pigs with diarrhea and in 5 (45%) of the 11 feces samples from pigs without diarrhea (Table 1).

*: 4 samples were examined for PCV2 only.

Discussion
PCV2 can be found in feces samples from pigs with and without diarrhea (enteritis), but;
• The mean PCV2 DNA copy load in PCV2 DNA positive feces was higher in pigs with diarrhea, and high PCV2 DNA copy loads (>10^4 copies/mgr) were found significantly more often in feces from pigs with diarrhea (enteritis)

Introduction

The correlation between the PCV-2 ORF3 gene and viral pathogenicity has been suggested previously. Three genogroups based on the ORF3 gene sequence (SG1, SG2 and SG3) were identified in Sweden and correlated to the PCVAD occurrence. The aims of this work were to determine the ORF3-based genotypes present in Brazilian herds, to establish their geographic distribution among main swine-producing states of Brazil and to correlate each genotype with lymphoid microscopic lesions.

Materials and Methods

Samples from 89 swines with clinical symptoms of PCVAD were collected in nine swine-producing Brazilian states. For histopathological evaluation, 44 samples were processed and the lesions were classified as discrete, moderate or severe. Thirty-three additional samples were collected from the same farms in a different time-point. DNA was extracted from the tissue suspension using guanidine thiocyanate and PCR product was purified and sequenced. The amino acid sequence alignment of the samples was made using Clustal W and phylogenetic tree was constructed based on the Neighbour Joining (NJ) method with 1000 bootstrap. Haplotype networks were constructed using the Network 4.2.0.1 software.

Results

The phylogenetic analysis of the ORF3 sequence allowed the identification of three genogroups (3.4% SG1, 12.3% SG2 and 84.3% SG3) and six subtypes (SG2A, SG2B, SG2C, SG2D, SG3A and SG3B). Furthermore, it was possible to observe that the majority of the samples were classified within subtypes SG3A and SG3B. The average distance of the amino acids was closer between the SG1 and SG2 genogroups. There was also a greater genetic proximity between the SG2A and SG2B subtypes and the SG3A and SG3B subtypes. Variations between SG1 and SG2 were detected at residues 41, 102, 103 and 104, and variations between SG1, SG2 and SG3 were detected at residues 41 and 103. Finally, the distance measured by the branch size was low, indicating a genetic proximity among the individuals. In samples from the same farm collected at a different time, 74.19% of the cases presented both samples were classified within the same genotypes (67.74% in SG3B and 6.45% in SG2D), whereas the remaining 25.81% of the samples were classified into different subtypes. When lesion severity was correlated with the ORF3 genogroup, subtypes SG1 and SG2 were associated with discrete lesions, SG3B was more frequently associated with discrete and moderate lesions, whereas SG3A was associated with moderate and severe lesions. Through the phylogeography analysis it was possible to group the sequences in 14 haplotypes. The H11 haplotype (from SG3B) grouped 55 (61.80%) representative sequences from the nine states and was considered to be the ancestral haplotype for SG3 due its ample dispersion.

Discussion

Our findings consist in the first identification of subtypes in SG2 and SG3 based on amino acids 102 to 104 indicating the emergence of PCV-2 genotypes in Brazilian herds. The presence of different ORF3 genogroups and subtypes in the nine states studied indicated the wide circulation of the PCV-2 variants. The change of genogroup in 32.26% of the samples from the same farms collected at a different time confirms these results. The frequency of the histopathologic lesions corroborates literature results, which suggested that the genogroup classification can be based on the description of the PCVADs present on the farm. Moreover it was also possible to observe that SG3A variants were more pathogenic than those in subtype SG3B. The detection of the SG1 genogroup in only three samples, which were associated with discrete lesions, is likely indicative of the low prevalence of this genogroup among animals with clinical signs of PCVAD, further it supports the hypothesis that genogroup SG1 is less pathogenic. The major number of samples was classified in the SG3B subtype, and its wide distribution in the haplotypes suggests that this PCV-2 variant circulated widely with only minimal alterations in the ORF3 sequences.

Introduction

The evolution of the PCV-2 genetic diversity has been intensely studied for a better understanding of the pathogenesis of the associated syndromes and development of prophylactic measures. The nonsynonymous, amino acid-altering/synonymous, silent, substitution rate ratio (ω = dN/dS) provides a measure of natural selection at coding regions, where ω = 1 represents neutral evolution; ω > 1 states positive selection, caused by an excess of nonsynonymous polymorphism and consequently increasing the rate (ω), while ω < 1, indicating purifying selection, where the new mutations are eliminated, probably due their deleting nature.

Materials and Methods

Alignment of the 27 ORF2 PCV-2 sequences plus 7 Genbank sequences (AY484416; AY682995; AY556476; AF117753; AY146993; AY256458; AF408635) were used. The amino acid sequence alignment was made using the CLUSTAL W software. The phylogenetic tree was constructed based on the Neighbour Joining (NJ) using the MEGA 4.0 software. Different measures of polymorphism variability and several statistics employed in neutral tests using the program DNAsp v.4.50.3 were used. The program CODEML from the software package Phylogenetic Analysis by Maximum Likelihood v. 4.2b (PAML) was used to fit models of sequence evolution to our circovirus type 2 dataset.

Results

In ORF2 all values LRTs indicated significantly better fits for the selection models M2 and M8 than the neutral models M1 and M7 respectively (Table1). Also, at the model M3, different omega values along the sequence fits better than M0 which consider the entire sequence, evolving under only one omega value. The codons that showed high values of omega are (69 R, 101 P, 185 S, with Probability of (omega > 1) > 95%). In addition, to the previous results provided for the likelihood analysis, tests of neutrality based on the sequence frequency spectrum (Tajima’s D; Fu and Li’s F) also provided evidences that corroborate these findings.

Discussion

Our work provided evidence that the ORF2 had undergone positive selection and identified 3 positively selected sites. Understanding the functional importance of these positively selected amino acid positions could help to predict possible changes in virulence, as well as responses to certain strains in future vaccination programs.

Introduction
Porcine circovirus type 2 (PCV2) is the cause of PCV2 associated diseases (PCVAD), a multifactorial disease that causes great economic impact on swine industry worldwide (2). Recently performed serological examinations indicated that this virus is widespread within the pig population (1). The aim of the present work was investigated the presence of antibodies against the PCV2 in pigs from commercial farms of the Northeastern States of Brazil detected by immunoperoxidase monolayer assay (IPMA).

Materials and methods
Herds and blood collection: 353 blood samples were collected from gilts with age between 20-28 weeks from 12 different farms of Northeastern States of Brazil. The major criteria used for the selection of the farms in the study were agreement permission the owners and no use of vaccines against PCV2. Second, the herd should be of at least 100 sows and monitored for the presence of clinical signs of the PCVAD.

Serologic analyses: Serum samples were evaluated for the presence of antibodies to PCV2 by IPMC (3). Serial dilutions of sera were performed from 1:20 to 1:5120 on 96 well plates containing fixed Swine Kidney (SK6) cells previously infected with PCV2. Titers equal or above 1:20 was considered positive and classified as low (1:20 to 1:160), medium (1:320 to 1:2560) and high (1:5120 or higher) titers.

Statistic analyses: The data were analyzed using the program R (R Foundation for Statistical Computing, 2009).

Results
The results show that 306/353 samples analyzed (86.7%) reacted against PCV2 antigens (equal or above 1:20). The results are summarized in Table 1 and Figure 1.

Discussion
The present study represents the first antibody survey against PCV2 in pigs on farms of the Northeast of Brazil. This ubiquitous infectious agent circulates in all farms, regardless of syndrome being present (1). The antibody profile titer in non vaccinated farms can be used to guide vaccination programs. Lower titers against PCV2 can were observed between the ages of 23 and 25 weeks. This result suggests that this period can be identified as a window in the herd immunity and it is suitable to implement vaccination programs.

Introduction
Postweaning multisystemic wasting syndrome (PMWS) is a disease that affects late nursery and fattening pigs. Diagnosis of PMWS is based on the presence of compatible clinical signs (mainly wasting and respiratory distress), characteristic histopathological lesions, and detection of PCV2 within characteristic lesions. Microscopically, the most relevant features are lymphocyte depletion and histiocytic infiltrates in lymphoid tissues. Therefore, the sole detection of PCV2 antibodies in serum and/or viral DNA or antigen does not constitute PMWS diagnosis, since it only indicates evidence of PCV2 infection. Histopathology and immunohistochemistry tests performed on a panel withdrawn from daily farm mortalities are fundamental tools for the diagnosis of PMWS. The objectives of this study were to evaluate the diffusion of PMWS in Northwestern Italy (Piedmont region) and the reliability of a histological grading in “farm diagnosis”.

Materials and Methods
Fourteen farms with clinical signs related to PMWS were selected and a questionnaire to evaluate their clinical and management situation was drawn up.

Three to five animals (4-16 weeks old) were necropsied and samples from lung, tonsil, tracheobronchial and superficial inguinal lymph node, spleen and ileum were collected from all pigs for histopathological and PCR analysis for PCV2. Portions of tissues were fixed in 10% neutral-buffered formalin and processed by standard paraffin wax techniques for histological analysis. Samples were cut in 4±2 μm sections and stained with haematoxylin and eosin (HE) and immunohistochemically (IHC) using a monoclonal antibody against PCV2 (Ingenansa, Spain). Lung sections were scored for the presence and severity of interstitial pneumonia ranging from 0 (normal) to 6 (severe diffuse); lymphoid tissues sections were evaluated for the presence of lymphoid depletion ranging from 0 (normal) to 3 (severe) and for histiocytic inflammation and replacement of follicles ranging from 0 (normal) to 3 (severe).

In addition, they were all tested by PCR for porcine reproductive and respiratory syndrome virus (PRRSV) and bacteriological and parasitological investigations were made on the basis of signs during necropsy.

Results
At post-mortem examinations some animals revealed mild to moderate hyperplasia in superficial lymph nodes and consolidation of lungs in association with broncopneumonia. Five of the 14 farms resulted positive for PMWS with at least one piglet showing typical lesions and immunohistochemical and molecular positivity. Lesion score for depletion target from 1 to 3 and for histiocytic inflammation from 1 to 2. Further 9 farms resulted negative for PMWS and lesion score resulted 0 or 1 for both depletion and histiocytic inflammation. Lesion score for lung was quite variable in all farm analyzed whit values from 0 to 6. PRRSV resulted also positive in all farms with PMWS and it was also present in eight of other farms. Only one showed no presence of viruses. Streptococcus suis, Pasteurella multocida, Haemophilus parasuis, Bordetella bronchiseptica, Salmonella tiphymurium were isolated form several collected organs.

Discussion
Histology and immunohistochemistry are considered essential for PMWS diagnosis. In this field the lesion score could be useful to understand the evolution of the pathology within the farms. It is noteworthy that lesions with score 2-3 of lymphoid depletion and 1-2 of histiocytic inflammation were more frequently associated with immunohistochemical positivity. In our cases histiocytic inflammation resulted from low to moderate but not severe and the depletion appeared to be the most frequent lesion. The lungs showed a variable score, in fact we observed severe interstitial pneumonia in subject with no also confirmed PMWS, probably related to the diffuse infection of PRRSV as described previously. The results obtained from the analyzed farms suggest to emphasize the role of PRRSV and the importance to keep it under control.

Commercial spray-dried porcine plasma contains high amounts of PCV2 DNA and high levels of anti-PCV2 antibodies but is not infective to naïve pigs

Tanja Opriessnig1 Huigang Shen1 Shayleen Harrison1 Joy Campbell2 Terry Faidley2 Louis Russell2 Patrick Halbur1
1. Iowa State University, Ames, IA, USA; 2. APC, Inc., Ankeny, IA, USA

Introduction
Porcine circovirus type 2 (PCV2) is a small DNA virus and is resistant to inactivation [1]. Spray-dried plasma (SDP) of porcine origin is widely used in modern swine production to improve growth and health. However, SDP has been proposed as a possible source of PCV2 transmission. Recently, PCV2 transmission was demonstrated using experimentally produced SDP from a clinically diseased pig and a laboratory spray-dryer [2]. Currently available results on infectivity of PCV2 present in commercial spray-dried products are conflicting and to date the importance and impact of this route of PCV2 transmission is not fully understood. The objectives of this study were (1) to determine the amount and variation of PCV2 DNA and antibodies in commercial spray-dried plasma products from different geographic regions in the U.S. and (2) to determine if naïve pigs fed a diet containing 4% inclusion rate of PCV2-PCR positive commercial SDP become infected with PCV2.

Materials and Methods
Samples from 2 spray-drying facilities located in the US were collected weekly for a 3 wk collection period. The samples included plasma from 14 different slaughterhouses (PSla) representing the major swine producing regions across the US. Samples were collected from liquid pooled plasma as it entered the spray-drying facility. In addition, concentrated plasma (PLiquid) and SDP (PDry) were collected at four different time points in the process. The samples represented approximately 60% of a single day’s US swine slaughter. All samples were subjected to PCV2 ELISA and quantitative PCV2a/b real-time PCR [3]. A feeding trial was conducted in order to further evaluate the infectivity of the PCV2 DNA present in commercially produced spray-dried porcine plasma. Nine PCV2 naïve pigs (65 kg BW) were randomly assigned to 1 of 3 groups of 3 pigs each including (1) negative controls, (2) positive controls, and (3) SDP pigs. The positive controls were inoculated with an infectious PCV2 stock inoculum. Negative and positive control pigs were fed a diet free of animal proteins. The SDP pigs received a diet with 4% spray-dried porcine plasma for entire duration of the study. The SDP utilized in the feeding trial was selected based on presence of PCV2a and PCV2b DNA as determined by PCR. Blood was collected weekly from the pigs and the experiment was terminated 42 days post inoculation.

Results
All collected samples (PSla; PLiquid; PDry) were positive for anti-PCV2 IgG when tested with the PCV2 ELISA. In general, there was no significant difference found between the S/P values of the PSla, PLiquid and PDry samples. PCV2a DNA was found in 0/52, 0/32 and 2/32 of the PSla, PLiquid and PDry samples, respectively. In contrast, PCV2b DNA was found in 31/52, 22/32 and 16/32 of the PSla, PLiquid and PDry samples, respectively. Concurrent presence of PCV2a DNA and PCV2b DNA was found in 13/52, 1/32, and 7/32 of the PSla, PLiquid and PDry samples respectively. In the feeding trial, the positive control pigs became PCV2 DNA positive by 7 days post inoculation and remained positive. In contrast, negative control pigs and SDP pigs remained PCV2 PCR negative through 28 days of the trial. The trial is still ongoing at the time of abstract submission and final results will be presented.

Discussion
The high prevalence of PCV2 antibodies in pooled plasma collected in slaughter facilities from healthy animals across the U.S. is consistent with previous reports. Whereas PCV2a DNA was found only in a few of the SDP batches, most plasma samples tested were positive for PCV2b. This was similar across all stages in the SDP production process. This finding is especially interesting as most grow-finish pigs in the U.S. are vaccinated against PCV2 (using a PCV2a-based product) and potentially indicative of a lack of thorough cross-protection between genotypes. Preliminary results indicate that highly susceptible, PCV2 virus- and antibody-naive specific-pathogen-free pigs fed a high concentration of spray-dried PCV2 DNA positive plasma over at least 28 days remained PCV2-free. This evidence suggests that the commercial spray-drying process employed in the US is effective in eliminating the infectivity of PCV2, likely among the most difficult pathogens to inactivate.

Introduction
Porcine circovirus associated diseases (PCVAD), caused by porcine circovirus type 2 (PCV2), has been considered one of the most important disease in swine industry worldwide. The characteristic immunosuppressivity of the virus predisposes the host to secondary infections, increasing mortality in herds and the cost of production. Despite many efforts, there are many questions to answer about occurrence, pathogenesis and epidemiology of the infection yet, especially in Brazil. With the purpose to identify PCV2 DNA in the pigs from intensive production system in the State of Goiás, Brazil, a retrospective investigation on paraffin-embedded organs samples which had been submitted to histopathological diagnosis in Laboratory of Animal Pathology (LAP / UFG) of Veterinary School of Federal University of Goiás was performed.

Materials and methods
A total of 42 samples from 26 pigs necropsied during 2000 to 2002, were chosen from the archival collection of the LAP / UFG based on typical histopathological lesions of PCVAD, such as lymphadenopathy, interstitial pneumonia, hepatitis, enteritis and/or interstitial nephritis. Blocks are cutted in sections of 10μm thin. First, sections were deparaffinized as described in Ciacci-Zanella et al (2006) and after, tissues were submitted to DNA extraction with standard phenol protocols. A polymerase chain reaction (PCR) using specific primers for the ORF2 of the PCV2 DNA according Kim et al. (2001) was used to amplify a PCV2 ORF2 fragment. A sample of PCV2 achieved from pig with clinical signs and lesions of porcine circovirosis (Barthasson, 2009) was used as positive control and ultrapure sterilized water was used as negative control.

Results
Specific PCV2 ORF2 DNA fragment were detected in 20 (47.61%) out of 42 samples from 17 (65.4%) animals. No samples of eight from 2000 analyzed showed positivity. In the samples obtained from 2001, 8 samples (66.7%) from 15 blocks were positive. These samples were picked up from 4 out of 5 pigs. Viral DNA was found in kidneys (n=2), spleen (n=2), liver (n=2), lymph nodes (n=1), and lung (n=1). In 2002, viral DNA has been found in 12 (63.15%) out of 19 samples. Twelve out 13 pigs were positive. PCV2 DNA was found in lung (n=3), lymph nodes (n=3), liver (n=2), spleen (n=2), tonsils (n=2) and intestine (n=1) tissue fragments.

Discussion
The state of Goiás is the third largest swine’s producer in Brazil. So far, porcine circovirosis was not confirmed by any molecular or virologic test in this region. The results found in our study, confirm the clinical and pathological evidence of PCV2 infection in Goiás. Although other Brazilians’ studies showed that the PCV2 is present in the country since 1968, we did not analyze samples prior 2000, but we can point that PCV2 circulates in Goiás pig herds at least since 2001. Other study conducted in back yard pigs from Goiás had already identified PCV2 DNA in tissue samples, but to our knowledge, this is the first identification of PCV2 DNA in tissue from swine intensive production system in the state of Goiás with clinical and pathological evidence of PCVAD.

Introduction
Porcine circovirus type 2 (PCV2) is a non-enveloped, circular, single-stranded DNA virus of approximately 1.76 kb, belonging to the genus Circovirus in the family Circoviridae. The genome encodes three major open reading frames (ORFs) encoding the replicase proteins (ORF1), the viral capsid protein (ORF2), and a protein with suggested apoptotic activity (ORF3). The cap gene is considered a reliable phylogenetic marker for PCV2 strains since it was able to reconstruct the same tree as the whole viral genome (3). The aim of this study is to determine the clustering of PCV2 detected over this 7-year.

Materials and Methods
Twenty four ORF2 sequences were selected and multiple-aligned with representative sequences of ORF-2 PCV2 available at the GenBank database using Clustal X v. 1.8. The analyses were with the following samples: 5 from 2002 (am2; am5; am13r; am22R; am25R); 6 from 2003 (am10; am3; am5; am9; am4; amC); 4 from 2004 (am13; am15; am16; am21); 5 from 2007 (am148k; am182k; am61k; am62k; am7k) and 3 from 2009 (CINamF3; CINamF4; CINamF7). The identity among sequences at nucleotide and aminoacid levels was determined using BioEdit v.7.0.5. The phylogenetic tree was performed using the distance based Neighbor-joining method and substitution Kimura 2-parameters model in the Mega v.2 package (Bootstrap 1000).

Results
Variations in the aminoacid composition among the 24 sequences were distributed across the whole capsid protein sequence, but more concentrated between the 57 and 91 position. In the sequences from this study the most substitutions was observed in 57, 63, 80, 86, 88, 89, 91, 151, 190 and 191 position. Interestingly, these regions were almost located in putative epitope domains of PCV2 capsid protein (Fig 1). The 24 sequences are distributed within both subgroup (PCV2-1 and PCV2-2) since 2002 (e.g. am22r and am25R). Most of the sequences (14/24) are grouped in PCV2-1A/B group and one (am6) is in PCV2-2D group.

Discussion
This study confirms that both, PCV2-1 and PCV2-2 are circulating in Brazilians swine herds since 2002 (1). The sequences obtained from samples collected recently (2007 – 2009) are grouped in PCV2-1 group. However some sequences (old and new) are still without classification, creating a separated group within both PCV2 group (PCV2-1 and PCV2-2).

Efficacy of Circumvent® PCV preventing PCVAD and maintaining growth performance during an outbreak of PRRSv in a Canadian pig herd with a history of PCVAD

Charles Surprenant1 Francisco de Grau1 Benoit Laplante2 Brad Thacker3 Alex Eggen4

1. Intervet Canada Corp, Kirkland, QC, Canada; 2. Menard Inc, Ange-Gardien, QC, Canada; 3. Intervet, Inc., Millsboro, DE, USA; 4. Intervet International BV, Boxmeer, Netherlands

Introduction

The efficacy of Circumvent® PCV (Intervet Schering Plough Animal Health) was demonstrated during the severe PCV2 disease outbreaks in Canada (de Grau et al., 2007). Many of these outbreaks involved co-infections with PRRSv, SIV, Mycoplasma hyopneumoniae and other bacteria (Carman et al., 2006). PRRSv plays an important role in enhancing PCV2 replication and PCV2 viremia (Rovira et al., 2002). The objective of this field trial was to compare the efficacy and performance of Circumvent® PCV in comparison to unvaccinated control pigs. A severe PRRSv outbreak occurred during the vaccination trial.

Materials and Methods

The trial was carried out using a randomized, non-blinded and controlled design. In total, 350 pigs were selected and ear tagged at three days of age (D) and allocated to one of two treatment groups, vaccinated (VAC) or control (CON) n = 175 pigs. Vaccinations were performed per label recommendations at weaning (~18 D) with a booster 3 weeks later. All pigs were weighed at 3 D, weaning, end of nursery (56 D), 106 D, 143 D and slaughter (165 D). Individual pig treatments were recorded for assessing morbidity. A post mortem was performed on every dead pig. Blood samples were collected from 12 pigs per group at 3 D, end of nursery, 106 D, 143 D and slaughter (165 D). Individual pig treatments were recorded for assessing morbidity. A post mortem was performed on every dead pig. Blood samples were collected from 12 pigs per group at 3 D, end of nursery, 120 D, and slaughter to evaluate antibody titers by ELISA and viremia by qPCR. Viral presence in the nose at 120 D and slaughter and feces at slaughter was determined in the same pigs. All pigs were observed for local and systemic reactions during the first 72 hours after each vaccination. At slaughter, carcass quality information was retrieved.

Results

Due to the PRRSv outbreak in the nursery, birth to finish mortality was approximately 14 % and did not differ between treatment groups. PRRSv was confirmed by laboratory analysis (PCR, genotyping, histopathology) and caused a mortality peak in the first third of the finisher stage. VAC pigs did not develop PCVAD and only CON pigs exhibited gross and microscopic lesions compatible with PCV2 infection. ADG, ELISA titers and viremia differed between the groups. In the finisher (20 to 120 Kg), ADG was 948 g for CON pigs vs. 973 g for VAC pigs (25 g difference). However, the difference in ADG between the groups during the highest PCV2 viremic period (106 D to slaughter) was 40 g (1,053 g vs. 1,013 g). Grower-finisher ADG was lower in viremic pigs in the sampled group (925 g) in comparison to non-viremic sampled pigs (994 g). ELISA titer patterns differed between CON and VAC pigs as CON pigs were seronegative during the disease challenge. PCV2 viremia was first detected in CON pigs at 56 D while no viremia was found in VAC pigs before the second dose or during the remaining of the grower-finisher period. At slaughter, 91% of CON pigs were viremic whereas low levels of PCV2 DNA were detected in 2 VAC pigs (17%) (10E+04 genome copies) (p < 0.001). Nasal and fecal samples were qPCR positive for all pigs sampled. The CON pigs had much higher viral load in the nose.

Discussion

The animals used in this trial originated from a pig flow that had been vaccinated to prevent PCV2 infection for more than 18 months and PCV2 challenge appeared to remain high based on the reduced performance in CON pigs and the presence of PCV2 in feces and nose indicating a constant challenge due to shedding mainly by CON pigs. Vaccination appears to be an important tool to reduce shedding and prevent viremia even in presence of severe PRRS challenge. VAC pigs maintained an adequate ADG. Quantitative ELISA titers and qPCR levels appear to provide a good predictor and indicator, respectively of PCV2 viremia prevention in vaccinated pigs.

Comparative Efficacy of Ingelvac CircoFLEX®-Ingelvac MycoFLEX® Combined vaccine versus Circumvent PCV2™ and Respisure ONE® in a Commercial Herd

Martin Misener
Linwood Veterinary Services, Linwood, ON, Canada

Introduction
Mycoplasma hyopneumoniae (Mhyo) vaccines have been routinely used in the growing pig population in North America for nearly two decades. Porcine circovirus type 2 (PCV2) pig vaccines quickly became incorporated as standard vaccination for growing pigs once their availability was established. Since vaccination against Mhyo and PCV2 is widespread for the growing pig it was a logical extension that these two vaccines would be combined to be delivered in a single shot (1).

The objective of this study was to compare an off-label regimen which was being commonly used by veterinarians in Ontario at the time of the study to vaccinate against PCV2 and Mhyo with a combination recently licensed in Canada and the US, Ingelvac CircoFLEX-MycoFLEX. Efficacy and production parameters were evaluated in this study.

Material and Methods
This study was conducted in an 1500-sow, commercial production herd in Ontario, Canada, weaning about 600 pigs weekly at three weeks of age. A total of 1064, three-week-old pigs were divided into two groups.

Group 1: On the day of weaning, 532 pigs were vaccinated with 1 mL of Circumvent PCV2™ and 1 mL of Respisure ONE®, both vaccines mixed in a single syringe and delivered as a single dose. Group 1 pigs were revaccinated three weeks later with 1 mL of Circumvent PCV2 and 1 mL of Respisure ONE®. Again, both vaccines were mixed in a single syringe and delivered as a single dose. Group 1 pigs received an off-label regimen which was being commonly used by veterinarians in Ontario at the time of the study.

Group 2: On the day of weaning 532 pigs were vaccinated with 1 mL of Ingelvac CircoFLEX® and 1 mL of Ingelvac MycoFLEX® as a single 2 mL combined dose. After vaccination pigs were moved, over a two-week period to fill a one-room finisher barn. Group 1 pigs were placed in pens on one side of the barn and Group 2 pigs placed in pens on the other side of the same room in the barn, all pigs sharing the same airspace, and feed delivery. Measurements were average daily gain total weight gain, (ADG), feed conversion (FC) mortality, and carcass grade.

Results
At marketing, the end of the study period, total weight, ADG, FC and mortality were 136.6 kg vs 133.2 kg, 880.5 g/day vs 822.8 g/day, 2.658 vs 2.742 and 2.63% vs 8.46%, for Group 2—vaccinated pigs vs Group 1 pigs, respectively (Table 1). Group 2 pigs attained a carcass grade of 103.0 vs 104.0 for Group 1 pigs.

(Table 1). Group 2 pigs went to market 4.7 days faster than group 1 pigs. Cost/ kg of gain was calculated to be 92.4c for Group 2 pigs vs 95.3c for group 1 pigs (Table 1). The net advantage for vaccinating with the combined Ingelvac CircoFLEX-MycoFLEX® calculated to be $6.38 per pig.

Table 1. Production parameters for Circumvent PCV2™ and Respisure ONE® vaccinated pigs (group 1) vs Ingelvac CircoFLEX-MycoFLEX® (group 2).

Effect of Ingelvac CircoFLEX® on the live weight and uniformity of pigs in a herd with mild PCVD

Peggy De Backer; Guy Cluydts

SCS Boehringer Ingelheim Comm.V., Brussels, Belgium

Introduction
Infections with Porcine Circovirus Type 2 (PCV2) are widely distributed in the Belgian pig population, however in many cases without obvious clinical symptoms. The objective of this study was to determine the effect of PCV2 vaccination in a herd with mild PCVD.

Materials and Methods
The trial was performed in a Belgian gilt multiplying herd. Two years earlier, severe PCVD problems were observed in the herd. The problems concerned high mortality at the end of the nursery and early finishing, PMWS and diarrhea. Due to several changes in management such as batch farrowing and all-in all-out management, the problem became milder and at the start of the trial there was an absence of clinical signs associated with PCV2.

Sows farrowed in batches, in a 3 week interval. In total 6 batches of piglets were involved in the trial. Of these batches, every other batch was vaccinated with Ingelvac CircoFLEX® at an average age of 19.5 + 2.1 days. The other batches were left as unvaccinated controls.

The female piglets (future gilts) were individually eartagged and followed during the growing period. Individual live weight registration of the gilts was performed at selection, at an average age of 176.7 days for the Ingelvac CircoFLEX® and 176.3 days for the unvaccinated control group.

Results
At 25 weeks of age, the vaccinated pigs had a 7.5 kg higher live weight compared to the unvaccinated control animals (P<0.001) and there was a trend towards a lower variance (P=0.078) in the live weights of the vaccinated group (table 1). Both the higher live weight and better uniformity in the Ingelvac CircoFLEX® group are reflected in figure 1. The distribution of live weights of the vaccinated animals is shifted to the right, indicating the 7.5 kg higher live weight and is narrower, indicating the better uniformity of the animals.

Discussion
The results of this field study show that even in mild cases of PCVAD, with no apparent clinical signs, PCV2 vaccination can result in a significant improvement of production parameters such as daily gain. This better daily gain with tendency towards better uniformity may be a decisive argument for the use of the vaccine, in order to have an optimal expression of the genetic potential of gilts.

Figure 1 Live weight distribution of gilts at 25 weeks of age
Introduction
Porcine Circovirus type 2 (PCV2) infection is regarded as an important, but not the only, causative factor in the development of Porcine Circovirus Disease (PCVD) in piglets. Many other pathogens, management factors and as well as immunostimulating compounds (Krakowka, 2001; Grasland, 2005) have been mentioned as contributory to the clinical expression of the disease.

PCVD can occur in pigs of different ages and under field conditions, and the timing of the PCV2 virus infection is often unknown. Pigs are normally vaccinated early in life against PCVD all over the world.

The object of this study was to demonstrate the safety of a potent adjuvated vaccine (Porcilis PCV) in piglets of 3 weeks of age in the presence of PCV2 field virus.

Materials and Methods
The farm was selected because it had suffered an outbreak of PCVD, confirmed by clinical and post mortem investigations according to the guideline “PMWS case definition (herd level)”. PCV2 DNA was detected in pigs by Q-PCR prior to and during the study.

In all, 2.5 production batches (517 piglets) were vaccinated and the parameters measured were compared with a reference group of 696 unvaccinated piglets from previous production batches.

Porcilis PCV is a sub-unit vaccine containing the capsular protein coded by ORF2 of PCV2 virus in an adjuvant consisting of α-tocopherol and light mineral oil (X-Solve®). The product was allowed to reach room temperature (20 -25°C) and shaken before use. A 2ml dose was administered to piglets of 15-21 days of age in the farrowing unit, by intra-muscular injection with a needle 25mm long.

Sows were routinely vaccinated against PRRS, Parvo, Erysipelas, Gläsor, E.coli, Clostridium and Influenza. Piglets were treated with amoxicillin on day 1 and on days 3-5 and with iron. No other vaccines were given concurrently.

The piglets were scored for local and systemic (general health) reactions at the time of vaccination, 4 hours later, and on Day 7 and Day 14 following vaccination. Food intake was also scored during the same 14-day period.

The individual pig served as the statistical unit and descriptive statistics were used to present and summarize the data. Mortality data were recorded for the whole period up until slaughter, as a general indication of the effect of vaccination on performance.

Results
All piglets were healthy before the start of the study.

Local reactions: none of the 517 piglets vaccinated with Porcilis PCV showed any reaction during the 14-day observation period.

Systemic reactions and general health: none of the 517 piglets vaccinated with Porcilis PCV showed any systemic reaction or deviation from normal health during the 14-day observation period.

Feed intake was normal for the age of the pigs, which reinforced the assessment of their good general health.

Mortality: the mortality in the reference group (n=696) was 5.19%, 6 pigs died and 30 were culled. In the Porcilis PCV vaccinated group (n=517), 11 piglets died (2.13%) and none were culled.

Discussion
Porcilis PCV is a highly efficacious vaccine based on the immunogenic capsular protein of PCV2 virus, with X-Solve as a potent adjuvant. This study shows that Porcilis PCV, although highly immunogenic, can be used safely on farms with confirmed PCVD (PMWS). No adverse effects of the immune-stimulation, as described by Krakowka, were noted, which accorded with Astrup’s (IPVS 2010) report of a safety study executed in Denmark involving different breeds.

However, the package leaflet of Porcilis PCV (EMEA 2009) does contain a warning of possible local and systemic reactions following injection, and Astrup (IPVS 2010) found such reactions. It appears that differences between farms, and the health of the piglets at the time of vaccination, account for the differences in the degree and extent of the side-effects of vaccination (data on file). Nevertheless, the incidence of these side-effects is low, and piglets recover completely when no other debilitating factors are present.

This study confirms the safety of Porcilis PCV. The importance of the handling and administration of the vaccine in strict accordance with the manufacturer’s instructions cannot be overestimated, and should always be brought to the attention of anyone involved in its administration.

**Immunogenicity of “DS Circo Pigvac” in the Various Levels of Maternal Antibodies against Porcine Circo Type 2 virus (PCV-2)**

Won Hur; Pill Soo Lee; Kang Soeng Joung; Yung Sik Mun; Sung D. Jung  
*Dae Sung Microbiologicals Co. Ltd., Eui Wang, Kyung Ki Do, Korea*

**Introduction**

Currently available circo vaccines in the market are classified into two types. One type is vaccine for piglet mostly at three weeks old; another type is claimed for sow. The reasons for the claims can probably be attributed to the absence of the effective evaluating methods for the antibodies against circovirus after vaccination.

In order to evaluate the immunogenicity of “DS Circo Pigvac,” we developed immunofluorescent assay (IFA) against circovirus and applied to the field test in post-weaning piglets with the various level of maternal antibodies after vaccination in the field.

**Materials and Methods**

1) Each group of piglets of 3 weeks old born from sero-positive sow against PCV-2 was selected and housed to estimate the level of the maternal antibodies in the isolator.

2) A total 60 piglets of 3 weeks old were tested for the initial level of the maternal antibody titers against PCV-2 and monitored for their antibody trends after vaccination.

**Results**

1) The maternal antibodies against PCV-2 were rapidly decreased in piglets. Initially log210 titer by IFA was decreased to log27 at 6 weeks old piglets. The piglets of negative titer showed the increase of antibody titer from 14 weeks due to the natural PCV-2 infection (Table 1).

2) The immunogenicity of “DS Circo Pigvac” in 3 weeks old piglets revealed that while piglets with maternal antibodies titer lower than log28 showed the increased antibody titers from 6 week, the group with higher than log29 from 10 week after vaccination (Table 2).

**Discussions**

Since the maternal antibodies was rapidly disappeared and showed the variable antibody levels by the colostral intake, the preventive strategies through maternal antibodies is not proper.

Even in “DS Circo Pigvac” which has the enough antigen amount was also interfered with the immune responses of piglets about the maternal antibody titers more than log29.

However, it was found that the antibody titers were increased in piglets at 10 week mainly results from the oil adjuvant based formula. This result indicated the oil adjuvant efficacy in PCV-2 vaccination.

Moreover, the present data suggest the vaccination on pregnant sow is not proper strategy for the preventive measures against PCV-2.

For the effective PCV-2 protection in the sow claim, actually pre-mating vaccination is recommended than pre-parturition from our side.

Field trial comparing two PCV2 vaccines on a farm with late PCV2 infection

Roselyne Fleury1 Jessica Thomas1 Francois-Xavier Orveillon2
1. Pigalys, Vannes, France; 1. Boehringer Ingelheim, Ingelheim am Rhein, Germany

Introduction

This study took place on a farrow-to-finish farm of 700 sows in France. In Q3 2008, the mortality rate in fattening reached 5.8% and average daily gain (ADG) over the same period 794 g/d. Circovac® vaccination was routinely implemented in sows (2ml) since 2006 and in piglets of four weeks of age (0.5ml) since September 2007. A screening of the farm in September-October 2008 demonstrated that the PCV2 infection was particularly high at the end of fattening. Necropies revealed typical PMWS lesions in lymphoid tissues which were also positive for PCV2 antigen by IHC. From that time point, due to the continued occurrence of PMWS cases, the veterinarian in agreement with the farmer decided to change the routine PCV2 vaccination in piglets to Ingelvac CircoFLEX®. Two months later, a study aiming at comparing the ability of both vaccines in preventing the impact of the PCV2 infection on growth performances and mortality, was implemented.

Material and methods

The trial was conducted in compliance with the good clinical practice. A total of 1185 4-week-old piglets originating from CircoFLEX® vaccinated sows were included over three week groups (WG1, WG2 and WG3) and divided into two treatment groups: CircoFLEX® group (n=535) was injected with Ingelvac CircoFLEX® (1ml IM), Circovac® group (n=548) was injected with Circovac® (0.5ml IM). A control group (n=102) was included to demonstrate presence of PCVD during the trial, control pigs were injected with water for injection (1ml IM). Groups were balanced with regard to initial body weight and litter assignment. All animals from the three groups were co-mingled throughout the study ensuring that all animals were under the same housing and infection conditions. Approximately 8% of the control animals were sampled at 5 time points (4, 10, 15, 19 and 22 weeks of age) to identify the time and profile of the PCV2 infection by Real-Time PCR. All study animals were weighed three times (4, 11 and 23 weeks of age). Weight gain differences between groups were tested using analysis of variance and subsequent t-tests. Mortality between vaccinated groups were compared by Fisher’s exact test.

Results

PCV2 infection was confirmed to occur after 15 weeks of age (study week 11) with a peak at the end of fattening. The presence of PCV2 was further confirmed in necropsies (including IHC).

During the fattening period (11 to 23 weeks of age) when the PCV2 field infection took place, the mortality was significantly reduced in the CircoFLEX® group (1.5%) when compared to the Circovac® group (3.7%, p=0.0338). The increase in mortality coincided with the onset of viremia (Figure 1). Over the same period, the CircoFLEX® and Circovac® groups out-performed the control group respectively by 1.75 kg (p=0.0640) and 1.46 kg (p=0.1226). Weight gain between the two treatment groups did not differ significantly (p=0.5881). When interpreting the differences between the two treatment groups and the control group, it should be taken into account that the control group was primarily included for epidemiological reasons and only comprised 102 pigs.

Discussion

The presence of PCVD on the farm and the late onset of PCV2 infection were confirmed in control animals during the study, demonstrating that sow vaccination does not protect pigs through to slaughter. In addition, Ingelvac CircoFLEX® provided superior protection compared to Circovac® used in piglets, as shown by a significant reduction in mortality. A significant difference in weight gain between the two treatment groups was not expected as the PCV2 infection occurred late. Furthermore, it is likely that the higher mortality rate in the Circovac® group positively influenced the weight gain by eliminating the poor doers from the calculation. Beside the study results, the superior efficacy of Ingelvac CircoFLEX® is confirmed by the consistently good performance after implementing piglet vaccination with Ingelvac CircoFLEX®. Indeed, in Q2 and Q3 2009 when all pigs where vaccinated with Ingelvac CircoFLEX® mortality in fattening was 3.1 and 3.8%, compared to 4.9 and 5.8% in Q2 and Q3 2008 when only Circovac® vaccinated pigs where present, reflecting a reduction in mortality of about 2%, very similar to what has been observed in this side-by-side study.

Value through vaccination: vaccination against ileitis and PCV2 in a Danish herd

Kristian T. Havn² Hanne Bak¹
1. Boehringer Ingelheim Vetmedica, Copenhagen, Denmark; 2. Svinevet, Haderslev, Denmark

Introduction
Vaccination against either ileitis (1) or PCV2-virus (2) has proven to be economically efficient tools to increase the performance of pigs infected with ileitis or PCV2. Many herds are infected with both organisms, and the question is, whether the economical benefits will hold when using the 2 vaccines in the same herd. This paper evaluates the benefits of vaccinating against Lawsonia intracellularis and PCV2 in a herd affected by both pathogens.

Materials and Methods
The study was carried out in a Danish SPF herd that received 1000 weaners every 7th week. At 30 kg live weight, pigs were moved to fattening units at a different site. Before the vaccination program, the pigs had reduced average daily weight gain (ADWG) and an increase in feed conversion rate (FCR) and mortality. About 10% of the pigs became pale and lost weight at the end of the finishing period. After blood sampling, a high amount of PCV2-virus was detected by qPCR, and antibodies against Lawsonia intracellularis were found. Vaccination against PCV2 and ileitis started at the same time, with Ingelvac CircoFLEX® (Boehringer Ingelheim) administered i.m. at 2 weeks of age in the sow herd, and Enterisol® Ileitis Vet. (Boehringer Ingelheim) given in the drinking water at 4 weeks of age after arrival to weaning unit. Every 7th week, production data was collected. Comparison of vaccinated and non-vaccinated pigs was done with ANOVA for ADWG, FCR and prescriptions of antibiotics, and with Fishers Exact test for mortality, using p≤0.05 as significance level. The economical benefit was calculated using key values from the Danish Pig Producers Organisation (3).

Results
A statistically significant improvement of the performance of pigs vaccinated with the 2 vaccines was recorded for the 4 parameters (table 1): ADWG, feed conversion, mortality and antibiotic expenses (p-values 0.0130, 0.0010, <0.0001 and 0.0156). The economic value of the improvements exceeded the vaccine cost, with a positive return of investment (ROI) of 1:2.5.

Discussion
This study shows that it is economically beneficial to vaccinate against ileitis and PCV2. Every € spend on vaccines is paid back 2.5 times due to an increased ADWG and reductions in FCR, mortality and antibiotic expenses.

A Philippine Farm Experience using Ingelvac CircoFLEX

Jonathan Olanday1 Rolando Tambago1 Marc Bautista2

1. Asturias Farm, Asturias, Cebu, Philippines; 2. Boehringer Ingelheim Philippines Incorporated, Makati City, Philippines

Introduction
Porcine Circovirus 2-associated disease has clearly become a major and complex international problem (1). It is also a common disease in swine farms in the Philippines. This disease can create problems in the farm like increase post-weaning mortality (Post W.M.) and decrease average daily weight gain (ADWG). This study evaluates the benefits of using Ingelvac CircoFLEX on a 1,100 sow farm.

Materials and Methods
The farm is positive for PCV2, Haemophilus Parasuis, Actinobacillus Pleuropneumoniae, Mycoplasma Hyopneumonia. The farm implemented Ingelvac Circoflex vaccination, 1ml at day 21, in December 2008. Weaning day is at day 28-30. The farm records from June 2008 to October 2009 were compiled into a longitudinal study. Except PCV2 vaccination, no other major changes occurred on the farm. The monthly data of ADWG and Post W. M. was evaluated through Statistical Process Control (SPC, Statistica v8.0). Data from June – November 2008, December 2008 to April 2009 and May 2009 to October 2009 were grouped into three periods namely Pre-vaccination, Transition and Vaccination respectively. The Transition period was included to ensure that only fully vaccinated groups were compared to completely non-vaccinated ones.

ADWG is evaluated by Simple ANOVA, and adjusted by the Dunnett test. Mortality is evaluated using a Chi-square test. All are tested for an Alpha value equals 0.05.

Results and Discussion
The wean-to-slaughter ADWG of the farm during the vaccinated period is 545 grams/day. It has improved by 39 grams/day as compared to the ADWG during the Pre-vaccination period (p < 0.0004, fig. 1). Mortality in nursery was not significantly different between the two groups (4.6% vs. 5.9%, p=0.17) In contrast, the grow-finisher mortality was significantly reduced after introduction of PCV2 vaccination by 50% from 10.4% to 5.2% (p< 0.004, fig. 2).

Conclusion
Introduction of PCV2 piglet vaccination significantly reduced mortality and improved performance on the farm.

Efficacy of Ingelvac CircoFLEX® in mild forms of PCVD in Thai swine farms

Nathaya Duangwhae; Lerdtida Meedacha; Sopon Kongtes; Jitjaroen Channarong
Boehringer Ingelheim (Thai), Bangkok, Thailand

Introduction
Recently several PCV2 vaccines have been launched in Thailand. The introduction of PCV2 vaccines has allowed greater control of PCVD. Significant reduction in mortality and improvement in finishing production parameters of swine herds using a single dose PCV2 piglet vaccine, Ingelvac CircoFLEX®, were observed throughout Thailand, even though most farms had both PRRSv and PCV2 infection.

The objective of this study was to compare finishing performance parameters in non-vaccinated and Ingelvac CircoFLEX® (Boehringer Ingelheim) vaccinated groups of pigs on two farms, with low mortality in finishing (< 2%).

Material and method
Two conventional, finishing pig farms, farm A and B, were included in this evaluation. Both farms have used Ingelvac® PRRS MLV and are PRRS stable. The piglets in these farms are serologically negative to PRRS up to 16 weeks of age but seropositive to M. hyopneumoniae and PCV2 virus. Piglets are weaned at 3 weeks of age, raised in the nursery then moved to the finishing site when 8-10 weeks old. This study included, 1,152 non-PCV2 vaccinated pigs (before vaccination) and 1,161 vaccinated pigs (after vaccination). Vaccinated pigs received a single dose 1 ml IM of Ingelvac CircoFLEX® at 21 day of age. Parameters recorded in finishing farms included ADG, total losses, mortality and culling rate, i.e. pigs euthanized before slaughter. The difference in total finishing losses (mortality plus culls) was statistically evaluated using a Chi-square test (Statistica, v.8.0)

Results
Performance data of the vaccinated and the non-vaccinated pigs are shown in Table1. The ADG of the vaccinated groups was higher than in the non-vaccinated groups, +56g on farm A and +81g on farm B. Total losses were significantly reduced in vaccinated groups on both farms: 1.65 vs 4.51 % (p=0.002) on farm A and 2.69 vs 5.49% (p=0.04) on farm B.

Discussion and conclusion
Vaccinating piglets with Ingelvac CircoFLEX® in PCV2 infected, PRRS stable herds with low mortality improved finishing performance parameters. This comparison clearly shows the economic benefit of Ingelvac CircoFLEX® under field conditions in face of mild form of PCVAD in finishing period.

Field Experience with a subunit PCV2 vaccine in a Chinese Farm with severe PCVD

Longtao Yao¹ Huarong Dai² Brook Fang³ Nian Huang¹ Hanchun Yang⁴
1. Shanghai Fengxiang Veterinary Center, Shanghai, China; 2. Yuejin Pig Farm, Zhanjiang, China; 3. Boehringer Ingelheim Int’l Trading (Shanghai) Co. Ltd., Beijing, China; 4. China Agricultural University College of Veterinary Medicine, Beijing, China

Introduction
Porcine Circovirus type 2 (PCV2) is widespread and is recognized as the causal agent of post weaning multisystemic wasting syndrome (PMWS) [1] [2]. PMWS was first described in Canada in 1996. Nowadays PMWS and other PCV2 related diseases (PCVD) are present in virtually all pig producing countries [3], causing huge losses to the global swine industry if not effectively controlled. In China PCVD also has a great negative impact on the domestic pig industry. In this study, the efficacy of an imported PCV2 subunit vaccine was investigated in a severe case of PCVD in China.

Materials and Methods
A one-site production system farm of 1,200 sows in Shandong suffered from PCVD. Production performance was severely damaged by the PCV2 infection. High culling and death rates in the nursery and fattening stages were the main causes for economical losses. The farm was positive for PRRSV, PCV2-a, CSFV and Haemophilus parasuis (HPS). The farm started piglet vaccination against PRRS (Ingelvac® PRRS MLV) and HPS (Ingelvac® HP-1) around 7-10 days old from November 2008. However, production performance did not recover to the optimum level. In January 2009, a side-by-side trial was carried out including a total of 800 piglets in two weekly batches. Piglets in the vaccinated group (n=380) received an imported PCV2 subunit vaccine, Ingelvac® CircoFLEX, at 14 days old. The control group comprised 380 non-vaccinated pigs. Average daily weight gain (ADWG), mortality and FCR were recorded in nursery and fattening. The average daily weight gain (ADWG) was analyzed by t-test, mortality by Chi-square test.

Result
The results are summarized in Table 1 (nursery performance) and Table 2 (fattening performance). Performance was significantly improved in vaccinated pigs, both in nursery and fattening stages. In nursery mortality was reduced by about 80%, from 22.2 to 4.7% in vaccinated pigs, whereas ADWG was improved by more than 40g/day. Mortality in fattening was reduced by about 70% from 7.4 to 2.3% and ADWG increased by about 70g/day.

Discussion and Conclusion
In this farm with severe PCVD problems piglet vaccination with a PCV2 subunit vaccine showed excellent efficacy: it effectively controlled the negative impact of the PCV2 infection, significantly reduced PCV2 related mortality, improved the ADWG in nursery and fattening stages, finally stabilized whole herd production. Therefore, it can be concluded that proper use of PCV2 piglet vaccination can effectively control PMWS, PDNS and other PCV2 related diseases, with significant benefits for Chinese pig farms.

Serological timeline of Circumvent® PCV and MycoSilencer® ONCE compliance monitoring

Jeremy S. Pittman1 Brad J. Thacker2 John K. Johnson3 Sheela Ramamoorthy3
1. Murphy-Brown, LLC, Waverly, VA, USA; 2. Intervet/Schering-Plough Animal Health, Desoto, KS, USA; 3. Iowa State University, Veterinary Diagnostic Laboratory, Ames, IA, USA

Introduction
Previously it has been shown that the PCV2 Differential ELISA and Mycoplasma Tween 20 ELISA available at Iowa State University, Veterinary Diagnostic Laboratory (ISU-VDL) can be useful tools for vaccination compliance monitoring.1,2 Further value could be gained if these tools could be used retrospectively in an investigative manner to determine if groups of sick pigs had not been vaccinated properly. Accordingly, the objectives of this study were to determine the longevity of vaccine induced antibodies and potential development of “background” antibodies.

Materials and Methods
A total of 150 pigs from 30 litters were used. Within each litter, one pig (control – CON) was vaccinated at weaning (3 weeks of age) with single dose PCV2 and Mycoplasma hyopneumoniae (Mhyo) vaccines that do not induce measurable antibodies. The other 4 pigs were vaccinated with Circumvent® PCV and MycoSilencer® ONCE at weaning and 21 days later (VAC). At 15 weeks of age, 15 CON and 25 VAC pigs were vaccinated with Circumvent® PCV and are designated as RE-CON and RE-VAC, respectively.

All samples were tested at the ISU-VDL by PCV2 Differential ELISA and Mhyo Tween 20 ELISA.3,4 The PCV2 test was modified to measure antibodies to the baculovirus portion of Circumvent® PCV. In addition, the BV titer (BV S:P) is reported as an S:P ratio generated by dividing the BV optical density (OD) value by the OD value of serum pool obtained from Circumvent® PCV vaccinated, CDCD pigs. The positive/negative cut-offs were 0.250 and 0.240 for the PCV2 and Mhyo ELISAs, respectively.

Results
The BV S:P results are presented in Table 1. Four weeks after the second Circumvent® PCV, 95.8% of the pigs were positive while none of the controls were positive. Control pigs remained negative throughout the study while the BV titers of vaccinated pigs declined. Re-vaccination greatly boostered BV titers in previously vaccinated pigs and controls showed some titer increase.

The Mhyo titer results are presented in Table 2. Four weeks after the second vaccination, 85.0% of vaccinated pigs were positive while none of the controls were positive. The seroconversion rate in vaccinated pigs was 73.3% and 88.9% for seropositive and seronegative pigs at 3 weeks of age, respectively. Most vaccinated pigs remained positive while 51.1% of the control pigs seroconverted.

Discussion
The data provides field based confirmation of the usefulness of the two ELISAs for monitoring vaccination compliance for both vaccines when pigs are sampled 4 weeks after their second vaccination. For retrospective investigations, interpretation of data is less straightforward based on the decline in BV titers over time and the frequent field exposure of pigs to Mhyo.

Efficacy of Ingelvac CircoFLEX vaccination on improving swine production performance: a field trial in Northern China

Sidang Liu1 Aiguo Wang2 Liande Zhu2
1. Shandong Agricultural University, Shandong, China; 2. Boehringer Ingelheim Ingelheim International Trading (Shanghai) Co. Ltd, Beijing, China

Introduction

PCV2 related diseases (PCVD) have first been described in Canada in 1996, and nowadays are a major threat to the global swine industry. PCVD can have a huge economic impact on farms via increased mortality, reduced growth rate and poorer feed efficiency. Prevalence in China can reach up to 100%[1]. The purpose of this study was to evaluate efficacy of a single-dose PCV2 vaccine (Ingelvac CircoFLEX®, Boehringer Ingelheim) on a PCVD affected farm in Northern China.

Materials and Methods

The study was conducted on a single site, farrow-to-finish farm of 1800 sows in Shandong. The farm was PRRSv positive. Clinical signs on the farm included: Fever, thumping, jaundice, growth retardation, wasting, lethargy can be observed. Herd performance improved when vaccination with Ingelvac® PRRSV MLV was introduced, but did not reach an optimal level and was variable. Further diagnostics confirmed presence of PCV2. Based on that a field study was initiated, with a total of 693 pigs comprising two weekly batches. Half of the pigs (n=347) received a single dose (1 ml) of Ingelvac CircoFLEX® at 3 weeks of age, while the other half (n=346) remained unvaccinated and served as control group. Pigs were weighed individually at weaning, transfer into fattening and at slaughter. Mortality was recorded in nursery and fattening stages. Feed consumption was measured per group to determine FCR (feed conversion ratio). ADG in the two groups were compared with t-test and mortality by Chi-square.

Results

The results (Table 1 and Table 2) indicate significant improvements of vaccination groups in both nursery and fattening stages. During the nursery phase, ADG (average daily gain) in the vaccinated group improved by +40g/d improvement and mortality was reduced from 13.7% to 9.2% reduction; in the fattening phase as well, the vaccinated group showed significant advantages compared to the non-vaccinated group (+34g/d ADWG, -9.5% in mortality).

The high mortality in the nursery during this trial, even in the PCV2 vaccinated groups, can be explained by a PEDV outbreak in the nursery indicates, that only comprehensive disease control strategies targeting all major diseases together with good management can result in optimal performance.

Discussion

Ingelvac CircoFLEX® effectively controlled PCVD on the farm and significantly improved the production performance of the herd. However, the high mortality due to a PEDV outbreak in the nursery indicates, that only comprehensive disease control strategies targeting all major diseases together with good management can result in optimal performance.

Benefits of late vaccination with Ingelvac CircoFLEX® on a Korean grow-out farm

Yusik Oh¹ Donhwan Kim¹ Jina Jung¹ Seongkyu Kwak²
1. Boehringer Ingelheim Vetmedica Korea Ltd., Seoul, Korea; 2. ChungMiWon, Yangju, Korea

Introduction
Piglet vaccination has been proven to be very successful in controlling Porcine Circovirus Type 2 (PCV2) related diseases. Mostly vaccination is carried out around weaning. In many cases, vaccination has a very positive effect already on nursery mortality and performance, and protection last through finishing until slaughter. However, it has been shown previously that a single dose vaccine, Ingelvac CircoFLEX® can be used successfully at 6 weeks or even as late as 9 weeks of age, if pigs get infected in grow-finish only. In cases where pigs are traded, and are not accessible for vaccination early, it might be necessary to vaccinate piglets at placement into grow-finisher.

This field case describes the benefits of vaccinating early fatteners against PCV2 on a Korean grow-out farm.

Material & Method
Two successive weekly batches of pigs, a total of 594 animals, were included in this field observation. One batch of pigs (n=349) was left non-vaccinated, the next batch (n=245) was vaccinated with Ingelvac CircoFLEX, 1 ml i.m., at placement on the grow-out farm. Pigs were placed at 71 days with an average weight of 29.8kg (controls) or 72 days and an average weight of 31.3kg (vaccinates) on the farm. Vaccinated and non-vaccinated piglets were kept under comparable conditions in two separate buildings on the same site and where sourced from the same piglet producing farm. Pigs seroconvert to PCV2 between 60 and 90 days of age, as determined by Synbiotics ELISA. Various production parameters, including mortality, ADG and medication costs were recorded for the 2 treatment groups (Table 1).

Results
Results are summarized in Table 1.

*1 $ = 1,150 Korean won

Discussion and Conclusion
All parameters pointed in favor of the vaccinated group. This amounted to a total advantage of 9,000 KRW/pig.

In this farm with a late onset of PCV2 infection, vaccination with Ingelvac CircoFLEX at 10 weeks was still beneficial. However, vaccinating early fatteners is usually a compromise, as often infection occurs in late nursery and optimal performance would only be achieved by vaccinating around weaning.

**Effect of a single dose of Porcilis PCV at weaning on daily growth on a Danish high health herd with PCVD**

Peter Astrup\(^1\) Svend Haugegaard\(^2\) Anette Rasmussen\(^1\) Kirsten V. Larsen\(^1\)

\(^1\). Intervet/Schering-Plough Animal Health, Skovlunde, Denmark; \(^2\). Oe-Vet, Horbelev, Denmark

**Introduction**

Circovirus type 2 (PCV2) is one of the agents responsible for PMWS and PCVD, major causes of losses in pig production. Porcilis PCV has been developed to reduce the losses due to infection with PCV2. Vaccination of piglets with a single 2 ml dose at 3 weeks of age results in both humoral and cellular immunity (1). The purpose of this study was to investigate the efficacy of Porcilis PCV vaccination of piglets in a field case of naturally occurring PCVD.

**Materials and method**

A Danish pig farm received 250 piglets every other week from the same sow herd. For the first 8 weeks, the 250 piglets were housed in a separate section containing nine pens, which had previously been cleaned, disinfected, dried and heated. At around 30 kg, the pigs were moved to finishing accommodation operating continuously.

The herd’s general health was very high (Danish SPF-declaration: SPF +AP12 - meaning free from all serotypes of \textit{A. pleuropneumoniae} (except serotype 12), \textit{M. hyopneumoniae} and PRRS. Three months before the start of the trial, classical PMWS was diagnosed in piglets 4 weeks after introduction onto the farm. When the trial began, the clinical picture had changed, and the disease was classified as PCVD.

Out of a batch of piglets delivered to the farm, 100 pigs were vaccinated with 2 ml of Porcilis PCV on the day of arrival, and 100 pigs were left unvaccinated. These 200 pigs were randomly allocated to pens of 32-34 piglets each, thus mixing vaccinated and unvaccinated pigs in the same pen. This scheme was repeated with the next batch of piglets delivered two weeks later, in a separate section, thus providing, in all, 200 vaccinates and 200 unvaccinated controls.

For each batch, 3 vaccinated and 3 unvaccinated pigs from each pen were bled on days 0 (day of vaccination), 18, 56 and 109. The samples were analyzed by qPCR for PCV2 virus. On days 0, 56 and 109, all the pigs were weighed individually.

Statistical analysis of the ADG was by varians analysis (multifactorial ANOVA, Statgraphics software), and of mortality by the Chi-square test.

**Results**

During the trial, serious tail-biting occurred in one pen. Half of the deaths recorded were the result of euthanasia as a sequel to tail-biting and lameness. Apart from this, most cases of lameness and meningitis were cured by appropriate antibiotic therapy. The blood samples showed that the pigs were viraemic from day 56 onwards, throughout the trial period. Vaccinated pigs had lower levels of virus than the unvaccinated controls (Data not shown).

<td>11/200</td>
<td>18/200</td>
<td>NS</td>
</tr>
</tbody>
</table>

**Discussion**

The results showed that, even in a contaminated environment, with vaccinated pigs in direct contact with unvaccinated viraemic pigs, Porcilis PCV vaccination at weaning resulted in a significantly better ADG of 39 g during the finishing period. This is in accordance with the claim, in the SPC for Porcilis PCV2, that vaccination reduces weight loss due to infection with PCV2 (2). Since no other serious pathogens were present in the farm, the effect is related to vaccination against a ‘pure’ PCV2 infection.

Safety of Porcilis PCV in pure breed Danish pigs

Peter Astrup; Kirsten V. Larsen
Intervet/Schering-Plough Animal Health, Skovlunde, Denmark

Introduction
Porcilis® PCV is an inactivated vaccine containing a killed baculovirus vector carrying protective antigen against Porcine Circovirus 2 (PCV2) in Microsol Diluvac Forte® adjuvant. Porcilis® PCV is widely used in the pig industry because circovirus type 2 (PCV2) is considered to be the aetiologic agent of postweaning multisystemic wasting syndrome in pigs, a widespread and debilitating condition. Furthermore, it is considered the aetiological agent in porcine circovirus disease (PCVD), known as porcine circovirus associated disease (PCVAD) in the USA.

The data sheets for Porcilis® PCV warn against adverse reactions, which fall into two groups. Firstly, a transient, immediate systemic hypersensitivity-like reaction, and secondly, a transient, painless local swelling, sometimes in the order of several centimetres in diameter. These adverse reactions are to be distinguished from transient, very focal, erythema seen at the site of vaccination (1).

This study reports an investigation into the frequency and characterisation of these two adverse reactions in nucleus pigs from three pure breeds and one cross breed. The investigations were initiated due to speculations from the field, that pure breeds would have a high incidence of local reactions

Materials and Methods
Four hundred and sixty nine growing pigs between 21 and 40 days of age on two different breeding farms were selected. All were injected with Porcilis® PCV I/M and were observed 2, 15 and 60 minutes and 24 hours after injection for systemic reactions, and at days 1, 8 (or 11 on Farm two), 15 (or 18 on Farm two) and 42 after injection for signs of depression and of local swelling at the injection site. 469 pigs were included: 252 Yorkshire (YY), 119 Duroc (DD), 50 Danish Landrace (LL) and 48 crossbreeds of Yorkshire and Landrace (LY).

Results
Two of the 469 pigs showed mild, transient systemic side effects, within 15 minutes of injection. Transient, local swellings were observed to begin within twenty four hours after injection and of 469 vaccinated pigs 0.6 % showed reactions on day 1, 17.9 % on day 8/11, 34.4 % on day 15/18 (with the majority of reactions classified as a type B or C) and 0.8 % day 42 (Figure 1).

Local swellings occurred significantly more rapidly, and cleared more quickly, in DD pigs. Furthermore, LL, YY and LY groups exhibited significantly higher frequency of swellings than the DD group.

Nine (2%) of the pigs died during the trial: six from the YY group and 3 from the DD group. Post mortem examination found no evidence that vaccine reactions contributed to the cause of death (data not given)

Discussion
The purpose of this trial was to investigate the frequency and severity of adverse reactions to Porcilis® PCV vaccine in three different breeds of pigs and cross breeds of these. The reactions to vaccinations seen in this study were as expected from the data sheet advisory, i.e. mild, transient, immediate post vaccination shivering or depression and transient local swellings.

In no cases could treatment or mortality be related to the vaccination with Porcilis PCV. During autopsy of all dead YY-pigs it was judged probable, that deaths were not caused by the vaccination with Porcilis PCV.

Figure 1. The incidence of swellings in all pigs at Day 0, Day 1, Day 8 (and 11), Day 15 (and 18) and Day 42.

Conclusion
In this study swellings were seen after vaccination, but they were transient and did not negatively impact the vaccinated pigs. Hypersensitivity reactions were absent except for minor depression and shivering in two pigs.

Evaluation of the efficacy of an adjuvanted subunit vaccine (Circumvent® PCV) in the prevention of PMWS under field conditions in Vietnam

Alexander A. Eggen¹ Nguyen T. Toan² Tran T. Dan² Nguyen T. Nam² Le van Huy² Nguyen P. Nam² Vo T. An² Ho T. Nga² Nguyen T. Ninh² Le H. Ngoc²
1. Intervet/Schering-Plough, Boxmeer, Netherlands; 2. Nong Lam University, HCMC, Vietnam

Introduction
PWMS, largely caused by Porcine Circovirus Type 2, is endemic on pig farms in Vietnam. This study was designed to evaluate the efficacy of Circumvent PCV in protecting pigs on suspected PMWS farms. Circumvent PCV contains a PCV2 viral subunit (ORF2 protein) in X-Solve adjuvant. The antibody response was measured at the time the vaccine was given at 14 or 21 days of age, and again at 42 days.

Materials and Methods
The study was carried out on two commercial farms (Farms A and B with 400-1000 pigs) in two provinces in Vietnam. Both farms practiced 21-25 day weaning. Pigs were assigned randomly to either a vaccinated or a control group. On Farm A, 396 piglets of 14 days of age from various litters, were divided equally between vaccinated and control groups. On Farm B, 194 piglets of 21 days old, also from various litters were divided equally between vaccinated and controls.

All pigs in the vaccinated group were injected with Circumvent PCV (Intervet Schering-Plough, The Netherlands), on Farm A at 14 and 42 days of age, and on Farm B at 21 and 42 days of age. The trial vaccine was given intramuscularly on one side of the neck, and Mycoplasma vaccine on the other side. The controls did not receive Circumvent PCV. Pigs were observed daily for signs of illness and were weighed at 14, 28 (weaning), 75 and 120 days old on Farm A, and at 21, 84 and 165 days old (slaughter) on Farm B.

Blood samples were collected immediately prior to vaccination on Farm A (Days 14 and 42) and at 75 and 168 days of age. On Farm B, blood samples were also taken prior to vaccination (Days 21 and 42) and at 84 and 165 days of age. The sera were tested for antibodies against PCV2 by ELISA (Serelisa®, Synbiotics). The result was taken to be positive when SNc<0.5 and titers were calculated from OD at three dilutions of serum, as recommended.

Results
On both farms, the vaccinated pigs had better ADG across the age range, and lower mortality, than the controls.

Discussion
On both farms, vaccination with Circumvent PCV clearly resulted in sero-conversion after the second dose, indicating protection against PCV2 virus (Fort, 2009). This was further evidenced by a better ADG resulting in heavier slaughter weights (2.0% on Farm A and 3.5% on Farm B), lower mortality (4.5% (A) and 15% (B)) and a reduced incidence of clinical disease (25% (A), 12% (B)) compared to the controls.

Several individual parameters were statistically significantly better in the vaccinated pigs, e.g. post vaccination antibody titers and mortality. More importantly for the pork producer, the overall technical and economic performance improved on both farms.

Successful PCVD control on a pig farm in Southern China

D Xie1 Brook Fang2 Nian Huang2
1. Guangdong Chengxing Pig Farm, Guangdong, China; 2. Boehringer Ingelheim Int’l Trading (Shanghai) Co. Ltd., Beijing, China

Introduction
Porcine Circovirus type2 (PCV2) is the causative agent of various PCV2 associated diseases, including PMWS, PDNS, PRDC and PCV2 related reproductive failure or enteritis.

A recent epidemiological study revealed severe prevalence of PCV2 infection in China. Positive rates for samples tested for PCV2 in 2002-2003, 2004-2006 and 2008 reached 71 %, 81.2 % and 100% respectively [1]. This paper reports a successful case of PCVD control in a 900-sows pig farm suffering from PMWS in Guangdong, a southern province in China.

Materials and Methods
A one site production 900-sows farm built up in 1994 suffered severe PCVD. The breeding herd is vaccinated against PRRS, PRV, Atrophic rhinitis, CSFV, PPV, JEV and Streptococcus (Str.) suis, while piglets are vaccinated against PRV, CSFV, PRRSV, Haemophilus parasuis and Str. suis. Severe PMWS signs emerged since February 2009. Symptoms in late nursery included growth retardation, wasting, lethargy, anorexia and fever, while in the fattening herd, jaundice, diarrhoea, enlargement of inguinal and mesenteric lymph node, enlarged spleen with infarcts, enlarged kidneys with tan and waxy appearance and petechial haemorrhages and PDNS skin lesions were observed. The average morbidity and mortality ranged between 30-50% and 25-40%.

In May 2009, the farm started to use Ingelvac CircoFLEX in piglets around 14 days old. In total 40 weekly batches of piglet, 20 before vaccination (n= 3769), 20 vaccinated with Ingelvac CircoFLEX® (n= 3927) were included in the evaluation. Diseased pigs (morbidity) as well as dead pigs (mortality) and culls were recorded per batch.

Frequencies of morbidity, mortality and culling were analyzed by Chi-square test.

Results
Since piglet vaccination with Ingelvac® CircoFLEX, the health status of the vaccinated batches were significantly improved. Morbidity, mortality and culling were significantly reduced in vaccinated pigs, in nursery as well as in fattening (Table1 and Table2). PMWS, PDNS and PCV2 related enteritis was effectively controlled in the farm.

* p<0.05 ** p<0.01

Discussion
This farm was severely affected by PCVD as indicated by a high mortality and culling rate in the nursery and fattening period. PRRSV and CSFV were already controlled through vaccination.

Piglet vaccination with Ingelvac CircoFLEX® successfully controlled PCVD, as demonstrated by a significant reduction in morbidity, mortality and culling rate.

**The impact of PCV2 sow vaccination on PCVD in grower and finisher pigs**

Jake Waddilove  
*Eastgate Veterinary Group, Bury St Edmunds, UK*

---

**Introduction**

Porcine Circovirus Disease (PCVD) has a major impact on pig health and production throughout the world. It affects every category of pig, with its major impact being in the growing herd. Where disease is more established the focus often moves to older pigs. Costs of PCVD in the EU have been estimated at €562 – 900 million/year (1). Control has been achieved by vaccination of sows &/or pigs. The benefits of sow vaccination have been shown to extend well beyond the predicted duration of maternally derived antibodies (2). This field study further investigates the benefits of sow vaccination on the progeny of these sows.

**Materials and Methods**

The study took place in a 600-sow farrow-to-finish herd housed in a combination of straw based and slatted buildings. Growing pigs were housed in all-in, all-out rooms to 50kg, and then semi-continuous buildings. The herd had been affected by PCVD for several years. This combined with PRRS and *Mycoplasma hyopneumoniae* to lead to significant PRDC problems. Additionally *Streptococcus suis* meningitis and *Haemophilus parasuis* problems occurred up to 50kg. Attempted control had been by vaccinations for PRRS (MLV), *M. hyopneumoniae* and at times *H. parasuis*, plus various antimicrobial programmes. Results were of limited success.

In the study sows were vaccinated for PCVD using CIRCOVAC® (MERIAL) in addition to existing vaccines. A primary course given 6 and 3 weeks before farrowing was followed by boosters 3 weeks before farrowing. Progeny from these sows were monitored for pig health, medication, mortality and various slaughter parameters and results compared with previous throughput.

**Results**

Progeny from vaccinated sows reached the weaners on 08/05/08 and the finishers on 13/08/08. There was a progressive improvement in pig health. Levels of pneumonia and coughing reduced especially in finishers. Streptococcal meningitis in growers dropped to nearly zero, but increased when corrective medication was removed. It reduced again once medication was returned. Clinical evidence of *H. parasuis* decreased. The costs of medication (in feed, soluble & injectable) fell from 79p per pig in the 3 months before the pigs came through to 41p in the next 3 months & then 31p. Mortality (graph 1) progressively improved except for the temporary increase due to *S. suis* meningitis.

**Discussion**

These results show that vaccination of sows using Circovac can have benefits in their progeny though to slaughter. Control of complexed PRDC was improved while reductions in *S. suis* meningitis and *H. parasuis* problems suggested that vaccination helped reduce the impact of PCV2 on the immune competence of these pigs. These results further indicate that sow vaccination for PCV2 reduces PCVD in the finishing herd.

Prevalence of circovirus (PCV2) in vaccinated and non vaccinated swine’s from different Brazilian farms. January 2008 to August 2009

Fábio B. Rossi1, 2 Alberto Yocytaca Inoue2 Gilberto Spricigo2 Lissandro Almeida2 Masaio Mizuno Ishizuka3
1. Automomous, Campinas, SP, Brazil; 2. Fort Dodge Animal Health, Campinas, Campinas, SP, Brazil; 3. Universidade de São Paulo, São Paulo, Brazil

Introduction

Porcine circovirus type 2 (PCV2) was first described in 1998 and it was associated with a newly observed sporadic wasting disease in weaned pigs in Canada, USA (California), and France (ALLAN and ELLIS, 2000). Actually is known as one of the most important viruses in the global pig industry and the acronym PCVAD is recommended besides PMWS (systemic infection or postweaning multisystemic disease) and others PCV2-associated diseases as pneumonia, enteritis, reproductive failure, dermatitis and nephropathy syndrome (OPRIESSNIG et al., 2007). Clinical signs and lesions are observed in late nursery (8-10 weeks of age), and finisher pigs (2–3 wks after placement) (BATISTA, 2007; BRUNBORG et al, 2004)

Brazilian isolates of PCV2 were sequenced, analyzed and compared with isolates from other countries and the phylogenetic analysis showed that mostly variants were grouped as PCV2-1 (CIACCI-ZANELLA et al, 2009).

Material and Methods

Study design: this study included 2090 animals from 93 farms with medium level of biosecurity measures and clinical signs of PCVAD located in 6 states of south, south-east and west-center regions of Brazil (Paraná/PR, Rio Grande do Sul/RS, São Paulo/SP, Santa Catarina/SC, Mato Grosso do Sul/MS and Minas Gerais/MG). There were vaccinated 940 animals and 1150 were maintained as control. The SUVAXYN® PCV2 chimeric vaccine was applied intramuscularly in animals aged between 21 and 28 days and serum samples were examined 40, 60, 80 and 100 days after vaccination to quantify viral load by TaqMan® real time PCR assay (BRUNBORG et al, 2004). Statistic procedures were the test for difference of the parameters of two proportions for prevalence’s and the Mann Withney test for two median values differences (SIEGEL, 1975) and fixed α = 0,05.

Results

There were considered positive all serum with 4500 or more DNA copies of PCV2. Among vaccinated pigs the frequency of positives samples at 40, 60, 80 and 100 days were respectively, 22,5%, 14,7%, 23,6% and 13,3%. Among non vaccinated pigs the frequency of positives samples at 40, 60 and 100 days were respectively, 36,2%, 22,5%, 35,4% and 58,2%. The Graphic 1 illustrates the variation of frequencies in vaccinated and non vaccinated and age of serum examination.

Discussion

In vaccinated and non vaccinated animals, the statistical comparison of frequencies between successive ages (40 with 60 days, 60 with 80 days and 80 with 100 days) revealed a decreasing except at 80 days that could be explained as a result of high challenge due to placement to finishing houses with mixture of animals of different growing rooms. These results permit to do inference about the role of natural immunity among non vaccinated pigs and the efficacy of SUVAXYN®PCV2 in the vaccinated group in farms were de PCV2 is endemic. These results reveal a widespread PCV2 virus in Brazil mainly in areas of important swine industry similarly to mention by OPRIESSNIG et al (2007).

Serological response and influence on virus load in pigs vaccinated with Porcilis PCV

Peter Astrup1 Svend Haugegaard2 Claus B. Larsen3 Charlotte K. Hjulsager4 Lars E. Larsen4
1. Intervet/Schering-Plough Animal Health, Skovlunde, Denmark; 2. Oe-Vet, Horbelev, Denmark; 3. DanVet, Hobro, Denmark; 4. DTU Veterinary Institute, Copenhagen, Denmark

Introduction
Circovirus type 2 (PCV2) is one of the agents responsible for PMWS and PCVD, major causes of losses in pig production. Porcilis PCV has been developed to reduce the losses due to infection with PCV2. Vaccination of piglets with a single 2 ml dose at 3 week of age results in both humoral and cellular immunity (1). The purpose of this study was to investigate the efficacy in controlling viraemia of Porcilis PCV vaccination of piglets in a field case of naturally occurring PCVD.

Materials and Methods
The trial involved two high-health (SPF + AP12) farms. Farm 1 was a wean to slaughter herd and had vaccinated and unvaccinated pigs in the same pen. Farm 2 was a sow herd which produced 350-400 weaned piglets every third week, which were moved into clean, disinfected, all in/all out accommodation. They had no contact with other pigs until sold at 30 kg (half of them) or slaughtered at 105 kg. Pigs from two consecutive batches comprised one block and were randomly allocated to a treatment group (2ml Porcilis PCV, 4-6 days before weaning) or an unvaccinated control group. In all, 6 blocks (12 batches) were studied.

In each batch, 5 pigs were blood sampled four times in the growing phase (at treatment time, and at around 6, 12 and 18 weeks after weaning). Samples from the first 4 batches (20 pigs) were analyzed individually by ELISA for antibodies against PCV2. From all 8 batches, virus particles/ml were measured by real time PCR performed on pools of 5 samples from the same batch. (ELISA and PCR to National Veterinary Institute, DTU standards.)

On Farm 1, 6 vaccinated and unvaccinated 6 pigs from the mixed groups were also sampled, at weaning (day 0), days 18, 53 and 109.

Results
All vaccinated pigs in both farms seroconverted to levels of 1:250 – 1:31250 within the first 6 weeks after vaccination. These levels were slightly declining, anyway all, but one, stayed at least 1:250 throughout the observation period. Non-vaccinated reached a higher level of serological response

Figure 1: Shows antibody level in individual pigs at farm 1. Light rows are non-vaccinated, dark are vaccinated. 1-6 indicates levels of antibodies from 1:10 through to 1:31,250.

Table 1. Number of PCV2 copies (log(10)) from pools of 5 pigs from individual batches at farm 2. A-F = Blocks of 2 batches. V=Vaccinated, N=Non-vaccinated. Week = Week post weaning.

Number of PCV2 copies were significantly lower in vaccinated pigs that were co-mingled with non-vaccinated (farm 1; data not shown) and no copies (above the detection limit of 1 x 103) were found in vaccinated that were housed separated from non-vaccinated.

Discussion
Vaccination with Porcilis PCV is shown to elicit an equal and safe immuneresponse in vaccinated pigs. Even though PCV2 virus is shown to circulate in vaccinates at low numbers the measured response seems to be protective against any further stimulation of the immunesystem, indicating that the vaccination have induced an immuneresponse strong enough to avoid the proliferation of virus in infected pigs housed with highly infected littermates.

If pigs are housed only with other vaccinates the vaccine is able to protect pigs from having any development of virus at all. These results show that the strong cellular and humoral immune response developed by vaccination with one dose of 2 ml of Porcilis PCV in pigs older than 3 weeks, that Fort et al (1) found under laboratory conditions, are highly protective under field conditions.

1. Diagnostico y Consultoria Veterinaria CA, Maracay, Venezuela; 2. Universidad Central de Venezuela , Maracay, Venezuela; 3. AABL, Maracay, Venezuela; 4. Universidad Nacional de Colombia, Bogota, Colombia; 5. Empresa de Diagnostico Veterinario CA, Maracay, Venezuela

Introduction and Objectives
Recent studies have shown the effectiveness of vaccines for control of diseases associated with Porcine Circovirus Type II (PCV2). The goal of this study is to demonstrate the efficacy of an autogenous vaccine against PCV2 for the control of Porcine Multisystemic and Wasting Syndrome (PMWS) in a commercial 1000 sow farrow to finish operation in Venezuela.

Materials and Methods
The study was performed in one pig farm positive to PRRS, Mycoplasma hyopneumoniae, Glasser disease and PMWS. Samples were collected from animals with PMWS clinical signs in order to be evaluated by histopathology and immunoperoxidase assay (1). Tissues from animals identified as positive were used as source of virus for the killed autogenous vaccine.

Seven hundred forty 4 week-old-piglets were randomly selected and divided in two groups:
- Group A: 370 piglets were vaccinated with 2ml of the PCV2 autogenous vaccine at four and six weeks of age;
- Group B: 370 piglets were injected with 2ml of saline solution at 4 and 6 weeks of age.

Both groups were divided in 10 pens with 37 animals per pen, and were fed and managed under the same conditions. A clinical evaluation was assessed to each group weekly. The parameters evaluated were as follows:
- Cough index, sneezing index, prevalence of depression, lameness, conjunctivitis, diarrhea, wasting, skin lesions, pig size uniformity in the same pen and mortality rate.

Results
A summary of the results is shown in Table 1. A higher percentage of wasting pigs, presence of conjunctivitis and sneezing pigs was observed in the control group as compared to that detected in the vaccinated group. On the other hand, a lower mortality rate was observed in the vaccinated group (2.16 vs 5.40).

No evidence of diarrhea was observed in any of the groups under study.

Values with different superscripts differ significantly; a,b: p<0.05.

Discussion and Conclusions
The efficacy of commercial vaccines for the control of PCV2 associated diseases have been previously demonstrated (1). A significant difference in the mortality rate was observed in the vaccinated group as compared with the control non vaccinated group. Even though the weight of the pigs was not evaluated, the proportion of wasting pigs was significantly higher in the control group. These findings suggest the efficacy of the use of an autogenous vaccine for the control of PMWS.

On the other hand, a higher percentage of pigs with conjunctivitis, skin lesions and sneezing were observed in the control non vaccinated group, signs that could be associated with a synergic effect of PCV2 with other infectious agents.

Evaluation of the safety and the immune response after different vaccination schedules in sows: preliminary results

Eric Pagot2 Florian Voisin2 Anne Trotel2 Alassane Keita2 François Joisel1
1. Merial S.A.S., Lyon, France; 2. CTPA Zoopole développement, Ploufragan, France

Introduction
Post-weaning Multisystemic Wasting Syndrome (PMWS), Parvovirus, Erysipelas, Neonatal Colibacillosis are major diseases in pig farms worldwide. Previous internal trials which tested the effects of simultaneous vaccination of gestating sows/gilts (non-published data) with either PMWS (CIRCOVAC® coded CIR, Merial) and Parvovirus/Erysipelas (PARVORUVAX® coded PAR, Merial) or CIR and Colibacillosis (NEOCOLIPOR® coded NEO, Merial), both vaccination schemes did not raise safety concerns. This paper reports a study which was conducted in a larger scale under field conditions in France, and evaluates the safety of the two simultaneous vaccination schemes in comparison with the recommended schedules.

Material and Methods
Overall 181 sows, coming from 2 different commercial farms usually vaccinated with CIR and PAR were included into the study. In each farm, sows of each farrowing batch were randomly assigned to one of three identical treatment groups according to parity: Group 1 (G1): simultaneous vaccination with CIR,PAR 3 weeks before farrowing, and with NEO 2 weeks before farrowing. Group 2 (G2): simultaneous vaccination with CIR,NEO 2 weeks before farrowing, and with PAR during lactation. Group 3 (G3) was the control group: CIR vaccination 3 weeks before farrowing, NEO 2 weeks before farrowing and PAR during lactation. The study was planned to vaccinate the sows for 2 breeding cycles. Systemic and local site reactions as well as rectal temperature were checked during the first cycle on D0, D0+4H, D1, D2 and D7 after each injection. Statistics (1) used ANOVA (or Kruskall-Wallis test if non-normal data) and Mantel Haenszel chi-square test with p<0.05 as level of significance.

Results
The results for the second cycle are not yet available, only those from the first cycle are shown.

^a,b Different superscripts in the same column mean significantly different values. NS: non significant

For P1 and P3, no significant difference was observed between the rectal temperatures of the three groups. For P2, at D0+4h and at D1, a significant higher temperature was observed in the group 2 compared to the groups 1 and 3. However, it was moderate (0.2°C to 0.3°C more) and very transient, temperatures being similar in all groups after D1.

At any time point of the study, no significant difference was observed between groups in general condition.

No significant difference was observed between the numbers of piglets born alive per sow of the three groups: respectively 13.3, 14.3 and 13.4 in the groups 1, 2, 3.

No significant difference was observed between groups in the proportion of sows with local reactions after vaccination.

Discussion and Conclusion
A moderate and transient higher temperature was observed in the group receiving CIR,NEO 2 weeks before farrowing, with no impact on the general condition. Since no adverse reaction was observed in born alive piglet, these results support the safety of the different simultaneous vaccination schedules.

Simultaneous vaccination of weaner pigs with SPRINTVAC® and CIRCOVAC® (Merial)

H.C. Lim¹ B.K. Lim² P.Y. Choo³

1. Rhone Ma Malaysia (M) Sdn Bhd, Selangor, Malaysia; 2. Vet Food Agro Diagnostic (M) Sdn Bhd, Selangor, Malaysia; 3. Asia Pacific Special Nutrients (M) Sdn Bhd, Selangor, Malaysia

Introduction

Recommended vaccination schedules for Mycoplasma hyopneumoniae (M. hyo) and porcine cirovirus type 2 (PCV2) for piglets may overlap. The administration of different vaccines simultaneously often gives rise to concerns about safety and efficacy. The present study was conducted to determine the safety and the serological response after simultaneous administration of SPRINTVAC, an oil adjuvanted bacterin vaccine against M. hyo and CIRCOVAC, a killed PCV2 vaccine containing Immuneasy®, the same adjuvant, in piglets.

Method and material

A batch of thirty four 4-week old weaners from a farm known to be free of Aujeszky’s disease, Porcine Respiratory and Reproductive Syndrome (PRRS) and classical swine fever were randomly allotted to 4 groups (Table 1). When simultaneous vaccination was performed, the vaccines were injected on opposite sites on the neck region. Vaccines were given intramuscularly at 4 weeks of age. All pigs were housed in adjacent pens and managed in same manner throughout the trial period.

Serums collected weekly from 4 to 10 wks of age and then at 12 and 20 weeks of age were tested for antibodies to M. hyo and PCV2 using the IDEXX test kit, and Synbiotics SERELISA PCV2 test kit respectively. The effects of local site reactions and anorexia were observed for up to 3 weeks after vaccination.

Results and Discussion

The serological profiles for M. hyo and PCV2 antibodies are shown in Figures 1 and 2.

Three weeks after vaccination, 100 % and 87.5% of pigs in the S and C+S groups were tested positive for M. hyo antibodies and had similar profiles throughout the period of the trial. Pigs in the C and Control group were negative for M. hyo antibodies until 10-12 weeks of age most likely due to exposure to field M. hyo infection.

All piglets were positive for the presence of maternal antibodies to PCV2 titer at the beginning of the trial. As the pigs aged, reduction in the PCV2 antibody titer was observed in pigs from S and Control group from 8 weeks of age. In the C and C+S group, PCV2 antibody titers were maintained at high levels up to 20 weeks old when the study was terminated.

There were no adverse local reactions to the vaccinations or anorexia observed post-vaccinations

Conclusion

In this study, no adverse local reactions or anorexia were observed with the simultaneous vaccination on two different sites intramuscularly in the neck muscles of 4 week-old piglets with SPRINTVAC and CIRCOVAC. The present study showed that simultaneous vaccinations using the vaccines that were tested induced similar serological responses as vaccines used separately.

The impact of PCV2 viremia in a high health Canadian swine herd, a vaccination trial comparing two commercial vaccines

Melissa Reindl1 Cate Dewey1 Kevin Vilaca2 Francisco de Grau3 Karen Richardson1 Zvonimir Poljak1
1. University of Guelph, Guelph, ON, Canada; 2. Maitland Veterinary Professional Corp., Listowel, ON, Canada; 3. Intervet Canada, Kirkland, QC, Canada

Introduction
Subclinical infections with PCV2 are common1,2 and can occur in the absence of co-factors or if vaccination does not prevent viral replication3. PCV2 viremia produces immune system activation4 which causes the redirection of nutrients intended for growth to counteract disease challenge5. The objective of this field trial was to compare the productivity of nursery and grower-finisher (G-F) pigs vaccinated with a labeled dose of one of two commercial circovirus vaccines or a placebo. Productivity was measured as average daily gain (ADG), feed disappearance, and mortality.

Materials and Methods
A total of 2,146 pigs were selected from a PRRS- and M. hyopneumoniae-free herd. The pigs were assigned to one of three treatment groups: 1. One dose (1-D) pigs vaccinated with Circoflex® BIVI (n=1026); 2. Two dose (2-D) pigs vaccinated with Circumvent® ISPAH (n=1020); and 3. Controls injected with saline (n=100). Pigs were individually weighed at approximately 3, 11 and 20 weeks of age as well as prior to slaughter (at least 107 kg). Blood samples were taken from a random sample of 122 pigs at approximately 3, 9, 15, 19, and 23 weeks of age and also during the final week of shipping. Viremia was measured using qPCR.

Results
Throughout the entire G-F phase, the ADG of vaccinated animals outperformed that of unvaccinated controls (p<0.01). Also during this time, controls had a higher mortality (5.1%) than 1-D (1.7%) and 2-D (1.6%) pigs (p<0.05). While the control group had a higher percentage of viremic pigs during the G-F phase compared to the vaccine groups (p<0.01), the 1-D vaccinated pigs were also more likely to be viremic compared to the 2-D vaccinated pigs (p<0.01).

In the second half of the G-F phase, when qPCR results indicated the highest natural PCV2 challenge, the ADG of the 1-D pigs began to decrease. From 19 weeks of age to slaughter, the 1-D vaccinates had an ADG that was 42.3 g/day lower than the 2-D vaccinates (p<0.01) after controlling for starting weight and weaning cohort. In addition, the 1-D vaccinates and 1-D controls had a higher amount of feed disappearance compared to the 2-D vaccinates and 2-D controls throughout the G-F phase. This means that, although the 1-D pigs were growing at a slower rate, they were potentially eating more feed than the 2-D pigs.

Implications
Overall, vaccination reduced mortality and increased ADG. However, only the 2-D vaccine was able to control viremia and maximize ADG during the high PCV2 challenge in the finisher phase.

Reduction of porcine circovirus type 2 load in vaccinated pigs with Circumvent™ PCV

Yeong Hun Kim¹ Myung Hyee Kim² Jeong Hee Han¹
1. School of Veterinary Medicine and Institute of Veterinary Science, Kangwon National University, Chuncheon, Korea; 2. Intevet Schering-Plough, Seoul, Korea

Introduction
A new emerging disease termed “post-weaning multisystemic wasting syndrome” (PMWS) was identified and reported in Canada. PMWS manifests as systemic disease characterized by weight loss, a relatively high mortality rate among pigs in the 10-to 17-week-old age group and lymphadenopathy causing immunosuppression. PMWS diagnosis is based on the presence of characteristic histopathological lymphoid lesions and PCV2 within these lesions. Also, the presence in a sample of animals of high PCV2 loads is suggested as indicating the presence of PMWS lesion using real time PCR. Thus, this study was to evaluate whether vaccination against PCV2 can reduce PCV2 load or not.

Materials and Methods
159 piglets from 3 different farms, Farm A, B, and C located in Hongsung-gun, Choongnam province, Korea, that had a history of PCVD will be included in this study and divided into 2 groups, vaccinated and placebo. Pigs in the vaccination group were given CIRCUMVENT™ PCV (Intevet Schering-Plough) IM in 3 and 6 weeks of age. Control pigs were handled in a similar manner as vaccinated pigs with saline. For quantification of the PCV2 viral load in serum, serum samples were analyzed by TaqMan real time PCR as described previously (A. Olvera et al. 2004)

</tr>
</tbody>
</table>

Results and Discussion
The profile of PCV2 load during the course of the study is described in Fig. 1, 2 and 3. All of the farm had the presence of high maternal derived antibodies against PCV2. Peak level of PCV2 positive animals were reached when animals were approximately 10-16 weeks of age in placebo-treated group. In vaccinated group, level of positive animal decreased dramatically than placebo-treated group. Animals with high viral loads (10⁶ PCV2 genome/ml in serum) were observed in the acute phase when is 10 to 16 weeks of age. Compared to the placebo-treated group the proportion of PCV2 positive animals in the vaccinated group was significantly lower (P=0.0021, Farm A; P<0.0001, Farm B; P<0.0001, Farm C). Based on the results, vaccination with CIRCUMVENT™ PCV would reduce PCV2 load in serum.

References
**Introduction**

PCVAD is now well established as a wasting disease associated with PCV2 and has rapidly become one of the most devastating and economically important concerns in all pig-producing areas of the world. And PCV2 could be an important contributor to PRDC characterized by slow growth, decreased feed efficiency, and increased clinical sign index, such as lethargy, anorexia, fever, cough and dyspnea. In this disease, although the exact pathogenic mechanisms responsible for these diseases are unknown, several studies have suggested that PCV2 infects macrophages and B lymphocytes, inducing apoptosis of the B cells and the damage of lymphoid tissues resulting in extensive lymphocyte depletion. Immunosuppression is believed to be a key of PCVAD. The purpose of this study was to evaluate the effects of inactivated PCV2 vaccine in Korean commercial farms that had a history of PCVD.

**Materials and Methods**

50 piglets from a farm, located in Choongnam province, Korea, that had a history of PCVD will be included in this study and allocated into 2 groups equally, vaccinated and placebo. Pigs in the vaccination group were given the PCV2 vaccine IM in approximately 3 weeks of age. On the other hands, Control pigs were handled in a similar manner as vaccinated pigs with saline. ADG was obtained by dividing weight gain by the number of days from vaccination to the end of the nursery phase, by number of days from the end of the nursery phase to the entry into the finishing phase. Immune response in serum sample was analyzed using IFA. Mortality rate was calculated for each group. For statistical analysis, student t-test or Wilcoxon Mann-Whitney test was used in order to assess differences with regard to ADG and serology. Fisher’s exact test was used to investigate possible differences in mortality.

**Results**

Mean ADGs during the overall period for experiment were increased by 19.2% in vaccinated group. compared with placebo group. Vaccinated group had consistently a significantly higher mean PCV2 antibody titer than placebo group in 10 weeks of age when is the onset of PCV2 viremia. During the period following the vaccination placebo group had an 24.0% higher mortality rate than it of vaccinated animals.

Immune response by vaccination with Circumvent™ PCV

Yeong Hun Kim¹ Myung Hyee Kim² Jeong Hee Han¹
¹. School of Veterinary Medicine and Institute of Veterinary Science, Kangwon National University, Chuncheon, Korea; ². Intevet Schering-Plough, Seoul, Korea

Introduction
PCVAD is now well established as a wasting disease associated with PCV2 and has rapidly become one of the most devastating and economically important concerns in all pig-producing areas of the world. In this disease, although the exact pathogenic mechanisms responsible for these diseases are unknown, several studies have suggested that PCV2 infects macrophages and B lymphocytes, inducing apoptosis of the B cells and the damage of lymphoid tissues resulting in extensive lymphocyte depletion. Immunosuppression is believed to be a key of PCVAD. The purpose of this study was to evaluate the immune response of inactivated PCV2 vaccine in Korean commercial farms.

Materials and Methods
159 piglets from 3 different farms, Farm A, B, and C located in Hongsung-gun, Choongnam province, Korea, that had a history of PCVD will be included in this study and divided into 2 groups, vaccinated and placebo. Pigs in the vaccination group were given CIRCUMVENT™ PCV (Intevet Schering-Plough) IM in 3 and 6 weeks of age. Control pigs were handled in a similar manner as vaccinated pigs with saline. Immune response in serum sample was analyzed using SERELISA PCV2 Ab Mono Blocking (Synbiotics, France) according to the manufacturer’s instructions. For statistical analysis, student t-test or Wilcoxon Mann-Whitney test was used in order to assess differences with regard to serology. Statistical analyses were performed using SAS software release 8.2.

Results
Maintenance of antibody responses in vaccinated group had been continued with high antibody level until 16 weeks of age in Farm A and 24 weeks of age in Farm B and Farm C by vaccination. However, infectious antibodies in placebo-treated group were confirmed at 13 or 24 weeks of age. Interestingly, at 24 weeks of age, the lower antibody response was observed in vaccinated group than in placebo-treated group.

Discussion
Analysis of immune response against PCV2 revealed that vaccinated group had the higher immune response more than placebo-treated group at 10 to 16 weeks of age when is the period of acute infection with PCV2. In conclusion, vaccination against PCV2 would have an effect to activate immune response against it.

A field efficacy of growth performance and mortality rate in vaccinated pigs with *Circumvent*™ PCV

Yeong Hun Kim¹ Myung Hyee Kim² Jeong Hee Han¹

1. School of Veterinary Medicine and Institute of Veterinary Science, Kangwon National University, Chuncheon, Korea; 2. Intevet Schering-Plough, Seoul, Korea

Introduction
Porcine circovirus type 2 has been reported throughout the world since it is first described in Canada in the early 1990s. Recently, these diseases are also called as porcine circovirus associated disease (PCVAD) PCVAD has been reported with increasing frequency in swine herds in Western Europe, North America and eastern Asia. The problem with PCV2 is similar to previous results reported in above country. The introduction of PCV2 vaccines is contributing to reduce the incidence of PMWS and their associated diseases. However, there have been a few investigations demonstrating the efficacy of PCV2 vaccine and no published study on commercial Korean farms. The purpose of this study was to further investigate the effects on growth performance and mortality of vaccination against PCV2 on commercial Korean farms having positivity for PCV2

Materials and Methods
159 piglets from 3 different farms, Farm A, B, and C located in Hongseong-gun, Choongnam province, Korea, that had a history of PCVD will be included in this study and divided into 2 groups, vaccinated and placebo. Pigs in the vaccination group were given a single dose of the PCV2 vaccine (Intevet Schering-Plough) IM in 3 weeks of age. A second dose of vaccine was administered 3 weeks after the first dose. Control pigs were handled in a similar manner as vaccinated pigs with saline. The individual body weight of all study animals was measured at 3, 6, 9, 13, 16 and 24 weeks of age. Mortality rate was calculated for each group. For statistical analysis, student t-test or Wilcoxon Mann-Whitney test was used in order to assess differences with regard to ADG. Fisher’s exact test was used to investigate possible differences in mortality. Statistical analyses were performed using SAS software release 8.2.

Results
As seen average daily weight gain, it was considered to be an objective measurable parameter to determine the severity of PCVAD and the effects of vaccination in a large number of animals. Vaccinated groups had significantly improved growth performances more than placebo-treated group in either or both Entry into the finishing phase or/and midpoint of the finishing phase. The total of mortality rate from vaccinated group was significantly lower during the finishing phase, compared with placebo-treated group.

Discussion
Pigs vaccinated against PCV2 showed more increased ADGs and more reduced mortality rate with statistical differences in the finishing phase compared with placebo-treated group. Thus, vaccination against it can reduce economic losses from PCV2 infection To our knowledge this is the first report of the efficacy of vaccination against PCV2 in Korean field farms.

Reduction of lung lesions in vaccinated pigs with Circumvent™ PCV

Yeong Hun Kim1 Myung Hyee Kim2 Jeong Hee Han1
1. School of Veterinary Medicine and Institute of Veterinary Science, Kangwon National University, Chuncheon, Korea; 2. Intevet Schering-Plough, Seoul, Korea

Introduction
Porcine circovirus type2 (PCV2) is the primary causative agent of porcine circovirus-associated disease (PCVD), which is recently replaced from postweaning multisystemic wasting syndrome (PMWS). PCV2 is required to cause the characteristic lymphoid depletion of PCVAD. Coinfection with several other viral and bacterial pathogens has been shown to cause an increase in incidence and a markedly more severe clinical course of disease. The agent implicated as creating the greatest risk is porcine reproductive and respiratory syndrome virus (PRRSV), porcine parvovirus (PPV), and Mycoplasma hyopneumoniae. Therefore, this study performed to evaluate whether vaccination against PCV2 reduce mycoplasmic lung lesions in pigs or not.

Materials and Methods
100 piglets from 2 different farms, Farm A and B located in Hongsung-gun, Choongnam province, Korea, that had a history of PCVD will be included in this study and divided into 2 groups, vaccinated and placebo. Pigs in the vaccination group were given CIRCUMVENT™ PCV according to manufacturer’s instrument. Control pigs were handled in a similar manner as vaccinated pigs with saline. For lung lesion analysis, at 24 weeks of age, macroscopic lung lesions were estimated based on the amount of lung parenchyma affected by lesions according to Straw et al (1986). Statistical analysis performed with Wilcoxon Mann Whitney test for lung lesion analysis.

Results and Discussion
In case of farm A, piglets in vaccinated group had a significant lower (P<0.05) mean of lung lesions score (1.4±0.7) than piglets in placebo-treated group (2.7±1.3). Vaccine efficacy in reducing lung lesions score was 48%.

In case of farm B, although there was no significant difference in lung lesions between treatment groups, piglets in vaccinated group had lower mean of lung lesions score with placebo-treated group and vaccinated group being 1.8 and 2.5, respectively. Under the conditions described in this study, vaccination against PCV2 in piglets would reduce lung lesions at slaughter.

Detection of Mycoplasma hyopneumoniae from porcine nasal cavity in vaccination against PCV2 in Korea

Seung Hyuk Yang; Yeong Hun Kim; Jeong Hee Han
School of Veterinary Medicine and Institute of Veterinary Science, Kangwon National University, Chuncheon, Korea

Introduction
Mycoplasma(M) hyopneumoniae, the primary pathogen of enzootic pneumonia, is an integral component of the porcine respiratory disease complex(PRDC). M. hyopneumoniae causes to increase susceptibility to other respiratory disease. The vaccination is easy to control MH infection. Porcine circovirus type 2(PCV2) is considered to be the causative agent of PMWS. PCV2 infection affects pig's immune system and increases susceptibility of other viruses and bacteria. PCV2 is widely prevalent in pigs with PRDC and should be considered a major respiratory pathogen. The interaction of PCV2 with other respiratory pathogens plays an important role in developing PRDC. The PCV2 vaccination reduces clinical signs of respiratory and the detection rate of other respiratory pathogens in vaccinated pigs. The interactions with different respiratory pathogens, porcine reproductive and respiratory syndrome(PRRS), swine influenza virus(SIV) and Actinobacillus pleuropneumoniae (APP) were studied. It was the purpose of this study to evaluated the detection rate of M. hyopneumoniae from nasal swabs in vaccination against PCV2.

Materials and Methods
A total of 40 3-week-old piglets were allocated into 2 groups and either vaccinated against PCV2(DSPCV2 ®,Korea) and treated with a placebo. Pigs were inoculated intramuscularly with 2.0 ml either the vaccine or saline at three weeks of age. Blood samples were collected in each pigs at four different points during their growth period: 3, 6, 9, 16 weeks of age. Antibody titers were evaluated by using ELISA Kit(Mycoplasma hyopneumoniae Antibody Test Kit (IDEXX,USA). Intranasal swabs were collected from nine pigs of vaccination groups and eight pigs of placebo group at 3, 6, 9, 16 weeks of age. M. hyopneumoniae DNA was extracted by using Accuprep® Genomic DNA extraction kit(Bioneer, Korea) and detected with nest-PCR and conventional PCR. For statistical analysis, student t-test or Wilcoxon Mann-Whitney test was used in order to assess differences with regard to serology. Statistical analyses were performed using SAS software release 8.2.

Results
The infection of M. hyopneumoniae was demonstrated by ELISA in serum and PCR in nasal swabs. The high antibody titers of M. hyopneumoniae were detected in non-vaccinated group against PCV2 compared to vaccinated group (table 1). M. hyopneumoniae seroconversion was observed at 9 weeks of age in non-vaccinated group against PCV2. M. hyopneumoniae DNA was detected in 37.5% at 9weeks of age , 25% at 16weeks of age in non-vaccinated group. M. hyopneumoniae DNA was only detected in 11% at 9weeks of age in vaccinated groups against PCV2 using nested PCR (table2).

Discussion
The infection and antibody titers of M. hyopneumoniae decreased in the PCV2 vaccination group. The high titers of PCV2 antibody is intended to decrease antibody of M. hyopneumoniae and decrease of detection of M. hyopneumoniae antigen in nasal swabs. The PCV2 is supposed to influence the infection of M. hyopneumoniae. In addition, the nest-PCR is effective method to detecting M. hyopneumoniae DNA in nasal swabs.

Efficacy of PCV2 Vaccination on Morbidity under Philippine Field Conditions

Edmundo C. Sy² Philip R. Lehrbach¹ Libertad S. Reyes² Civilo Q. Lima³ Jose R. Balantakbo⁴
1. Pfizer Australia, Melbourne, VIC, Australia; 2. Fort Dodge Animal Health Philippines, Inc, Mandaluyong, Philippines; 3. Sta Cruz Farm, Pampanga, Philippines; 4. Reva Farm, Laguna, Philippines

Introduction and Objective

In the Philippines a phylogenetic analysis of the sequences of PCV2, isolated from PMWS affected local farms, allocated isolates into a PCV2 subgroup with Canadian and European isolates (1). Suvaxyn® PCV2 (Fort Dodge Animal Health, USA) is the Chimeric PCV1-2 vaccine containing immunogenic capsid gene of PCV2 cloned into the backbone of the non-pathogenic PCV1. Experimental vaccination with the chimeric PCV1-2 significantly reduced viraemia and decreased the risk of clinical diseases (2). It is on this basis that an efficacy study was performed to measure the difference in morbidity cases between vaccinated and control animals under Philippine field condition.

Material and Methods

Three farms were selected where PMWS had been positively identified through the analysis of clinical signs, histopathology lesions and a specific PCV2 antigen fluorescent antibody test. At each trial site the pigs were individually ear tagged, numbered and colour coded to indicate the treatment group. Codes were not known to the farms and the identity of the vaccines (Suvaxyn PCV2 or placebo) was blinded when administered.

Individual animals were clinically evaluated on days 0, 21 and 84 post vaccination. The signs evaluated were body condition, presence of respiratory and digestive clinical signs (coughing, dyspnea and diarrhea) and behaviour. Pigs’ body condition was recorded by applying a numeric value ranging from 1 to 6, based on individual evaluation of the pelvis, vertebrae and ribs (3). Presence of coughing, dyspnea, diarrhea in the animals and their behaviour was recorded (4) with a numeric value ranging between 0 and 2. The clinical score (CS) was calculated as:

\[ CS = \frac{(\text{numeric value of diarrhea} + \text{numeric value of behaviour} + \text{numeric value of coughing} + \text{numeric value of dyspnea divided by 4}) + (6 - \text{numeric value of physical condition})}{4} \]

Morbidity, expressed as a percentage of the group was calculated as the number of animals with a CS higher than 0, divided by the total number of pigs of the clinical study on days 0, 21 and 84 of the study.

Result and Discussion

Morbidities (%) recorded on each farm are shown in Table 1. These percentages reflect the number of pigs transferred to nursery or hospital pens during the course of the trial.

</tbody>
</table>

The vaccinated groups had overall significantly reduced incidence of morbidity (one sided p < 0.001). The controls were 1.90 (95% confidence limits = 1.31, 2.77) times as likely to have morbidity.

These differences were not significant (p = 0.15) on piggery Farm 1, but they were on Farm 2 (p = 0.01) and Farm 3 (p = 0.02).

Thus on the majority of the farms there was a significant reduction in the levels of morbidity in the Suvaxyn PCV2 vaccine group. These results are consistent with an immune response that acts to lessen the impact of the presence of PCV2 on pig growth.

The reproduction and production improvements in a South African commercial piggery after introducing whole herd vaccination against PCV2

Pieter J. Grimbeek
Private Practitioner, Potchefstroom, South Africa

Introduction
A wide range of clinical signs and diseases can be associated with PCV2 infection, including PMWS, PDNS and reproductive failure. While piglet vaccination has been proven to be the most effective tool to control losses attributable to PCV2 infection in grow-finish pigs (1), sow and gilt vaccination might have a positive effect on reproductive performance (2). This is the first report evaluating the benefits of whole herd vaccination (sows, gilts, boars and piglets) with Ingelvac CircoFLEX®, a subunit PCV2 vaccine that became available in South Africa mid 2008 under a special import permit.

Materials and Methods
The piggery is a 4500 sow continuous flow, farrow to finish unit. Most if not all the modern diseases except for PRRS and SIV are present.

During the first quarter of 2008 a nutritional insult resulted in poor on farm performance that was exacerbated by an acute PCV2 challenge with subsequent clinical outbreaks of PMWS and PDNS. PCV2 infection was confirmed by both serology and immunohistochemistry. A Ingelvac CircoFLEX® vaccination program was then implemented in September 2008. All piglets were vaccinated at 18 days of age. As the reproduction parameters were severely challenged and had in fact been under pressure for some time a calculated decision was taken to vaccinate the breeding herd as well. All the gilts, sows and boars were vaccinated once with one ml of CircoFLEX® intramuscularly, irrespective of their status, and repeated with the same dosage when the sows were 90 days pregnant. All future gilts, when entering the herd as maidens, were vaccinated at 168 days of age and then, if successfully mated, repeated at 90 days of pregnancy.

Farrowing rate, number of piglets born alive and weaned/litter, pre wean mortality for the effect of breeding herd vaccination and post wean mortality for the effect of piglet vaccination were evaluated before and after implementation of PCV2 vaccination with one-way ANOVA, pairwise comparison, using vaccination status as variable factor, and the Dunnett’s Test as a post hoc test (Statistica® v8.0, Statsoft®, USA).

Results
Accurate and comprehensive on farm records are kept depicting all actions and performance levels. Results are summarized in table 1. Figure 1 demonstrates that not only the number of piglets weaned per litter increased, but consistency of production improved as well.

a,b: figures with different superscripts are significantly different (p< 0.05)

Discussion
The results of this field observation confirm that PCV2 piglet vaccination is a very effective tool to control PCVD in wean-to-finish pigs. PMWS and PDNS disappeared from the herd and post-wean mortality was reduced significantly. Furthermore, in this case the improvement in reproductive performance indicates that vaccinating the breeding herd with Ingelvac CircoFLEX might have additional benefits on top of piglet vaccination.

**Introduction and Objective**

Porcine Circovirus Associated Diseases (PCVAD) is a broad categorization of multi-systemic diseases that can be sub-clinical or cause a severe economic impact due to its ability to cause high mortality and lowered growth performance (1, 2). The main causative agent of the disease is Porcine Circovirus Type 2 (PCV2) but other factors are required for clinical signs and lesions to appear (3). In the Philippines, a phylogenetic analysis of the sequences of PCV2, isolated from PMWS affected local farms, allocated isolates into a PCV2 subgroup with Canadian and European isolates (4). Suvaxyn® PCV2 (Fort Dodge Animal Health, USA) is the Chimeric PCV1-2 vaccine containing immunogenic capsid gene of PCV2 cloned into the backbone of the non-pathogenic PCV1. Experimental vaccination with the chimeric PCV1-2 significantly reduced viraemia and decreased the risk of clinical diseases (5). This study determined the effects of PCV2 vaccine on market weight and mortality in commercial farms in the Philippines.

**Material and Methods**

Three 500 sow level farms in Luzon (the Philippines) were assessed for PCVAD using clinical signs, histopathology lesions and a specific PCV2 antigen fluorescent antibody test. A total of 770 piglets from the three farms were included in the study (Table 1). All piglets in the vaccinated group were given a 2mL Suvaxyn PCV2 intramuscular injection at 28 days of age. Harvest weights were taken at 165 days. Mortalities from day 28-150 were recorded.

**Results and Discussion**

**Impact of CIRCOVAC® sow PCV2 vaccination on piglet weaning weight**

N. Brons1 Ricardo Neto2 Thaïs Vila3 Sophie Longo4 François Joisel3

**Introduction**

Early exposure to PCV2 compromises the ability to respond to infectious agents (viral and bacterial) if the pig is exposed to PCV2 without the presence of protective passive immunity. The objective of this study was to evaluate the effect of CIRCOVAC® sow vaccination on the pre-weaning performance of the pigs.

**Material and Methods**

The chosen farm was a 1,270-sow indoor breeding unit farrowing 60 sows per week and weaning off site.

PCVD haven’t been previously diagnosed on the progeny of this breeding unit and no PCV2 vaccine was being used before this study.

Dam line gilts were weaned before the weighing and were not included in this study.

The average weaning age before and after was approximately 28 days. Sows started being vaccinated with CIRCOVAC in June 2008, following the recommended protocol.

To evaluate the impact of PCV2 sow vaccination on piglet weaning weight, 1,007 piglets from non-vaccinated sows and 955 pigs born from vaccinated sows were weighed at weaning. The skewness and kurtosis values of the weights at weaning were studied following a normal distribution (at 95%) and the live weaning weight (LWW) before versus after vaccination was compared using the following statistical tests, Bartlett test, student t-test and Kruskal-Wallis one way analysis of variance.

The distribution of pigs in different weaning weight groups was also evaluated using chi² test.

**Results**

The number of total pigs born alive per litter for a period of 35 weeks before and after CIRCOVAC sow vaccination started, was 11.1 and 11.3, respectively. The number of pigs weaned on average per litter for the same period was 9.5 and 9.4, respectively. This was due to the PRRS problems that affected the sow herd and impacted in the general sow health.

The results of the analysis of the data collected can be seen on table 1. A significant improvement in the average weaning weight after the use of vaccine of 0.93 Kg was showed (student t-test and Kruskal Wallis tests; p<0.001).

**Table 1: Evaluation of the weaning weights before and after sow vaccination**

</tbody>
</table>

¹, b Different superscripts in the same row mean significant difference (Chi² test; p<0.001).

**Discussion**

Lighter weaning weights and percentage of small pigs are associated with higher mortality and slower growth. Heavier pigs perform better from weaning to slaughter, result of higher daily live weight gains (1, 2).

A significant improvement in the mean weaning weight of 0.93 Kg was observed in this study.

Reduction of the number of pigs with a low weaning weight have the advantage of making multi-site systems easier to manage (2) and may also represent a direct financial improvement to the breeding herd as some weaner producers receive premiums based on weaning weights.

In this study, the use of CIRCOVAC resulted in the reduction of the percentage of pigs weighing less than 6 kg from over 12.1% to 1.8%. The improvements observed may be attributed to the protection granted by maternally derived immunity against PCV2 challenge, which improves the health of the animals from birth, improving the growth of the animals, resulting in a higher weight at weaning.

Comparison of CIRCOVAC® (Merial) and a recently licensed PCV2 weaner vaccine in UK condition

Frank Tobin
Holmefield Farm Services, Agriculture House, Murton, UK

Introduction
The first cases of PCV2 associated diseases (PCVD) in the UK occurred in 1999. The cost of PCVD to European pig producers was calculates to reach 562-900 M€ per year (1). PCV2 vaccines proved to be an efficient tool to control PCVD.

The first available vaccine, CIRCOVAC® (Merial) (CVAC) was licensed for use in breeding animals but was used to vaccinate piglets at weaning in cases where management factors would compromise the efficacy of sow vaccination. The objective of this study was to assess the impact of a recently licensed piglet vaccine (FVAC) on pig performance compared to the performance achieved using the previous PCV2 vaccine licensed for breeding animals (CVAC).

Material and Methods
A 700-sow indoor unit was chosen for this study. Pigs were allocated to either group randomly and individually weighed at weaning (W), end of the grower stage (EF) and before slaughter (S). The allocation of pigs was blinded to farm management. Pigs from 2 batches were individually identified and received either 0.5 ml of CVAC or 1 ml of FVAC administered deep intramuscularly at W. 91 pigs were included in the FVAC group and 100 pigs were included in the CVAC group. 20 pigs were bled at W and at the following weightings. The samples were tested by qPCR for quantification of PCV2 genome (minimum detection level 2x10^3/ml) and qELISA for quantification of PCV2 specific antibodies.

Both vaccines were compared on the following parameters: average daily weight gain (ADWG) in post-weaning, ADWG in finishing, ADWG from weaning to slaughter, weight at entry in finishing stage and slaughter weight.

Two-tailed student t-test was used to compare the different parameters of the 2 vaccines for each farm, separately.

Results
The mean parameter values of CVAC groups are always slightly higher than FVAC groups values in both farm (table 1), but there was no statistically significant difference between the two groups (CVAC and FVAC) for the ADWG. The difference between both vaccines is significant for the slaughter weight parameter only (p=0.040), in farm 1. Piglets vaccinated with the CVAC presented higher slaughter weight, in average, than the ones vaccinated with the FVAC.

The results of the blood samples can be seen on table 2. Both groups had high titres of antibodies at weaning. All pigs tested were negative at W and EF for qPCR, with 23.5% and 6.7% positives (of the sampled pigs) at S for FVAC and CVAC respectively, with 1 pig in the group FVAC above 10^6 PCV2 genome copies.

Discussion and Conclusion
Due to the small number of animals involved in this study it was not possible to show a statistical difference, except for slaughter weight in farm 1. Nevertheless average values of ADWG at all stages of production and the slaughter weight parameter are always slightly higher in CVAC vaccinated groups in both farms. In one of the vaccinated groups, FVAC had a slightly higher level of viremia, but this was not associated to disease (2, 3).

These results indicate that both vaccines are efficient tools for the control of PCV2, resulting in performance improvement.

Efficacy of CIRCOVAC® and 2 other PCV2 vaccines in piglets

Ronie Pinheiro³  Glauber Machado³  Edson Bordin²  Julie Venet¹  François Joisel¹
¹. Merial S.A.S., Lyon, France; ². Merial Animal Health Ltda., Campinas, SP, Brazil; ³. Integrall Soluções em Produção Animal Ltda, Patos de Minas, MG, Brazil

Introduction
Porcine circovirus diseases (PCVD) have been described in Brazil since 2000. PCV2 vaccination efficacy with CIRCOVAC® has been extensively confirmed (1, 2) so it has been decided not to carry out a trial with negative control.

The objective of this study was to evaluate the effect of CIRCOVAC vaccination over wasting versus 2 other commercial PCV2 vaccines marketed in Brazil, under Brazilian field conditions.

Material and Methods
The experiment was carried out in a commercial farm with PCVD clinical diagnosis previously established. A total of 1,800 3-week-old piglets were individually weighed and randomly allocated into 3 groups (600 per treatment) vaccinated at weaning:

- Treatment 1 (T1): CIRCOVAC, 0.5 ml once
- Treatment 2 (T2): Vaccine X, 2 ml once
- Treatment 3 (T3): Vaccine Y, 1 ml once

Serology was performed by ELISA using the IT-BAN-028-ELISA-Test (Nano-Core®, NJ, USA). Three hundred serum samples were collected before vaccination i.e. at 21 days of age and at 36, 66, 96 and 126 days. The experimental unit was the animal for the daily weight gain (DWG), and the pen (40 heads) for the feed conversion evaluation. Animals were fed throughout the experiment with ration according to the Brazilian charts values of poultry and swine (3). Feed consumption per pen was evaluated weekly.

The software package statistical analysis for genetic epidemiology (S.A.G.E.) was used for variance analysis and mean comparison. For mortality rates, Chi²-test and non-parametric tests like Kruskall-Wallis were used.

Results and Discussion
No difference in weights at weaning was found between groups while piglet vaccination significantly affected the nursery exit weight (p<0.05). CIRCOVAC vaccination and T3 led to higher weight gains at nursery and slaughter (see Table 1). T1 and T3 showed globally better growth performances than T2 (see Table 1). Performing serologies at different piglet ages, T1 showed higher titres and all treatments showed a significant increase starting at 66 days of age, which led to the hypothesis of wild virus exposition from that day on. In all groups a significant increase in the antibody titres for PCV2 was observed and these were kept high until 126 days (see Figure 2).

Conclusion
CIRCOVAC-vaccinated piglets (T1 group) and T3 induced similar weight performance. T1 group showed a stronger seroconversion after vaccination and kept higher ELISA antibody titres up to the end of the experiment compared with the 2 other treatments.

Report on the impact of early exposure by PCV2 in a vaccinated flow

Tom Gillespie
Rensselaer Swine Services, Rensselaer, IN, USA

Introduction
Porcine circovirus associated diseases (PCVAD) have had a massive negative impact on the global pig industry. The availability of efficacious commercial vaccines has vastly reduced the clinical signs associated with PCVAD, especially the high mortality rates, wasting and increased frequencies of co-infections with other pathogens. In this case report we describe the impact of shifting PCV2 infection dynamics in a herd in which PCVAD had previously been well controlled by pig vaccination at five weeks of age.

Case History
This case involves a PRRS naïve and Mycoplasma hyopneumoniae (M. hyo) positive, single site, 1100 sow farrow to finish facility. Pigs are weaned at three weeks of age. Nursery rooms are filled by two weaning events per week. Piglets are vaccinated with Ingelvac CircoFLEX® and Ingelvac MycoFLEX® at five weeks of age. The index nursery room was filled with weanings on August 3rd and August 6th. An increased mortality rate was observed beginning three weeks post weaning. The average mortality for the nursery stage had been 2.51% but increased to 10.8% for the index room. The average mortality for the finisher stage had been 1.77%, which increased to 4.25% in the room housing pigs from the index nursery room.

The clinical signs in the index nursery room included wasting body condition, respiratory distress, and acute mortality. On September 15th, tissue samples, nasal swabs and serological profiling diagnostics of the nursery pigs were performed. The average pig age for the index room was 60 days. The results from this initial workup showed moderate amounts of PCV2 antigen using IHC staining in the lung and lymphoid tissues confirming a systemic PCV2 infection. Bacterial pneumonia was also present and Streptococcus suis was isolated. M. hyo PCR testing was negative. Thirty gestating sows were then serologically profiled (September 17th) from different breeding weeks and various parities. The sow sera were tested using PCV2 quantitative PCR (qPCR) and all samples were below the detectable level of <4 logs/mL serum. Additionally, 60 total serum samples were collected (15 for each age) from randomly selected pigs 21, 31, 41 and 47 days. The growing pig sera were tested using PCV2 qPCR and only one sample in the 47 day of age group had detectable viremia (>4 logs of genetic copies of PCV2 virus/mL serum). On September 22nd, a more encompassing tissue collection from pigs 31, 41, and 68 days of age was performed. PCR results indicated PCV2 genetic material presence in pooled tissue samples of all ages. Tissue PCV2 IHC results were negative for PCV2 antigen in the 31 day and 41 day of age tissues but strongly positive in the lung and lymphoid tissue from the 68 days of age group.

Swine influenza, PRRS virus, M. hyo and other respiratory pathogens test results were negative. The laboratory diagnosis was severe interstitial pneumonia associated with PCV2 infection and a mild enterocolitis was also associated with PCV2 infection. PCV2 was detected at high levels in the tissue pools; therefore the diagnosis was confirmed to be PCVAD.

Although reproductive symptoms of PCV2 infection are sometimes hard to detect, and no abnormal reproductive clinical signs were observed, a parity 1 female aborted her developing litter on October 21st, 2009. Six fetuses were collected and submitted for diagnostic testing. Results for PCV2 IHC on heart samples were positive (3+) and multifocal areas of mineralization were present in multiple heart sections.

A diagnostic investigation that included intense profiling of sows in farrowing and their offspring was initiated. The colostrum from 30 sows was collected immediately after farrowing. Twenty-five piglets were selected from different litters, tagged and serially serum profiled at seven days of age, weaning (approximately 20 days of age), and again at 42 days of age. One colostrum sample was positive for PCV2 virus by qPCR, 30% of the piglets were positive by qPCR at 20 days of age, although there were no positive piglets detected at either 7 or 42 days of age by qPCR.

Discussion and Conclusions
PCV2 exposure does occur in the adult swine herd, although the results of the infection may be reproductively inapparent. Infection of the adult herd may result in viral transmission from the sow to her offspring. A comprehensive diagnostic program is necessary to understand PCV2 infection dynamics in cases of early clinical symptoms of PCVAD. Early exposure in this case (prior to planned vaccination) resulted in increased mortality and poor growth performance beginning in the nursery which persisted into the finisher stage. Although mass PCV2 vaccination of the sow herd and moving piglet vaccination earlier (to the time of weaning at 3 weeks of age) was followed by disappearance of clinical signs, additional work is needed to fully understand the risk factors involved in this case.

**Protection of viral shedding after challenge with porcine circovirus type 2 (PCV2) inactivated bivalent vaccine in vaccinated specific pathogen free (SPF) pigs**

_Hyoung Joon Moon; Dae Sub Song; Tae Hoon Oh; Min Joo Yeom; Bo Kyu Kang; Jong Man Kim_

Research Unit, Green Cross Veterinary Products, Yong In, Korea

**Introduction**

Porcine circovirus 2 (PCV2) is a non-enveloped single stranded DNA virus that causes the complicated syndrome called porcine circovirus-associated disease (PCVAD), which is one of the issues in the pig industry worldwide. To reduce the economic loss from PCVAD, many kinds of effective PCV2 vaccines have been developed and used[2]. This study aims to evaluate the vaccine efficacy through viral shedding in nasal discharges and feces after challenging piglets which were vaccinated with inactivated PCV2 vaccine containing both PCV2a and PCV2b strains isolated in Korea.

**Materials and Methods**

**Experimental design**

The details of the experimental designs were presented in Table 1.

*PCV2 inactivated bivalent vaccine (PCV2a+PCV2b) from Green Cross veterinary products co. ltd. (GCVP)
†Field isolates PCV2b, 105.0 TCID50/ml, two weeks after booster.
‡3-week old SPF pigs, §Two weeks interval, 1ml/dose, IM

**Clinical signs and sampling**

Clinical signs had been observed for 14 days after challenge. In order to measure the titers of released virus, nasal swabs and rectal swabs were collected at the day of challenge, 3, 7, 10, 14, 17, 20, 25 days after challenge.

**Virus shedding**

Shedding of PCV2 was measured using quantitative SYBR real time PCR in nasal swabs and rectal swabs. The released viral titer was converted to immune fluorescent assay (IFA) titer using standard curve. The viral titers in each group were compared statistically.

**Results**

**Clinical signs**

There were no clinical signs in vaccinated and PCV2 challenged group, however, pathognomonic signs of PCV2 infection including anorexia, mild loose feces, wasting were shown in some pigs which was challenged without vaccination.

**Virus shedding**

Viral shedding in nasal discharges and feces were low and stopped until 14 days after challenge in vaccinated group (vaccinated and challenged). However, the viral shedding in non vaccinated group was high and lasting more than 31 days after challenge in both nasal swabs and rectal swabs.

**Discussion**

So PCV2 is transmitted via fecal oral infection that this experiment was focused on viral shedding. The results of this experiment were nearly corresponded with previous study in viral shedding in nasal discharges and feces[1]. Unfortunately, this study did not cover with viremia and serology like in former study. However, as presented in this study this vaccine could efficiently reduce the viral spreading through the nasal discharge and feces. Reduction of the viral shedding could relieve the chance of the transmission of PCV2 to nascent pigs, and prevent the risk of PCVAD in pig herd. To our knowledge, this small experiment is the first report about the efficacy test of PCV2 inactivated vaccine including inactivated whole viruses of both PCV2a and PCV2b strains.

The mean titer in vaccinated group was \(10^{3.82}\text{TCID}_{50}/\text{ml}\) and \(10^{1.13}\text{TCID}_{50}/\text{ml}\) after challenge in nasal swabs and rectal swabs, respectively.
Seroprofile survey of anti-PCV2 blocking Elisa antibodies of non-vaccinated and CIRCOVAC® vaccinated pigs in PCVD-affected SPF farm

Ivan Soukup1 Ivan Psíkal2
1. GP Veterinarian, Velvary, Czech Republic; 2. Dyntec Ltd., Terezín, Czech Republic

Introduction
Infections of pigs with porcine circovirus 2 (PCV2) is associated with a broad spectrum of clinical conditions recognized as Porcine circovirus diseases (PCVD). Under certain circumstances the illness could be observed in the farm of specific pathogens free status (SPF), where low infection pressure and good standard of management are expected (1). The objective of this field observation was to describe the changes of the health situation in SPF pig farm caused only by PCV2 infection shortly after repopulation and to show an effect of sow vaccination by CIRCOVAC® on serological profiles in pigs of different age, on clinical changes and production results.

Material and Methods
The farrow-to-finish pig farm was repopulated in the end of year 2005. New health status of the farm was free of PRRSv, M.Hyo, APP, Swine dysentery and P. multocida DNT+. About 1 year after repopulation sporadic health disorder (suddenly died sucklings, wasting and icteric postweaners, suddenly died boars) and decrease of production results (total born and weaned piglets/sow) were observed. Investigation was focused on PCV2 infections using IHC method in lympho-nodes, quantitative PCR and competitive blocking ELISA (CB-ELISA) to show the dynamics of PCV2 antibodies (seroprofiles) in pigs before and after vaccination by CIRCOVAC® (batch vaccination and revaccination of pregnant sows and gilts). Blood samples were collected the same day from 5 pigs per group at 4, 8, 12 and 16 weeks of age and from 5 sows according the parity and from 5 gilts (70kg). Pigs from each group were bled before initialization of vaccination and at 3 and 6 month after the beginning of vaccination. CB-ELISA uses an HRP-labelled specific anti-PCV2 monoclonal antibody (1C6) as a conjugate which compete with serum antibodies for PCV2 antigen determinants on immobilized PCV2 proteins. Blocking PCV2 antibody titres were measured at three different dilutions 1:100, 1:1000 and 1:10000. Any serum sample presenting ≥ 40% of blocking activity at appropriate dilution was considered positive for the presence of PCV2 antibodies, any sample presenting <40% of blocking activity were considered negative. Mean antibody titres and standard deviation in each group were tested using a Student T-test between two groups for each defined age.

Results
PCVD diagnostic in SPF herd was confirmed by both IHC and quantitative PCR methods according to internationally recognized procedures (www.pcvd.org). Seroprofiles based on the mean of CB-ELISA PCV2 antibody titres in sows and their progeny are shown in Figure 1.

Discussion and Conclusion
Except of health status and production parameters improvements, the effect of sow vaccination by CIRCOVAC® was observed in serological profiles comparable with other authors (2): i) the mean of CB-ELISA PCV2 antibody titres were more homogenous in vaccinated sows of all parity and in their piglets till 8 weeks of age, ii) the active PCV2 antibody increase in pigs born to vaccinated sows occurred later in life and it was gradual indicating lower PCV2 infection pressure within the herd.

Comparison of performance before and after the institution of a Circumvent PCV vaccination program

Suraphan Boonyawatana1 Winai Thongmak2 Kridtasak Sang-Gassanee1
1. Intervet (Thailand), Sathorn, Thailand; 2. Live Informatics Company Limited, Moung, Nonthaburi, Thailand

Introduction
Porcine circovirus (PCV) is one of the factors involved in the disease entity known as porcine respiratory disease complex (PRDC). When it was introduced into the country, it provided Thai pig producers with a unique challenge in diagnosis and control.

Current PCV2 vaccination has reduced the problem markedly (Thanawongnuweach, R., 2009). Circumvent PCV was introduced into Thailand in May 2009, and is the vaccine of choice. The aim of this study was to compare performance before and after instituting a vaccination program with Circumvent PCV.

Materials and Methods
This trial was carried out on a 4,000-sow farrow–to-finish farm, on which pigs were weaned at 24 days of age on average, and kept in the nursery for 3-4 weeks, before being moved to the finishing house where they remained until slaughter at an average 24-25 weeks old. The farm was experiencing a severe problem with PRDC.

Pigs were vaccinated with 2ml Circumvent PCV 4 and 6 week of age. Pigs were observed for local or systemic reactions following vaccination, culling and mortality rates (% Loss), average daily weight gain (ADG) and feed conversion ratio (FCR) were all recorded. These performance data were compared with the same parameters before the start of Circumvent PCV vaccination.

Results and Discussion
Local reactions were observed in 0.8% of pigs after the first Circumvent PCV dose, and 0.16% after the second.

The performance data are compared in Table 1.

Table 1: Comparison of performance data before and after the Circumvent PCV program

The Circumvent PCV vaccination program led to a lower percentage mortality (and fewer culls), lower FCR and greater ADG when compared with the period prior to the use of the vaccine (Francisco de Grau, A. et al., 2007; Thacker, B. et al., 2008).

Effect of Piglets PCV2 Vaccination with CIRCOVAC® in the Farm with Severe Porcine Circovirus Type 2 Disease (PCVD) in Post-Weaning

Ivan Soukup¹ Pavel Dusˇek²
1. GP veterinarian, Velvary, Czech Republic; 2. GP veterinarian, Česká Brˇíza, Czech Republic

Introduction
Porcine multisystemic wasting syndrome (PMWS) is well known and described as caused by porcine circovirus type 2 (PCV2) in post-weaning period of piglet rearing (1,2). The main clinical symptoms are wasting, daily weight gain (DWG) depression, heterogeneity in size, high mortality and outbreak of co-infections. CIRCOVAC®, an inactivated, adjuvanted vaccine is possible to use successfully in sows in accordance with the leaflet recommendations (3). PCV2 vaccination of piglets may also be an effective way to prevent PMWS.

The objective of this field study was to analyse the effect of CIRCOVAC® piglets vaccination in a farm with clinical symptoms of PMWS and high viral pressure.

Material and Methods
The studied farm is a conventional 100-sow farrow-to-prefattening farm where clinical signs of PMWS were observed and PCV2 presence was confirmed. Clinical symptomatology, DWG and mortality were recorded in 4 batches and compared to results of the following post-weaner batches under CIRCOVAC® vaccination. The farm was serologically ELISA-positive to PRRS, M. Hyo, APP 2,9,11, bacteriologically Str. Suis, H. parasuis, and S. typhymurium were earlier identified.

Sow vaccination schedule: commercial vaccines EC+Clostridium, Ery+Parvo, APP in label recommendation, live PRRS vaccine 14 days after farrowing.

Piglets vaccine schedule: Respisure One (Pfizer Animal Health), APP at 9+12 weeks of age. CIRCOVAC® vaccine 0,5 ml, IM at 21 days of age, into neck behind the ear. No new changes of husbandry (Madec’s point) had been implemented during the study.

Lab investigations: presence PCV2 in lesions was confirmed by immunohistochemistry (IHC) and qPCR (4,02E7 – 4,19E9/).

Statistical analysis: a Student t-test was used to compare the DWG, and a Chi-square test was used for mortality rate comparison. Statistical analyses were performed with STATGRAPHICS 5.1 (for Windows) and SAS 9.1 (SAS Institute, Cary, NC) software. Statistical significance is based on a two-tailed test of the null hypothesis resulting in p-values of 0.05 or less.

Results
The production result comparison is shown in table 1. The effect of vaccination was noticed in the first vaccinated batch of post-weaners. Absence of wasting, better homogeneity in pig size, better vitality, less cases of post-weaning diarhoea and sharp decrease of mortality were observed. Polyserositis were found less frequently during necropsy in the group of vaccinated piglets.

</tbody>
</table>

¹ Chi-square test. ² Student t-test.

Discussion
Nowadays the use of vaccines is very effective tool in prevention of PCVD. The use of this vaccine in piglets significantly reduced mortality in both sections and dramatically increase DWG in post weaning stage. DWG during fattening showed an important variability due to other cause (checking of different feedstuff formula in last period of fattening due to its price) and the difference between vaccinated and control did not appeared to be significant.

Conclusion
In this study, very significant and quick effect on DWG and mortality rate was confirmed when using CIRCOVAC® in piglets in age 21 days of age, in the farm with high disease incidence in the postweaning sections where the disease was most prominent.

Further development of a differential ELISA for PCV2 vaccination compliance

Sheela Ramamoorthy1 John K. Johnson1 Jeremy S. Pittman1 Brad J. Thacker2
1. Murphy-Brown, LLC, Waverly, VA, USA; 2. Intervet/Schering-Plough Animal Health, Desoto, KS, USA; 3. Iowa State University, Veterinary Diagnostic Laboratory, Ames, IA, USA

Introduction

Previous work has shown the potential for our PCV2 Differential ELISA as a compliance monitoring test for PCV2 vaccination by measuring antibodies that are uniquely induced by PCV2 vaccination.1 This test is based on using a coating antigen (PCV2 ORF2 expressed in baculovirus grown in SF9 insect cells) that is similar to the antigen used in some commercial vaccines plus a coating antigen that lacks the ORF2 expression (referred to as the wild type antigen, WT).2 This system has worked well when pigs are tested 3-4 weeks after vaccination with a two dose product (Circumvent® PCV, Intervet Schering Plough Animal Health). However in some operations, non-vaccinated pigs will develop antibody to the WT antigen as they progress through the finishing phase. We presume that this non-specific titer is due to exposure to cross-reacting insect antigens. Our objective was to determine the components of the immune response in vaccinated pigs and if accounting for SF9 antigen cross-reaction could improve test specificity.

Materials and Methods

Samples from a variety of previous field and laboratory studies that were used to develop the PCV2 Differential ELISA test were tested by ELISA in duplicate using ORF2, WT and SF9 coating antigens. Representative data is reported here. Samples originated from pigs vaccinated with Circumvent PCV at 3 and 6 weeks of age or non-vaccinated control pigs. For the ELISA, appropriate controls including serum from vaccinated and non-vaccinated CDCD pigs were used on each plate. Calculation of the net optical density (OD) due to baculovirus (BV) was done by subtracting the SF9 OD from the WT OD. Results are reported as the group mean average optical density value (ODV). Positive/negative cut-offs for the WT antigen and the BV calculated values were 0.300 and 0.100, respectively.

Results

Table 1 presents WT, SF9 and BV results from 3 separate experiments. Sample times were at vaccination and 3 weeks after the second vaccination for PRE and POST, respectively. Table 2 presents BV results from two field studies where the pigs were bled periodically until near market weight. Background BV antibodies were detected in Herd A at 15 and 21 weeks of age but not in Herd B at 14 and 25 weeks of age. BV titers and the percentage of positive animals were similar.

Discussion

Vaccination with Circumvent PCV induced titers to the ORF2 and WT antigens but not the SF9 antigen, indicating that SF9 antigens may not be a major component in the vaccine or are not sufficiently immunogenic to induce a measurable antibody response. This finding suggests that the vaccine induces antibodies mainly to ORF2 and BV but not SF9 (insect cell) antigens. Overall, the calculation of the BV net OD (WT minus SF9) appears to improve the specificity of the test and may provide a better method for compliance monitoring compared to the WT antigen alone. However, the utility of the BV titer in older pigs is questionable due to the decline in titers observed 6 weeks or more after the second vaccination (both herds) and the development of positive BV titers in non-vaccinated pigs in Herd A.

Evaluation of a commercial ELISA method for measuring PCV2 antibodies

Brad J. Thacker¹ Chinta M. Lamichhane² Cindy Thomson²
1. Intervet/Schering-Plough Animal Health, Desoto, KS, USA; 2. Synbiotics Corporation, College Park, MD, USA

Introduction
Several tests have been developed for measuring antibodies to porcine circovirus Type 2 (PCV2). In the United States, the main tests currently in use include an ELISA and an indirect immunofluorescence antibody (IFA) test. These tests are routinely performed in several state/university diagnostic laboratories. Recently, a competitive ELISA based on a three dilution method has been developed and marketed by Synbiotics Corporation. This three dilution method enables calculation of a titer which provides a quantitative evaluation of PCV2 antibody levels. In this report, we present data generated from testing samples of vaccinated and non-vaccinated pigs over time.

Materials and Methods
The samples originated from several previous studies and had been stored at -20 °C for up to 2 years prior to testing. Vaccinations were done per label directions with Circumvent® PCV. Pigs were vaccinated at 3 and 6 weeks of age. Sows were vaccinated twice at a 3 week interval. Blood was collected prior to vaccination. Post vaccination sample times are listed in the result tables. The competitive ELISA uses a single well blocking technique. The test is performed in three serum dilutions. Wells are incubated for 1 hr followed by a wash. Peroxidase conjugate PCV-2 Mab is added and incubated for 1 hour. After a second wash, TMB substrate is added and incubated for 30 minutes. Stop solution is added and the optical density is measured. Each value is compared to a linear model using a logistic regression model and interpolation between the three results is correlated to a titer. Group results are expressed as geometric mean titers (GMT).

Results
Table 1 presents titer data in non-vaccinated pigs from Herd A over time. Maternal antibody levels decline to their lowest level at 9 weeks of age and then seroconversion due to field exposure results in increased titers at 12 weeks of age.

Table 2 presents titer data in vaccinated and control pigs from Herd B over time. In vaccinates, seroconversion started after the first vaccination and the highest titers were observed 3 weeks after the second vaccination. Titers in control pigs indicated that seroconversion due to field exposure occurred later relative to Herd A.

Table 3 presents titer data in sows and pigs from Herd B prior to vaccination and at 3 weeks after their second vaccination. Sow titers prior to vaccination along with relatively high titers after vaccination indicate previous exposure to PCV2. Pig titer responses are consistent with the data presented in Table 2.

Discussion
The PCV2 antibody titers generated with this test were consistent with the vaccination status and age of the pigs. We conclude that this 3 dilution format provides an effective method for measuring PCV2 antibodies.

A field study to assess the efficacy of the PCV2 sow vaccine Circovac® in a Danish sow herd

Charlotte S. Kristensen1 Kaj Vestergaard1 Mai-Britt F. Nielsen1 Leon Lau2 Poul Bækbo1
1. Pig Research Centre, Danish Agriculture & Food Council, Kjellerup, Denmark; 2. Merial, Copenhagen, Denmark

Introduction
PCV2 is the cause of economic losses to the pig producers all over the world. Vaccines against PCV2 are now available and used world wide. The first licensed vaccine on the market was a killed PCV2 vaccine for use in sows (Circovac®, Merial). The objective of this study was to assess the efficacy of Circovac®. The study was carried out in three herds – two herds with focus on weight gain and one with focus on mortality. Only results from the latter will be presented here.

Materials and Methods
The study was designed as a randomised, controlled, and blinded trial comparing the offspring of vaccinated and placebo injected groups of sows. The study was performed in a Danish sow herd where Post Weaning Multisystemic Wasting Syndrome (PMWS) was diagnosed according to the EU definition (www.pcvd.eu).

The study herd was a two-site farrow-to-finish herd accommodating 260 sows and with a wean-to-finish mortality above 8% at the time of selection of the herd for the trial. The sows and the weaners up to appr. 30 kg were on one site and the finishers on another site. The herd was infected with M. hyopneumoniae but free from pleuropneumonia and PRRSV.

In each farrowing batch the sows were allocated at random to one of two experimental groups. Group GREEN (165 sows) was vaccinated with 2 ml Circovac® 6 and 3 weeks before expected farrowing. Group WHITE (164 sows) was injected with a placebo (saline) at the same time. Cross fostering of piglets was only allowed within the two sow groups and only for the first 24 hours after farrowing. At farrowing all piglets were given individually numbered ear tags in colours GREEN or WHITE according to the mother sow colour. At weaning the pigs were moved to nursery units and housed in separate pens according to ear tag colour. The pigs were individually weighted three times: at weaning (4 weeks of age; 6.2 kg), at transfer to the finishing units (10 weeks of age; 31.5 kg) and just before shipment to slaughter (20 weeks of age; 94 kg). All dead pigs and the number of individual antibiotic treatments were recorded from weaning to slaughter.

The statistical analysis was done in SAS®, version 9.13 using a logistic regression model for mortality and number of antibiotic treatments (PROC GENMOD) and a linear model (PROC MIXED) for growth (average daily gain (ADG)).

Results
No side effects after vaccination were observed.

Weaners after vaccinated sows had a significant reduced mortality of 1.1%, an increase in ADG by 19 g/day and a reduced number of antibiotic treatments compared to pigs after non-vaccinated sows (Table 1).

For finishers the mortality was 0.2% lower (1.9% versus 2.1%), and the ADG 14g higher (910 versus 896) for pigs after vaccinated pigs compared to non-vaccinated pigs, but none of these differences were significant (P: 0.59 and 0.15, respectively). The number of antibiotic treatments was the same in the two groups of finishers.

Discussion
As it will be noted, the overall wean-to-finish mortality dropped from above 8% when the herd was selected to around 5% when the study took place. This not uncommon when doing clinical trials.

However the vaccine was still able to significantly increase the productivity in the weaner phase of the production, but only marginally in the finishing phase of the production.

The size of effect of the vaccine shown in this study is in good accordance with some preliminary results from a Swedish trial in one herd (1), but in farms with high losses a numerical higher reduction in mortality might be expected as indicated in a Japanese study in one herd (2)

Evaluation of the performance of growing pigs after a single dose of Porcilis® PCV

Henrique v. Comprido1 Francisco Fagundes2 João C. Lopes2
1. Agro Pec Valinho, SA, Alcobaça, Portugal; 2. Intervet Shering-Plough, Lisboa, Portugal

Introduction
Nowadays, Porcine Circovirus type 2 (PCV2) is considered to be key to many of the important economic losses in the swine industry, mainly in its relationship with Porcine Circovirus Associated Disease (PCVAD). This syndrome leads to considerable performance failures in weaning and fattening pigs due to increased mortality rates and reduced feed conversion efficiency.

Materials and Methods
This field study took place on a multi-site 800-sow farm. It involved 192 piglets from 18 litters of a single weaning. The herd was experiencing clinical signs compatible with PCV2 infection. The presence of PCV2 was confirmed by direct quantification of viral load by qPCR.

At vaccination, the litters were weighed and divided into two uniform groups of 96 piglets with an average age of 24 days. All animals with a low birth weight and/or clinical problems were excluded.

Group 1: Vaccinated simultaneously with Porcilis® PCV and Porcilis® M Hyo (average weight - 7.15 Kg).
Group 2: Vaccinated with Porcilis® M Hyo (average weight - 7.28 Kg) as controls.

All piglets were monitored for signs of local and systemic reactions in the 14 days following vaccination.

When transferred to the fattening site, the pigs were re-weighed, mortality recorded, and the uniformity of the batches assessed. During the final stage of the fattening period, randomly selected pigs were blood sampled periodically and tested for PCV2 antibodies by ELISA. At 23 weeks of age, all the animals from both groups were individually weighed.

Statistical analysis was carried out using the T-test.

An economic analysis was undertaken to quantify the return on investment based on current average meat price, financial loss from deaths/culls (60€ per pig) and vaccination cost.

Results
No abnormal clinical signs or local reactions were observed after vaccination.

As can be seen in Table 1, the vaccinated group had a better ADG and lower mortality/culling rate, which amounted to a benefit over the controls of 4.21€ per pig sold. The difference in body weights between the groups (+4.35 Kg) was statistically significant (p=0.0043).

Discussion
Both technical and economic parameters were superior in the group which received a single dose of Porcilis PCV, with significant difference with respect to end weight.

There was also greater homogeneity in the PCV vaccinated group. This is an important feature for profitable pig production.

The data collected in this study showed that a single dose of Porcilis® PCV is effective in improving the performance of growing pigs.

Serological response in piglets to PCV2 and Mycoplasma hyopneumoniae vaccines administered separately and simultaneously

Juan M. Palacios1 Alfredo G. Rendón2
1. Intervet Schering Plough AH, Huixquilucan, MEX, Mexico; 2. Rancho Covadonga, Cuautla Morelos, Mexico

Introduction
The use of vaccines to control diseases associated with PCV2 infection (PCVAD) has increased the number of times piglets need to be handled. Agents often associated with PCV2, such as Mycoplasma hyopneumoniae, have been shown to increase the severity of clinical signs, as well as the damage caused by PCV-21.

The need to avoid the unnecessary handling of piglets while maintaining effective protection has led to the use of vaccines with combined antigens or multiple application systems. The combination of PCV2 and Mh antigens is not available in a commercial vaccine, and the possibility of combining both agents without affecting individual responses is being evaluated2,3. The aim of this study was to compare the results of applying two different antigens to piglets, either separately or simultaneously.

Materials and Methods
A weekly production batch of 49 of piglets of three weeks of age were identified individually, and assigned randomly to one of four treatment groups, as follows:
Ta: vaccinated against PCV2 (Circumvent PCV©); Tb: vaccinated against M.hypopneumoniae (M+Pac©); Tc: vaccinated against both PCV2 and M.hypopneumoniae; and Td: Control group injected with 2ml of sterile diluent. All injections (vaccines and placebo) were administered at 3, 6 and 12 weeks of age. The simultaneous administration was given using Dua Vac© equipment (NJ Phillips Ltd).

The piglets were bled prior to the first dose and again at 6, 13 and 15 weeks of age. The sera were analyzed for antibodies against M.hypopneumoniae using the ELISA test (IDDEX - s/p < 0.4 was taken as the cut-off), and PCV2 by means of an ORF-2 antigen blocking ELISA (Synbiotics - s/p ≤ 0.15 was taken as the cut-off).

The data were analyzed by means of an ANOVA test of two factors (treatment and time) using the SPSS version 15.0 software.

Results
The following graphs show anti-PCV2 and anti-Mh titers.

Discussion
There are no statistically significant differences between the responses to the PCV2(ORF-2) and the M.hypopneumoniae antigens at the recorded times. However, these responses both differ significantly from those of the unvaccinated controls (p≤ 0.05). The titres against Mycoplasma sp are positive (s/p ≥ 0.4) at week 6 and 15 of age.

Several different authors report that the response to the antigens of PCV-2 and Mycoplasma sp do not alter whether the vaccines are given individually or simultaneously. Giving the vaccines at the same time is thus a possible option for the producer, as long as the vaccination regimes are not interfered with by passive immunity (MDA), especially in the case of PCV2 for which the dose is given at weaning (Mycoplasma spp vaccination is given during the first week of life). Both vaccines can be applied simultaneously between 3 and 4 weeks of age, either in individual or combined programs.

Economic evaluation of a combined vaccination against PCV-2 and Mh on a commercial farm

Juan M. Palacios1 Florencio Mancilla2 Enrique Mariscal3
1. Intervet Schering Plough AH, Huixquilucan, MEX, Mexico; 2. Granja El Volantin, El Grullo, JAL, Mexico; 3. Insumos Veterinarios SA, Guadalajara, JAL, Mexico

Introduction
One of the agents most commonly involved in PRDC is Mycoplasma hyopneumoniae (Mh). Its effects on the defense mechanisms of the respiratory tract mean it is the major cause of economic loss, worldwide. Its co-infection with Porcine Circovirus Type 2 (PCV2) increases the severity of disease, both clinically and pathologically1. Vaccinating piglets against Mh has been common practice all over the world.

Every vaccination has the potential to be yet another stressor on piglets in the production cycle. Because some farms were experiencing both PCV2 and Mh infections, it was decided to vaccinate piglets simultaneously against PCV2 and Mh2,3. The aim of this trial was to investigate the economic effect of the combined vaccination against PCV2 and Mh on a commercial farm.

Materials and Methods

The trial was conducted on a 500-sow farm operating a continuous flow system. 60 piglets of 26 days of age were chosen from a weekly production batch. Each piglet was identified individually, and randomly assigned to one of two treatment groups. Group 1 was vaccinated against PCV2 (Circumvent© PCV). Group 2 was vaccinated against PCV2 but also against Mycoplasma spp (M+Pac©). Both groups were vaccinated at 26 and 42 days of age. The simultaneous application of the products was carried out using a double syringe system (Dua Vac© NJ Phillips Ltd).

All the piglets were weighed at 26, 73 and 146 days of age. The average daily weight gain (ADG) was calculated separately for the periods 26 to 73 days and 73 to 146 days of age. Feed intake was measured in each pen for each growing phase, and the total weight for each pen was used to calculate the feed efficiency. All deaths were recorded.

The data were analyzed by student t-test, and variance homogeneity was analyzed using the SPSS program version 15.0. The economic analysis was carried out at 146 days of age, before the largest pigs had been selected. The cost of feed and vaccination was deducted from the gross income to determine the gross margin.

Results

Chart 1 shows the mortality and production parameters for each group. Chart 2 shows the economic analysis for both groups.

Discussion

The synergistic effect between PCV2 and Mycoplasma sp has been well reported. However, the effect of PCV2 is currently more often associated with the growth and fattening phases, when replication is related to the circulating pathogens. With respect to Mycoplasma sp it is the prevalence around the time of weaning that will determine the overall effect.

From 26 to 73 days when feed-efficiency is greatest and the piglet tends to gain more weight, the simultaneous vaccination group performed better than the single vaccine group.

Most producers vaccinate against PCV2, but many fail to do so against M. hyopneumoniae, and the synergy of the combined infection has a greater impact on herd health. The use of simultaneous vaccination against both organisms will improve production performance.

Comparison of production performance between pigs vaccinated with a single-dose or a double-dose PCV2 vaccine

Juan M. Palacios1 Victor Martínez2
1. Intervet Schering Plough AH, Huixquilucan, MEX, Mexico; 2. Granja La Joya, Atlixco, Puebla, Mexico

Introduction
The attention of swine producers all over the world has long been directed against diseases associated with PCV2 (Porcine Circovirus type 2). Their detrimental effect on production led to various vaccination schemes being considered. Two-dose regimes are aimed at generating a memory response to inactivated antigens, giving rise to a more lasting response, providing protection during both growth and fattening. In spite of the need to handle piglets twice, this system represents both health and economic advantages to justify its use1.

The aim of this study was to compare the performance of a single-dose vaccine with a double-dose product in four consecutive production cycles.

Materials and Methods
On a multipurpose farm in Mexico, 3,684 piglets were chosen from four consecutive production runs. Two of these groups (1,887 piglets) were vaccinated with Suvaxin Respifend® PCV: a single intramuscular dose of 2 ml in the base of the neck at 21 days of age. The other two groups (1,797 piglets) were vaccinated twice with Circumvent®PCV: two 2ml doses at 21 and 42 days of age on alternate sides of the neck.

The evaluation was carried out in two phases, from 21 to 86 days of age and from 86 to 156 days of age (finished weight). The averages for each group were taken for the purposes of comparison.

Results
Total mortality in the single-dose Suvaxin Respifend® PCV group was 6.31% and in the double-dose Circumvent®PCV group, 7.16%. Total of culled and runt pigs was 10.64% and 3.91% in the single- and double-dose groups respectively. Table 1 shows the feed cost for each treatment group.

</tbody>
</table>

Discussion
During the first production phase (21 to 86 days of age) the groups behaved alike. The differences between them arose during the second phase (86 to 155 days of age). The percentage of culled pigs and runts was critical because of the effect on feed efficiency.

After deducting the cost of the vaccines, the double-dose Circumvent®PCV group showed a 2.2% better profit per kg sold than the single-dose Suvaxin Respifend® PCV group. This trial demonstrated that Circumvent®PCV had a beneficial effect in the older pigs conferring an obvious advantage in terms of the economics of production.

Comparison of the effect on economic performance of two vaccines for the control of diseases associated with porcine circovirus on a commercial farm in Mexico

Juan M. Palacios1 Fernando Curiel2
1. Intervet Schering Plough AH, Huixquilucan, MEX, Mexico; 2. Granja El Ensueño, Zumpango, MEX, Mexico

Introduction
The use of vaccines in the control of diseases associated with PCV2 (PCVAD) has been shown to offer health and production benefits in farms in Canada, USA and Mexico, and has become common practice. Most of the current products are single-dose vaccines.

Intervet-Schering-Plough has developed a double-dose vaccine, the purpose of which is to reduce the risk of interference from maternally derived antibodies, and to produce a booster response, thus reducing viremia1 in the growth and fattening phases. The aim of this study was to compare the effect on production and health of a single-dose vaccine (Respifend® PCV-2), with that of a double-dose product (Circumvent® PCV).

Materials and Methods
On a commercial farm in Mexico, one group of 238 piglets was vaccinated with Respifend® PCV-2 (a single 2ml dose by intramuscular injection in the neck at 29 days old). Another group of 309 piglets was vaccinated with Circumvent® PCV (2ml by the same route at 23 and 43 days of age). From each group, 30 piglets were chosen at random, individually ear-tagged, weighed at 99 and 155 days of age and their daily weight gain calculated. Mortality was also recorded. At the end of the cycle, age and weight at sale, and feed efficiency were recorded. The data were analyzed by T-test using SPSS 15.0 software.

Results
Mortality began in week 6 in both groups, reaching a peak in weeks 7 and 11. The disease affected the alimentary system, and was characterized by progressive wasting. At the necropsy of 3 pigs, Salmonella cholerae suis was isolated from the liver and ilioceleval valve. Table 1 shows the mortality results:

</table>

Different superscript letters in the same row indicate significant differences

Discussion
There were significant differences in mortality between the two vaccine systems. In the Circumvent® PCV group, the second dose reinforced the immunity leading to better mortality rates after week 10, in the critical growth and finishing stages.

The inferior performance of the Respifend® PCV-2 group was not only evident in the higher mortality rate, but also in the weights at sale which were lower than the Circumvent® PCV group (84.52 and 90.25 kg respectively). However, the wide variation in the end weights in the Respifend® PCV-2 group led to the trial being abandoned when the first pigs were sold, otherwise the differences would have been even greater.

The pigs vaccinated with Circumvent® PCV had heavier end weights. The other group had more second class pigs and thus poorer feed efficiency. The profit per kg sold is a measure of the better performance of the pigs vaccinated with Circumvent® PCV.

Clinical case: improved sow fecundity after CIRCOVAC® vaccination

Guillaume Perreul1 Bernard Delahaye2 Jean-Bernard Herin4 Thaïs Vila3 Julie Venet3 François Joisel3
1. Merial, Lyon, France; 2. Vétérinaire, Thorigne-sur-Due, France; 3. Merial S.A.S., Lyon, France; 4. Merial S.A.S., Ancenis, France

Introduction
Porcine circovirus type 2 (PCV2) is well known to be involved in reproductive disorders. The objective of the present paper is to describe a clinical case in which PCV2 was suspected to be involved and vaccination with CIRCOVAC® brought an improvement in the reproductive indexes.

Farm/Case Description/Methods and Actions
Farm: 450-sow 1-week farrowing batch management PRRS-negative operation. Weaning at 24 days; new buildings and good husbandry practices. AI with semen collection on farm.

Case description: poor reproduction indexes for 12 years; high % of returns to oestrus mainly in parity 4 & 5 with fecundity as low as 72%; 1% abortion and good global productivity: 27.7.

Differential diagnosis and corrective measures: for the last years, a lot of work has been done to optimize reproduction, mainly in depth review of on farm AI management, full review of the feeding system and full revaccination against Porcine Parvovirus.

PCV2 suspicion: based on big size mummified piglets >0.5 per litter, hyperthermia and anorexia at mid-lactation, high prevalence of ear necrosis in 10 of the 7-week-old piglets and pig size heterogeneity in the flow.

PCV2 antibody titration in sows: Serelisa® PCV2 Ab (Synbiotics, Lyon, France).

Vaccination: CIRCOVAC was implemented in sows and gilts as recommended. Boars were vaccinated twice, 2ml IM.

Fecundity: results were recorded using the batch files collected on farm. Returns to oestrus were recorded on 5-month periods, before and during the vaccine implementation.

Statistical analysis: fecundity indexes were compared using a Yates-corrected Chi² test.

Savings per avoided return to oestrus was evaluated at 57€ according to the reference given by the French Institute for Pig Industry (www.ifip.com) IFIP, Paris, France.

Results
The sow PCV2 Ab profile before vaccination is shown in Figure 1. Titres are heterogeneous with only 40% at 4log10 or more.

Fecundation after 1st AI was significantly improved from 76.0% to 83.5% after vaccination (Yates-corrected Chi² test; p<0.01). Percentage of returns to oestrus before and during the vaccination of the sows with CIRCOVAC significantly dropped down from 21.15% to 13.51% respectively.

Discussion
Heterogeneity of PCV2 ELISA titres showed an inconsistent immune status. A confirmation of the presence of high quantity of PCV2 in late mummies would have been interesting to make sure PCV2 involvement. However, since vaccination of sows with CIRCOVAC, the number of return to oestrus dramatically dropped down. This is coherent with Mateusen et al. (1) findings which showed that embryos were susceptible to PCV2 as soon as they get rid of the zona pelucida. Unfortunately today, no conclusive diagnosis tool does exist for evidencing PCV2 involvement in early embryo death. Only based upon returns to oestrus, CIRCOVAC vaccination brought savings of around 10€ per sow per year.

Onset of Immunity induced by Porcilis® PCV in MDA positive pigs given at 3 weeks of age by a single dose of 2 ml and challenged with PCV2 virus at 5 weeks of age

Alexander A. Eggen1 Frank Roerink2 Ulrike Schmidt1
1. Intervet/Schering-Plough, Boxmeer, Netherlands; 2. Intervet/Schering-Plough, DeSoto, KS, USA

Introduction
Porcine Circovirus type 2 infection in pigs is regarded as the causative factor for development of Porcine Circovirus Disease (PCVD). PCVD occurs in pigs of different ages. Infection of piglets is associated with low levels of Maternally Derived Antibodies (MDA) and the presence of PCV2 virus. Under field conditions timing of PCV2 virus infection is often unknown. It is important that pigs are protected early and for the whole fattening period (Eggen). Pigs will be vaccinated early in life against PCVD in the presence of varying levels of MDA. The object of this study is to demonstrate efficacy against PCV2 virus of a single dose of 2 ml Porcilis PCV in piglets of 3 weeks of age with MDA. At 5 weeks of age, 2 weeks after vaccination, vaccinated and control animals were challenged with PCV2 virus.

Materials and Methods
Progeny of SPF sows with PCV2 antibodies were studied. Male piglets were spread across litters to make 2 uniform groups of 10 piglets. At 3 weeks of age, Group 1 was vaccinated with 2 ml of Porcilis PCV and Group 2 with placebo. At 5 weeks of age the pigs were challenged intranasally with 4.5 log10 TCID50 of a heterologous wild type PCV2 challenge virus strain I-12/11. All animals were observed daily for clinical signs and were weighed at critical times.

Three weeks post challenge all animals were necropsied. At post mortem, mesenteric lymph nodes and tonsils were sampled for the determination of PCV2 antigen. Serum samples were taken at vaccination, at challenge, one week later and at necropsy, and were examined for PCV2 antibodies and nucleic acid. Fecal swabs were taken at challenge, one week later and at necropsy, and were examined for PCV2 nucleic acid. Statistical analysis of the serology employed Dunnett’s multiple comparison method. Q-PCR data was analyzed by ANOVA and Dunnett using a linear mixed model assuming constant correlation of repeated measurements of a subject.

Results
All piglets were healthy before and after vaccination. Bodyweight gain did not differ significantly between groups at time of challenge or for the period between challenge and necropsy (see table 1).

</tbody>
</table>

* wpv = weeks post vaccination ** wpc= weeks post challenge

At challenge, the average PCV2 antibody titer was significantly higher in the vaccinated group (P<0.0004)

Q-PCR: At the time of challenge, the amount of viral DNA was negligible in both groups. Three weeks after challenge, the amount of virus in sera of the vaccinated group was significantly lower than the control group (P<0.05). No PCV2 DNA was detected in feces of this group one week after challenge, and in significantly lower amounts at 3 weeks post challenge (P<0.05), the amount of PCV2 nucleic acid in tonsils and mesenteric lymph nodes was significantly lower (P<0.05).

Discussion
A single 2ml dose of Porcilis PCV in piglets of 3 weeks of age induced a rapid and strong immunity. Piglets were protected when challenged at 5 weeks of age. This was confirmed by the significant reduction in virus shedding and the PCV2 DNA load in lymphoid organs. The MDA titers in the piglets were purposely low. MDA titers >5log2 present at 5 weeks of age can be protective and these MDA influence the take of the challenge virus (Fort, 2009) which will result in no PCV2 load in the controls leading to inconclusive results. This rapid onset of immunity by a single dose in the face of MDA is a feature unique to Porcilis PCV.

Effect of Porcilis® PCV on mortality in finishers in the presence of late severe PCVAD

Jesus M. Bollo1 Marta Jimenez1 Rut Menjon1 Jesus V. Lopez1 Maria T. Tejedor2
1. Intervet Schering Plough, Madrid, Spain; 2. Dept. of Anatomy, Embryology and Genetics
Unit of Genetics - Faculty of Veterinary Medicine, Zaragoza, Spain

Introduction
In Spain, porcine circovirus-associated disease (PCVAD) is seen less frequently than in the first few years after the initial reports of the disease. The aim of this study was to assess the efficacy of vaccination with Porcilis® PCV in the presence of late severe PCVAD.

Materials and Methods
The study was performed on an 800-sow farm operating a closed cycle, three week batch system. Pigs were weaned at 28 days of age, and the farm had facilities to fatten 40% of its production. The other 60% were fattened on other farms. The farm was positive for PRRS and Mycoplasma.

In 2008, mortality rates in the fatteners varied between 3 and 5%, and there were approximately 1% of runts. At the beginning of 2009, there was a notable increase in mortality rates and percentage of runts, reaching a peak of 13.3% mortality, 16.4% for deaths and runts together. The clinical presentation began at 13 weeks old, the signs being pallor, general enlargement of lymph nodes, stomach ulcers and a variable number of pigs with porcine dermatitis and nephropathy syndrome (PDNS).

From April onwards, blood samples were taken at 4, 7, 10, 13, 16, 19 and 21 weeks of age. Serum was tested for PCV2 IgG and IgM antibodies (Ingezim PCV2 ELISA®, Ingenasa), and showed that seroconversion coincided with the start of the clinical signs (Graph 1).

In the light of this, it was decided to vaccinate as many pigs as possible in the shortest possible time. Thus, all batches of pigs at either 45 or 70 days of age were vaccinated with Porcilis®PCV. Thereafter, all pigs were vaccinated at weaning (28 days old).

In the light of this, it was decided to vaccinate as many pigs as possible in the shortest possible time. Thus, all batches of pigs at either 45 or 70 days of age were vaccinated with Porcilis®PCV. Thereafter, all pigs were vaccinated at weaning (28 days old). [Data from this latter vaccination regime were incomplete at the time this abstract was submitted.] The results of the following groups were compared:

- Controls: unvaccinated animals (from 10 batches)
- Porcilis PCV (A): a single 2 ml dose of Porcilis®PCV given to pigs 70 days old (note that the disease was probably already present in most of these animals).
- Porcilis PCV (B): a single 2 ml dose of Porcilis®PCV given to pigs 45 days old.
- The Pearson’s chi-square test was used to compare the treatments (percentages), using the SPSS 15.0 software package.

Results
There was a statistically significant reduction in mortality rates during fattening in both vaccinated groups compared with the unvaccinated controls (p<0.001), the best results being in the pigs vaccinated closer to the recommended schedule (at 3-4 weeks of age). The percentage of runts was also significantly better in the Porcilis PCV (B) group (p<0.05).

Graph 1: Percentage of samples positive for IgG/M/age

In the light of this, it was decided to vaccinate as many pigs as possible in the shortest possible time. Thus, all batches of pigs at either 45 or 70 days of age were vaccinated with Porcilis®PCV. Thereafter, all pigs were vaccinated at weaning (28 days old).

[Data from this latter vaccination regime were incomplete at the time this abstract was submitted.] The results of the following groups were compared:

Discussion
The efficacy of Porcilis®PCV was demonstrated using different administration protocols. Vaccination with a single dose of Porcilis®PCV was found to be very effective in the presence of late severe PCVAD.

Better uniformity was observed in the vaccinated pigs; the lower percentage of runts being one of the reasons.
Efficacy of different vaccines against Porcine Circovirus type2 administered as single shot to 3 week-old piglets with high maternal derived immunity against PCV2

Ulrike Schmidt; Melanie Sno; Alexander A. Eggen
Intervet/Schering-Plough, Boxmeer, Netherlands

Introduction
Porcine Circovirus type 2 (PCV2) is widespread and has, as major causative agent for development of Porcine Circovirus Disease (PCVD), great economic impact in the swine industry. Infection of sows with PCV2 leads to varying antibody levels in blood and colostrum. High levels of maternal derived antibodies (MDA) can prevent PCV2 infection of piglets during first weeks of life, but may interfere with active immunization of piglets against PCV2 (Palzer,IPVS 2010). In recent years, several vaccines against PCV2 were brought to the market. All piglet vaccines can be given as a single shot vaccination from 2 or 3 weeks of age, when MDA can still be on a high level. Thus, it is essential that this single vaccination at young age is efficacious against possibly high levels of MDA.

The objective of this study was to compare the efficacy of commercially available PCV2 vaccines in piglets with high MDA against PCV2 after a single vaccination at 3 weeks of age.

Materials and Methods
Fifty piglets from sows with high PCV2 antibody titres (9.8 to 12.5 log2 ELISA units before farrow) were available for this study. Allocation of piglets to five groups of 10 was done across litters the way that average MDA titres per group were comparable.

At three weeks of age one of the following PCV2 vaccines was injected:

- Group 1 was vaccinated with 2 ml of Porcilis PCV (subunit vaccine),
- group 2 received 2ml of a PCV2 vaccine containing inactivated chimeric PCV1-2 virus as antigen,
- group 3 was injected with 1ml of a PCV2 subunit vaccine,
- group 4 received 0.5ml of an inactivated whole virus vaccine and
group 5 was treated with 2ml of a physiological salt solution and served as negative control group.

At 12 weeks of age, all piglets were challenge infected with wild type PCV2 challenge strain I-12/11 by intranasal route.

All animals were observed daily for clinical signs and blood samples were taken on several time points. Three weeks post challenge all animals were necropsied and tonsil, mesenteric lymph node and lung were sampled for determination of PCV2 viral nucleic acid by Quantitative PCR (QPCR). Serology data at time points >3 weeks were analysed by Analysis of Covariance (ANCOVA) by time point using the titre at time of vaccination and sow as covariate. Equality of serum antibody titre prior to vaccination was checked by ANOVA. Tukey’s multiple comparison method was used to compare treatments. Descriptive statistics were used to summarize QPCR results on organs.

Results
No clinical signs were observed throughout the study.

Serology: at time of vaccination the piglets had individual PCV2 antibody titers between 9.3 and 15.5 log2 ELISA units, resulting in mean group titres of around 11 log2 ELISA units.

Conclusion
In this study, a single vaccination with Porcilis PCV induced a significantly higher humoral immune response in piglets with high MDA as compared to other PCV2 vaccines. The excellent protective efficacy of Porcilis PCV was confirmed by the low load of PCV2 DNA in all tested organs upon challenge infection.

Evaluation of three commercial PCV2 vaccines in a commercial swine farm

Kwang Soo Lyoo1 Brian Caldwell2 Hyeon Bum Kim1 Jerry Torrison1 Peter Davies1 Han Soo Joo1

1. University of Minnesota, St. Paul, MN, USA; 2. Choice Connection, Mapleton, MN, USA

Introduction

Three commercial PCV2 vaccines have been licensed in the U.S., and all of them are widely used on commercial swine farms. The efficacy of these vaccines is well documented, and all of the vaccines reduced mortality and improved growth performance under field conditions1,2,3. However, the 3 vaccines vary in the nature and concentration of the antigen, the type of adjuvant, and the dose of administration. At present, no report is available on the comparative efficacy side by side of the 3 vaccines under conventional field conditions. The purpose of this study was to compare clinical signs, viremia, antibody responses, and average daily gain (ADG) of conventional pigs following vaccination at 3-weeks of age with the respective commercial PCV2 vaccines.

Materials and Methods

At a commercial farm in Minnesota, 4 pigs of similar body weight were selected from each of 20 litters and ear tagged. Three pigs from each litter were inoculated intramuscularly at 3 weeks of age with PCV2 vaccine A, B, and C, respectively. The fourth pig from each litter remained unvaccinated controls. All 80 pigs were moved into one pen of a wean-to-finish barn together with 520 pigs housed in other pens. The 20 pigs inoculated with vaccine A were revaccinated at 6 weeks of age (3 weeks after the first vaccination) according to the manufacturer’s recommendation. All pigs in the barn were monitored daily for clinical abnormalities by the farm manager. Blood samples from each pig were collected at 3 weeks intervals. All pigs were individually weighed at 3 weeks and 24 weeks of age. Antibody responses of each pig were measured by indirect fluorescent antibody (IFA) test. Serum samples were also tested for viremia. The mean antibody titers, viral load, and body weight between the groups were analyzed by student t-test.

Results

There were no clinical signs observed in any of the pigs in the vaccinated and control groups, although 2 pigs in group B were found dead overnight from unknown causes during the first 3 weeks of the experiment. No medication was used for pigs during the study. ADG for all 4 study groups was calculated for the interval 3 to 24 weeks of age (Table 1). There was no significant difference in the mean body weights among the 4 groups at 3 weeks of age. The ADG of pigs in groups A (0.81kg ± 0.03, P <0.016) and B (0.80kg ± 0.05, P <0.048) were significantly higher than ADG of the control group (0.74kg ± 0.05). The ADG of pigs of the group C (0.78kg ± 0.05) did not differ significantly from the controls (P =0.132) or the other vaccinated groups (P >0.173)

*Statistically significant of group A and B at 24 weeks of age and ADG were P <0.05 when compared to those in control group.

Discussion

The present study found differences in growth performance and body weight at marketing age among the study groups. Mean ADG and body weight just before the marketing of all 3 vaccinated groups were numerically higher than those of the control group, although statistically significant differences were observed only for groups A and B. The differences were concordant with the results for viremia which showed higher levels of viremia in the control at several time points. The study confirms likely production benefits from PCV2 vaccination even in the absence of clinical PCV2 related diseases.

References

Introduction
The aim of the present study was to evaluate the safety, efficacy and economic benefits of vaccination with Porcilis® PCV when pigs are confronted by a severe porcine circovirus infection late in the production cycle.

Materials and Methods
The study was carried out on a closed-cycle 650-sow farm in central Spain, producing pigs in weekly batches. Piglets are weaned at 21 days old, and moved to separate barns for the nursery, growing (10-16 weeks of age) and finishing periods. The farm suffered confirmed PRRS, and also Mycoplasma, for which piglets were vaccinated in their first and third week of age. Clinical signs associated with PCV2 were more evident from 14 weeks of age onwards, that is, mostly during growing and finishing. The average mortality rate (weaning-slaughter) of piglets born in 2008 was 13%, with a peak of 16%. The problem was aggravated by a high percentage of runts (culls).

Prior to vaccination, a serological profile was obtained monitoring the optical density ratios for IgG and IgM (Ingezim PCV Elisa), which demonstrated seroconversion from 15 weeks of age, still evident at 19 weeks.

Initially, all animals between 21 and 70 days of age were vaccinated. Thereafter, pigs were vaccinated 4 days after weaning with a single 2 ml dose of Porcilis® PCV. Mortality rate, percentage of runts, weight at slaughter and days to slaughter were recorded for the following groups: Control Group: unvaccinated. Group A: vaccinated with Porcilis® PCV between 55 and 70 days of age. Group B: vaccinated younger with Porcilis® PCV: slightly more than 2/3rds of the group at 21 days old (the recommended age according to the leaflet instructions), and the rest (4 batches) between 32 and 55 days of age. During the whole study period, no relevant management changes were implemented on the farm.

The different treatments were compared using the Pearson’s chi-square test (proportions) and the Levene test (variances), together with an ANOVA (means), using the SPSS 15.0 software package.

Results
No local or systemic reactions were observed in the vaccinated animals, regardless of the time of vaccination.

PCV2 was considered to be involved during the growing and finishing periods. The recorded production data are shown in Table 1. For Group B, compared to the controls, the number of culls, and the mortality rate were reduced significantly during all the production phases (p<0.001), leading to greater uniformity at slaughter.

Discussion
The present study demonstrated that vaccination of pigs with Porcilis® PCV is safe, effective and profitable, even in the face of a severe PCV2 infection, late in the production cycle, contributing to a reduction in production losses caused by PCV disease. Regardless of the age at vaccination with Porcilis PCV, it was shown to be highly profitable, yielding a substantial return on investment.
Safety and efficacy of PCV-2 inactivated vaccine in weaned piglets under field conditions in Brazil

Raquel L. Santos1 Djane Dallanora2 Roniê W. Pinheiro2 Glauber S. Machado2 Zélia I. Lobato1 Roberto M. Guedes1
1. Universidade Federal de Minas Gerais, Veterinary School, Belo Horizonte, MG, Brazil; 2. Integrall Soluções em Produção Animal, Patos de Minas, MG, Brazil

Introduction
In July 2007, the first commercial vaccine against Porcine Circovirus type 2 (PCV-2) was launched in Brazil. This vaccine consists of inactivated PCV-2 in oil adjuvant, recommended for gilts and sows, protecting the piglets through passive transfer of antibodies (1). Sow vaccination has given good results in farms with PCVAD. However, different serological titration profiles against PCV-2 were observed in farms in Brazil and indicated different exposure and viral circulation. (2). Due to the limited availability of other conventional PCV-2 vaccines in Brazil and the concern regarding the development of the disease in fattening pigs, this vaccine started to be empirically used in weaned piglets. Thus, this field study was conducted in order to evaluate the safety and efficacy of this procedure.

Materials and Methods
A total of 1140 piglets, males and females, were divided into two groups: vaccinated (single dose, 0.5 ml of vaccine) and control (not vaccinated), blocked by gender. All animals were evaluated from the application of the experimental treatment until market. Safety was evaluated by clinical and body temperature daily examinations in the four days after vaccination. Efficacy was based on comparison of performance (body weight and average daily gain), mortality, antimicrobial usage, diarrhea, coughing and sneezing indexes. Post examination was performed in all dead animals, followed by histopathology and PCV-2 immunohistochemistry evaluation. Lung lesions were evaluated at slaughter. Blood samples were collected at weaning, at the end of nursery and before slaughter and used for IgG serology using IPMA.

Results
No adverse effects were observed after vaccine application. Vaccinated males had a higher slaughter weight (2.73 kg, p = 0.029) and a higher average daily gain (0.025 kg, p = 0.027) when compared to control males. In contrast, females had no difference in body weight or average daily gain between vaccination and control groups. However, there was a greater final body weight of 1.50 kg (p = 0.07) in vaccinated females compared to the control group. There was no significant difference between groups regarding mortality and culling rates, coughing, sneezing or diarrhea indexes, medication use, pneumonia index, pathological and histopathological lesions, and antibody titration.

Discussion
Vaccination did not induce any significant adverse effect, as observed by others (3). The results of daily weight gain, slaughter weight and mortality rate in this study agreed with other reports under field conditions (3; 4). As there was no reduction in mortality, it was suspected that other conditions were playing an important role.

The absence of statistical difference in the final weight of females (p= 0.07) can be explained by the difference in housing conditions compared to males, as the females were continuous in feces contaminated solid floors, were in more densely populated pens and were managed much more often for breeding selection.

PCV2D lesions and PCV2 antigen were observed in both vaccinated and control groups from both genders with no difference among them. If animals had been randomly selected for euthanasia, as was done by Segalés et al. (6), we may have seemed difference between groups.

These data indicate that vaccination against PCV-2 is safe and effective in improving the final weight and the average daily gain in piglets vaccinated under field conditions in Brazil.

The effect of a single dose of Porcilis PCV® in piglets at 3 weeks of age on mortality, daily weight gain and carcass weight at slaughter

Paolo Martelli¹ Antonio Caleffi² Stefano Gozio³ Alberto E. Cevidalli⁴ Stefano Guazzetti⁵ Paolo Borghetti¹
¹. Dept. Animal Health - University of Parma, Parma, Italy; ². Veterinary Practitioner, Mantua, Italy; ³. Intervet/Schering-Plough A.H., Boxmeer, Netherlands; ⁴. Intervet/Schering-Plough A.H., Milan, Italy; ⁵. ASL, Reggio Emilia, Italy

Introduction
The control of PCVD is based on management strategies, reduction of co-infections and vaccination. Under field conditions, all commercial PCV2 vaccines lead to reduced mortality and cull rates, and significantly improved weight gain, along with a reduction in co-infections in PMWS-affected herds (Kixmoller et al., 2008; Segalés et al, 2009).

The object of the present study was to investigate the efficacy of a single dose of PCV2 subunit vaccine on two different farms suffering from PCVD by monitoring mortality and culling rates, average daily gain and carcass weight at slaughter.

Materials and Methods
A double-blinded, randomised and controlled field trial was conducted on two farms with a history of PMWS (Farm 1: 900-sow farrow-to-finish herd; Farm 2: 3-site 1850-sow herd). A total of 818 piglets were included in this study and distributed between two treatment groups.

At inclusion (weaning at 21±3 days of age), a total of 408 animals (Group B) received a 2ml intramuscular dose of Porcilis PCV®, a commercial PCV2 capsid-based subunit vaccine expressed in inactivated baculovirus. To act as controls (Group A), 410 pigs received 2mls of the adjuvant Diluvac Forte®, by the same route.

All animals were individually identified, and their weights were recorded at inclusion, and at 12 and 26 weeks of age, and the average daily gain (ADG) calculated. The carcass weights of the pigs from Farm 2 were recorded at slaughter (274 days old). All dead animals (died or were culled) were submitted for post-mortem diagnostic investigation, in order to classify them as PMWS-affected (according to the accepted case definition) or not.

To estimate the effect of vaccination on the probability of a pig dying, a mixed effect logistic regression model was constructed to take account of the non-independence of repeated measurement of the same subjects and the effect of the sow (litter effect), using the ‘lme4’ package.

Results
Total losses from PMWS were 9.02% and 0.2% in control and vaccinated groups, respectively. For fatal conditions other than PMWS, the proportion of pigs lost were 7.3 and 7.8 in Groups A and B, respectively.

The estimated Hazard Ratio for losses related to PMWS in Group B as against Group A was 0.082 (c.i.95%: 0.030-0.229; p< 0.0001).

The ADG and carcass weight at slaughter for both groups are shown in Table 1.

Discussion
In this study, the probability of a pig vaccinated with a single dose of Porcilis PCV at 3 weeks of age dying from PMWS was 12 times less than that of an unvaccinated control pig. Moreover, vaccination improved the average daily gain when animals became infected with PCV2.

In addition, the difference in average carcass weight (+4.5 kg in vaccinated) in pigs slaughtered at 274 days of age demonstrated the long term positive effect of Porcilis PCV vaccination on productive performance.

Comparison of the efficacy of Porcilis® PCV and an alternative PCV vaccine under field conditions

Juan L. Ubeda1 Rut Menjon2 Jesus M. Bollo2 Marta Jimenez2 Jesus V. Lopez2 Javier Rodriguez2
1. Veterinary Practitioner, Zaragoza, Spain; 2. Intervet Schering Plough, Madrid, Spain

Introduction
The aim of the present study was to compare the efficacy of Porcilis®PCV with another commercial vaccine, under field conditions, with respect to health and production, on a farm with a history of severe losses caused by porcine circovirus-associated disease (PCVAD).

Materials and Methods
The study was performed on two different sites of a 1000-sow farm in northern Spain. The farm had a history of PCVAD-related problems, with an average 5% mortality rate in the nursery, a 6-8% mortality rate in fattening pigs, with 4% referable to PCV, and a late clinical picture appearing from 14 weeks of age onwards, and persisting up to 18-20 weeks of age. The farm had tested positive to Mycoplasma and PRRS (unstable and with resurgence at 7, 9 and 16 weeks).

Before the start of the study, PCV2 had been confirmed by clinical signs and gross pathology in diseased pigs, virus isolation from 3 of 4 culled pigs, and clear evidence of seroconversion by 18 weeks of age. After confirmation of the diagnosis, piglets from two weekly batches were selected (a total of 829 piglets) and randomly allocated into 3 groups according to gender, dam and weight, individually identified, and treated at 3 weeks of age.

Group 1: 272 piglets vaccinated with a single 2ml dose of Porcilis® PCV; Group 2: 276 piglets vaccinated with a single 0.5ml dose of another commercial vaccine (Vaccine B); Group 3: 281 piglets injected with 2 ml Diluvac Forte® as placebo, acting as controls.

In addition, 60 piglets were selected (20 piglets per group), for serological controls at 3, 7, 10, 14, 18, 22 and 25 weeks of age.

After weaning, the pigs were housed in the same barn, with each group in a separate pen. At 10 weeks old, they were moved to the fattening barn, again penned separately in their groups. Temperature and humidity were recorded throughout, as well as individual treatments and mortality. All pigs were weighed at 3, 10, 18 and 25 weeks of age (earliest slaughter date).

</tr>
</tbody>
</table>

Group 1 (Porcilis PCV) was 1.42kg, 13g/day better than Group 2 (p=0.09), and 3.14kg, 29g/day better than Group 3 (p<0.001). Group 1 had significantly fewer treatments than the other two groups (p=0.01). Group 1 was significantly better for all parameters than the controls, whereas Group 2 (Vaccine B) performed no better than the controls.

A clinical picture compatible with PCV was found in 41.4 % of dead pigs. Laboratory diagnosis (IHC) confirmed the presence of PCV in none of the Porcilis® PCV group, 3.45% of the Vaccine B group, and 10.3% of the control group.

Discussion
Vaccination of a high percentage of the pigs commingled in the same house probably improved the results of the control group due to a reduced infection pressure, otherwise greater differences would have been expected between groups.

The use of Porcilis® PCV in this situation led to an improvement in all the recorded health and production parameters, not only compared to the control group but also compared to the other commercial vaccine (Vaccine B). In addition to this, the robust seroconversion induced in the presence of maternally derived immunity allows the firm conclusion that Porcilis®PCV was the better choice of vaccine to protect against a severe, late problem with PCVAD.
Safety of Porcilis® PCV in conventional piglets under field conditions

Juan Luis Ubeda¹ Ruth Menjon² Jesus M. Bollo² Marta Jimenez² Jesus V. Lopez²
1. Veterinary Practitioner, Zaragoza, Spain; 2. Intervet/Schering-Plough AH, Cantabria, Madrid, Spain

Introduction
Porcine Circovirus Type 2 (PCV2) is involved in the development of several diseases of swine and is undoubtedly of major clinical importance in modern pig production. Vaccination against this pathogen is therefore a very common precaution, usually piglets at weaning.

There are four available vaccines, and as with other products, the main selection criteria used by veterinarians are efficacy and safety. The object of this trial was to compare the safety of piglet vaccination with a subunit vaccine (Porcilis® PCV) with another PCV vaccine by monitoring local and systemic reactions under field conditions (1).

Materials and Methods
Porcilis® PCV is a subunit vaccine containing the viral capsular protein coded by the ORF2 of the PCV2 genome in an adjuvant containing dl-α-tocopherol acetate and paraffin (Xsolve). The efficacy of this vaccine has been demonstrated previously (2).

The vaccine was tested on the piglets of a 1000-sow herd in the province of Zaragoza, in north-east Spain, managed on a two-phase production system. The piglets suffered a PCV2-related disease from 14 weeks of age.

829 piglets of about 3 weeks of age were randomly assigned to three groups:
Group 1: 272 piglets vaccinated with a 2ml dose of Porcilis® PCV.
Group 2: 276 piglets vaccinated with 0.5ml of another PCV vaccine (Vaccine B).
Group 3: 281 piglets injected with 2ml Diliuc Forte, a dl-α-tocopherol acetate based adjuvant, acting as controls.

The animals were observed for local and systemic effects for 1-2 hours post injection, and at 24 hours, and 7 and 14 days after vaccination.

All the pigs were individually identified, and weighed at 3 weeks old (vaccination time) and 10 weeks old (at the end of the post-weaning period) and the average daily gain (ADG) of each group was calculated.

Statistical analysis was performed using the General Linear Model (GLM-SPSS 15.0 for Windows). The means and variances were compared using the ANOVA and Levene tests.

Results
No local reactions were observed in any of the groups post vaccination. In Group 1, 0.7% of the piglets showed mild systemic signs that disappeared spontaneously a few minutes after injection.

In Group 2, vomiting was observed in 3.5% of the piglets about 10 minutes post vaccination. The animals recovered between 5 and 15 minutes later. No systemic signs were observed in Group 3.

There were no significant differences between any of the groups with respect to ADG between 3 and 10 weeks of age. Table 1 summarizes the performance data of the three groups.

Table 1: Performance Results

<table>

</tr>
</tbody>
</table>

There was no significant difference in performance between the three groups (p = 0.307).

At the end of the trial (25 weeks of age) Group 1, however showed significant differences for all parameters in comparison to the control group (Group 3), whereas Group 2 (Vaccine B) did not present significant differences vs the control group.

Discussion
There were no local reactions to the simple vaccination of conventional piglets with Porcilis® PCV. There were a few systemic reactions after vaccination, but they were very moderate and transient.

There was complete equivalence between control and vaccinated piglets as regards growth during the nursery period. According to this study, the vaccination of piglets of 3 weeks of age with Porcilis® PCV has no negative effect on performance, in the few weeks following vaccination.

Economic impact of reduced variation of slaughter weights involving different PCV2 vaccinated groups

Dennis DiPietre² Eric Lewandowski³ Remy Jagu³ Matthias J. Adam¹
1. Boehringer Ingelheim Animal Health, Ingelheim am Rhein, Germany; 2. KnowledgeVentures, LLC, Columbia, MO, USA; 3. Boehringer Ingelheim Vetmedica , Pace, France

Introduction
Pig producers selling at the same average weight may have widely different profit outcomes depending on the fraction of production which qualifies for the highest price sections of the buying grid. The main reason for this is variation in slaughter weights. It is not unusual for modern production systems to have a range of 45kg (100 lb) live weight between the largest and smallest animals sold at the time of slaughter. Slaughterhouse pricing schemes provide the highest prices in a relatively narrow range of weight and lean percent combinations to incentivize producers to produce and market animals which bring the highest returns to the processing and up-chain sales activities. Pigs falling outside this range are subjected to increasingly severe discounts as they depart farther from the ideal weight and lean parameters.

It is therefore crucial for pig producers to measure, understand and control the variance of production. Many factors contribute to variation in final kill weights including natural variation inherent in biological production processes. Insults to the pigs during the production process (such as feed out events, lack of proper ventilation etc.) as well as disease increase the variation of finished weights as each animal varies in its growth and quality response to challenges in the growing environment. Disease is thought to be the most important cause of variation in final slaughter weights. Vaccination measures can affect the standard deviation of the distribution of weights and other production parameters by reducing disease pressure. This paper investigates the economic impact of two vaccination protocols taking into account only the reduction in standard deviation of slaughter weights between the two groups.

Materials and Methods
A 5,000 head nursery-finish unit in Brittany, France receives weekly, 21-day-old piglets from a unique 900-sow unit. In this side-by-side trial, pigs were randomly assigned at weaning to two treatment groups, Circovac® (CV) or Ingelvac CircoFLEX® (FLEX). Pigs of both groups were kept in separate pens, but in the same rooms. The producer was blind to the treatments and employed his standard selection and marketing procedures to both groups. At slaughter, individual data were gathered for all pigs marketed. While actual average slaughter weights per group were nearly identical, carcass weight and lean percent standard deviations were significantly different in favor of the FLEX group.

10,000 paired carcass weights and lean percents were randomly drawn from correlated distributions estimated from the actual sales data for each group. The total feed costs were estimated from standard growth and intake curves adjusted to match the historical closeout data of the farm (average feed cost/Mton W-F: €200; base carcass price: €1.30/kg). All observations in each set of sampled observations were priced in the French slaughterhouse grill (matrix) to which the farm sold pigs.

Results
Standard deviation of weight at slaughter was 16.7% lower in the FLEX group generating an "as marketed" advantage of €1.85/head for the FLEX group.

Discussion & Conclusion
The above differential return takes only into account the reduction in standard deviation of slaughter weights and does not include other production parameters e.g. mortality or growth. However pig producers evaluate different strategies based on the most commonly available information, such as the average of production parameters (feed efficiency, etc.) and overlook the hidden economic benefit generated from reduced variation. Understanding of variation at slaughter is critical to capturing more profit, and since slaughter data is for many farms the only availability of individual animal performance data, it is crucial to collect and analyze this important metric. In this trial a differential return of €1.85/hd was generated by a 16.7% reduction in standard deviation of slaughter weights for the FLEX group.

Comparison of the serology of piglets with Porcilis® PCV and an alternative PCV vaccine

Juan L. Ubeda¹ Rut Menjon² Jesus M. Bollo² Marta Jimenez²
¹. Veterinary Practitioner, Zaragoza, Spain; ². Intervet Schering Plough, Madrid, Spain

Introduction
The aim of the study was to compare the development of specific humoral immunity (IgG and IgM) against PCV2 over the whole production cycle of animals vaccinated with two different commercial vaccines and unvaccinated animals, taking account of possible interference with maternally derived antibodies (MDA).

Materials and Methods
The study was performed on two different sites of a 1000-sow farm in northern Spain. The farm had a history of PCVAD-related problems, with an average 6-8% mortality during fattening, and a late clinical picture appearing from 14 weeks of age onwards which persisted up to 18-20 weeks old. Prior to the study, PCV2 was confirmed by clinical signs and gross pathology in diseased animals, isolation from tissues of 4/5 culled piglets, and seroconversion evident at 18 weeks of age.

60 three week old piglets were individually identified and randomly allocated to three groups of 20 animals each, according to dam, sow parity, gender and weight. The pigs were treated at 3 weeks old as follows: Group 1 was vaccinated with Porcilis® PCV (single 2ml dose); Group 2 with a single 0.5ml dose of another commercial product, Vaccine B; Group 3, the controls, were injected with 2ml Diluvac Forte®. Blood samples were taken at 3, 7, 10, 14, 18, 22 and 25 weeks old. Serum was tested for PCV2 IgG and IgM antibodies (Ingezim PCV2 ELISA®, Ingenasa).

Results
At 3 weeks of age, the animals of all three groups had high levels of MDA, with a high percentage being positive for IgG, but with average optical density (OD) titers showing no significant differences between the groups (p=0.601). (Group1: 0.7191±0.1; Group 2: 0.853±0.1; and Group 3: 0.758±0.1). All the groups were negative for IgM at this age.

At 7 weeks old, the piglets of Group 1 had 94.7% and 84.2% animals positive for IgG and IgM, respectively, statistically significantly greater than the other groups (p<0.001), and an average 1.36 ± 0.11 OD titer compared with that of the other groups which fell below the threshold.

At 10 weeks old, IgM had disappeared from all groups, but Group 1 had 87.5% animals IgG positive, significantly more than the other groups (p<0.001) which were nearly negative, and remaining so until 25 weeks of age.

At 14 weeks old the percentage of IgM positive animals in Groups 2 and 3 increased significantly, while Group 1 animals remained negative.

Discussion and Conclusions
At 3 weeks old, the IgG levels represent the level of MDA, when all piglets were negative for IgM. Unlike the Porcilis® PCV vaccinated group, the Vaccine B group did not seroconvert at 7 or 10 weeks of age, and the control group did not do so until 14 weeks of age, on contact with field virus. This indicates that all previous immune responses had been induced by the vaccine without interference from MDA (1). A high percentage of the Porcilis® PCV vaccinates continued with positive IgG titers until week 25, whereas the other two groups needed the field virus challenge to induce seroconversion. After challenge, the increased percentage of IgM positive pigs in the Vaccine B and control groups, but not in the Porcilis® PCV group, demonstrates the priming induced by this vaccine.

**Benefit of Porcilis® PCV® PCV vaccination on a farm with late mild PCVAD**

Juan C. Ezpelata¹ Alicia Echave¹ Rut Menjon² Marta Jimenez² Jesus M. Bolo²

1. Grupo AN.Pamplona (Navarra), Pamplona, Spain; 2. Intervet Schering Plough, Madrid, Spain

**Introduction**

The clinical presentation of porcine circovirosis has modified over recent years, with cases often being less severe, and arising at the end of the production cycle. Nevertheless, the virus still causes significant production losses which it is very important to avoid. The aim of the present study was to assess the benefits of vaccination with Porcilis® PCV against late, subclinical PCVAD.

**Materials and Methods**

The study was carried out on a 1500-sow farm in northern Spain, managed in 2 week batches, in a two-phase production system. The farm, which uses LW*LD genetics, finishing with halothane-negative Pietrain, had tested negative for PRRS and Aujeszky’s Disease, but positive for Mycoplasma, against which piglets were vaccinated. The average mortality rate had been 3.5% and culling rate 1.3%.

The clinical presentation of Circovirus was mild and occurred between 20 and 22 weeks of age (the end of fattening period). Prior to this study, PCV2 had been identified by *in situ* hybridization (in two unthrifty pigs which were culled), and confirmed by high levels of maternally derived antibodies in young animals and seroconversion to PCV2 at 18 weeks of age.

At 3 weeks of age, the pigs were randomly allocated to two equivalent groups of 750 animals each, according to gender and weight. The treatment group received a single 2 ml dose of Porcilis®PCV; the control group was left unvaccinated. In the pre-fattening period, the groups were kept in separate barns, and during the fattening period they were housed in two twin barns, each holding 750 animals. Handling, feeding and treatment procedures were similar for both groups. Blood samples taken from 10 animals of each group at 5, 7, 10, 14, 18 and 26 weeks of age, were assessed for IgG and IgM (Ingezim PCV Elisa).

**Results**

Serology shows that Porcilis®PCV vaccination at 3 weeks old, even in the presence of medium-high levels of MDA, led to significant increases in mean IgG and IgM values, which persisted to 14 weeks old, before decreasing. The unvaccinated pigs had lost their IgG titers (MDA) at 7 weeks of age and continued with low levels until seroconversion in week 18 (Graphs 1 & 2). This indicates that MDA did not interfere with the vaccine take. Animals vaccinated with Porcilis®PCV also showed improvements in various production parameters, including optimal end weight and better carcass yield at slaughter.

</table>

The Return on investment (ROI) by using Porcilis® PCV was 3,19 €.

**Discussion**

Pigs showed clear evidence of seroconversion after Porcilis®PCV vaccination, even in the presence of high levels of maternally derived antibodies.

Vaccination with Porcilis®PCV has been proven to be effective even with late onset and mild, subclinical infections, thus contributing to reduced production losses caused by PCV2.

Field trial of Circumvent™ PCV in South Korea

Yeong H. Kim2 Myunghyee Kim3 J H. Pi4 J H. Han2 Alexander A. Eggen1
1. Intervet/Schering-Plough, Boxmeer, Netherlands; 2. School of Veterinary Medicine and Institute of Veterinary Science, Kangwon National University, Chuncheon, Korea; 3. Intevet Schering-Plough Korea, Seoul, Korea; 4. Greeen Farming Corporation, Seoul, Korea

Introduction

Porcine circovirus type2 (PCV2) is the primary causative agent of porcine circovirus-associated disease (PCVAD). PCVAD has been reported with increasing frequency in swine herds. It is difficult to recognize and diagnose because the exact pathogenic mechanisms responsible for the disease are still under review. Nevertheless, immune suppression is considered to be a key factor. Clinical signs of pigs with PDNS include weight loss/unthriftiness, dyspnea, enlarged lymph nodes, diarrhea, pallor and jaundice, with an increased mortality rate. However, the introduction of PCV2 vaccines is contributing to the reduction of the incidence of PMWS and its associated diseases. The purpose of this study was to further investigate the effects on PCVAD of CIRCUMVENT™ PCV on commercial Korean farms testing positive for PCV2.

Materials and Methods

159 piglets from 3 different farms with a history of PCVD (Farms A, B, and C located in Hongsung-gun, Choongnam province, Korea), were included in this study, and divided into 2 groups, vaccinated and placebo. Piglets in the vaccinated group received CIRCUMVENT™ PCV (Intervet Schering-Plough) IM at 3 and 6 weeks of age. The placebo-treated controls were treated in a similar manner but with saline instead of vaccine.

All the pigs were weighed, blood samples were taken, and nasal and fecal swabs collected at 3, 6, 9, 13, 16 and 24 weeks of age. The mortality was recorded and the rate was calculated for each group. Sera were analyzed to measure the immune response using SERELISA PCV2 Ab Mono Blocking (Synbiotics, France). The PCV2 viral load was quantified by TaqMan real time PCR. Lung lesions were assessed according to Pointon et al (1982) at moment of slaughter.

Statistical analysis was by student t-test. Wilcoxon Mann-Whitney test was used to assess differences with respect to ADG, serology and lung lesions. The `C2-test and Fisher’s exact test were used to investigate possible differences in PCV2 viremia and mortality. Statistical analyses were performed using SAS software release 8.2.

Results

Average daily weight gain (ADG) was considered to be an objective measurement by which to determine the severity of PCVAD and the effect of vaccination in a large number of animals. The vaccinated group had significantly better ADG than the placebo group either at entry to the finishing phase or at the midpoint of the finishing phase, or both.

The mortality rate in the vaccinated group was significantly lower during the finishing phase, compared with placebo group. Pigs on all the farms had high levels of maternally derived antibodies against PCV2. The vaccinal antibody response in the vaccinated group continued at high levels until 16 weeks of age on Farm A and 24 weeks of age on Farms B and C. However, field virus antibodies in the placebo group were confirmed at 13 or 24 weeks of age. Interestingly, at 24 weeks of age, there was a lower antibody response in the vaccinated group than in the placebo group.

In the real time PCR, PCV2-positive animals reached a peak at approximately 10-16 weeks of age in the placebo group. In the vaccinated group, the level of positive animals decreased more dramatically than in the placebo group. Animals with high viral loads (106 PCV2 genome/ml in serum) were observed in the acute phase at 10 to 16 weeks of age. Compared to the placebo group the proportion of PCV2-positive animals in the vaccinated group was significantly lower (FarmA: P=0.0021; Farm B: P<0.0001; Farm C: P<0.0001).

There were no significant differences between the groups overall in respect of lung lesions, but on Farm C, the vaccinated group had significantly lower lung lesion scores than the placebo group.

Discussion

Based on these results, vaccination with CIRCUMVENT™ PCV was shown to reduce economic losses from PCV2 infection. This appears to be the first report of the efficacy of vaccination against PCV2 on commercial Korean farms.

**Effect of a single dose of Porcilis® PCV at three weeks of age on mortality caused by Porcine Circovirus type 2**

**Stefan von Rüden1 Ralf Werner1 Patricia Roesner2 Thomas Noé1 Alex Eggen3 Hans Holtslag3 Jos Smeets3**

1. Intervet Schering Plough Animal Health, Unterschleissheim, Germany; 2. Tierzucht Nordhausen GmbH Co KG, Nordhausen, Germany; 3. Intervet Schering-Plough Animal Health, Boxmeer, Netherlands

**Introduction**

Porcine circovirus type 2 (PCV2) is associated with several swine diseases such as PMWS (Post weaning Multisystemic Wasting Syndrome), PDNS (Porcine Dermatitis and Nephropathy Syndrome), and reproductive and intestinal failures.

The object of this study was to demonstrate a reduction in mortality in a herd affected by PCV2 virus circulation, using a single 2ml dose of Porcilis® PCV (Intervet/Schering-Plough Animal Health), mainly by reducing the number of PDNS cases.

**Materials and Methods**

The study was carried out on a large German pig herd (6,000 sows and 29,000 finishers) with a high PCV2-related mortality rate during the finishing phase (beginning around the 55th day of finishing). The presence of PCV2 was confirmed by histologic and serological examination.

The farm operated three separate production lines. To evaluate the effect of Porcilis® PCV on mortality, the piglets from one of these lines were vaccinated with a single 2ml dose of Porcilis® PCV before weaning at three weeks of age. On the same day, the piglets were also vaccinated with Porcilis® PRRS intra-dermally with IDAL equipment (Intra Dermal Application of Liquids).

During the nursery and finishing phases, mortality and other disease data were monitored for every batch according to the farm’s usual routine. Each nursery unit could accommodate approximately 660 animals and each finishing unit, approximately 550 animals. The data were collected over three periods:

1) The pre-study period: no PCV2 vaccination (March - October 2007)

2) The study period: only batches of piglets from production line 1 were vaccinated with Porcilis® PCV. The piglets from production lines 2 and 3 served as controls (October - December 2007).

3) The post-study period: piglets of all three production lines were vaccinated with Porcilis® PCV (December 2007 - February 2008).

To determine the effect of herd vaccination on the incidence of PDNS, the data from the pre- and post-study periods were compared, the pre-study period serving as historical control. The total mortality data per production line were analyzed for variance (ANOVA) with production line as the independent variable. The PCV2-related mortality data were analyzed using the one-sample T-test.

**Results**

During the study period, 43 batches of piglets were included in the trial (27 nursery batches and 16 finishing batches). In all, 5,796 vaccinated animals were involved in the batches used for the analysis. The total mortality during the nursery phase was not significantly different (ANOVA: P-value 0.1078) between the vaccinated line 1 (0.96%) and control lines 2 and 3 (0.68% and 1.34% respectively), and no PCV2-related mortality was recorded.

However, during the finishing phase of the study period, the total mortality was significantly lower (ANOVA; P-value 0.0004) in the vaccinated line 1 (1.66%) than in the unvaccinated line 3 (3.93%). In production line 3, the PCV2-related mortality was 1.22%, while 0.04% PCV2-related mortality with respect to PDNS was recorded in the vaccinated line 1 (ANOVA; P-value 0.0012).

A total of 21,703 vaccinated animals were included in the batches used for the historical comparison. This analysis showed that the average total mortality was reduced from 4.77% in the pre-study period to 1.61% in the post-study period when all three production lines were vaccinated. The PCV2-related mortality decreased from 2.22% (pre-study) to 0.04% (post-study).

**Discussion**

The efficacy of single-dose vaccination at 3 weeks of age was clearly demonstrated by the significant reduction in total mortality by more than 50% during the whole finishing phase: 1.66% in the vaccinated line against 3.93% in the controls. The reduction in PCV2-related mortality was even clearer in the comparison between the vaccinated post-study period (1.61%) and control pre-study period (4.82%).

It can be concluded that there was a highly significant decrease in PDNS losses in the finishing phase after PCV2 vaccination with Porcilis® PCV. In the control group however, signs related to PDNS were evident in the majority of the pigs which died.

The economic benefits due to a single 2ml dose of Porcilis® PCV realized in this trial were considerable: 3.22 € (study period) and 4.74 € (pre-study versus post-study period) per fattening pig.
**Economic impact of CIRCOVAC® in a PCV2 subclinically infected breeding farm in Switzerland**

Xaver Sidler1 Jeremias Kurmann1 Esther Buergi1 Enrico Brugnera1, 2 Titus Sydler2
1. Division of Farm Animals, University Zurich, Vetsuisse Faculty, Zurich, Switzerland; 2. Institute of Veterinary Pathology, University Zurich, Vetsuisse Faculty, Zurich, Switzerland

**Introduction**
Postweaning Multisystemic Wasting Syndrome (PMWS) in pigs became worldwide one of the most economical important diseases. In Europe annual losses associated with PMWS amount to 500 to 900 million Euros (Armstrong and Bishop, 2004).

The objective of this study was to investigate the efficacy of the vaccine Circovac® Merial SA Lyon in a small subclinically infected herd under field conditions and to test the effect on reproductive parameters, daily weight gain, days to slaughter, mortality rate and farm economics under Swiss commercial conditions.

**Materials and Methods**
This study was conducted in a small breeding herd with 90 sows in 2007. Piglets were sold every week to a regional finisher at the age of approximately ten weeks and with a body weight of 23 to 27 kg. In 2006 only sporadic cases of PMWS had occurred on the breeding herd, but there had been considerable losses in the finishing farm.

Randomly sows were chosen either for vaccination or were injected with Circovac® adjuvans as control group. In the vaccinated group the sows were vaccinated with 2 ml Circovac® two and four weeks before artificial insemination and in the 12th week of gestation. Parity number, litter weight, number of live and dead piglets, number of mummies, number of piglets weighing below 1kg, piglet losses during the nursing period and the cause of piglet death were recorded for each sow. The carcass weight was considered to represent 78% of the live weight at slaughter and was used to calculate the average daily weight gain (ADWG, g/d). A feed price of 0.43 €/kg, a feed conversion rate (FCR) of 1.7 kg feed/kg body weight, a price for slaughtered pigs of 2.87 €/kg and a price of 3.47 €/kg per piglet at 25 kg were taken as a basis for the calculation (average Swiss market prices from 2006 - 2008). The vaccination costs were calculated on a base of 7.00 € a dose, 2.3 parities/year and 33 % replacements of young sows.

**Results**
There were no significant differences of litter size, litter weight, number of live and dead piglets, and number of mummies, number of piglets weighing below 1kg and number of lost piglets during the nursing period between offspring of vaccinated and non-vaccinated sows.

**Table 1: Average daily weight gain (ADWG)**

<table>
<thead>

<td>786±20*</td>
<td>734±20</td>
</tr>
<tr>
<td>Ø Slaughterage (d)</td>
<td>168±2*</td>
<td>177±2</td>
</tr>
</tbody>
</table>

However there were significant differences (* p≤0.05) in ADWG between offspring of vaccinated and non-vaccinated sows. The feed costs in the vaccinated group were 4.10 €/pig lower than in the non-vaccinated group respectively 9254 € for all produced piglets in this farm in 2007.

**Table 2: Mortality rate before and after vaccination (2007)**

<td>n=53 (2.2%)</td>
</tr>
<tr>
<td>ØSlaughterage (d)</td>
<td>182</td>
<td>168</td>
</tr>
</tbody>
</table>

Moreover, during the vaccination period the mortality rate dropped significantly from 6.1 % (before vaccination) to 2.2 % in the fattening farm and after weaning from 3.2% to 3.0% (Table 2). The higher mortality rate corresponded to losses of about 25'664 €.

**Discussion**
The lower mortality rate and feed costs of the piglets of the vaccinated sows were producing an economical benefit about 34’918 € even in a subclinically infected breeding farm. The investment for vaccination in 2007 amounts to 3360 €. Hence it resulted a Return on Investment of (ROI) on 1: 10.4.

The effect on PCV2 viremia in pigs vaccinated with a single dose of Porcilis PCV®

Introduction
PCV2 vaccines have been demonstrated to reduce losses (mortality and culling rates), and significantly improve the average daily gain, while reducing the frequency of co-infections. Moreover, they are claimed to reduce virus load and viral-induced lymphoid lesions.

This study was aimed at investigating the effect of a single dose of a PCV2 subunit vaccine administered at weaning, by measuring the proportion of viremic animals and the PCV2 virus load in two herds suffering from PCVD in pigs older than 15 weeks of age.

Materials and Methods
A double-blinded, randomised and controlled field trial was conducted on two farms with a history of PMWS in pigs older than 15 weeks (Farm 1: 900-sow farrow-to-finish herd and Farm 2: 3-site 1850 sows herd).

A total of 818 piglets (males and females) was enrolled in the study and distributed between two treatment groups. At inclusion (weaning - 21±3 days of age), a total of 408 animals (Group B) received a 2ml intramuscular dose of Porcilis PCV®, a commercial PCV2 capsid-based subunit vaccine expressed in inactivated baculovirus. To act as controls (Group A), 410 pigs received 2mls of the adjuvant Diluvac Forte®, by the same route.

On Farm 1, 22 piglets/group were bled at 3 weeks (inclusion / weaning /vaccination), and 4, 5, 6, 7, 9, 12, 15, 16, 17, 18, 19, 20, 22, 26 and 35 weeks of age. On Farm 2, blood samples were collected from 22 animals/group at 3 weeks of age (inclusion / weaning /vaccination), and at 4, 6, 12, 16, 18, 20, 22, 24, 26, and 35 weeks of age.

Real-time quantitative PCR (qPCR) was performed according to Olvera et al. (2004), and the results expressed as the number of PCV2 genome copies/ml of serum.

To estimate the effect of vaccination on the probability of a pig becoming viremic, a mixed effect logistic regression model was constructed to take account of the non-independence of the repeated measurement of the same subjects and the effect of the sow (litter effect) using the “R” software.

Results
The onset of PCV2 viremia was observed on both farms at 16-17 weeks of age in the control pigs and two weeks later in the vaccinated group. The proportion of PCV2-positive animals in the vaccinated group was statistically significantly lower than that of the controls (p< 0.001). Vaccinated pigs, when Q-PCR positive, never had a viral load higher than 106.

Discussion
The present study confirms that a single dose of Porcilis PCV® administered at 3 weeks of age significantly reduces the proportion of viremic pigs and the viral load. These reductions were associated with an absence of clinical signs, improved daily gain and reduced mortality and are correlated with an increase in the antibody response.

References
Introduction
Under field conditions, PCV2 vaccines improve performance, reducing mortality, clinical signs, the frequency of co-infections, viral load and viral-induced specific lymphoid lesions. Some studies indicate that these effects are related to total and neutralising antibody responses, as well as to cell-mediated immunity (Fort et al., 2009). The present study was aimed at investigating the antibody response and the PCV2 IFN-γ secretion (by ELISpot) after vaccination and exposure to a natural infection, under field conditions.

Materials & Methods
A double-blinded, randomised and controlled field trial was conducted in a 900 farrow-to-finish sow herd with a history of PMWS in pigs older than 15 weeks. A total of 411 piglets (males and females) were enrolled in the study. At inclusion (weaning - 21±3 days of age) 205 pigs (vaccinated group) received a 2ml intramuscular dose of Porcilis PCV®. To act as controls, 206 pigs (placebo/control group) were injected with 2mls of Diluvac Forte®. Thirty randomly selected piglets (20 controls and 10 vaccinated) were bled at 3 (inclusion /weaning /vaccination), and 4, 5, 6, 7, 9, 12, 15, 16, 17, 18, 19, 20, 22, 26 and 35 weeks of age. The sera were tested with a blocking ELISA for the detection of PCV2-specific antibodies in porcine sera, and the titers expressed as log2. The levels of IFN-γ secreting cells (SC) in the peripheral blood of pigs were determined according to Martelli et al. (2009). The in vitro recall response was stimulated by the addition of a wild PCV2 strain (I12/11) solution. A mixed effects regression model was fitted to take into account the hyperarchical structure of the observations, using the “nlme” package within the R.

Results
Vaccination elicited a rapid increase of antibodies with a tripling of titres within 6 weeks, even in pigs with the highest levels of maternally derived antibodies (MDA) at the time of vaccination. In the controls, passively acquired antibodies gradually declined, disappearing altogether by 12 weeks of age. Three weeks post-vaccination the number of IFN-γ SC peaked with an average of 120 cells. At 16-17 weeks of age, when the PCV2 field infection occurred, the antibody levels increased in both groups. In the controls, a marked IFN-γ secretion was detectable (190-240 cells) within 3 weeks of the field infection. Conversely, the infection stimulated only an erratic course of IFN-γ SC response in the vaccinated, clinically protected animals.

Discussion
After vaccination, there was a rapid and remarkable PCV2-specific IFN-γ secretion, as well as a significant increase in antibodies. After infection high levels of antibodies in the vaccinated animals were associated with a reduced or absent PCV2 viremia, and a lack of specific clinical signs. Comparing our results with those of Fort et al. (2009) in experimentally challenged pigs, it could be proposed that the intensity of IFN-γ secretion depends on the in vitro stimulation (in this case, whole PCV2), as well as on the type of isolate, viral load and replication in vivo.

Serology and safety of the simultaneous use of Porcilis® PCV and M+PAC® in the field

Josep Farreres2 Daniel Puig2 Rut Menjon1 Jesus M. Bollo1 Jesus V. Lopez1 Marta Jimenez1
1. Intervet Schering Plough Animal Health, Alcobendas (Madrid), Spain; 2. Cooperativa de Bellcaire, Bellcaire d’Urgell, Lleida, Spain

Introduction
Porcine Circovirus Type 2 (PCV2) and M. hyopneumoniae vaccines are probably the most frequently used in the pig industry all over the world. As both vaccines are very often given at weaning, their simultaneous use would simplify herd management and improve animal welfare. The simultaneous administration of various commercial products has previously been shown to be effective (1). The object of this trial was to demonstrate that the simultaneous administration of Porcilis® PCV and M+PAC® is safe and efficacious in terms of serological response.

Materials and Methods
The trial was performed on a 250-sow farrow-to-finish herd in north-east Spain, in which piglets had been routinely vaccinated with another PCV2 vaccine at 4 weeks of age, but had not been vaccinated against M. hyopneumoniae.

Porcilis® PCV is a subunit vaccine containing the viral capsular protein coded by the ORF2 of the PCV2 genome adjuvanted in X-Solve®. M+PAC® is an inactivated M. hyopneumoniae vaccine in Emunade®, an oil-in-water dual-action adjuvant.

A total of 397 four-week old piglets were allocated to two experimental groups:
- Group 1: 197 piglets, vaccinated with a mixture of 2ml Porcilis®PCV and 2ml M+PAC® injected in a single site on the left side of the neck.
- Group 2: 200 piglets were vaccinated with 2ml Porcilis® PCV and 2ml M+PAC® in separate sites on either side of the neck.

All animals were identified individually by ear tag, and 10 animals of each group were bled at 4, 7 and 10 weeks of age.

All the pigs were monitored for signs of local or systemic reactions.

The immune response to Porcilis® PCV was evaluated comparing the PCV2 IgG and IgM titers of each group using Ingezim® PCV-ELISA (Ingenasa, Madrid, Spain).

Levene test was used for the comparison of variances and Mann-Whitney U-test for the comparison of means.

Results
No local or systemic reactions were observed in any of the animals of Group 1 (mixed vaccination). One piglet of Group 2 (separate vaccinations) exhibited a transient systemic reaction which rapidly disappeared without any remedial action needed.

Graph 1 shows the PCV2 serology. There were no statistically significant differences between groups either for IgM or IgG at any age (p>0.1).

Graph 1. PCV2 IgG and IgM seroconversion

ELISA Ingezim PCV IgG index >0.520 and IgM index >0.66 – positive result

No clinical signs of PCV2 or M. hyopneumoniae infection were detected in any treatment group.

Discussion
This trial has demonstrated the compatibility of Porcilis® PCV and M+PAC® in terms of safety and the immune response against PCV2 IgG and IgM, even in the presence of maternally derived antibodies.

Although further studies will be needed to confirm efficacy in the field, these data suggest a way herd vaccination strategies might be simplified and animal welfare improved.

Safety and efficacy of the simultaneous administration of Porcilis® PCV and Porcilis® MHyo under field conditions

Josep Farreres² Daniel Puig² Rut Menjon¹ Jesus M. Bollo¹ Jesus V. Lopez¹ Marta Jimenez¹

1. Intervet Schering Plough Animal Health, Alcobendas (Madrid), Spain; 2. Cooperativa de Bellcaire, Bellcaire d’Urgell, Lleida, Spain

Introduction

*M. hyopneumoniae* and PCV2 infections are widespread in pig populations, which are frequently vaccinated against both pathogens. However, as these vaccines are commonly administered at weaning, it is important that they do not interfere with each other. The efficacy of the simultaneous administration of Porcilis®PCV and Porcilis®MHyo has been previously demonstrated under laboratory conditions (1). The aim of this study was to confirm the same under field conditions.

Materials and Methods

The trial was performed in a 250-sow farrow-to-finish herd in north-east Spain, in which piglets had been routinely vaccinated against PCV2 at 4 weeks of age, but not against *M. hyopneumoniae*.

The trial vaccines were Porcilis®MHyo (a 2-dose inactivated vaccine against *M. hyopneumoniae* with dl-α-tocopherol acetate as adjuvant) and Porcilis®PCV, a subunit vaccine containing the viral capsular protein coded by the ORF2 of the PCV2 genome, adjuvanted in dl-α-tocopherol acetate and paraffin.

All the trial pigs received a 2ml priming dose of Porcilis®MHyo at 1 week of age. At 4 weeks old, 515 piglets were allocated to one of two experimental groups:

- Group 1: 325 piglets were vaccinated with a mixture of 2ml Porcilis®PCV and 2ml Porcilis®MHyo injected in a single site on the left of the neck.
- Group 2: 190 piglets were vaccinated with 2ml Porcilis®PCV and 2ml Porcilis MHyo in separate sites on either side of the neck.

All animals were individually identified by ear tag, and 10 of each group were bled at 4, 7 and 10 weeks of age. All the pigs were examined post mortem, at slaughter.

Safety was assessed by monitoring the piglets for any local or systemic reaction.

All sera were examined for PCV2 IgM and IgG antibodies (Ingezim PCV-ELISA), and the antibody response of the groups were compared.

The efficacy of Porcilis®MHyo was assessed by scoring the severity (0-5) of any post mortem lung lesions typical of enzootic pneumonia. Lung lesion scores were compared with those observed in contemporary, but unvaccinated, animals from the same farm. For practical reasons not all piglets vaccinated were scored at the slaughterhouse. Statistical analysis was performed using the Levene test, Mann-Whitney U-test and Pearson’s chi-square test.

Results

No local or systemic reactions were observed in any of the animals of Group 1. Five piglets of Group 2 showed a transient systemic reaction that rapidly disappeared without any remedial action needed.

Graph 1 shows the results of PCV2 serology. No significant difference was found in IgM response between the groups, at any age. Although there was a statistically significant difference in IgG response (p=0.049) at 7 weeks of age, it had disappeared 3 weeks later. No clinical signs of PCV2 infection were detected in any treatment group.

Graph 1. PCV2 IgG and IgM seroconversion

IgG index >0.460 and IgM index >0.518 – positive result

Lung lesion scores are summarized in Table 1. No significant differences were found between the two vaccinated groups, but the scores of both groups were significantly statistically different compared to the unvaccinated animals (p<0.001).

Table 1. Lung lesions at the slaughterhouse:

</tr>
</tbody>
</table>

², ³, ⁴: values with different superscripts in the same row are statistically significantly different: ², ³: p<0.001, ⁴: p<0.01

Discussion

The simultaneous use of Porcilis®PCV and Porcilis®MHyo has been shown to be safe and efficacious under field conditions, with no statistically significant differences between being mixed and injected in a single site or injected separately in two distinct sites, even in the presence of MDA. These results might be used to simplify herd vaccination strategies and improve animal welfare.

Efficacy of 3 PCV vaccines in a commercial farm situation

John S. Richardson¹ Mark E. White²
1. Intervet/Schering-Plough UK, Milton-Keynes, UK; 2. Haven Veterinary Group, Hedon, Hull, UK

Introduction
The use of vaccines to control diseases associated with the infection caused by Porcine Circovirus type 2 (PCV-AD) generally has resulted in success. In some farm situations however response to vaccination has been disappointing necessitating a change of PCV vaccine. This study reports such an occurrence.

Background
The farm has 300 sows, weaning occurs weekly at 4 weeks of age, progeny are finished on site at 100 kg live weight. Pigs are PRRS and M.hyo positive. In December 2006 wean – finish mortality was 15% when breeding stock vaccination commenced to control PCV2 infection in piglets; this resulted in wean-finish mortality reducing to 6% for 7 months to August 2007. Mortality then started to increase to 15%, and whilst previously in pigs at 7-10 weeks of age was now seen later in pigs at 13-14 weeks of age. Piglet PCV vaccination was then instigated using a chimeric PCV1/PCV2 vaccine at 7-8 weeks of age due to concerns about interference from maternally derived antibody (MDA); mortality then decreased to 10%. When sow vaccination had been stopped for more than 6 months, piglets were PCV vaccinated at 3 weeks of age. Mortality then increased to 15% during early 2009, and then declined to 10% in early summer 2009, before increasing dramatically to 28% in autumn 2009 despite antibiotic use. PCV-AD was confirmed via post mortem examination, histopathology, virus isolation and immunohistochemistry Porcilis® PCV vaccination at weaning commenced autumn 2009.

Materials and Methods
Two pigs were bled from each of 10 litters at approximately 3 - 4 weeks of age prior to vaccination with Porcilis® PCV, the same pigs were then sampled later at 8, 12 and 15 weeks of age. The serum was analysed to detect antibodies against PCV2 using an ELISA test (Boxmeer R&D labs). Samples were also q-PCR tested for PCV virus at VLA Weybridge, as were samples from pigs vaccinated with the first chimeric PCV piglet vaccine. Pig mortality was recorded on a monthly basis.

Results
The following graph shows PCV2 antibody titers at 4 and 8 weeks of age after Porcilis PCV vaccination at 3 weeks of age, on a Log2 scale.

Littermate pairs showed similar PCV2 antibody titres. Response to Porcilis® PCV vaccination in pigs with medium levels of MDA showed a strong positive humoral response.

Antibody titres remained particularly high and uniform at 12 and 15 weeks, and all exceed the protective antibody titre level of 5 Log2 (Fort, Vaccine 2009). Significant challenge occurred in pigs at 13 weeks of age on transfer to finishing; whilst q-PCR showed that all pigs that had been vaccinated with Porcilis® PCV were PCV virus free at 12 and 15 weeks of age, and clinical signs of PCV-AD were absent in these pigs. Pigs vaccinated with the initial piglet vaccine had 40% of pigs q-PCR positive for PCV virus associated with clinical signs of PCV-AD. Pig mortality has been reduced from 28% to 5% within 6 months, growth rate has increased by 14% and medication in finishing diets has been discontinued since commencing vaccination using Porcilis® PCV.

**Shedding of Infectious Porcine Circovirus 2 (PCV2) Into Colostrum And Milk Of Vaccinated And Non-Vaccinated Naturally Infected Sows**

Priscilla Gerber; Flávia Garrôcho; Zélia Lobato

Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil

**Introduction**

Porcine circovirus type 2 (PCV2) has been associated with swine diseases, collectively referred to as porcine circovirus diseases (PCVD). Epidemiological studies have demonstrated that clinical manifestations of PCVD can be influenced by non-infectious factors such as passive immunity and maternal viremia in the peripartum [1]. Recently, the PCV2 DNA was detected in colostrum and milk [4].

The objective of this study was to evaluate the profile of anti-PCV2 immunoglobulins and the presence of infectious PCV2 in colostrum and milk of vaccinated and non-vaccinated naturally infected sows.

**Materials and Methods**

Forty-one sows from 8 conventional farrow-to-finish herds were sampled, 21 non-vaccinated and 20 vaccinated with CIRCOVAC (Merial) at 30 and 15 days before parturition. Serum samples (n=41) were collected on parturition day. Milk samples (n=20) were collected 10 days post-partum.

Serum and colostrum were tested for total (TA) and neutralising (NA) anti-PCV2 antibodies as described elsewhere [3]. PCV2 isolation in lacteal samples was performed as previously described [2]. PCV2 titre was expressed in TCD50/50μl. The results of the NA and TA was tested by IPMA and expressed as the average of log2 titre. Mann-Whitney test was used to analyse the difference in the antibody levels and the viral titres between the vaccinated and non-vaccinated groups. Differences were considered significant when P<0.05.

**Results**

Infectious PCV2 was detected in 22/41 (53.6%) of colostrum samples, and a difference was observed between vaccinated (7/20, 35%) and non-vaccinated sows (15/21, 74%) (P=0.02). Vaccinated sows excreted a minor amount of infectious PCV2 into colostrum, compared to in the non-vaccinated sows (100.50±081 vs. 101.63±1.20; P<0.01). PCV2 was isolated in 5/20 (25%) of milk sampled. There was no correlation between the PCV2 titre in colostrum and milk samples or PCV2 titre and the level of anti-PCV2 immunoglobulins.

There was no difference between TA and NA titres in colostrum of vaccinated and non-vaccinated sows, although vaccinated sows had an higher serum NA titre compared to the non-vaccinated sows (P=0.048).

**Discussion**

In this study, we observed that PCV2 is shed into milk from vaccinated and non-vaccinated naturally infected sows, even in the presence of high neutralising antibodies titres. Despite the fact that the vaccination of the sows did not prevent the PCV2 shedding in those secretions, it was capable of reducing PCV2 shedding into colostrum.

PCV2 was detected more frequently in samples of colostrum than milk. This difference may be related to PCV2 associated with monocytic lineage cells shedding (Park et al., 2009) that are present in a greater number in the colostrum. The association of PCV2 in the cellular fraction of milk may have an important role in the viral protection against the NA present in those secretions.

The importance of PCV2 shedding into colostrum in the early infection of piglets needs further investigation, especially because herds in which the piglets are infected earlier with PCV2 have a higher risk of developing PCVD. Also, it has previously been shown that sow PCV2 viremia was related to piglet mortality [1].

In conclusion, PCV2 can be shed into milk and colostrum of naturally infected sows even in the presence of high titres of neutralising antibodies. Vaccination of sows can reduce viral shedding in milk secretion, but cannot eliminate it.

**PCV2 associated mummification and stillbirth in gilts**

**Titus Sydler** 2 Enrico Brugnera 1, 3 Monika Engels 2 Esther Buergi 3 Xaver Sidler 3

1. Institute of Veterinary Pathology, University of Zurich, Vetsuisse Faculty, Zurich, Switzerland; 2. Institute of Virology, University of Zurich, Vetsuisse Faculty, Zurich, Switzerland; 3. Division of Farm Animals, University of Zurich, Veterinary Faculty, Zurich, Switzerland

**Introduction**

Porcine circovirus type 2 (PCV2) is the causative agent for postweaning multisystemic wasting syndrome (PMWS) and is considered to be one of the most important viral pathogens of pigs in many countries. PCV2 has also been associated with additional diseases, referred to as PCV associated diseases (PCVAD) which include PMWS, PDNS, some types of pneumonia, enteritis and also reproductive failures (1). In Switzerland a PMWS epizooty commenced at the end of 2003 (2). However we observed cases of reproductive failures in Swiss sows for the first time in autumn 2008.

**Materials and Methods**

In April 2008 gilts originating from a jointly held mating and gestation facility (ringsystem) in 4 farrowing to wean farms showed raised numbers of mummified and stillborn piglets (Ø 0.6 dead piglets and 2 mummies per litter whereas the pluriparous sows had Ø 0.3 stillborn piglets and 0.3 mummies). All gilts had been vaccinated twice against parvovirus and erysipelothrix before insemination.

In August we received tissue fluids to check for PCV2 from 2 mummies from two litters (farm A) which were negative for parvovirus by virological examination. Our quantitative PCR detected high PCV2 titers (4-9x10^6 templates/μl tissue fluid). Subsequently we investigated 3 cases with mummies and/or stillborn piglets from 3 other farms (farms B, C, and D) belonging to the same ringsystem. Unfortunately, we did not receive further mummies from the first farm (farm A) but a 3 weeks old dead littermate and blood of the two sows that produced the mummies mentioned above 3 weeks after gestation. Altogether we investigated 2 mummies (16 and 25 cm) from farm B, a non-mummified fetus (23 cm) from farm C and 4 mummified fetuses from farm D (13, 17, 22, 22 cm) by necropsy, histology, virological methods for parvovirus detection, immunohistochemistry (IHC) for PCV2 (F217 monoclonal antibody (3)) and conventional PCR for PCV2. A quantitative PCR for PCV2 was achieved on the blood samples of the two gilts. We also performed electron microscopy on 2 mummies.

**Results**

All fetuses were negative for parvovirus or antibodies against parvovirus. The 3 weeks old littermate from farm A, as well as the non-mummified fetus from farm C were IHC negative for PCV2. The fetus showed no inflammatory reaction anywhere and the 3 weeks old littermate had died from an intestinal obstruction (invagination). The tissues of both mummies from farm B and 3 mummies out of 4 from farm D were highly IHC positive for PCV2. However, the fourth mummy was IHC negative. In some cases the myocard was the most positive organ but also lymphatic tissues (lymph nodes and spleen) as well as liver, lung, kidney and lamina propria of the gut could be very highly positive, sometimes even more so than the heart. An inflammatory reaction could no longer be detected in the mummified tissues, but multifocal distrophic calcification in the myocard was a prominent change in 3 of the 5 PCV2 positive hearts. Interestingly, the electron microscopic preparation of mummified paraffin embedded tissues revealed paracrystalline arrays of icosahedral viral-like particles as described for PCV2 inclusions (4). These were at least still preserved in the liver of one of the investigated mummies. All positive fetuses harbored a PCV2b genotype. Only one of the two gilts mentioned from farm A was slightly viremic 3 weeks after gestation (500 templates/μl blood).

**Discussion**

Gilts only had raised numbers of mummies and stillborn piglets. The problem diminished half a year after but only vaccination against PCV2 of all sows finally solved the problem.

Mummies showed always high PCV2 IHC positivity and never moderate or low signals. Myocarditis was not seen due to the poor tissue conservation, however, distrophic calcification in the myocard was prominent. Well preserved viral particles were found by electron microscopy even in these mummified tissues. Interestingly, surviving littermates in affected litters developed normally.

The implication of PCV2 in reproductive failures has still to be estimated in Switzerland.

Retrospective field study of the evolution of growth performances after piglet vaccination against PCV2

Pascal Fourchon² Aude Miorcec³ Vincent Auvigne¹ Catherine Belloc³
¹. Ekipaj, Pozuelo de Alarcón, Spain; ². Coopagri Bretagne, Landerneau, France; ³. National College of Veterinary Medicine, Nantes, France

Introduction

In the mid nineties, when PMWS appeared in France, mortality in affected herds was frequently above 10% during the post-weaning period. Fifteen years later, the disease caused by PCV2 looks very different. Post-weaning losses have decreased to normal range in most herds. Few pigs exhibit clinical or post-mortem signs linked to PCV2 infection but poor growth rates resulting in high within-batch weight variability are frequent. Consequently many vets advise farmers to vaccinate piglets when growth heterogeneity is high even without clear evidence of PCV2 associated disease. In that context, we wanted to evaluate the impact of piglet vaccination against PCV2 on pig growth in a group of herds.

Materials and Methods

The study took place between March and August 2009 in 69 farrow-to-finish herds. For each herd we compared data from (i) three batches before and (ii) three batches after the implementation of vaccination. Piglets were vaccinated either with Circovax® (1 ml), or Circovac®, (0.5 ml). The criteria analysed were: Average Daily Gain from birth to slaughter (ADG), mortality rate from 30 kg to slaughter (MR), lean thickness (M2), percentage of pigs with carcass weight below 80 kg (CW<80). For several reasons (quality of recording, batch mixing, other management change during the study) only 23 herds were included in the analysis and some criteria were not available for all herds. Mann-Whitney test was used to compare the three batches before to the three batches after vaccination.

Results

In nearly half of the herds an increase, or a trend, of growth rate after vaccination was observed. This proportion was the same for both vaccination programs. In these herds, the average increase was 29 g/day and a positive impact on lean thickness was observed. The proportion of underweight pigs was also improved in six out of 15 herds. Nevertheless we didn’t observe a decrease of mortality rate during the fattening period.

Discussion

An improvement of technical performances after vaccination was observed only in approximately half of herds. This is probably related with the fact that most often PCV2 associated diseases had not been clearly diagnosed. Our study did not demonstrate an effect of vaccination on mortality rate. This can be linked to some difficulties to collect reliable data on mortality. Additionally, in France, mortality rate associated with PCV2 are currently less important than ten years ago.

Our study has some limitations. It did not compare contemporaneous batches. Consequently results are dependent on other changes in the farm during the study period such as management changes or sanitary events. Nevertheless data obtained here are complementary to those collected in field trials assessing simultaneously several treatments in the same herds. Other limit of our study is the number of herds that were finally included since 46 herds had to be removed because of lack of reliable data.

To conclude, our results suggest that circovirus vaccines can be of economical interest by improving technical performances. However a more accurate diagnosis of PCV2 infection leading to a more relevant vaccine indication could result in a higher success rate of vaccination.
Introduction
Porcine Circovirus type 2 related diseases (PCVD) are a major threat for pig production all around the globe. Fortunately, in recent years PCV2 vaccines became available and piglet vaccination has proven to be very effective in controlling losses associated with PCV2 infection (1,2).

This long term field observation evaluates the performance of fatteners from a 2000 sow head farm using different PCV2 piglet vaccines.

Material and method
The field observation included in total more than 85,000 pigs from a 2,000 head sow farm in Thailand. Pigs are transferred from the sow farm to the fattening units at about 8 weeks of age. PCV2 piglet vaccination was first introduced in Spring 2007. The first vaccine used was ChoongAng vaccine (produced in Korea), mid 2007 the farm switched to Suvaxyn PCV2 and about a year later Ingelvac CircoFLEX was introduced. Pigs were vaccinated with all vaccines at about 3 weeks of age.

Mortality, culls (pigs euthanized during fattening), and average daily gain (ADG) were recorded per fattening unit. Total loss is the sum of mortality and culls, i.e. the pigs not reaching slaughter age.

The differences between treatment groups in average performance variables (ADG, mortality, culls and total loss) were evaluated using pair-wise Wilcoxon test with a Bonferroni adjustment (SAS System, SAS Inst., Cary, North Carolina, v 8.2).

Results
Finishing mortality, culls and total loss were significantly reduced in CircoFLEX vaccinated pigs compared to the other two groups, while ADG was significantly improved (table 1).

a,b: Values with different superscripts differ significantly (p <0.05/3)

Discussion and conclusion
PCV2 piglet vaccination has become global routine use (3). The data of this field observation indicates that the choice of vaccine might significantly influence production performance. Ingelvac CircoFLEX vaccinated pigs performed significantly better than pigs vaccinated with two other PCV2 vaccines.

Comparative humoral immunity response to vaccination with Porcilis®
PCV, a second commercial vaccine and unvaccinated animals

Enric Marco1 Jesus M. Bollo2 Rut Menjon2 Marta Jimenez2
1. Marco y Collell, St Paulí de Nola, Barcelona, Madrid, Spain; 2. Intervet Schering Plough, Madrid, Spain

Introduction
Monitoring the correct humoral immune response to vaccination is important when using routine vaccination procedures at early ages (3-4 weeks of age). This can be considered as the first step to assess possible interferences of vaccination with maternally-derived antibodies, and gives an indication about the response that will be obtained in subsequent production phases.

Materials and Methods
The study was performed in a farm housing 1680 sows, located in central Spain. Pigs from this farm showed evident PCVAD-related problems during fattening. The symptoms appeared at first at 13 weeks of life, and the most critical phase of the disease concluded 4 weeks later. Sixty-three animals with a mean age of 24 days (2 days before weaning) were selected for the study. The animals were uniquely identified using double ear-tags and were randomized into 3 groups, according to their dam and its parity, and piglet weight and gender, as follows:
• Porcilis®PCV group, single 2 ml dose, 21 piglets.
• Vaccine A group, single 1 ml dose, 23 piglets.
• Control group, single 2 ml dose of Diluvac Forte® (as a placebo), 19 piglets.

A commercial test was used for the detection of IgG and IgM (Ingezim PCV2 ELISA®, Ingenasa), comparing the results obtained at 3, 7 and 9 weeks of age. The cut-off thresholds differed for each antibody detection time: from the 1st to the 3rd sampling, the values for IgG were 0.7, 0.69 and 0.65, respectively and 1.02, 0.74 and 0.71 for IgM, respectively.

Statistical evaluation was performed using the Kruskall - Wallis test, the Pearson’s chi-square test, the Fisher’s exact test and the Mann-Whitney-U test.

Results
The first sampling time coincided with the administration of the three treatments, and all the groups presented high levels of maternally-derived immunity, as shown by the high mean optical density ratio (OD) values and the high percentage of animals positive for IgG (Graph 1). Very low or negative values were found for IgM. All the parameters were comparable (p<0.05).

The second sampling at 7 weeks showed a stronger IgG response to vaccination in the Porcilis®PCV group, with significant differences for the percentage of positives animals compared to the other two groups (p<0.05). Vaccine A did not present significant differences vs. the Control group for both parameters (p<0.05). The Porcilis®PCV group showed a stronger IgM response (Graph 2), with significant differences when comparing the percentage of positives vs. the Control group (p<0.05) and vs. Vaccine A (p<0.001), with no differences between the Vaccine A and Control groups. The percentage of animals of the Vaccine A group positive for IgM at 4 weeks post vaccination was 0% At week 9, a marked increase of the mean OD values was found in the Porcilis®PCV group vs. the other two groups (p<0.001), and for the percentage of positives vs. the other two groups (p<0.05). No significant differences were found for both parameters between the other groups. A strong IgM response occurred in the Control group. Significant differences were found vs. the Porcilis®PCV group (p<0.05) and the Vaccine A group (p<0.001). No significant differences occurred between both vaccinated groups (p<0.05).

Discussion and Conclusions
The strong response to the Porcilis® PCV vaccine obtained 4 weeks after vaccination, contrary to the findings for the Vaccine A and Control groups, indicates a correct immunisation of the animals, thus preventing interferences with maternally derived immunity.

Even though the farm had a history of late problems, the increase of IgM values in the Control group at week 7, which was more evident at week 9, probably was due to contact with the field virus.
**Vaccination with Circovac® in Iberian sows and gilts: effects on insemination results**

Guillermo Ramis1 Angel Garrido2 Francisco J. Pallarès3 Helena Sanjosé2 Manuel Toledo2 Juan J. Quereda1 José M. González2 Antonio Muñoz1

1. Universidad de Murcia, Murcia, Spain; 2. Piensos Jiménez S.A. & Juan Jiménez García S.A.U., Lorca, Spain; 3. DPTO Anatomía y Anatomía Patológica Comparadas. Universidad De Murcia, Murcia, Spain

**Introduction**

Porcine Circovirus type 2 associated diseases (PCVD) is the current name for those pathologies directly related to PCV2. Apart from the classical clinical expression formerly called postweaning multisystemic wasting syndrome (PMWS), has been describe a wide range of diseases, including reproductive alterations (1,2). The launch of vaccines against PCV2 has offered a very useful tool to manage the PCVAD, but there is no wide knowledge about the improvement of reproductive performances directly derived of the vaccination (3, 4). On the other hand, there is much less knowledge about the effect on Iberian pig breed, a Spanish minority indigenous breed.

The aim of this study was to assess the effect of the vaccination against PCV2 with Circovac® on reproductive performance in Iberian gilts and sows.

**Material and Methods**

The experience was carried out in a large unit of Iberian pig production (850 sows) in multiple-sites-production. The breeders were mass vaccinated and revaccinated in a period of 3 weeks. Subsequently, the animals were revaccinated every gestation at least 3 weeks before farrowing expected date. The reproduction is completely based on artificial insemination, and every ejaculate is tested using classical seminal quality tests. Gilts and sows are vaccinated against PRRSv three times per year, alternating modified live and killed vaccines. Boars remained unvaccinated.

The reproductive performance recorded during one year before vaccination and revaccination were used as control.

The analyzed data were: fertile inseminations unfertile inseminations, number of inseminations, return to estrus and type of return to estrus depending on the day returning; early (0-17 dpi), early cyclic (18 to 24 dpi), early acyclic (25-30 dpi), later acyclic (31-38 dpi), later cyclic (39-43 dpi) and later (>44 dpi). A total of 2,741 and 2,897 inseminations performed in control and vaccinated groups, respectively, were analyzed. All data were analyzed using the SPSS v. 15.0 software (SPPS Inc, USA).

**Results**

Data obtained from gilts and sows in both experimental groups are shown in the following table:

<table>
<thead>
<tr>
<th>Group</th>
<th>AMG</th>
<th>FM</th>
<th>NFM</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control</td>

<td>Gilts</td>
<td>1.18</td>
<td>77.4</td>
</tr>
<tr>
<td></td>
<td>Sows</td>
<td>1.08</td>
<td>87.4</td>
</tr>
</tbody>
</table>

Where AMG: average mating per gestation, FM: fertile mating, NFM: non fertile mating.

There was no difference for the frequency of each return-to-estrus type neither for gilts nor sows (p=0.47 and p=0.45, respectively). Early and cyclic returns in gilts and sows from both groups were the most frequently types found.

**Discussion**

There is controversy regarding the effect of PCV2 on reproductive performance, even when some negative effects have been described by practitioners. This trial shows an improvement in parameters such us average mating per gestation, fertile inseminations and non-fertile inseminations, resulting in reduction of production costs. These findings suggest that the PCV2 could be producing a subclinical effect on reproductive performance and the improvement of health status in sows and gilts derived from PCV2 vaccination could result in these better performances in Iberian pigs reared under intensive conditions.

**References**

**Introduction**

Porcine Circovirus Diseases (PCVD) is the current name for those pathologies directly related to PCV2. Apart from the classical clinical expression formerly called postweaning multisystemic wasting syndrome, has been describe a wide range of diseases, including reproductive alterations (1, 2).

The aim of this study was to assess the effect of the vaccination against PCV2 with Circovac® on farrowing performance in Iberian gilts and sows.

**Material and Methods**

The experience was carried out in a large unit of Iberian pig production (850 sows) in multiple-sites-production. The breeders were mass vaccinated and revaccinated in a period of 3 weeks. Subsequently, the animals were revaccinated every gestation at least 3 weeks before farrow expected date. The reproduction is completely based on artificial insemination (AI), and every ejaculate is tested using classical seminal quality tests. Gilts and sows are vaccinated against PRRSv three times per year, alternating modified live and killed vaccines.

As control the reproductive performance recorded during one year before vaccination and revaccination were used. The analyzed data were: length of gestation (GL), alive born piglets (ALB), stillborn piglets (SBP), weaned piglets per litter (WPL) and mortality during suckling (MS). All data were included in a SPSS data base analyzed using the SPSS v. 15.0 software (SPPS Inc, USA) by means of ANOVA. Results from 2,273 and 2,317 farrowings in control and vaccinated group, respectively, were analyzed.

In control group 515 and 1,580 farrowings from gilts and sows, respectively, and in vaccinated groups 361 and 1,956 farrowings from gilts and sows, respectively, were recorded.

**Results**

There was no difference for lactation length (22.3 vs 22.6 and 21.5 vs. 22 for sows and gilts, respectively). Data obtained for gilts and sows are shown in the table 1.

**Discussion**

The length of lactation did not influence other parameters. We have found differences for all studied parameters except for ABP in sows, but, there was no difference in gilts. To have a clear idea it should be taken into account that Iberian pigs show a lower reproductive performance than commercial crossbreds. However, there were important advantages derived from the vaccination with Circovac® in sows: the reduction of SBP and mortality during suckling result in a significant increase in weaned piglets per litter. There is also an interesting result: the increase of gestation length in more than one day. This could result in a better vitality and maturity of piglets. The most important difference was mortality during suckling in sows, showing a decrease of more than 57% (17.2 vs 9.9% in control and vaccinated group, respectively) which could be a direct result of immunity against PCV2 derived from specific colostral antibodies against the virus, in agree with several previous studies. The lack of effects in gilts group could be explained because gilts are vaccinated only when they are included in the breeder group. So, despite the vaccination every farrow, the sows would have immunity produced by mass vaccinations.

Introduction

Postweaning Multisystemic Wasting Syndrome (PMWS) in pigs, caused by porcine circovirus type 2 (PCV2), has become one of the most important diseases in swine. Pigs are most commonly affected at 5 to 12 weeks of age. PCV2-specific antibodies can be detected in almost all pigs. In 2008 Circovac®, (Merial SAS, Lyon) was introduced in Switzerland. Circovac® is used to vaccinate pregnant sows to increase the concentration of colostral antibodies.

Materials and Methods

In this study we used Circovac® in two different farms with a history of naturally occurring PMWS. Herd A was a breeding herd with 90 Yorkshire sows. Piglets were sold to a regional finisher at the age of approximately ten weeks and at a body weight of 22 to 27 kg. Only sporadic cases of PMWS had occurred in herd A since 2006, but there had been considerable losses in the finishing operations. 10 to 15% of these pigs developed PMWS. Herd B was a breeding herd with 150 Yorkshire x Landrace crossbred sows. Approximately 5-20% of the pigs had low daily weight gain and profuse untreatable diarrhoea with a herd mortality rate of 5-10%, also indicators to a serious PMWS problem.

Randomly sows were chosen either for vaccination or were injected with Circovac® adjuvans as control group. Sows were vaccinated with 2 ml Circovac® two and four weeks before artificial insemination and in the 12th week of gestation. 10 ml blood was collected from the jugular vein from of all sows immediately before the first injection, four weeks after the second injection and two weeks after the third injection. 2-5 ml blood was collected from 100 individually tagged piglets at the age of 3, 10, 31, 42 and 63 days p.p. An improved competitive ELISA (SERELISA® PCV2 Ab Mono Blocking Systems (Synbiotics Corporation Europe SAS, Lyon) was used for antibody detection. The carcass weight represents 78% of the live weight at slaughter and was used to calculate the average daily weight gain (AWDG, g/d).

Results

In both farms the vaccinated sows showed a significant increase of PCV2 antibody titre from the first to the second vaccination (** p<0.001)

Discussion

We succeeded by vaccination in elevating antibody titres in sows. At day 42 offspring of vaccinated sows had nearly the same antibody titres as piglets from non-vaccinated sows at day 3 pp. These higher antibody titres ameliorated growth parameters of piglets in both farms.
Introduction

Proliferative enteropathy caused by Lawsonia intracellularis (Li) and porcine circovirus associated diseases (PCVAD) caused by porcine circovirus type 2 (PCV2) are two of the most important swine-diseases in Switzerland. The objective of this study was to investigate the efficacy of the vaccines Enterisol® Ileitis against Li and Ingelvac CircoFLEX® against PCV2 under field conditions and to test whether there is an additive effect on performance parameters when using both vaccines. The absence of Mycoplasma (M.) hyopneumoniae and porcine reproductive and respiratory syndrome virus (PRRSV) in Switzerland allows a proper investigation of the impact of vaccination against these two pathogens.

Materials and Methods

This study was conducted in a 200 sow farm operating in a weekly rhythm with eight farrowing sows per batch and a finishing site with 800 places. The sites were tested negative for PRRSV, M. hyopneumoniae, Salmonellae, Brachyspira (B.) hyodysenteriae and B. pilosicoli. PCV2 was confirmed by dissection and IHC, Li by faecal PCR and ELISA. In total 1405 piglets were included into the study, 384 vaccinated with Enterisol® Ileitis and Ingelvac CircoFLEX® (EI + CF), 376 with Ingelvac CircoFLEX® (CF), 318 with Enterisol® Ileitis (EI) and 327 with oral and parenteral placebo (Control). Because of the unbalanced genetics and the small number of sows per week group, all piglets of two consecutive batches were included into one treatment group. This resulted in 24 week-groups with three repetitions of eight weeks, where the sequence of the treatment groups per repetition was random. Piglets were vaccinated at an average age of 23.5 days. Average Daily Weight Gain (ADWG) was calculated from individual weight measurements at four time points (week 3, 12, 18 and slaughtering) during the entire study. Almost all dead animals were dissected and tested for PCV2 and Li. Blood and faecal samples were taken from at least 10 pre-selected animals per batch at 3, 7, 12, 15 and 18 weeks of age. Blood samples were tested by qPCR for PCV2 and by ELISA for anti-Li antibodies. Faecal samples were tested by PCR for Li.

Results

The results from serology and PCR indicate an infection of Li and PCV2 at the end of the nursery/beginning of fattening (data not shown).

The mortality rate and the ADWG of the fattening period are indicated in table 1.

Table 1: The mortality rate and the ADWG of the fattening period. Different letters (a/b/c) indicate a significant difference (P≤0.05).

</tr>
</tbody>
</table>

For the control and the EI group 18 and 10 death losses were after necropsy diagnosed to be related to PCV2 whereas for the PCV2 vaccinated animals none of the losses were related to PCV2. Li was detected in four dead animals but was never seen as the cause of death.

Discussion

The observed effects of the mono applications (CF and EN) during the fattening period were comparable with other efficacy studies<sup>1, 2</sup>. The data indicates that the concurrent application of Enterisol® Ileitis and Ingelvac CircoFLEX® had additive effects on pig performance parameters. It was also demonstrated that the use of both vaccines was profitable<sup>3</sup>. The results of this study indicate that after introduction of PCV2 vaccination ileitis vaccination has still a significant impact on performance parameters even when Li is sub-clinically present in a farm.

Introduction
Proliferative enteropathy caused by Lawsonia intracellularis (Li) and porcine circovirus associated diseases (PCVAD) caused by porcine circovirus type 2 (PCV2) are two of the most important swine-diseases in Switzerland. The objective of this study was to investigate the efficacy of the vaccines Enterisol® Ileitis against Li and Ingelvac CircoFLEX® against PCV2 under field conditions and to test whether there is an additive effect on performance parameters when using both vaccines. This abstract covers the impact of the ileitis and PCV2 vaccination on fattening performance and farm economics under Swiss commercial conditions.

Materials and Methods
This study was conducted in a 200 sow farm operating in a weekly rhythm with eight farrowing sows per batch and a finishing site with 800 places. The farms were tested negative from porcine reproductive and respiratory syndrome virus (PRRSV), Mycoplasma hyopneumoniae, Salmonellae, Brachyspira (B.) hyodysenteriae and B. pilosicoli. PCV2 was confirmed by necropsy and IHC, Li by faecal PCR and ELISA. In total 1405 piglets were included into the study, 384 vaccinated with Enterisol® Ileitis and Ingelvac CircoFLEX® (EI + CF), 376 with Ingelvac CircoFLEX® (CF), 318 with Enterisol® Ileitis (EI) and 327 with oral and parenteral placebo (control). Because of the unbalanced genetics and the small number of sows per week-group, all piglets of two consecutive batches were included into one treatment group. This resulted in 24 week-groups with three repetitions of eight weeks, where the sequence of the treatment groups per repetition was random. Piglets were vaccinated at an average age of 23.5 days. Average Daily Weight Gain (ADWG) was calculated from individual weight measurements at four time points (week 3, 12, 18 and slaughtering) during the entire study. All dead animals were recorded. The economic impact of the fattening farm (week 12 to slaughtering) is expressed by the return on investment (ROI) per year, i.e. the extra profit of X Swiss francs generated per 1 Swiss franc invested. A price for slaughtered pigs of 3.60 sfr/kg (2.40 €/kg), a price of 4.40 sfr/kg (2.93 €/kg) per piglet at 30 kg and a price of 6.00 sfr (4.00 €) for both vaccines in total were taken as a basis for the calculation.

Results
The comparison of the control group and the PCV2 vaccinated group is showed in table 1. The pigs vaccinated with Ingelvac CircoFLEX® (CF) had a significant higher ADWG (+ 21 g/d) and a significant lower mortality rate (~ 3.8%).

Discussion
The comparison of the ROI of the PCV2 and the additional ileitis vaccination indicates the economic relevance of both vaccinations. On this farm, the effects of the PCV2-vaccine against the clinical PCVAD were a decisive reduction of mortality and an improvement of the ADWG. Despite the fact that the ileitis infection was subclinical vaccination with Enterisol® Ileitis was highly profitable.

Effect of Porcilis PCV one shot vaccination on slaughter weight and mortality in a subclinically infected pig farm

Sonja Agten; Stefaan Van Gorp; Bart M. Balis
Intervet Schering Plough, Ukkel, Belgium

Introduction
PCV2 infections are ubiquitous among pigs worldwide. Olvera (2004) and Krakowka (2005) showed that there is a relationship between viral load and the occurrence of disease. High infection levels lead to clinical disease while lower levels induce a subclinical course. The latter may however induce significant economical losses.

The majority of pigs in Belgium are subclinically infected with low levels of PCV2. Even without clear signs of PMWS or PDNS, a subclinical infection with PCV2 often has a negative impact on average daily weight gain, feed conversion, days to slaughter and/or slaughterweight.

The timing of a PCV2 virus infection is often unknown under field conditions. It is important that pigs are protected as early as possible and for the whole of the fattening period (Eggen IPVS 2010).

In the present field study three week old piglets were vaccinated once with Porcilis PCV vaccine. The objective was twofold. It was intended to measure the effect of this Porcilis PCV one shot vaccination on slaughter weight, as well as to evaluate the mortality rate during the growing period, with respect to unvaccinated controls.

Materials and Methods
A large conventional closed farm with hypothetical subclinical problems of PCV2 was selected.
At 3 weeks of age, group 1 was vaccinated with 2 ml of Porcilis PCV and group 2 was indicated as a control group. Group 1 contained 572 animals and group 2 contained 714 animals. All animals were observed daily for clinical signs and mortality. The body weights were measured at slaughter. Mortality rates between vaccinated and unvaccinated controls were compared and evaluated by the non-parametric test of Kruskal-Wallis. Differences in weights at slaughter were examined using the one-way Anova.

10 serum samples for each were taken at vaccination, at 10 weeks of age, at 14 weeks of age and one week before slaughter. These samples were examined for PCV2 and PRRSv antibodies and nucleic acid of PCV2.

Results
All piglets were healthy before and after vaccination. Slaughter weights were scored individually for group 1 and 2 and the mean and standard deviation are shown in Table 1. The mortality rate is shown in Table 2.

</tbody>
</table>

*p<0.05; * numbers refers to numbers of slaughtered animals, **BW= Body Weight at 10 weeks, ***from 10W of age on.

The Porcilis PCV-group showed a significant difference of 2.1kg in slaughter weight within the same fattening period (p<0.05). The mortality rate in the Porcilis PCV group was significantly reduced to 2.09%, which is a decrease of 54.5% (p<0.05).

Discussion
A single 2ml dose of Porcilis PCV in piglets of 3 weeks of age, used in subclinical field conditions, led to significantly higher slaughter weights within the same fattening period. This result could justify a vaccination with Porcilis PCV at three weeks of age in subclinically infected farms.

Although, the mortality rate in the control group was reasonably low, it was even 54.5% lower in the Porcilis PCV vaccinated group. This may indicate that the vaccine was able to significantly reduce mortality, resulting from a subclinical PCV infection.

Effects of Porcilis® PCV vaccination in a significantly large batch of animals with high levels of maternally-derived immunity

Miguel A. Jimenez1 David Escalada1 Ivan Mayor1 Rut Menjon2 Jesus M. Bollo2 Marta Jimenez2
1. Uvesa, Ctra. Zaragoza, TUDELA, Navarra, Spain; 2. Intervet Schering Plough, Madrid, Spain

Introduction
Porcine circovirus infection causes important production losses. Over recent years the disease has been found to occur with an increasingly later onset, with negative effects on the fattening phase of production. Vaccination against this disease, which is usually carried out at an early age, may reduce these losses, but on some farms it will coincide with high maternally-derived antibody (MDA) levels. The aims of the present study were to assess the improvement in production parameters resulting from a Porcilis®PCV vaccination program and to evaluate the possible interference by maternally-derived immunity.

Materials and Methods
The study was undertaken on a 2,600-sow farm in North-East Spain (LD x LW, finished with Pietrain), operating a two-phase production system. The herd was positive for M. hyopneumoniae (M. hyo), PRRSv and circovirus. The onset of clinical PCV2 occurred at 17 weeks of age.

Production results were compared of a total of 33,580 piglets which entered phase two between January and September 2009. The animals were housed in different fattening units. The 16,120 pigs entering the units between January and April were not vaccinated with Porcilis® PCV, used as controls. The 17,460 pigs entering the units between May and September were vaccinated against PCV2 (Porcilis® PCV: single 2 ml dose) at weaning at 3 weeks of age. All the animals in the study were also vaccinated against M. hyo (M+PAC*: single 2 ml dose) at 3 weeks of age. The vaccinated group thus received two vaccines at the same time, in separate injections.

Average production indicators for all the animals were recorded over the whole fattening phase (feed conversion rate, ADG, % mortality, % runts, treatment cost/pig). A cross-section serological study was also carried out on 10 animals of each group at different ages during the cycle. A commercial test was used to assess PCV2 antibodies in the serum (Ingezim PCV2 ELISA®, Ingenasa), for the detection of IgG and IgM.

Results
Porcilis®PCV vaccination at 3 weeks of age, even in the presence of high levels of MDA, led to significant increases in mean IgG and IgM values at 10 weeks of age, before they declined. The control group had lost their IgG titers (MDA) at 7 weeks of age and continued with low levels until seroconversion at 17 weeks of age (Graphs 1&2). This indicates that MDA did not interfere with the immune response to the vaccine.

Discussion
Vaccination with Porcilis®PCV at 3 weeks of age, even in the face of high levels of MDA and the occurrence of a late, severe clinical PCV2 infection, improved the production indicators of the farm, leading to significant economic benefits with a 8.8 ROI.
Introduction
Combating other diseases and improving management routines has decreased the impact of Post weaning Multisystemic Wasting Syndrome (PMWS) (1). PMWS is associated to porcine circovirus type 2 (PCV2), and the impact of PMWS has been further decreased following introduction of vaccines directed against PCV2 (2). The present study aimed to scrutinise the relevance of vaccinating against PCV2 in a herd previously affected by PMWS, but declared free from clinical disease.

Materials & Methods
The study was carried out in a gilt producing herd previously deemed for PMWS, but declared free from PMWS at herd basis since one year. Batches of 24 sows farrowed every third week in previously emptied and cleaned units. Piglets born were weaned at the age of 6 weeks and kept as intact litters in the unit until the age of 12 weeks. At that age barrows were sold, while gilts were transferred to a growing unit with continuous production.

At three weeks of age, 12 litters of one farrowing batch were vaccinated against PCV2 (Ingelvac Circoflex, BI-Vet). The other 12 litters remained unvaccinated. All piglets were weighed at weaning and at 11 weeks of age. The gilts that remained at the herd were also weighed at the age of 21 weeks. Blood from two pigs per litter was collected at 5, 8, 12 and 16 weeks of age and analysed for presence of serum antibodies to PCV2 with an IPMA technique.

Results

**Figure 1.** Log antibody titers to PCV2 in vaccinated (◊) and unvaccinated (■) pigs.

There were no significant differences in mean body weights between the groups at any occasion (Figure 2). However, vaccinated gilts gained significantly more weight from 11 to 21 weeks of age. None of the 48 vaccinated gilts weighed less than 70 kg at 21 weeks of age. In comparison, 6 out of 54 unvaccinated gilts weighed less than 70 kg at 21 weeks of age. Out of 53 weaned vaccinated gilts, 48 were still at the herd at the age of 21 weeks (92%). The corresponding figure for the control group was 54 out of 60 (90%).

**Figure 2.** Body weights of pigs vaccinated or not against PCV2 at three weeks of age

Discussion & Conclusions
We saw no effect of the vaccination in the farrowing unit were the PCV2-load according to the serology was low. Thus, vaccinations against PCV2 with the aim of protecting weaned pigs in such units appear pointless.

However, vaccinated gilts seroconverted earlier when they met PCV2 in the unit with continuous production, indicating a positive effect of the vaccination. They also performed better (p<0.05) from 11 weeks of age, which was achieved by a lower number of poor performing pigs.

The results obtained support theories of improved performance following PCV2-vaccination also in herds without clinical PMWS. However, it ought to be remembered that this herd effectuated continuous production from 12 weeks of age, which coincided with the time when the pigs appeared to meet the infection with PCV2. Therefore, further studies ought to be made in herds with batch wise production to confirm the true relevance of vaccinating young pigs in herds without presence of clinical PMWS. Not the least since a decrease in number of underweighted pigs has a potential to shorten the effective rearing time for the entire batches.

References
Vaccination against Porcine Circovirus type 2 and Lawsonia intracellularis in a two-site production system with subclinical manifestations of the microbes

Carl-Johan Ehlorsson2 Maria Persson1 Per Wallgren1

Introduction

The superior growth of SPF pigs has raised questions on the impact of subclinical infections on the growth of pigs. Vaccines have recently been registered for the common microbes Porcine Circovirus type 2 (PCV2) and Lawsonia intracellularis. The present study aimed to scrutinise the relevance of vaccinating piglets against these microbes in a two-site production system with presence of these microbes, but without obvious problems with either of them.

Materials & Methods

The study was carried out in a piglet producing herd with 1,000 sows that farrowed in batches of 43 sows every week, and in a fattening herd recruiting full batches from the sow herd at an age of 11 weeks. The herds were free from clinical PMWS and proliferative enteritis, but PCV2 and Lawsonia were demonstrated by serology. All piglets in one farrowing batch were given a unique identity. Piglets in each litter were allotted into three groups. At four weeks of age, group A was vaccinated against PCV2 (Ingelvac Circoflex, BI-vet), group B against Lawsonia (Enterisol Ileitis, BI-Vet), and group C was left as an unvaccinated control. However, gilts had been vaccinated twice against PCV2 (Circovac, Merial), and all sows were revaccinated during pregnancy.

All pigs in the experimental batch were weighted at 4, 10 and 22 weeks of age. Blood was collected from ten pigs per group (from different litters) at 4, 7, 10, 13, 16 and 19 weeks of age. Serum was analysed for presence of antibodies to PCV2 by IPMA (1) and Lawsonia by a commercial ELISA (BioScreen, Münster, Germany).

Results

All piglets received a high maternal protection to PCV2. Piglets vaccinated for PCV2 increased the amount of antibodies to PCV2 at 13 weeks of age and the other groups at 19 weeks of age (Fig. 1). No pig showed any sign of PMWS.

All piglets were seronegative to Lawsonia at 4 weeks of age (Fig 1). At 16 weeks of age, three pigs vaccinated to Lawsonia were seropositive (PI>34) to Lawsonia compared to one pig in each of the other groups. At 19 weeks of age, three vaccinated pigs were still seropositive compared to 5 or 6 in the other groups. The mean PI-values never differed statistically between groups.

The growth rate was equal for the three groups from 4 to 10 weeks of age (Fig 2). The weight of the pigs was equal for also groups also at the age of 22 weeks.

Discussion & Conclusions

Piglets vaccinated for PCV2 seroconverted between 10 and 13 weeks of age, indicating that PCV2 became activated at that time. However, antibody levels had not increased at 16 weeks in the other groups, indicating a low load of PCV2, presumably achieved by the vaccination of sows and the high amounts of maternal antibodies. Thus unvaccinated pigs seroconverted at a high age when they are less likely to develop PMWS.

Likewise, the serology indicated only a limited load with Lawsonia prior to 16 weeks of age. A protective role of the vaccine may be indicated by somewhat lower PI-values at 19 weeks of age in vaccinated pigs.

We saw no difference in weight gain between the three groups. Thus, vaccinations against PCV2 or Lawsonia with the aim of protecting recently weaned pigs in apparently healthy herds appear pointless, and a true significance of these microbes ought to be proven before expecting any effect in fattening enterprises.

Field experiences with Ingelvac CircoFLEX® in mild cases in Spain

Jose L. Lorenzo; Marisa Rosas
Maporc s.l., San Cristobal de Segovia, Spain

Introduction

PCVD is a worldwide disease and PCV2 is present in nearly all swine herds. Luckily for technicians and producers, in last years, very effective vaccines have been developed and using Circovirus vaccines has been shown to be very profitable (1). Even in cases of mild disease, return of investment of vaccinated animals justify the use of the vaccine (2).

The objective of the present field observation was to evaluate the effect of PCV2 vaccination in mild to moderate cases of PCVD on 3 different farms in Spain.

Materials and Methods

This field observation included 3 sow farms and 5 fattening units that suffer mild-moderate problems of PCVD. In all cases, peak of signs were observed between 14 and 16 weeks of age. Animals were vaccinated at 3 weeks of age using one shot of 1ml of Ingelvac CircoFLEX® (Boehringer Ingelheim) following label recommendations. Piglets were moved at 10 weeks of age to the fattening units. Control groups were non vaccinated animals grown in the same building just before vaccinated ones, during 2009. Health status is similar in the three farms: PRRS and Mycoplasma positive (vaccination at 3-4 weeks of age) and APP negative.

Case 1: Farrow-to-finish farm with 550 sows, producing weekly batches of 240 piglets in an AIAO system. Performances in the nursery are really good but animals suffer from respiratory signs and wasting starting at 14 weeks of age.

Case 2: Farrow-to-finish farm with 600 sows, producing weekly batches of 270 piglets. Final Boar is Pietrain. In the nursery there are some problems of Glässer and Streptoccocus suis disease but there are no clinical signs of PCVD in the fattening, only few wasting pigs.

Case 3: Farrow-to-finish farm with 650 sows with genetic nucleus, producing weekly batches of 300 piglets. Final Boar Pietrain. Good performances in nursery and fattening, mild PCVD case with few respiratory problems.

Mortality in controls and vaccinated animals were evaluated using a Chi-square test.

Results

Case 1: Performance after vaccination on this farm was improved substantially (table 1). Weight gained in the fattening unit was 5,45 kg more in the vaccinated group spending the same number of days in fattening.

Vaccinated pigs were slaughtered 10 days younger than the control group.

Discussion

Several authors showed improvements of performance in animals vaccinated with Ingelvac CircoFLEX® in different systems around the world (1-6). Data presented in this article confirmed the efficacy in 3 farrow-to-finish farms in Spain. In mild or moderate cases, where mortality is not the main goal, we can appreciate that ADG could be increased by more than 100 grams/day and FCR could be reduced by more than 0.2.

Effect of vaccination against PCV2 and Lawsonia intracellularis administered concurrently

Gonzalo Cano; Joan Sanmartin
Optimal Pork Production, S.L., Lleida, Spain

Introduction
Prevention of endemic diseases in farms should be the main objective of the veterinarians in the next years. PCV2 and Lawsonia intracellularis are two of the most widely spread infectious disease in Spain. Both are endemic in all major pig producing countries (1,2). Clinical presentations in farms are variable depending to external factors like nutrition, facilities, co-infections or climatic conditions. Successful experiences with Ileitis vaccination or PCV2 vaccination have been reported in numerous cases. (3–10).

The objective of this study was to evaluate the effect of concurrent PCV2 and Ileitis vaccination administered few days before weaning on performance parameters in fattening.

Materials and Methods
The study took place in two sow units of the same company, one unit with 4,900 sows and the other one with 2,200. Both units were producing weekly batches and shared gilt source (same quarantine) and did have the same health status: PRRS, APP, and Ileitis positive. Sow and piglet vaccination program were identical and management in both units was very similar.

Performance parameters in the sow farms were good. Piglets were weaned between 21 and 24 days, allocated in nursery until 10 weeks of age and then moved to different fattening units in an all-in/all-out regime (each origin in a separate fattening unit). Identical feed programs and in-feed medications were applied for sows, piglets and pigs.

The before-after study included 18,381 animals divided in 4 groups: non vaccinated, vaccinated against Ileitis (Enterisol® Ileitis, 2ml via drench at 17 days of age), vaccinated against PCV2 (Ingelvac CircoFLEX®, 1ml IM at 17 days of age) and vaccinated against Ileitis+PCV2 (both vaccines administered concurrently at 17 days of age).

All data presented is from different fattening units of the same production system. All batches of all groups were entered simultaneously in fattening units between late November 2008 and late January 2009. Mortality rate was compared between treatment groups using the Chi-square test.

Results
Performance results show an improvement in each vaccinated group compared to non-vaccinated animals, with the best results in the group vaccinated with both vaccines (table 1).

In the group vaccinated against Ileitis and PCV2 compared to the group with Ileitis vaccination only mortality was reduced by 43% and medication costs by 36%. Comparing the group with concurrent Ileitis and PCV2 vaccination with the group vaccinated against PCV2 only, the improvement is obvious in FCR and medication costs.

a,b,c: values with a different superscript, differ significantly (p< 0.05)

A return of investment of 3.8:1 was calculated for the concurrent ileitis and PCV2 vaccination when compared to the non-vaccinated animals.

Discussion
The data presented in this study demonstrate that vaccinating pigs concurrently against Ileitis and PCV2 improve the fattening performance compared to non-vaccinated animals and animals vaccinated against only one of the diseases. ROI for using both vaccines was 3.84:1 compared to non-vaccinated pigs.

Finally, in this case, both vaccinations were done at the same time, one orally by drench and the other IM. No adverse reaction was observed. This is an example how producers can benefit of doing two treatments together, saving stress to the animals and saving money.

**Porcine Circovirus Associated Diseases (PCVAD) – Control**

**P.121**

**PCV2 vaccination prevented clinical PCVAD and reduced PCV2 viremia and semen virus shedding in boars concurrently infected with PCV2b and Mycoplasma hyopneumoniae**

Tanja Opriessnig¹ Darin Madson¹ Huigang Shen¹ Susan Brockmeier² Nathan Beach³ Xiang-Jin Meng³

¹. Iowa State University, Ames, IA, USA; ². National Animal Disease Center, USDA-ARS, Ames, IA, USA; ³. Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

**Introduction**

It has been determined that porcine circovirus type 2 (PCV2) DNA is shed in semen of naturally and experimentally infected boars (1). Recently, it also has been shown that PCV2 DNA present in semen is infectious in a swine bioassay model (2). However, under experimental conditions the amount of PCV2 shed in semen is low and not sufficient to be transmitted into naïve breeding animals (2). In the growing pig model, Mycoplasma hyopneumoniae infection has shown to potentiate PCV2 replication, PCV2-associated lesions, and disease (3). Under field conditions, young boars that enter boar studs are often exposed to infectious agents (i.e. M. hyopneumoniae) for the first time, are given multiple adjuvanted vaccines, and are exposed to other stressors (mixing, transportation) that are thought to enhance PCV2 replication in growing pigs. The main objective of this study was to determine if the amount of PCV2 shed in semen can be increased in boars experimentally coinfected with M. hyopneumoniae and immune-stimulated via killed parvovirus-leptospira-erysipelothrix (PLE) vaccination. In addition, we wanted to determine if PCV2 vaccination of the boars prior to PCV2 exposure will reduce PCV2 viremia and virus shedding in semen.

**Materials and Methods**

Twelve specific-pathogen-free PCV2 and M. hyopneumoniae naïve boars were randomly divided into one of four groups with three animals in each group. Half of the boars were vaccinated against PCV2 35 days before PCV2 challenge using a commercially available inactivated product (Suvaxyn® PCV2; Fort Dodge Animal Health Inc). Fourteen days before and at the day of PCV2 inoculation all 12 boars were vaccinated per label with a commercially available PLE vaccine (FarrowSure®, Pfizer Inc.). In addition, 14 days before PCV2 inoculation, 6/12 boars were intranasally inoculated with M. hyopneumoniae. All boars were challenged with PCV2b on Day 0 of the study. Semen and serum samples were collected on a weekly basis and all boars were euthanized 35 days post-PCV2 inoculation. All samples were analyzed for the presence of anti-PCV2 IgG antibodies by ELISA and for the presence and amount of PCV2 DNA by quantitative real-time PCR as described (1).

**Results**

All vaccinated boars had seroconverted to PCV2 by the time of PCV2 challenge, whereas non-vaccinated boars were seronegative. After M. hyopneumoniae challenge, inoculated boars developed moderate respiratory disease characterized by coughing, respiratory distress, and mucopurulent nasal discharge. After PCV2 challenge, one of three coinfected, non-vaccinated boars became lethargic, lost condition, and died. M. hyopneumoniae infected boars had significantly (p<0.05) higher PCV2 DNA levels in serum compared to boars singularly infected with PCV2. Non-vaccinated boars had significantly (p<0.05) higher PCV2 DNA loads in serum compared to vaccinated boars. Moreover, PCV2 vaccination resulted in significantly (p<0.05) reduced incidence of shedding of PCV2 in semen.

**Discussion**

In this study we showed that boars experimentally infected with PCV2 and M. hyopneumoniae can develop clinical manifestation of porcine circovirus associated disease (PCVAD). In addition, PCV2 vaccinated boars did not develop clinical disease and had significantly reduced PCV2 viremia and PCV2 shedding in semen. This information will guide boar stud owners in their decision process when considering PCV2 vaccination.

Attenuated vaccine against PCV2 infection by abrogation of ORF3 function

Jimmy Kwang
Temasek Life Sciences Laboratory, Singapore, Singapore

Introduction
Porcine circovirus 2 (PCV2) is a pathogen causing significant economic impact on swine production. Interestingly, the virus is one of the smallest known viruses with a genome of 1.7 kilobases and has only three identified genes. This virus infection has a high morbidity and leads to severe pathogenesis in more than 20% of the infected pigs. The principle feature of Porcine Circovirus associated Disease (PCVD) is the compromise of the immune system, marked by lymphadenopathy, lymphocyte depletion and lymphoid organ destruction. The PCV2 infection is usually found with other viral and bacterial co-infections. Our lab identified a novel gene in the PCV2 genome, ORF3, which plays a central role in the apoptosis induced by the virus infection.

Results
PCV2 open reading frame 3 (ORF3) codes a 105 amino acid protein that causes apoptosis of PCV2 infected cells. In infected cells, the ORF3 causes the accumulation of p53 by interacting with pPirh2 and possibly by disrupting the association of p53 and pPirh2 (J. Virol. 81(2007)9560). Mutant PCV2 lacking the expression of ORF3 are infectious and replicate in cells in vitro, but do not cause apoptosis of the infected cells. The ORF3 of PCV2 has been shown to be involved in pathogenesis of the virus in mice model (J. Virol. 80(2006)5065). The pathogenicity of the ORF3 deficient virus is attenuated in the piglets. The mutant virus did not cause any observable disease or perturbation of the lymphocyte count in the inoculated piglets and elicited an efficient immune response. When compared with the wildtype virus infection, the mutant virus infection was characterized by mild viremia and absence of pathological lesions. The lymphoid organ depletion in the ORF3 deficient virus was almost absent as opposed to the wildtype virus infection, which resulted in the characteristic loss of lymphnode architecture. The findings highlight the role of ORF3 in the pathogenesis of PCV2 infection in its host.
Piglet vaccination against PCV2 with CIRCOVAC® (Merial) in 59 German herds: evaluation of the effect on mortality in weaners and fatteners

Ariane Schade² Zrinjka Bradaric² Julie Venet¹ Thaïs Vila¹ Sophie Longo³ François Joisel¹

¹. Merial S.A.S., Lyon, France; ². Merial GmbH, Munich, Germany; ³. BPC, Labruguière, France

Introduction
CIRCOVAC® has been registered in mid 2007 in the European Union for the use in sows. Piglet vaccination has been implemented in Germany under special allowance according §17c. Abs.2 TSG since May 2008. Vaccination under special allowance requires collection and report of information on the outcome of the vaccination to authorities. The efficacy of CIRCOVAC sow vaccination in preventing porcine circovirus type 2 (PCV2) infections in piglets and therefore in improving production parameters of their offspring has been extensively proven (1). However in some cases, e.g. piglets from different origins being grouped for fattening, piglet vaccination can be useful (2).

The objective of this study is to evaluate the effect of one-shot vaccination of piglets with 0.5 ml CIRCOVAC from 2 weeks of age when used in field conditions.

Material and Methods
Veterinarians taking part in the field study completed questionnaires provided by Merial for vaccine evaluation including questions on production data of the herds before and during CIRCOVAC piglet vaccination.

The analysis was performed in 59 herds from which evaluable information on production data before and during CIRCOVAC piglet vaccination under special allowance was provided. In some herds PCV diseases (PCVD) have been presumed before vaccination as the data showed high mortality and high numbers of wasting animals and animals affected by PDNS. So the vaccination was intended as metaphylactic approach. On other farms vaccination was implemented without presumption of PCVD and with already good performance parameters. Reasons for this could be a preventive approach or the fact that PCV2 piglet vaccination is often requested by swine marketing organisations. Such farms were not excluded from this analysis.

The types of farms are shown in Table 1.

Table 1: Number of present herds by production type

<table>

</tr>
</tbody>
</table>

Mortality data and percentage of wasting pigs were obtained from the records on each farm, if they were available. The parameters were analyzed for nursery and fattening period.

Means of each variable were compared between the two different periods of time (before and during vaccination) using Student t-test and/or Kruskal-Wallis test. The level of significance was 5% for all the tests.

Results
Mortality rates are significantly decreased after CIRCOVAC vaccination (table 2).

Table 2: Mortality improvement, before versus during vaccination (STD= standard deviation)

<table>
<thead>
<tr>
<th></th>
<th>Mean (%)</th>

</tr>
</tbody>
</table>

Further, the incidence of wasting was lower in both weaners and fatteners after vaccination (-1.6% in both periods). The difference was close to significance in fatteners (p=0.060).

Conclusion
CIRCOVAC piglet vaccination induced a distinct improvement with a significant decrease in mortality. This large study demonstrates the positive impact of CIRCOVAC piglet vaccination. For the interpretation of the results, it needs to be taken into account, that farms which vaccinated in a preventive approach were not excluded from the statistics. Therefore it can be hypothesized that restricting the analysis to farms with diagnosed PCV2 problems and reduced performance could lead to even better results.

Evaluation of the safety of an inactivated porcine circovirus type 2 vaccine (CIRCOVAC®) administered to boars: absence of impact on spermatogenesis

Thaïs Vila; Valérie Cozette; François Joisel
Merial S.A.S., Lyon, France

Introduction
Porcine circovirus type 2 diseases (PCVD) have been reported throughout the world as a major cause of losses in pig herds (1). PCV2 can clearly be associated with some cases of reproductive failure. Furthermore, the presence of infectious PCV2 in semen has been demonstrated (2,3,4). Consequently, PCV2 boar vaccination is commonly used in pig farms. This study was designed to assess the safety of CIRCOVAC® administered to reproductive boars.

Material and Methods
The study was performed in a European artificial insemination center. A total of 15 9-month-old boars provided by the same nucleus farm were included in the study and randomized as follows: 5 boars vaccinated twice 3 weeks apart with CIRCOVAC, 2 ml (group 1); 5 boars vaccinated according to the same protocol and treated with paracetamol dose for 3 days since the day before vaccination (group 2); 5 boars non vaccinated but injected with NaCl 0.9%, 2 ml twice (group 3). Boar semen was sampled once a week from 3 weeks before 1st vaccination to 8 weeks after 2nd vaccination. The criteria followed up were: body temperature and semen quality (volume, spermatozoon concentration, motility, abnormality, viability and healthy spermatozoon per ejaculate meaning mobile, with normal mobility and non agglutinated). A one-way analysis of variance (ANOVA) was used to compare temperature results between groups. Semen parameters were compared by a Student t-test after pooling both vaccinated groups 1 and 2 (vacc.) which were similar.

Results and Discussion
Body temperature was slightly increased after vaccination (4 boars out of 5 were above 39.5°C in group 1); this was limited to 1 and 3 boars respectively after 1st and 2nd injection in group 2 treated with paracetamol.

Semen quality parameters for each period (before, during and after vaccination) for the vaccinated and control groups are presented in table 1. No group effect was evidenced whatever the period (p>0.05).

Only one boar in group 2 had a lower semen concentration during vaccination period. The statistical analysis only evidenced higher values for spermatozoon concentration and viability for vaccinated groups.

Very few impact of CIRCOVAC vaccination was observed in this study on semen quality parameters over a period of 10 weeks after 1st injection.

Conclusion
CIRCOVAC vaccination showed no impact on spermatogenesis as far as semen parameters of reproductive boars are concerned.

**IL4, IL5 and IL13 gene expression in porcine PBMC after PCV2 vaccination**

Juan J. Quereda¹ Guillermo Ramis¹ Francisco J. Pallarés² Ludvine Chapat³ Anne Goubier³ François Joisel³ Catherine Charreyre³ Antonio Muñoz¹

1. Universidad de Murcia, Murcia, Spain; 2. Dpto Anatomía y Anatomía Patológica Comparadas, Universidad De Murcia, Murcia, Spain; 3. Merial S.A.S., Lyon, France

**Introduction**

Several studies have demonstrated that PCV2 vaccines increase the level of antibodies in the pigs and reduce the severity of the injuries associated to this virus. In the human specie the TH2 response is mainly regulated by the interleukins (IL) IL4, IL5 and IL13. Sometimes the ELISA technique is not enough sensitive to detect cytokine levels in culture supernatants (1). Nowadays there is no kit for pig IL5 and the ELISA for IL13 is brand new and has never been demonstrated to work with antigen specific response. Quantitative PCR (Q-PCR) is a specific and sensitive technology to quantify the gene expression of mRNA (2). The aim of the present study was to evaluate the TH2 immune response of PCV2-vaccinated pigs when their peripheral blood mononuclear cells (PBMC) are stimulated with antigenic peptides of the open reading frame 2 (ORF2) of PCV2.

**Material and Methods**

Ten SPF 10 weeks old Large White pigs were divided in two groups: vaccinated (n=5) and control (unvaccinated, n=5). Animals in the first group were vaccinated the day 0 of the experiment with CIRCOVAC® (Merial, France). The day 21 of the experiment a blood sample was obtained and two and a half million PBMC were cultured per well in a total volume of 1 ml complete RPMI under two different conditions: stimulation with PCV2 ORF2 antigenic peptides and a non activation condition where the culture media was composed exclusively by complete RPMI. Gene expression was determined at 24h poststimulation. RNA was extracted and retrotranscribed into cDNA. Relative gene expression was calculated using the 2- Δ ΔCt method. Q-PCR for IL4, IL5, IL13 and cyclophilin was developed using published sequences (3, 4) in a 7500 real time PCR system (Applied Biosystems, EEUU).

**Results**

Major gene expression changes were observed for IL13 compared to IL4 and IL5 in PBMC. No difference for interleukin gene expression at day 0 between both groups was observed. At day 21 when the cells were stimulated with PCV2 ORF2 peptides a 17 times higher response of IL4 and a 21 times higher synthesis of IL13 was detected in the vaccinated group.

**Discussion**

At day 0 of the experiment no specific lymphocytes existed circulating in the blood because no change in IL gene expression was detected after stimulation with PCV2 ORF2 peptides. At day 21 a greater response in the synthesis of IL4 and IL13 was detected in the PCV2 vaccinated group when their PBMC were stimulated with PCV2 ORF2 peptides suggesting that specific lymphocytes have been developed against the vaccine antigens. IL5 gene expression did not show statistical differences between both experimental groups indicating that this IL is low expressed in the pigs as Levast et al., (5) previously demonstrated. Some authors have described that Large White pigs do not express IL4 (6), but the results of the present study showed that gene expression of IL4 took place in the Large White pigs analyzed, suggesting that differences could exist among different Large White genetic lines. Bautista et al., (7) suggested that IL13 could replace IL4 functions in the pigs, but our results showed IL13 and IL4 gene expression changes in response to PCV2 ORF2 peptides in the vaccinated group indicating that both IL could be important in the pig TH2 response.

Swine herd with a prevalent PCV2 subclinical infection: diagnostic investigation results before and after PCV2 vaccination

Andrea Luppi1 Paolo Bonilauri1 Claudio Mazzoni2 Rosanna Di Lecce3 Michele Dottori1
1. Istituto zooprofilattico sperimentale Lombardia and Emilia Romagna, Reggio Emilia, Italy; 2. Libero professionista, Reggio Emilia, Italy; 3. Dipartimento di Sanità animale, Sezione di Patologia Generale ed Anatomia Patologica, Facoltà di Medicina Veterinaria, Università di Parma, Parma, Italy

Introduction
Porcine circovirus type 2 (PCV2) may cause a variety of diseases (PCVAD - Porcine Circovirus Associated Disease), including post-weaning multisystemic wasting syndrome (PMWS) (1). Because subclinical infections are common, diagnostic methods used should be able to perform the PCVAD diagnosis and also evaluate the PCV2 viremia in pigs. In the present longitudinal study the Authors described the use of a diagnostic approach, before and after the PCV2 vaccination, in a herd where PCV2 subclinical infections were prevalent.

Materials and Methods
The clinical case took place between March and June 2008 in a farrow to finish herd with 170 sows in the Northern Italy. The clinical symptoms of the disease were mainly observed in pigs 12 weeks old and were characterized by loss of appetite, rough hair, paleness, dyspnoea, cough and diarrhoea. Total losses reaching over 7% in some batches. Before vaccination against PCV2, blood samples and lymph-nodes (Ln. inguinales superficiales) were collected from 15 pigs 5, 12 and 19 weeks old (5 pigs for each age) without clinical signs and from 10 pigs 12 weeks old with clinical signs PMWS compatible. Cytology and histology of lymph-nodes were respectively performed on air dried impression smears and on formalin-fixed, paraffin-embedded tissue sections. Cytological and histological slides were stained by the May-Grunwald Giemsa and Ematoxilin-Eosin methods respectively (2). Immunohistochemistry was performed on the same paraffin embedded tissues using a home made monoclonal antibody against PCV2. Real time PCR was performed on blood (sera) samples described above, using primers and probe designed by Olvera et al. (2004). Vaccination against PCV2 was performed using a one-shot commercial vaccine, administered to piglets 3 weeks old. Post vaccination, blood samples and lymph-nodes (Ln. inguinales superficiales) were collected from 15 pigs 5, 12 and 19 weeks old (5 pigs for each age) and submitted to the same investigations described above.

Results
No microscopic lesions were observed in the lymph-nodes belonging to pigs without clinical signs. No PCV2 viral load was observed on sera of pigs 5 weeks old. Real time PCR logarithmic values (PCV2 genomic copy no./gr.) of sera belonging to pigs 12 and 19 weeks old, without clinical signs, showed moderate (4.7, 5.8, 5.9, 6.1, 6.8) and absence or mild viral load (0, 0, 0, 5.1, 5.1) respectively. On 10 pigs with clinical signs PMWS compatible, only 4 animals showed characteristic PMWS microscopic lesions of lymph-nodes and high sera viral load (the real time PCR logarithmic values - PCV2 genomic copy no./gr. were 7.5, 8.3, 9.0, 7.5). The diagnosis was confirmed by immunohistochemistry. The others results of real time PCR on pig sera belonging to this group showed moderate viral load (the real time PCR logarithmic values - PCV2 genomic copy no./gr. were 5.1, 5.6, 5.9, 6.1, 6.9, 7.0). No viral load was observed on 15 pig sera samples collected 2, 9 and 16 weeks after PCV2 vaccination.

Discussion
The field study was conducted to investigate the use of a diagnostic approach, based on cytology and histology of lymph-nodes and sera PCV2 real time PCR, on pigs belonging to an herd showed prevalently a subclinical PCV2 infection. The study was performed before and after the PCV2 vaccination. The results of this study suggested that in herds in which a subclinical PCV2 infection is present, real time PCR on sera seems to represent the better approach to understand the disease development and the subclinical PCV2 infection severity. Two, nine and sixteen weeks after the vaccination, pigs showed no viremia, as well as a significant improvement of productivity performances with a consequent reduction of herd losses (<3-4%). This indicates that in absence of obvious clinical PCVAD signs, the virus still induced a detrimental effect on growth and mortality. However, the results of real time PCR on pig sera after vaccination, need to be further investigated and must not be used to evaluate the vaccination efficacy.

**Duration of immunity by PCV2 challenge in 17 week-old conventional piglets vaccinated at 3 weeks of age with CIRCOVAC® (Merial)**

Mathieu Chevalier\(^1\) Laurent Fischer\(^2\) François Joisel\(^2\)

1. Merial CRSV, Saint-Vulbas, France; 2. Merial S.A.S., Lyon, France

**Introduction**

The aim of this study was to demonstrate, in conventional piglets, the duration of immunity conferred by vaccination with the inactivated adjuvanted PCV2 vaccine CIRCOVAC.

**Material and Methods**

Three-week-old piglets were randomly assigned in 2 groups: 15 piglets vaccinated once with CIRCOVAC 0.5 mL, IM and 12 piglets injected with 0.5 mL of PBS as control. Both groups were kept in isolation and subsequently challenged at 17 weeks of age with an infectious PCV2b field strain. The 2 groups were compared according to body weight evolution and PCV2 viral load in sera and faeces.

**Results**

Before challenge, body weights of vaccinated and control animals were similar. After challenge, vaccinated animals were heavier although not significantly (ADWG \(p=0.116\)) than controls: +2.4 kg in average at D28 post challenge (Figure 1).

**Figure 1: Evolution of average body weight after challenge**

Further, post challenge PCV2 viral DNA load in the sera of vaccinated piglets was significantly reduced as compared to the viral load in the sera of placebo-injected animals (Figure 2a).

The mean viral load during the whole monitoring period as area under the curve (AUC) was significantly lower for vaccinated piglets compared to control animals (Student \(t\)-test \(p<0.001\)) (Figure 2b).

Vaccination also contributed to a significant reduction of post challenge viral excretion in faeces (Figure 2c).

The mean viral load during the whole monitoring period (AUC) was significantly lower for vaccinated piglets compared to control ones (one-tailed student \(t\)-test \(p=0.011\)) (Figure 2d).

**Discussion and Conclusion**

All together, these results demonstrated a significant reduction of PCV2 viral load in sera and in faeces, in CIRCOVAC vaccinated animals after PCV2 challenge at 17 weeks of age. A growth improvement (+2.4 kg in 28 days post challenge) in vaccinated animals has been also observed.

Beneficial impact of an inactivated PCV2 vaccine (CIRCOVAC®) under Portuguese conditions: a large scale field study

J.M. Lopes Jorge1 Thaís Vila2 Sophie Longo3 François Joisel2
1. Merial Portuguesa, Lisbon, Portugal; 2. Merial S.A.S., Lyon, France; 3. BPC, Labruguière, France

Introduction
CIRCOVAC has been registered in Europe for sow vaccination since 2007 and has proved efficacy to reduce mortality rate from birth to slaughter (1), improve growth performance (2) and reproductive parameters (3). In an attempt to control PCVD in already born when sow vaccination is started, piglets can be temporarily vaccinated up to the batch of piglets born from completely (2-times vaccinated) sows reaches weaning. This successful method was already described earlier (4).

The objective of this study was to evaluate the effect of this CIRCOVAC vaccination programme under Portuguese conditions.

Material and Methods
The study was performed in 10 farms located in Azores and Continental Portugal, with clinical PCVD signs after weaning: 8 farrow-to-finish farms and 2 farrow-to-post-weaning units. Farm size ranged from 220 to 1,551 sows, average: 557 sows/farm.

PCV2 sow vaccination was implemented from September 2007 to April 2008 as follows: mass vaccination of all sows, 2 injections of CIRCOVAC (2 ml) 3 weeks apart, and a booster 15 days before farrowing. At the same time, temporary piglet vaccination was implemented in 8 farms as follows: piglets from weaning to 7 weeks of age were injected with CIRCOVAC once, 0.5ml. All weaned piglets born from non 2-time-vaccinated sows were vaccinated. Then, piglets vaccination was stopped as soon as piglets born from sows vaccinated twice reached weaning. A total of 5,573 sows, 138,017 weaned piglets and 131,925 slaughter pigs were monitored. Effect evaluation was based on post-weaning and fattening mortality rates and on weaned piglets/sow/year that summarizes all aspects of reproduction. A questionnaire was sent to the vets in charge of 33 farms that started CIRCOVAC vaccination between 09/2007 and 04/2008. Global data concerning the different parameters were collected from farm software.

Two similar periods of time were compared for each farm: before the date of first vaccination and during vaccination starting at the date of mass vaccination (duration: 13 to 52 weeks according to available data). Mortality rates were compared using a Kruskal-Wallis test and number of weaned piglets a Student t-test.

Results and Discussion
Mortality rate in post-weaning decreased in every single farm, as well as the average mortality went significantly down, p=0.023 (Table 1). In fattening, completed data were obtained only for the 8 farrow-to-finish farms. Mortality rates decreased in 7 of them. In one farm, mortality that was very low before vaccination (0.42%) went up to 0.91% due to a S. suis outbreak in the period during vaccination. Average decrease of mortality in fattening was not statistically significant due to the small number of farms but the improvement magnitude confirmed what was already seen (1).

The number of weaned piglets/sow/year was improved in 9 out of 10 farms (Table 2). One farm experienced a slight decrease (-0.19) due to a Swine Influenza outbreak during vaccination period. Increase in weaned piglets/sow/year was not found statistically significant but the improvement magnitude confirmed what was already seen (3).

Conclusion
The beneficial impact of CIRCOVAC using a vaccination programme including short-term piglet vaccination and long-term sow vaccination has been confirmed in this study. Return on investment must include the decrease of mortality rates and the improvement in reproduction as shown by the increase of weaned piglets/sow/year which was welcomed as an unexpected additional benefit.

Monitoring PCV2 viremia in pigs on Canadian farms after using PCV2 vaccination
Francisco de Grau
Intervet Canada Corp, Kirkland, QC, Canada

Introduction
Since PCV2 discovery in the early 90’s, by Harding1, PCV2 was commonly found in blood samples from Canadian pig farms with PCVAD and on farms where no clinical signs were observed 2. PCVAD occurred sporadically in Ontario and Quebec before 2004 2, 3, 4. However, a PCVAD outbreak occurred in these provinces in the winter of 2004 and spread to the rest of Canada in 2005. A new strain of PCV2 (2b) was associated with these outbreaks 5. PCV2 vaccination was introduced in Canada in the spring of 2006. Mortality decreased significantly after vaccination. However, subclinical presentations are still a common problem. The objective of this study was to determine the prevalence of PCV-2 viremia after 3 years of the use of PCV-2 vaccines in Canadian farms.

Materials and Methods
Twelve swine veterinarians from four veterinary practices and five private companies participated in this study. The data was collected from 23 swine herds from across Canada. All herds were routinely vaccinating with commercial PCV2 vaccines. Practitioners collected 50 pooled blood samples from randomly selected pigs on each farm: 10 pigs at weaning, 10 pigs at the mid nursery stage, 10 pigs at the end of the nursery stage; 10 pigs at the middle of the grower-finisher period, and 10 just before slaughter to determine the vaccine program efficacy and viremia control. Blood samples were centrifuged and the sera recovered. Serum samples were sent to the diagnostic lab for PCR testing.

Results
In total 1260 pigs were sampled. The average herd size was 1580 sows with a range of 170 – 6000. Forty-four percent of the farms were farrow-to-finish and 56% multiple-site production. Twenty-two herds were using a commercial vaccine to control PCV2. Viremia was found on 14 (61%) herds. According to the practitioner reports, 40% of these farms reported clinical signs of PCVAD. Ninety percent (9/10) of the farrow-to-finish farms, and 38% (5/13) of the multi-site operations presented PCV2 viremia.

A total of 65% (14 /23) farms sampled were PRRV+. Within these farms, PCV2 viremia was found on 71 % (10/14). A total of 61% (14/23) of the herds were Mycoplasma positive. Within these mycoplasma positive farms 57 % (8/14) had PCV2 viremia.

Thirty-five percent (8/23) of the nurseries, and 48% grower-finisher (11/23) were positive for PCV2 viremia. Eighty percent of all the viremic samples were from grower-finisher barns pigs. More than half of the positive samples 8/14 (57 %) were found to be positive in more than one production phase.

Sixty one percent (14/23) herds reported using the vaccines off-label. Fifty seven percent of them were positive for PCV2 viremia. PCV2 viremia was found on 57% percent of the herds where PCVAD signs had been observed.

PCV2a was found on 26% (6/23) of the herds, PCV2b on 39% (9/23) herds, and both strains were found in only one herd. PCV2 was not detected on 7 farms (30 %). Three out of 7 herds negative to PCV2 viremia were also negative for PRRS and Mycoplasma. Only one herd negative to PCV2 viremia was a farrow-to-finish operation.

Conclusions and Implications
The data revealed higher PCV2 viremia in grower-finisher pigs. PCV2 viremia is more prevalent on farms positive for PRRSV and Mycoplasma. PCV2 viremia was found on more than half of the farms where vaccines were used off label.

PCV2a was found on 25 % of the farms ninety percent of these farms were located in Western Canada (Alberta, Manitoba). This study shows that PCV2 still present in the field even after three years after PCV2 commercial vaccine introduction and use. The Practitioners participated voluntarily and farms were not selected randomly therefore these results may be biased and cannot be extrapolated to all farms in Canada.

**Introduction**

PCV2 has been associated with reproductive disorders and is regarded as a causative agent of foetal death in swine (1, 2). The objective of the present paper is to report a clinical case in which CIRCOVAC® vaccination gave an improvement in the reproductive parameter in a farm where PCV2 was suspected to be involved in abortions.

**Farm description**

These results come from a 1600-sow farrow-to-finish French farm, having faced reproductive disorders on the long run. Litters coming from non-vaccinated gilts and sows did not show any PMWS clinical signs. This closed farm observes strict 2-month quarantine. The farm productivity was below its potential, and abortions occurred regardless sow parity. But the fertility rate (> 92%), the number of mummified foetuses (0.3/litter) and stillborns (0.73/litter) consistently remained at a normal level. Piglets used to be weaned at 21 days.

Gilts are raised in a specific unit away from the rest of the other pigs of the farm. The routine vaccination program of the farm use to count a mass-vaccination with PROGRESSIS® against PRRS every 3 1/2 months, GRIPOVAC® vaccination against swine flu, and vaccination against parvovirus and erysipelas.

**Case Description – Diagnosis**

For the last years, lots of changes were carried out to improve the farm reproductive parameters, mostly to reduce the abortion rate. No other classical abortion infectious causes were identified except *Leptospira* sp. which were found to be the causative agents of abortions (PCR-positive). Repeated antibiotic metaphylactic treatments were put and kept in place (2 to 3 times / year) and a strict control of rodents was implemented.

Despite these measures, abortions up to 80 gestation days still occurred. Thus, PCV2 infection was suspected: at the first attempt, 4 aborted foetuses hearts were found PCV2 negative by PCR. A second analysis was performed 1 year later and large amounts of PCV2 was found by IHC or qPCR in hearts or livers of 8 aborted foetuses from 4 sows.

**PCV2 vaccination**

It was decided to carry out a mass-vaccination of all breeding animals with CIRCOVAC. All pens were vaccinated starting with a primo-vaccination of gilts in quarantine followed by a second injection 3 weeks before the insemination.

**Results**

Reproductive parameters of gilts are shown in table 1. After CIRCOVAC vaccination, four reproductive parameters were improved although non-significantly: abortions rate, return of oestrus rate, farrowing rate and the weaning to effective service interval at the 1st weaning.

**Table 1: Reproductive parameters before and after CIRCOVAC vaccination (p=Chi-square test p-value)**

</tr>
</tbody>
</table>

No difference in mummified and stillborn per litter was noticed between vaccinated and non-vaccinated gilts.

**Discussion and Conclusion**

Although none of the differences before and after vaccination in gilts seem to be statistically significant, most probably due to the low number of animals, the improvement looked quite spectacular for the farmer. It may be hypothesized that gilts raised in a premise separated from the rest of the farm had minimal contact with PCV2 during their pre-mating life. Then, the suddenly increased viral pressure when they joined back the sow herd may have been the cause of the abortions. At least, a systematic vaccination of the whole herd with CIRCOVAC seemed to have solved the reproductive issue.

Immediate efficacy of CIRCOVAC® (Merial) administered to 3 week-old SPF piglets against a challenge at 5 weeks of age

Mathieu Chevalier¹ Laurent Fischer² François Joisel²
1. Merial CRSV, Saint-Vulbas, France; 2. Merial S.A.S., Lyon, France

Introduction
The aim of this study was to demonstrate, in SPF piglets, the onset of immunity conferred by vaccination with the inactivated adjuvanted PCV2 vaccine of Merial: CIRCOVAC®.

Material and Methods
Three-week-old piglets were randomly assigned in 2 groups: 15 piglets vaccinated once with CIRCOVAC 0.5 mL, IM and 15 piglets injected with 0.5 mL of PBS as control. Both groups were kept in isolation and subsequently challenged at 5 weeks of age with an infectious PCV2b. The 2 groups were compared according to body weight evolution, and PCV2 viral load in sera and faeces.

Results and Discussion
After challenge, the median RDWG was significantly higher for vaccinated piglets when compared to controls (Mann-Whitney test; p=0.030) (data not shown), leading to a difference of 1.5 kg between the average weight of vaccinated and control animals at D42 (Fig. 1).

Figure 1: Evolution of body weights before and after challenge (D14)

Further, post-challenge PCV2 viral DNA load in the sera of vaccinated piglets was significantly reduced as compared to the viral load in the sera of placebo-vaccinated animals (Fig 2a). Both vaccinated and control piglets had no detectable PCV2 in serum before challenge.

The mean viral load on the whole monitoring period (AUC) was significantly lower for vaccinated piglets compared to control animals (one tailed Student t-test p=0.003) (Fig. 2b).

Vaccination also contributed to a significant reduction of post-challenge viral excretion in faeces (Fig. 2c). The mean viral load on the whole monitoring period (AUC) was significantly lower for vaccinated piglets compared to control animals (one tailed Student t-test p=0.004) (Fig. 2d).

Conclusion
Collectively, these results demonstrated a significant reduction of viral load in blood and faeces of PCV2 and a significant difference of the median RDWG (relative daily weight gain) between vaccinated and controls piglets leading to a difference of +1.5 kg of body weight in average at the end of the animal phase in CIRCOVAC vaccinated animals against a virulent PCV2 challenge performed only two weeks after vaccination, i.e. at the age of 5 weeks.

*CIRCOVAC is a registered trademark of Merial in Canada and elsewhere.

Figure 2: a) evolution of the mean PCV2 viral load in the sera; b) distribution of the AUC PCV2 viral load in the sera according to groups; c) evolution of the mean PCV2 viral excretion in faeces; d) distribution of AUC PCV2 viral excretion in the faeces according to groups
Clinical and pathologic lesions after simultaneous vaccination with PCV2 and Mycoplasma vaccine in 3 week old piglets

Alvaro Ruiz² Juan M. Palacios¹
1. Intervet Schering Plough AH, Huixquilucan, MEX, Mexico; 2. Universidad de Concepción, Chillan, Chile

Introduction

The use of simultaneous PCV-2 and Mycoplasma sp vaccines has been a common practice in order to reduce piglet management and stress, both vaccines are used in a similar age at weaning, even there is no a commercial vaccine that combines both antigens the products can be injected each at one neck side or in the same point. The objective of this trial was to evaluate the safety of a simultaneous use of a PCV2 vaccine¹ and a Mycoplasma sp bacterin².

Materials and Methods

311 piglets, with 3 weeks of age, from a conventional herd were utilized; piglets were vaccinated with 2.0 ml of PCV-2 vaccine and 1.0 ml of Mycoplasma bacterin one day after weaning followed by a second vaccination at six weeks of age. Vaccination was performed using an automatic double syringe (NJ Phillips Ltd) at the same site of the neck (first dose at the right site, second dose 3 weeks alter at the left site). Another group of 26 animals received the vaccines separately (first PCV-2 dose at the right site of the neck and Mycoplasma sp bacterin at the left site) and the second dose 3 weeks later. All animals were observed for two days following each vaccination for changes in general condition (e.g. feed intake) and local reactions at the injection site. Any abnormality or alteration observed during the further test period were recorded. In addition, 5 animals per group were euthanized and necropsied at 10 weeks of age to perform an histopathological analysis in the injection sites.

¹ PCV2 vaccine: Circumvent PCV (Batch no. 213893207).
² Mycoplasma sp bacterin; M+PAC (Batch no. 05605). Intervet Schering-Plough A.H.

Results and Conclusions

After vaccination, no systemic or local reactions were observed. The histopathological observations did not reveal any inflammatory or necrotic lesion that could be related to vaccination with PCV-2 and/or Mycoplasma sp bacterin. These field data, demonstrate that concurrent administration of PCV-2 and Mycoplasma sp bacterin whether using an automatic syringe which injects the two vaccines on the same side of the neck, or injecting them each to one side of the neck, did not induce any systemic or local reaction. In conclusion, concurrent use of PCV-2 with Mycoplasma sp is safe in pigs from 3 weeks of age.

Serological follow-up in SPF piglets vaccinated with CIRCOVAC® (Merial) at 3 weeks of age

Mathieu Chevalier¹ Laurent Fischer² François Joisel²
1. Merial CRSV, Saint-Vulbas, France; 2. Merial S.A.S., Lyon, France

Introduction
The aim of this study was to monitor the serological response in SPF piglets vaccinated with the inactivated adjuvanted PCV2 vaccine CIRCOVAC.

Material and Methods
A group of 8 piglets was vaccinated with 0.5ml of CIRCOVAC by intramuscular route at 3 weeks of age, and a group of 3 piglets was left as an unvaccinated control.

The two groups were kept in isolation and compared according to PCV2 anti-ORF2 ELISA and PCV2 seroneutralizing antibody titres.

Results
Animals from both groups were seronegative for anti-ORF2 PCV2 antibodies measured by ELISA at D0. Control piglets remained seronegative throughout the study (D42). A serological response was clearly observed for piglets belonging to the group vaccinated with CIRCOVAC. All vaccinated piglets had detectable level of anti-ORF2 ELISA antibodies one week after vaccination except one piglet that exhibited detectable level of anti-ORF2 antibodies at D14 and one piglet that showed detectable level of anti-ORF2 at D42 only. Evolution of anti-ORF2 PCV2 antibody titres per group is presented in Figure 1.

Figure 1: Evolution of the mean anti-ORF2 PCV2 antibody titres (ELISA)

Figure 2: Evolution of the mean anti-PCV2 antibody titres (seroneutralization)

Conclusion
The seroconversion induced in SPF piglets vaccinated at 3 weeks of age with CIRCOVAC was demonstrated by ELISA and seroneutralization techniques.

Improved production parameters and profit as a result of PCV2 piglet vaccination in the United Kingdom.

Nico Brons2 Allison M. Hughes1 Matthias J. Adam3
1. Boehringer Ingelheim, Berkshire, UK; 2. Easey Veterinary Services Ltd, Hoxne, UK; 3. Boehringer Ingelheim Ltd, Ingelheim, Germany

Introduction
Porcine Circovirus Disease (PCVD) was first described in the UK in 1997.1 The introduction of PCV2 vaccines has allowed greater control of PCVD; a significant reduction in mortality and an improvement in production parameters in herds throughout the UK.2 This study looks at the reduction in mortality, improved performance and additional gross margin following the introduction of Ingelvac CircoFLEX® (Boehringer Ingelheim) to a farm in the UK. This farm is part of a 28 breeding unit pyramid.3

Materials and Methods
Routine PCV2 piglet vaccination (a single, 1ml, dose at weaning) was introduced to a 900 sow, outdoor pig unit in East Anglia, England, in May 2008. The farm practiced a 3-week batch cycle and piglets were weaned and transported to one of five all in/all out, rearing units (wean to slaughter). Pig performance was closely monitored on the rearing units from Nov 2007 to Feb 2009 (before and after vaccine introduction). Data collected included post weaning mortality (PWM), average daily weight gain (ADWG), feed conversion ratio (FCR) and veterinary costs per pig. Eleven batches of pigs (11,075 in total) before vaccination and seven batches of pigs (5,851 pigs in total) after vaccination were monitored. Veterinary costs were also compared and these comprised of veterinary visits (routine and emergency) and total antibiotic expenditure per pig. Additional gross margin per pig was calculated on the basis of the average improvements observed after vaccination and the reduction in antibiotic expenditure (assuming a slaughter live weight of 100kg; prices: feed - £170/t, weaner - £36/pig & carcass - £1.23/kg).

Data was also collected from the top performing rearing unit (subclinical PCVD farm).

No other significant management, genetic or nutritional changes occurred on these rearing units during that period.

Results
The average mortality of successive batches of pigs showed a statistically significant decline from 6.4% to 2.8% (figure 1) due primarily to the disappearance of PDNS and the improved control of respiratory disease. ADWG per pig increased from 669g/day to 729g/day and FCR reduced from 2.53 to 2.44kg/kg. Variation was reduced for all parameters measured. The top performing unit experienced a reduction in mortality of 25%, an increase in ADWG of 36g/day and a reduction in FCR of 0.6 after vaccination. In addition, veterinary costs were reduced by 22% per pig, following PCV2 vaccination.

Based on the average improvement observed, the increased gross margin was calculated at £6.77/pig.

Discussion
The introduction of PCV2 vaccination to pigs at weaning resulted in a statistically significant reduction in mortality, the disappearance of PDNS, an improvement in ADWG and FCR and an additional gross margin of £6.77 per pig, from wean to slaughter.

In addition, there was a reduction in veterinary costs of 22% per pig. Substantial improvements in production were also observed in the rearing unit with subclinical PCVD.

**Full dose vs half dose of Ingelvac CircoFLEX: field data in Spain**

Joaquim Bringas  
*Sat Suis, Banyoles, Spain*

**Introduction**

Every day more, PCVD vaccination is becoming a routine in pig production, in some countries, vaccination rates are reaching extremely high percentages, like in US, about 95% in early 2010. Efficacy and return of investment have been demonstrated in several cases of PCV2 vaccination (1, 2).

On the other hand, since 2006, huge economical and financial crisis is affecting pig producers all over the world. Reducing input costs is one of the main objectives, therefore some producers in Spain decided to cut doses of PCV2 vaccines.

The objective of this study is to compare the efficacy of a PCV2 vaccine, Ingelvac CircoFLEX® (Boehringer Ingelheim) at full dose in comparison to half dose in mortality, medication costs and fattening performance.

**Materials and Methods**

This study was performed in a farrowing farm with 750 sows. This site one is producing approximately 23 piglets/sow/year, which is not as good as should be due to a high mortality in farrowing period. The herd is PRRS positive, sows are vaccinated against Aujeszky’s disease, Parvovirus and porcine Erisypelas. Gilts come from external source and before entering the farm, are vaccinated against Aujeszky’s, Parvovirus, Erisypelas and PRRS.

Piglets are weaned between 21 and 24 days and delivered to 3 nursery farms. All piglets are vaccinated against Mycoplasma at 7 days of age and against PCV2 at weaning.

Piglets remain in the nursery farm until they reach 20 kg of live weight, when they are moved to fattening units. In fattening, animals suffered moderate problems of PCVD. Peak of clinical signs were observed between 16 and 17 weeks of age. Before introduction of PCV2 vaccination mortality in fattening averaged at about 6% with medication costs of more than 3€ per pig, animals did not react to antibiotic treatments for secondary infections.

A total of 4.250 animals were included in this before-after study. First, 3 fattening batches (1.700 animals) were vaccinated at half dose (0,5ml per piglet) of Ingelvac CircoFLEX® off label. After that, 4 batches (2.550 animals) were vaccinated at full dose (1ml per piglet) following label recommendations.

All data presented is from fattening units. Mortality in both groups were evaluated using a Chi-square test.

**Results**

Animals vaccinated with full dose perform better than animals with half dose, (table 1). Weight gained in the fattening unit was 1,8 kg more in the vaccinated group with full dose spending 2 days more in fattening.

Difference in mortality was highly significant (p<0,001), obtaining a reduction of 56% in the group vaccinated with full dose in comparison with the results with half dose. Medication costs were reduced by 41% in the group of full dose.

**Discussion**

When comparing data of non vaccinated animals with animals vaccinated at half dose, some improvement was observed, but the clinical situation and mortality was still not satisfactory. Data presented in this field study, demonstrate that using full dose of Ingelvac CircoFLEX® instead of half dose improved the performance and lead to a significant reduction in mortality.

Based on reduction in mortality and medication costs, a yearly return of investment of 5,07:1 for every extra € spent on vaccine was calculated when moving from half to full dose of Ingelvac CircoFLEX.

The results of this study show that using full dose of Ingelvac CircoFLEX (compared to half dose) is improving the health situation on the farm and provides significant economic benefits.

Evaluation of CIRCOVAC® one shot vaccine applied in three-week-old piglets on production parameters in farms with and without a diagnosis of postweaning multisystemic wasting syndrome (PMWS)

Lorenzo Fraile1 Llorenç Grau-Roma1 Maribel Casas1 Patxi Sarasola2 Nuria Sinovas2 Miquel Nofrarias1 Rosa Lopez-Jimenez1 Sergio Lopez-Soria1 Marina Sibila1 Mathieu Chevalier3 Joaquim Segales1
1. Centre de Recerca en Sanitat Animal (CReSA), Bellaterra, Spain; 2. Ondax Scientific HQ, Hondarribia, Spain; 3. Merial, St. Vulbas, France

Introduction
Porcine circovirus type 2 (PCV2) vaccines have demonstrated to be very efficient to control postweaning multisystemic wasting syndrome (PMWS) under experimental and field conditions (1,2,3). Vaccination of sows and gilts increases PCV2 antibody titres in serum or colostrum providing protection of piglets against disease development (4). CIRCOVAC® is registered in many countries to be used in sows and gilts with the former indication. The objective of the present study was to evaluate the efficacy of the above-mentioned vaccine in farms infected with PCV2 and with or without a PMWS diagnosis.

Material and Methods
CIRCOVAC® was tested in 17-26 day-old conventional pigs of 2 different Spanish farms. Both farms were selected by their previous recent PMWS history. In each farm, about 300 pigs received one single dose of 0.5 mL of CIRCOVAC®, while 300 control animals received the same amount of placebo. Also in each farm, 50 pigs from each group were bled and a rectal swab was also taken. PCV2 viral load in serum and rectal swab (real-time PCR) were investigated at 3, 6, 10, 14, 17, 20, 23 weeks of age and before slaughter (S). All animals were weighed and scored for physical condition at 3 and 10 weeks of age and S. Average daily gain (ADG) for the whole postweaning period was calculated. All pigs were necropsied and sampled for a PMWS diagnosis assessment (histopathology and PCV2 in situ hybridization, ISH).

Analysis of variance with Bonferroni multiple comparisons (for normally distributed variables) and Kruskal-Wallis and Mann-Whitney tests (for non-normally distributed variables) were used to compare ADG, PCV2 DNA loads in sera and faeces between vaccinated and control animals in each sampling time.

Results
PCV2 infection was demonstrated to occur in both studied farms (measured by qPCR and ISH in tissues). PMWS individual case definition was fulfilled only in farm 1, while no cases accomplishing the diagnostic criteria were found in farm 2. ADG was significantly higher in vaccinated versus control animals in farm 1 and 2. Moreover, PCV2 viral load in serum was significantly lower (1-2 log) in vaccinated compared to control animals in most sampling times after PCV2 exposure in both farms. A similar result was obtained regarding PCV2 viral load in faeces.

Discussion
Vaccination with CIRCOVAC® in piglets under field conditions was able to significantly improve production parameters and reduce significantly PCV2 viremia and faecal load. These results agree with other publications using piglet vaccination in PMWS affected farms by means of different vaccine approaches, such as a PCV1-2 chimera vaccine (5) and a subunit vaccine based on PCV2 ORF2 protein (1). The present results support the idea that production parameters are suitable indicators of PCV2 vaccine efficacy.

Effect of PCV-2 vaccination protocols on late term mortality

Imre Biksi1 Tamás E. Kis1 Zoltan Nemet2 Márk Kovács3
1. Szent István University, Úllő, Hungary; 2. SZIU FVSC Large Animal Clinic, Dóra Major, Hungary; 3. Dalmandi Mg. ZRt., Dalmand, Hungary

Introduction
PCV-2 associated diseases and related losses might occur in high health status herds. With the advent of PCV-2 vaccines, these losses can be successfully reduced. In this study we have observed the effects of different vaccination protocols on late term mortality in a gilt development unit of a high health status breeding herd in Hungary.

Materials and Methods
PCV-2 related problems were detected in the gilt development unit (GDU) of a large breeding complex in Hungary. Pigs were transferred to the GDU at approximately 80 days of age (~35 kg bw). PCVAD was manifested mainly in PDNS and gastric ulceration possibly related to systemic illness. The majority of losses occurred between approx. 140-170 days of age (Figure 1.). The herd was free from PRRSV, M. hyopneumoniae, and pathogenic APP strains. No lesions related to these agents were found in necropsy.

From the beginning of 2009, we have tested two different vaccines and three protocols in order to prevent PCV-2 associated losses in the GDU. We have tested Circovac® (Merial) in 0.5 ml/pig dose, CircoFLEX® (Boehringer-Ingelheim) in 1 ml/pig dose applied at two different ages, and also observed unvaccinated groups of animals. The sole measure of vaccine efficacy was mortality in the GDU (between ~85-190 days of age). Dams of all pigs in this study were vaccinated with Circovac® according to the manufacturer’s instructions. All groups entering GDU received the same medication regime against proliferative enteropathy. No major changes in feed composition of feeding technology occurred in the study period. Mortality data were collected for all groups for their entire stay in the GDU. Mean mortality figures were compared by nonparametric statistics (Kruskal-Wallis test with Dunn’s multiple comparisons test). Results are summarized in Table 1.

Discussion
From these mortality data it appears, that on this farm the best protection from PCVAD in the 140-170 days age group was achieved with CircoFLEX® vaccination at approximately 22 days of age. Other vaccination approaches did not decrease total mortality rate compared to unvaccinated controls. It also appears, that vaccination of dams alone or in combination with late vaccination of pigs with CircoFLEX®, or with Circovac® did not affect total mortality rates. This observation is in line with findings from other studies (Guillaume et al., 2009).

**Immunization program to control PCV2-associated reproductive failure in sows using a commercial vaccines**

Carlos Martin del Campo² Francisco Aguilar² Salvador Espinoza² Lucia A. Garcia-Camacho¹ Victor Quintero¹

1. FESC-UNAM, Cuautitlán, MEX, Mexico; 2. Propeca SA. de CV., Tepatitlan, JAL, Mexico

**Introduction**

Porcine circovirus type 2 (PCV2) has been related to reproductive failure (RF) in sows, resulting in infertility, abortions, stillborns, increased non-viable piglets.1,2,7,8 PCV2 detection in stillborn, and newborn piglets, transplacental transmission without participation of other infectious agents and RF experimentally induced have been documented.3,4,6,7,8 It has been proved that PCV2 replicates in heart, lung, liver, kidney and lymphoid tissues by intrafetal inoculation. The most consistent neonatal and fetal are non-suppurative myocarditis and encephalitis associated to PCV2 detection by immunohistochemistry and/or in situ hybridization (ISH).8 Regarding vaccination, an improvement of reproductive parameters has been confirmed after vaccination with an inactivated PCV2 vaccine.2

**Material and methods**

The aim of this work was to evaluate an immunization program and its effect on controlling RF in a herd with history of PCV2 associated RF (PCV2-RF). The present study was done in a farm with 2800 sows of central Mexico with reproductive problems such as low parturition rate, late-term abortions (up to 7% in affected groups), and 3-7% mummified fetuses. The PCV2 presence was confirmed by diagnosis of non-suppurative myocarditis on histopathology examination and ISH PCV2 detection in aborted fetuses. In addition, the farm has history of positivity to PRRSV, H1N1 influenza virus, and porcine parvovirus. The herd was massive immunized with a commercial vaccine (Baculovirus-expressing PCV2 capsid protein). The data prior vaccination and after vaccination of 21 groups were compared as follow: parturition rate (PR), born alive piglet total average (BAT), born alive piglets (BA), stillborns, and mummified fetuses (MF). Results were analyzed by central tendency tests, and media comparison.

**Results**

The values from all evaluated parameters are shown in Table 1.

**Table 1.**

</tbody>
</table>

*Data between brackets depict to standard deviations

**Discussion**

Based on the results, a significant improvement of PR after vaccination (over 5.4%) was observed. The differences regarding BAT and BA were no significant and minimal. A similar finding was observed in BA and stillborns with no significant variation. The standard deviation of mummified fetuses was open with a tendency to narrow after vaccination. These findings are in agreement with reported data2 which there was an improvement of 2.1 in PR, and marginal improvements of BAT and BA. The latter were higher than our results. Regarding abortion percentage no significant variation was determined as opposed to reported data.

Immunity induced by recombinant adenovirus expressing capsid protein of porcine circovirus 2

Kyoung Ki Lee; Choi Kyu Park; Seong Hee Kim; Yun Kyung Song; Chae Wun Bae; Chang il Yeo; O Soo Lee
National Veterinary Research and Quarantine Service, Anyang, Korea

Introduction
Porcine circovirus associated disease (PCVAD) caused by porcine circovirus type 2 (PCV2) was one of the most important diseases currently threatening global swine industry. To prevent and control this disease, various types of vaccine have been developed and tested for their immunological effects. This study investigated the immune response induced by a recombinant adenovirus (reAdV) expressing the capsid protein, which is involved in the production of protective antibody against PCV2.

Materials and Methods
The ORF2 gene from field isolate was altered to replace with the codons preferred in mammalian cell for its high-level expression. The replication-defective reAdV was created by homologous recombination in E. coli using human adenovirus serotype 5 DNA deleted the early transcribed E1 and E3 genes. The capsid protein expressed in 293A cell was identified with immunochromical assay and western blotting. Groups of four female mice were immunized with ten-fold serially diluted reAdV (1 * 10^7 - 1 * 10^4 TCID_{50}/mouse) given intramuscularly. Mice were periodically bled under anesthesia by retro-orbital puncture. The antibody titers were detected by IFA test and ELISA.

Results & Discussion
The reAdVPCV2cap was produced by homologous recombination of a transfer vector, pAdenoVatorCMV5 and adenovirus DNA, pAdenoVator ΔE1/E3. At 6 days post-transfection in 293 cells, the typical CPE was observed. The titer of purified adenovirus was finally 1 * 10^3 TCID_{50}/ml. The recombinant capsid protein was expressed in infected 293A cells by investigation of staining with specific MAb (12C48) against capsid protein of PCV2. In addition, bands corresponding to a molecular weight of about 28 kDa were detected in the 293A cell lysate with western blotting.

The immune response induced by reAdVPCV2cap was investigated with IFA test and ELISA. The results of IFA test showed that PCV2-specific antibodies were detected in two mice groups inoculated with 1 * 10^7 and 1 * 10^6 TCID_{50}/mouse of reAdVPCV2cap, whereas no immune response was found in two mice groups treated with 1 * 10^5 and 1 * 10^4 TCID_{50}/mouse and control group (Fig. 1). In mice group inoculated with highest titer (1 * 10^7 TCID_{50}/mouse), the average antibody titers were 1:128, 1:1024, 1:2436, 1:2048 and 1:2436 at 10, 20, 30, 60, 90 days after immunization, respectively. In mice group inoculated with 1 * 10^6 TCID_{50}/mouse titer, the average antibody titers showed more than 1:256 at 30 days after immunization. These results indicated that virus titer of at least more than 10^6 TCID_{50}/mouse was required to induce the hummoral immune response in mice with the reAdVPCV2cap. The results of ELISA analysis also were similar to those of IFA test (Fig. 2).

Although titers of antibodies varied in individual mouse, geometric mean titers of each group showed dose dependent. These results show that the reAdV can effectively produce the capsid protein of PCV2 and induce sufficient immune responses.

Introduction
Porcine circovirus type 2 associated diseases (PCVAD) has become one of the most concerned diseases in swine industry (4). Though the novel PCV2 vaccines have shown good protection for PCVAD control, implementation of a strict biosecurity and enhancement of host innate immunity are also very important in PCVAD control (2, 3). Sugar cane extract (SCE), a natural product, has displayed immunostimulating effects on porcine leukocyte functions (1). Therefore, this study was aimed to evaluate the effects of SCE and managerial improvement on PCV2 and/or PRRSV infection.

Materials and methods
Experimental design: The study was conducted on two separated experiments. In experiment I, the experimental pigs were weaned at 18 days old and moved into an experimentally controlled house to avoid PRRSV infection. In experiment II, the experimental pigs were weaned and raised at the original farm with PRRSV endemic until 8 weeks old for PRRSV natural exposure and then moved into experimental house. Experimental pigs were grouped and treated as indicated in table 1.

A, Provided by Shin Mitsui Sugar Co. Ltd., Japan; 500mg/kg.bw
B, 3 consecutive days every two weeks before PCV2 challenge.
C, 3 consecutive days after PCV2 challenge
D, Pigs were challenged with PCV2 at 9 weeks of age.

Evaluation:
1. Clinical record: The body temperatures (BT) were recorded daily and fever was determined by the BT > 40°C. Body weight was weighted weekly.
2. Pulmonary impairments (PI, %) were scored depending on the area of bronchopneumonia (% grossly) and the severity of interstitial pneumonia (% microscopically) at the end of experiment, i.e. 4 weeks post PCV2 challenge.
3. PCV2 virus loads were determined by real time PCR.

Results
Pigs in group POS-1 that weaned early and segregated to the clean house had significantly lower PRRSV infection and ~21.5% lower MDWG after PCV2 challenge. In contrast, pigs in experiment II were all naturally exposed to PRRSV infection. After PCV2 challenge, all pigs were more seriously affected by PRRSV and PCV2 synergistic infection, with a decrease of 44.6% in MDWG (POS-2). However, SCE administration showed 9.4% to 20% improvement on the decreasing injury caused by PRRSV and PCV2 synergistic infections (table 2).

</tbody>
</table>

A, MFD: mean fever day; B, pulmonary impairment (%); C, MDWG: mean daily weight gain

Discussion
Administration of SCE can decrease the injury, but may not avoid the effect of PRRSV and PCV2 synergistic infection. In contrast, early weanling and segregation system can efficiently decrease or control PRRSV infection and also decrease the effect of PRRSV and PCV2 synergistic infections.

First report of the incidence and distribution of PCV2 virus in Mexico

Francisco Robles1 Ricardo Angulo2 Jean Claude Chevez1 Edgar Diaz2
1. Boehringer Ingelheim Vetmedica S.A. de C.V., Guadalajara, JAL, Mexico; 2. Boehringer Ingelheim Inc., St. Joseph, MO, USA

Introduction and Objective
Porcine circovirus type 2 (PCV-2) has been reported as the cause of PMWS and others syndromes (1,2,3). This virus was identified in Mexico during 2001 (4) and different reports show the current presence of PCV-2 in Mexico. Nevertheless, there is not enough information about the prevalence and distribution in Mexico, just some reports of antibodies’ presence (5). The main objective of this study was to establish the prevalence of PCV2 in different regions of Mexico using the PCR technique.

Materials and Methods
The study was conducted in 34 farms located in 10 different regions of Mexico. In 20 of these farms, the pigs showed clinical PMWS, according with the case definition (4). The sampling period was from January to September of 2006, collecting serum (n=3094), organs (n=122) plus lymph node, lung, ileum, and fecal swab samples (n=437.) The samples were pooled in accordance with the type of sample. There were 888 pools in total. The conduction of a PCR test amplified a fragment of 506 nucleotides of the ORF2.

Results
The number of samplings was 89 with 72 samplings equaling 80.89%, testing positive. The analysis showed that 33 of 34 farms, equaling 97.06%, were PCV2 PCR positive.

The analysis for each Mexican state shows that 9 out of 10 states are positive; this represents the 90% of positives. The only negative state was Coahuila. Nevertheless, for this state only one farm (3 samples) was subject to analysis.

Table 2 shows the results for each type of sample. In this case, the samples showing more findings that are positive were rectal swabs with 56 %, and the ones showing fewer positives were semen samples with less than 10%.

Discussion
PCR is a sensitive diagnostic method widely used for pathogen detection, including PCV2. Since PMWS was described in Canada (1997), PCV2 has been isolated from different samples in Germany, France, Spain, Korea, Japan and other important pig-producing countries (3.) In America, there are reports of the presence of PCV2 in United States, Canada and Brazil, but in Mexico there is only one report of the antibodies’ presence and few reported cases have been isolated. Our results are the first report of the incidence and distribution of PCV2 in Mexico’s commercial farms (using the PCR method), and show that PCV2 virus is distributed throughout all of Mexico’s territory. In this research there was no difference between tissue samples and blood samples. The best samples for diagnostic purposes were found to be rectal swabs (56 per cent positives) and the worst were semen (almost 10 per cent positives). Nevertheless all the different sample types analyzed showed positive results.

The percentage of positives found during this investigation is similar at other reports from around the world. It is very important to research the sequences of the Mexican PCV2 virus in order to determine the homology with other PCV2 virus distributed around of the world.

Histopathologic findings of Porcine Multisystemic Wasting Syndrome (PMWS) with non suppurative myocarditis as a cause of sudden death in two pig farms

Elias J. Sogbe1 Carmen T. Diaz1 Jean Utrera1 Elias Ascanio1 Miguel E. Sogbe1 Andres Boulanger2 Susan V. Del Castillo1
1. Universidad Central de Venezuela, Maracay, Venezuela; 2. AABL Veterinaria C.A., Valencia, Venezuela

Introduction
In recent years Post Weaning Multisystemic Wasting Syndrome (PMWS) has become of significant concern in the swine industry in many countries, particularly Canada, United States of America, Europe, Asia and South America. The syndrome affects pigs mainly between 6 and 14 weeks of age. It is characterized by wasting or unthriftiness, dyspnea, jaundice and enlarged lymph nodes. The syndrome was been associated with myocarditis finding in aborted or stillborn piglets due to PCV2, it was also observed in 8-day-old piglet with PCV2 association (1) The present study was performed in piglets located in 2 porcine farms from Central State of Venezuela (Aragua/Carabobo).

The first description of the syndrome in Venezuela was in 2003 (4,5). Therefore in this report we focus on describe the heart histopathological findings in young pigs naturally infected in two Venezuelan pigs farms with sudden death piglets, both farms were free from classical swine fever, Aujesky's disease, Porcine reproductive respiratory syndrome and encephalomyocarditis

Material and Methods
The present study was performed in 20 piglets of 6 to 10 weeks of age from 2 pig farms placed at Central States of Venezuela (Aragua/Carabobo). All piglets showed signs of wasting, pallor, dyspnea, diarrhea and enlarged superficial inguinal lymph nodes and has history of sudden and unexplained death.

Each pig was necropsed and tissue samples were collected for the histopathological evaluation, fixed in Buffered formalin 10%, processed by rutinary methods, and stained with Hematoxilin-Eosin.

In situ hybridization studies (IHS) were performed on those specimens with histological evidence of PCV2 (heart included) as described by Segalés et al (3) (Fig. 1, 2)

Results and Discussion
Clinical aspects: All the evaluated piglets (20) showed signs of wasting, pallor, respiratory distress, diarrhea, and sudden death.

At necropsy there was evidence of pneumonia with non-collapsible lungs as well as inguinal, mesenteric and tracheobronchial lymph nodes enlargement, heart showed focal to locally extensive hemorrhagic areas in myocardium with white spots areas.

The histopathology study showed lymphoid depletion, with loss of follicles architecture in lymph nodes, spleen, and Peyers patches, histiocytic infiltration, basophilic cytoplasmatic inclusions in histiocitic cells, and syncytial cells. These findings described were suggestive of PMWS. (3). The heart study showed focal to locally extensive areas of myocarditis and fibrosis. Other areas showed degeneration of myocardium and infiltration of macrophages and lymphocytes in the heart (Fig. 1). In this areas cross striation in cardiomyocytes have disappeared and necroses foci were seen and could explain heart failure and sudden death (Fig 2)

The sample tissues specimen processed by a technique of IHS (Fig.3) revealed the presence of PCV2 in affected lymphoid tissue and heart and confirmed the diagnosis of PMWS.

Conclusions
The results confirmed the existence of PCV2 associated with nonsuppurative myocarditis as an important cause of sudden heart disease of young piglets in Venezuela

National Level Research on Porcine Circovirus Associated Disease (PCVAD), PCV2 Prevalence and Associations with Herd Level Health and Management Practices

Charles A. Haley¹ Bruce A. Wagner¹ Sumathy Puvanendiran² Michael Murtaugh²
¹. USDA:APHIS:VS:CEAH:NAHMS, Fort Collins, CO, USA; ². Department of Veterinary & Biomedical Sciences, University of Minnesota, Saint Paul, MN, USA

Introduction

Porcine circovirus 2 (PCV2) is associated with Postweaning Multisystemic Wasting Syndrome (PMWS) and other Porcine Circovirus Associated Diseases (PCVAD), but also is frequently isolated from healthy swine¹,². PCVAD threatened the swine industry in Europe and later North America for about 15 years. In North America in 2006 efficacious PCV2 vaccines was introduced. However, little research to answer basic questions on the disease has been done since 2006.

Molecular biologists warn that this lack of understanding weakens our ability to respond to new outbreaks¹. We need to increase our understanding of PCVAD should current control strategies fail.

Our objectives were to retrospectively:1. Determine the National Prevalence of PMWS and 2. the National Weaned Pig Mortality from PMWS, 3. Determine the Prevalence of PCV2 (Antibodies and PCR) and 4. Develop National Estimates for the impact of farm and animal level factors on incidence of PMWS.

Materials and Methods

Questionnaire data and blood samples were collected as part of the NAHMS Swine 2006 study³. Questionnaires administered during personal interviews with farm personnel were used to gather data on housing, health management and health status. Blood samples were collected from up to 35 grower/finisher market pigs (20-32 weeks old) on 185 farms in 16 states. A new ELISA (n=6,046) was used to test for the presence of PCV2 antibodies and a new PCR (n=4,147) was also used to test whether PCV2 DNA was present in the sera of these pigs. In a separate study, these tests’ accuracy was determined using Bayesian analysis. For the ELISA, the Sensitivity was up to 90% while that of the PCR was up to 92%.

Results

Nationally, approximately one in three sites with weaned market pigs reported PMWS during the 12 months prior to the interview, ranging from 29.7% of small sites (<2,000 head) to 59.9% (>4,999 head) of large sites. On sites that reported PCVAD in weaned market pigs, 15.4% of these pigs were affected and again, larger sites had more pigs affected (19.8% vs. 7.7%)³.

Out of 6,046 samples 78.8% were positive for PCV2 antibodies and out of 4,147 samples 82.6% were positive for PCV2 DNA. Over 80% of samples tested using both tests were positive for antibodies and DNA. All but two farms had one or more samples positive for PCV2 antibodies and all but one for PCV2 DNA.

We used a weighted logistic regression that generates estimates that can be directly extrapolated back to the population (>93% of the farms nationally with 100 or more pigs) rather than just the sample it comes from⁴. When farms had one respiratory disease (such as PRRS) the odds of PMWS being present went up almost 14 times compared to when no respiratory disease was present. If there were two or more respiratory diseases the odds went up over 30 times.

Discussion

Prior to the use of vaccines, more large farms than small farms had PMWS-affecting more animals. PCV2 elicits a humoral immune response yet fails to clear the virus for some unknown reason. Anecdotally, it was believed that PCV2 was ubiquitous but there has not been a study of this magnitude to give more accurate estimates.

Should the vaccines available now begin to fail to control PMWS or more broadly PCVAD, then we must return our efforts to reducing the impact of these respiratory pathogens modeled such as PRRS.

Porcine circovirus 2 as a causative agent for severe respiratory signs and polyserositis on a Specific Pathogen Free fattening farm

Victor Geurts1  Chris Schouten2  Antoine L.M. Cruijsen1  Mark W. de Groot1  Mieke P. Vrijenhoek1
1. Intervet Nederland BV, Boxmeer, Netherlands; 2. Veterinarian Practice, Heeswijk-Dinther, Netherlands

Introduction

The clinical expression of PCVAD embraces a complex of signs including those related to the respiratory system. The authors are not aware of any reports relating polyserositis directly to PCV2 infections. Experimental PCV2 infections in Specific Pathogen Free (SPF) pigs has led to severe respiratory signs with high mortality including lung edema, hyperemia of the lungs, icterus, lymphadenopathy and edema of the mesentery (1). In 2009 on 2 locations SPF fattening pigs from one origin suffered from severe respiratory symptoms (dyspnea, coughing), high fever and a high level of mortality in spite of vaccination at 4 and 6 weeks of age against Haemophilus.parasuis (Porcilis®Glässer). Necropsy revealed polyserositis with negative bacteriological results, hyperemia of the lung, and interstitial lung edema. Organs were highly positive for PCV2 by IHC. Paired serological investigation of acutely sick pigs, only revealed seroconversion to PCV2. This strongly suggests that the clinical signs were related to PCV 2 infections in a similar situation as described in experimentally infected SPF pigs by Gauger et al (1). A PCV-vaccination trial was set up in order to help the farm and to explore the relationship between the signs observed and PCV2 infections. After this trial, all new piglets that entered the fattening units were vaccinated.

Materials and Methods

In a batch of 350 piglets, 197 were vaccinated with a single dose of Porcilis® PCV at 10 weeks of age, on their arrival in the fattening unit. The rest were left unvaccinated. Vaccinated and unvaccinated pigs were housed site by site in three different units. Mortality was recorded and in each trial group serum of 10 pigs was sampled at 10-, 14-, 18- and 22-weeks of age. Sera were tested on antibodies against PCV2 (Symbiotics), PRRS(Idexx), H. parasuis (Biovet), M. hyopneumoniae (Idexx) and the 42 kD outer membrane protein of A. pleuropneumoniae (2). Sera were also tested on PCV2 virusload by qPCR. Average daily intake (ADI), feed conversion rate (FCR) and average daily gain (ADG) during 2 months after the start of the vaccination was compared with the results of not vaccinated pigs during 2 months before the trial.

Results

All samples were negative against PRRS and M. hyopneumoniae. Also A. pleuropneumoniae titers stayed at low levels in both groups. Some sera of the 10- and 14-week old fatteners were positive against H. parasuis in both groups. These positive results were likely due to the early vaccination because all 22-week old fatteners became negative.

Conclusion and Discussion

The clinical signs (respiratory distress and polyserositis) on this farm were likely caused by PCV2, no other causative agent was found in the diseased pigs and vaccination against PCV was successful in preventing the disease. Pigs vaccinated with Porcilis® PCV had a reduced mortality, a clear humoral response to vaccination and the amount of PCV2 virus positive pigs was reduced. The historical data show a clear improvement in ADG, ADI and FCR after starting the vaccination. The respiratory signs in this clinical field trial with SPF pigs were similar to those of experimentally infected SPF pigs after PCV2 challenge (1). The authors are not aware of any reports relating polyserositis to PCV2 infection. A possible explanation for this feature could be a co-infection with Mycoplasma hyorhinis (3, 4), an opportunist which is capable of causing polyserositis. Its involvement may be triggered by the immune suppression caused by PCV2 infection. The practical implication of the results of both this and the Gauger trial is that PCV2 can be the cause of acute respiratory signs with high fever and high mortality levels.

**Introduction**

Porcine circovirus type 2 (PCV2) is the etiologic agent of postweaning multisystemic wasting syndrome (PMWS) in pigs. However, PCV2 co-infection with some viral and bacterial agents may potentiate PMWS development (1). Particularly, a previous infection with Mycoplasma hyopneumoniae (M.) has been shown able to trigger PMWS in subsequently PCV2 infected pigs (2). The objective of this work was to study the effect of concurrent PCV2 and MH co-inoculation in conventional piglets.

**Material and Methods**

Thirty six 6-week-old male conventional piglets were divided into 4 groups: control (n=6, receiving 2 ml of PBS); PCV2 (n=6, intranasally challenged with 1 ml of 10^5 TCID50 PCV2b per nostril); MH (n=12, intratracheally inoculated with 5 ml of MH 10^7 CCU on two consecutive days); and PCV2+MH (n=12, same inoculum conditions as above). Clinical signs, rectal temperature and body weight were recorded during the study period. Blood samples, faecal and nasal swabs were collected on 0, 7, 14 and 21 dpi. At necropsy (21 dpi), tracheal and bronchial swabs were also taken. Extension of cranio-ventral pulmonary consolidation lesions (CVPC) was assessed (3). Moreover, lymphoid tissues and lungs were collected and fixed in 10% buffered formalin. Sera were examined for PCV2 (total and neutralising (4)) and MH antibodies. DNA extracted from serum samples, nasal and faecal swabs were analyzed by a PCV2 quantitative PCR (Q-PCR) (5). PCV2 in situ hybridization (ISH) from lymphoid tissues and lung was performed (6). MH DNA from nasal, tracheal and bronchial swabs was analyzed by Q-PCR.

**Results**

PCV2 infection remained subclinical although mild PMWS-like microscopic lesions were observed in two PCV2 pigs and in one PCV2+MH animal. PCV2 was detected by ISH in 3 PCV2 and in 4 PCV2+MH challenged pigs. No significant differences on mean body weight and rectal temperature were observed among the 4 groups. Total antibody and NA titres were similar in both PCV2-inoculated groups. Number of PCV2 Q-PCR positive pigs in serum was higher but not statistically significant in all samplings in PCV2+MH than in PCV2 inoculated pigs. No significant differences in viral loads on different sampling days and duration of viremia were detected among PCV2 inoculated groups.

Coughing was observed in 3 piglets from the MH group and in 6 PCV2+MH pigs but it was absent in non-MH inoculated pigs. Proportion of MH Q-PCR positive pigs and mean bacterial DNA load in nasal cavity were similar in MH and PCV2+MH groups. On the contrary, mean MH DNA load at bronchial and tracheal swabs was higher in the PCV2+MH group compared to the MH one. No significant differences on percentage of MH seropositive pigs among MH inoculated groups were observed. Eight pigs from MH group and nine from PCV2+MH group showed CVPC. No significant differences in mean lung scoring between MH group and PCV2+MH group were observed.

**Discussion**

In a previous study, MH inoculation two weeks before PCV2 challenge resulted in an increase of PCV2-associated lesions severity, amount of PCV2 antigen and incidence of PMWS in pigs (2). In the present study, the concurrent inoculation of MH and PCV2 did not produce that synergic outcome. These divergent results may be explained by the different timing of infection but also by the source of the animals used. In the present study, the inoculated animals were seropositive to MH- and PCV2 while in the previous one (2) the challenged animals were seronegative against both pathogens. Taking into account that infection with both agents was successful, the present study suggests that timing and initial pig serological status may be the most important issues for the final outcome of the co-infection.

High moralities in the nursery, growing and finishing pigs. Risk assessment in Colombian pig herds

Carlos A. Diaz² Maria N. Rodriguez¹ Gloria Ramirez² Jairo Jaime² Victor Vera² Jose D. Mogollon²

Introduction
Porcine Circovirus Associated Diseases (PCVD) have been associated with high mortality rates but PCV2 infection itself hasn’t been proved to be a risk factor for develop them (1, 2, 3). Some management practices, most be triggering the disease once PCV2 infects the pig. The main objective in this study was to determine what kind of swine industry practices and/or production indicators are associated with extremely high mortalities rates in Colombian swine herds.

Materials and Methods
Sample size was calculated in 70 herds considering a 95% confidence level, 10% precision and 50% prevalence. Herds were randomly selected from 163 farms located in the three major swine rearing areas in Colombia, with 200 or more sows that represent the 74% of national inventory. An epidemiological survey was applied, and extremely high mortality in the nursery and finishing was defined as mean plus 2 standard deviation of the sample without extreme values when calculating it. 43 serum samples were collected per production cycle and analyzed for PCV2 antibodies (SERELISA® PCV2 SYNBIOTICS). Samples of death animals were collected when present and analyzed for PCVD lesions and PCV2 antigen was identified by Immunohistochemistry (IHQ) within compatible lesions.

Statistical analysis was performed using STATA 9 ®. The null hypothesis was that exposure to any of the variables included in the survey do not modify the risk of developing extremely high mortality rates. Association between high mortalities and exposure variables were assessed through a logistic regression model estimating relative risk adjusting it for variables like clinical disorders or previously diagnosed diseases; backward stepwise regression analysis was performed for each outcome (high mortality in nursery and finishing).

Results
High positive ELISA reactivity was found in the sow herd (95.3%) without significant differences between proportions, within parities in the tested animals (p>0.05). High positive ELISA reactivity were also found in growing pigs 94, 90.7, 83.7, 89.8 and 93.6% for 1, 5, 10, 15 and 20 weeks of age respectively, being different the proportion of positive animals between animal 5 and 10 week of age (p=0.009) and between animals 10 and 15 weeks of age (p=0.026).

Mean mortality rate in the nursery was estimated in 1.41% SD 0.74 and 2.2% in the finishing pigs SD 1.45. The risk to have extremely high mortalities in the nursery was estimated to be 17.5 (IC 95% 1.8, 168.2; p=0.01) higher when farms don’t use shower baths at the entry to the nursery if the polyserositis (OR 6.1, IC95% 1.06-35.3; p=0.43) and low consumption (OR 25.3 IC95% 2.3 – 274.0; p=0.008) effect was controlled in the logistic model; all other variables were dropped off the model because they lost significance when the effect of this three was controlled. All of the variables included in the second model lost significance when the effect of low consumption was controlled in finishing pigs; it was estimated that finishing pigs have a risk 18.8 times higher to develop high mortality if low consumption was reported (IC95% 1.7 – 203.2; p=0.016). PCVD has been diagnosed and PCV2 has been identified within lesions in some farms but not all result where available at the time of this preliminary report. PCV2 exposure was determined in all farms evaluated and vaccination didn’t modify the risk of developing high mortality rates.

Discussion
PCV2 exposure itself was discarded to be associated with high mortality rates in the nursery and growing to finishing in farms with more than 200 sows in Colombia. Poor management practices could make possible that other swine pathogens, including PCV2, alter pig’s health status in such a way that high mortalities appeared. The difference between proportions in positive animals to PCV2 during the nursery and finishing period may be related to high mortalities in certain ages.

Growth depression after severe outbreak of porcine circovirus associated disease (PCVAD) in the finishing unit: case history

Piotr Kneblewski; Krzysztof Wilczynski; Pawel Karbowiak
Vet-Com, Olsztyn, Poland

Introduction
The first reports about confirmed PCV2 in Polish swine herds date back to 2000 (1,2). The aim of the investigation was to determine the impact of outbreak of severe porcine circovirus associated disease (PCVAD) on the performance in the finishing unit.

Materials and Methods
The investigation was conducted in a fattening farm located in the western part of Poland. The farm consisted of three barns for 2000 finishers with pens for 30-120 animals. Pigs for this study were sourced from a high health farm without clinical signs of PCVAD. They were not vaccinated against PCV2. A total of 1600 pigs were moved to the finisher farm at 40 kg of weight. The factors which aggravate problems were high temperature during transport and the quality of the feed in the beginning, which caused outbreak of watery, yellowish or grey diarrhea which affected up to 50% of the animals. After two weeks persistent cough appeared in 30-35% of pigs and the first cases of death were recorded. Numerous symptoms of PMWS and the first PDNS cases occurred. Weekly mortality increased to 5-10 pigs. Post mortem examination showed cachexia, paleness of the skin, reddish or blackish foci of cutaneous necrosis located mainly in the area of rump, neck and ears, enlargement of inquinal and mesenteric lymph nodes, various inflammation of digestive and respiratory system. Three sick pigs were culled. Their lymph nodes, samples of ileum, cecum, spiral colon and kidneys were analysed microscopically and tested by in situ hybridisation for PCV2(1,2). Additionally intestine samples were examined by PCR for Lawsonia intracellularis and Brachyspira hyodysenteriae. PMWS typical histopathological lesions and PCV2 DNA were detected in the submitted material. The result for Lawsonia and Brachyspira was negative. After two weeks treatment was started with Tiamulin 45% (tiamulin 8mg/kg for 6 days) and then Soludox 50% (doxycyclin 10mg/kg for 6 days) was administered in the drinking water. Such therapy only stopped the progress of disease for two weeks. After this time treatment had to be repeated. Moreover every sick pig was put in hospital pens. All facilities were cleaned and disinfected every day. Additionally all animals in hospital pens (300 pigs at the peak of disease) got TiaClor (CTC and Tiamulin) and Paracetam(NSAID) in the feed for 21 days. The weight of the pigs was recorded at introduction to the finishing unit and at slaughter. Average daily weight gain (ADWG) was calculated and number of days to slaughter were recorded. Performance of pigs affected with PCVAD was compared with pigs non-affected with PCVAD. Group A consisted of healthy pigs without any clinical symptoms of PCVAD and group B consisted of pigs with PCVAD.

Results
During the fattening period clinical signs of PCVAD infection occurred in 82% of the pigs (Group B). Only about 13% were not affected (Group A). Total mortality rate was 4.8%. The ADWG of pigs with PCVAD (Group B) was reduced compared to non affected (Group A) by 244g/day. Number of days to slaughter was extended by 21 days for group B compared to Group A (Table 1).

Table 1. Comparison between two groups of finishers. Group A pigs without any clinical sings of PCVAD and Group B pigs with clinical sings of PCVAD.

<td>96</td>
</tr>
</tbody>
</table>

Discussion
Outbreak of PCVAD infection had serious financial consequences, reduction of DWG by 244g/day and extension of feeding days by 21 for pigs with PCVAD and the loss was estimated at 35,200 USD or about 27 USD per pig. Had these treatments with antimicrobials, isolation of affected pigs in hospital pens, cleaning and disinfection of pens not been carried out losses would have been higher.

**Effect of co-infection of porcine circovirus type 2 and porcine reproductive and respiratory syndrome virus on porcine alveolar macrophages**

Fei Song¹ Qigai He¹ Weidong Chai¹ Wentao Li¹ Catherine Charreyre²

1. College of Veterinary Medicine, Huazhong Agricultural University, Wuhan, China; 2. Merial Limited, Lyon, France

**Introduction**

Porcine reproductive and respiratory syndrome virus (PRRSV) and Porcine circovirus type 2 (PCV2) are currently a major concern for the swine industry worldwide. A lot of field surveys have indicated that dual PRRSV and PCV2 infection is common in pigs (3, 4). However, whether the immunosuppression, in particular in alveolar macrophages, is stronger compared with the singular infection is still unknown.

**Materials and Methods**

Porcine alveolar macrophages (PAM) were isolated from lungs of 5-week-old piglets as Chang (2005) description. For subsequent experiments, PAMs were seeded at 24-well plates and infected with PCV2, PRRSV, PCV2+PRRSV (simultaneously inoculation) and PCV2 followed by PRRSV infection at 6hr later. The uninfected PAMs served as blank control. The supernatant and pellet of infected cells were collected at 0, 12, 24, 48, 60hpi.

We used quantitative real time PCR and indirect immunofluorescence assay (IFA) to analyze the adhesion and replication of PCV2 on PAMS, the cytopathic effect (CPE) and livability of PAMs were monitored and calculated by Typan Blue Staining Cell Viability Assay Kit, and mRNA levels of the cytokines (TNF-α, IFN-γ, IL-8) in PAMs were detected by semi-quantitative real-time PCR.

**Results**

The infection of PAMs with PRRSV neither increased the adhesion nor the replication of PCV2, but the distribution of PCV2 was changed in PAMs. PCV2 could not replicated nor induced CPE in infected PAMs, whereas the co-infected with two viruses could induce the cell death compared to single virus infected group. The expression of TNF-α, IL-8 in PAMs induced by co-infected group (different orders) were found to significantly increase and the increase was stronger than singular virus infected groups (p<0.001). However the co-infected group inhibited the expression level of IFN-γ compared to virus infected alone (p<0.001).

**Discussion**

The object of our work was to study the effect of PRRSV and PCV2 co-infection on PAMs. The results showed that no replication of PCV2 in PAMs was observed and this phenomenon was not associated with the present of PRRSV or not, PCV2 probably evade the immune systems through low-dose infection. As to the difference of PCV2 distribution between co-infected groups and single virus infection, more evidence is needed to explain this consequence. Besides, the addition of PRRSV to PCV2 caused more severe cell death and increased the expression of TNF-α, IL-8 than single virus infection, the results indicated co-infection may cause more serious pulmonary pathological lesions. IFN-γ is the broad-spectrum anti-virus agent, the stronger inhibition of expression caused by co-infected groups indicated PCV2 and PRRSV co-infection caused more severe immune suppression than infection with PCV2 or PRRSV alone.

**PDNS was not a homogenous entity in the Swiss PMWS epizooty between 2003 and 2006**

Sandra Welti\(^2\) Titus Sydler\(^1\) Esther Buergi\(^2\) Enrico Brugnera\(^3,2\) Xaver Sidler\(^2\)

1. Institute of Veterinary Pathology, Vetsuisse Faculty, Zurich, Switzerland; 2. Division of Farm Animals, University of Zurich, Veterinary Faculty, Zurich, Switzerland; 3. Institute of Veterinary Pathology, University of Zurich, Vetsuisse Faculty, Zurich, Switzerland

**Introduction**

Porcine circovirus type 2 (PCV2) is the causative agent for post-weaning multisystemic wasting syndrome (PMWS) and is considered to be one of the most important viral pathogens of pigs in many countries. PCV2 has also been associated with additional diseases, referred to as PCV associated diseases (PCVAD) which include PMWS, some types of pneumonia, enteritis, reproductive failures and another distinct disease condition, the porcine dermatitis and nephropathy syndrome (PDNS). In Switzerland a PMWS epizooty commenced at the end of 2003 (1). We attempted to reconstruct this epizooty and the retrospectively reevaluated PDNS cases are presented here.

**Materials and Methods**

The Institute of Veterinary Pathology, Zürich, is the only laboratory in Switzerland which diagnoses PCV2 infections by immunohistochemistry (IHC) with the monoclonal antibody F217 according to the rules of the sixth framework program (2). A retrospective investigation of all available cases from our archive and the archives of other Swiss laboratories between 2003-2006 were used to elucidate the Swiss PMWS epizooty, which began at the end of 2003. In this material only 14 of 538 declared PCV2 infected animals were IHC negative after reevaluation. 131 cases had a low PCV2 antigen load in the lymphatic tissues and 383 moderate to high. For this communication we selected the cases where PDNS was diagnosed using the "typical" glomerulonephritis as the diagnostic criterion.

**Results**

PDNS was diagnosed in 43 out of 538 animals. 21 PDNS cases had only minimal PCV2 antigen in lymphatic tissues and 22 had a moderate to high PCV2 antigen load. The PMWS animals were, as expected, significantly younger than those with PDNS. The PDNS pigs with low PCV2 antigen load in the lymphatic tissues were the same age as those with moderate to high antigen load (Ø 17 weeks) but they had significantly higher body weights (Ø 44.1 kg, n=19 with available data) than those with moderate to severe PCV2 antigen load (Ø 29.8 kg, n=13 with available data) (Table 1). The cases with moderate to high PCV2 antigen content also showed depletion and histiocytic infiltrates in lymphatic tissues similar to PMWS.

Not all cases had skin lesions.

**Discussion**

PDNS is suspected to be PCV2 induced (3), however we were not able to demonstrate any PCV2 antigen signal or DNA signal (by insitu hybridisation) within the glomerular lesions. PCV2 antigen signals were primarily in lymphatic tissues. However low PCV2 antigen load in lymphatic tissues is not defined as PCV2 disease because low quantities of PCV2 may be found in healthy animals.

Our set of PDNS cases was clearly divided into two subsets. One comprised PDNS animals with no to scarce PCV2 antigen and good body condition, the other subset suffered from PMWS (with high PCV2 antigen content and lesions in lymphatic tissue) followed by renal failure. We called these cases "mixed PDNS-PMWS".

PDNS cases were infrequent in this investigation probably because the easily recognizable typical cases with dermatitis were not submitted for necropsy by the owners.

Distribution of Porcine Circovirus type 2 (PCV2), Torque teno virus (TTV) and a novel porcine boca-like virus (PBo-likeV) in pigs from postweaning multisystemic wasting syndrome (PMWS)-affected and non-PMWS-affected farms in archival UK samples

Michael J. McMenamy1 Irene McNair2 Catherine Duffy1 John McKillen2 Bernt Hjertner1 Catherine Mulholland2 Gordon Allan2

1. Queen’s University Belfast, Belfast, UK; 2. Agri-Food and Biosciences Institute Northern Ireland, Belfast, UK

Introduction
Porcine circovirus type 2 (PCV2) is acknowledged as the essential infectious agent of postweaning multisystemic wasting syndrome (PMWS)1. However, it has been noted that PMWS may not develop even though a pig has been infected with PCV21. It is possible that other agents may contribute to the development of PMWS. A possible potentiating co-factor in the development of PMWS by immunologic dysregulation is Torque teno virus genogroup 1 (g1-TTV), even though it is not considered a directly causative agent2. Another candidate which may play a role in PMWS development is a recently discovered porcine boca-like virus (PBo-likeV), identified by high-throughput sequencing in lymph nodes taken in a Swedish study from PMWS-affected pigs2. Here we investigate the distribution of PCV2, TTV and the new PBo-likeV in archival serum and tissue samples recovered from pigs from 5 UK farms in 2002.

Materials & Methods
37 sera samples were collected from pigs on all 5 UK farms, 2 of which were known to be non-PMWS-affected and the other 3 PMWS-affected. 21 pigs from 3 PMWS-affected farms also had tissue samples collected. Tissues included lung, liver, kidney, spleen and lymph nodes from each pig. Viral nucleic acids were extracted from sera and homogenised tissue samples. All sera and tissue samples were analysed by PCR for the presence of PCV2 using ORF2 specific primers1. Where possible, resultant amplicons were sequenced to ascertain the PCV2 genotype5. The samples were also assessed for the presence of g1-TTV4, g2-TTV and PBo-likeV2 using real-time PCR. g2-TTV was detected using a set of primers kindly provided by Dr. Annette Mankertz (Robert Koch-Institut, Berlin, Germany) (data not published).

Results
Tissue sample PCR results were pooled due to little variation in virus presence from tissue to tissue. The percentage distribution of viruses detected in the samples are detailed in Tables 1 and 2.

Discussion
The disparity in virus distribution evident in the sera samples could result from the PMWS-affected samples being comprised of sera from the 1st week of life which would limit pig exposure time to these viruses. However, non-PMWS-affected samples also included terminal bleeds at 12 weeks of age. It is apparent from the tissue samples that g2-TTV and PBo-likeV were more prevalent in PMWS-affected pigs. It is also of interest that PCV2 genotype 2a was present in sera samples from non-PMWS-affected farms although genotype 2b was exclusively found in tissues from PMWS-affected farms5. Further statistical analysis of these results is required to assess if incidence of a virus or specific genotype can be significantly related to disease status.

Serum endotoxin in pigs affected by wasting syndromes
Paolo Candotti; Sara Rota Nodari; Claudia Nassuato
IZSLE, Brescia, Italy

Introduction
Postweaning multisystemic wasting syndrome (PMWS) is one of the disease syndromes which have been collectively named porcine circovirus diseases (PCVD). PMWS mainly affects nursery and/or fattening pigs and wasting is considered the most representative clinical sign of this disease. It is considered a multifactorial disease in which other factors in addition to PCV2 are needed, in most cases, to trigger the clinical disease. These factors haven't been clearly identified yet.

The aim of this study was to examine the levels of serum endotoxin in weaning piglets from farms with clinical symptoms of wasting compared to the levels in pigs from healthy farms.

Materials and Methods
Five (control farms) healthy farms and 13 (case farms) with a wasting syndrome that could be attributed to PMWS were selected for the study. Diagnosis of clinical PMWS and exclusion of other wasting agents was made through anamnesis, clinical findings and anatomo-pathological examination. Ten weaners were blood sampled in each farm (in control farms: animals perfectly healthy; in case farms: animals with a severe wasting syndrome). Blood samples were tested for lipopolysaccarides (LPS) with a Kinetic Cromogenic Assay.

Results
Mean and standard deviations (SD) of serum LPS (EU/ml) in the different farms are reported in table 1.

In figure 1 the graph of sensitivity-specificity and the cut off value is reported.

Discussion
The correlation between the presence of the disease and the level of LPS was statistically significant. The average LPS level in healthy animals was 0.34 EU/ml (CI 95%; 0.08-0.59) while in wasted animals 0.92 EU/ml (CI 95%; 0.76-1.08). In presence of wasting, LPS was on average 0.58 EU/ml higher (CI 95%; 0.28-0.88; p<0.001). The cut-off value identified for LPS was 0.44 EU/ml.

The limitation of these findings is that PMWS was not confirmed by histopathological examination of lymphoid tissues and detection of PCV2 in damaged tissues. However, these results could be useful in identifying triggering factors in animals affected by wasting syndromes that can't be attributed to specific pathogens and are clinically attributed to PMWS.

Introduction
Since 1999, field evidence of transplacental infection by PCV2 and reproductive failure has been reported (1). Several experimental studies were performed: trans-uterine inoculation of fetuses (2), oronasal inoculation of pregnant SPF (3) or conventional (4) sows, intra-uterine inoculation of SPF sows (5). The objective of this study was to evaluate the clinical and pathological consequences of PCV2 infection in conventional pigs by artificially infected semen.

Material and Methods
Nine prepubertal conventional pigs were randomly divided: 3 controls and 6 infected. Hormonal estrus synchronization was followed by artificial insemination (AI) with a single dose semen added with 10 ml of a PCV2 suspension. After ultrasonography at 29 day post-insemination (DPI), empty sows were euthanized at 30 DPI whilst pregnant ones between 52nd and 56th DPI. Cervix, nasal and rectal swabs, and blood samples were weekly collected from -2 DPI till the end of the experimental period. Serum samples were directly and indirectly tested for PCV2, PRRSV, PPV and ADV. Serum antibody titres were determined by competitive ELISAs (6, 7, 8). The protocol described by Olvera et al. (9) was employed for PCV2 real time-PCR. Serum progesterone levels were measured by radioimmunoassay (10).

Results
At the -2 DPI, none pig presented viremia for all tested virus. All animals showed a high anti-PCV2 antibody level at -2 DPI (range 1/1000-1/100000), but only one sow had a lower titre (1/100). Four out of 6 infected sows displayed viremia at 7, 21, 28 and 35 DPI (the subject with the lowest anti-PCV2 level kept showing positive blood results for two successive samplings at 21 and 35 DPI). This latter was also the only sow showing a positive swab (rectal, 35th DPI). The anti-PCV2 antibody proved a decline after 7 DPI followed by a plateau in controls, whereas in infected animals were recorded values higher than controls that declined only after 42 DPI (Figure 1).

No sows showed any signs of estrus after AI. Pregnancies were established in 3 out of the 6 infected sows and in 3 out of the 3 controls (one control sow aborted 3 fetuses at 21 DPI). Serum antibody titres against PPV, PRRSV and ADV (total and anti-gE) decreased between -2 DPI and at the last DPI. Progesterone was absent in all gilts at insemination and in all animals increased after estrus induction but in the three non-pregnant infected animals never raised until the 28 DPI.

Discussion
In the present study the assessment of a field situation employing conventional pigs and intrauterine PCV2 exposition was investigated. Viremia was recorded in 4 out of 6 infected animals, besides mean antibody titre higher only in exposed subjects. Three infected sows out of 6 were not pregnant, unlike controls were all pregnant. Moreover, it should be emphasized that only the infected sow with lower PCV2 antibodies titre at -2 DPI showed simultaneously viremia and fecal virus spread. Therefore, i) the PCV2 infection is possible in conventional sows by intrauterine exposition; ii) low antibody titres increase the probability of the infection; iii) PCV2 infection close to insemination reduces the pregnancy rate.

Introduction
Swine with Postweaning Multisystemic Wasting Syndrome (PMWS) under PCR analysis yields both Porcine Circovirus genotypes (PCV2a and PCV2b) as well as association with Torque Teno Virus (TTV), PRRSV, Parvovirus (PPV), Swine Influenza, Coronavirus and also E. coli, Streptococcus suis, M. hyopneumoniae, H. parasuis and A. pleuropneumoniae (1,2,3). This work was done to verify the occurrence of PCV2 and TTV genotypes in samples from swine with PMWS and possible other virus and bacteria co-infections.

Material and Methods
Eighteen samples from swine suspected of PMWS, collected during 2009 in Brazil, were analyzed. Ten samples were from fetus (group I) and eight from nursery/finishing animals (group II). Lymph nodes, lung/heart were investigated by PCR analyses for PCV2a, PCV2b, TTV1, TTV2 and PPV. The DNA extraction and the PCR analyses were done according to Kim et al. (2003). The secondary bacteria infection diagnosis was done by Microvet laboratory (Brazil).

Results
PCV2b was the most prevalent in both groups. Two samples from group I were positive for PCV2a/PCV2b but this co-infection was not detected in group II. In both groups the most common co-infection was PCV2b/TTV2 followed by PCV2b/PPV. Twenty percent of samples from group I and 50% from group II had TTV1/TTV2 co-infection (Table 1). In group I, 60% of the samples were co-infected with one bacterium, mainly, alpha hemolytic E. coli and in group II different species were detected (Table 2).

Discussion
The viral and bacterial co-infections are common in PMWS (1,2,3). The occurrence of PCV2 and TTV genotype infections could be related to differences in pathogenesis or animal origin. According to Horlen et al (2007) both PCV2a and PCV2b genotypes were found in isolates from PMWS-affected pigs. In this study the presence of PCV2a and PCV2b in group I needs more investigation since they were absent in group II. The PCV2a could be an antecessor in the primary infection or related to abortion or fetus anomalies when in association with PPV and TTV2. The presence of TTV1 and TTV2 in both groups was high, essentially the TTV2. The analysis of infection sequence in animals with PMWS can give interesting clues for the role of the TTV during infection. Taira et al. (2009) using nested PCR found positive results for TTV1 and TTV2 in different organs form PMWS swine. More studies are required to determine if other endogenous or exogenous cofactors are involved in the pathogenesis of PCV2a and PCV2b. In conclusion it can be stated that PCV2b and PCV2b/TTV2 were frequently observed and co-infection with bacteria were common in swine with PMWS.

Instituto de Pesquisas Veterinárias Especializadas Ltda (IPEVE), Belo Horizonte, MG, Brazil

Introduction

The porcine circovirus diseases (PCVD) rarely occur as a result of the infection from one infectious agent, like PCV-2, alone. Usually several pathogens work together with the PCV-2 to break down defenses leaving the respiratory tract susceptible to pathogenic organisms. The PCV-2 has been identified in association with lesions in swines with porcine respiratory disease complex (PRDC). The aim of this work was to investigate the presence and distribution of PRDC bacterial coinfections in swines with clinical signals of the PCVD among Brazilian states.

Materials and Methods

Samples from 150 swine lungs with clinical symptoms of PCVD were studied. The samples were originally from field infections collected in 9 different swine-producing Brazilian states and have been previously confirmed to be positive for PCV-2 by PCR. All samples were submitted to microbiological standard tests for bacteria isolation and identification. Histopathological evaluation was carried out in 71 of the 150 samples and microscopic lesions were correlated with presence or absence of associated bacteria.

Results

Forty-two samples (28.0%) did not present any bacterial agent associated. In 108 (72%) samples at least one of the following agents was detected: P. multocida type A, P. multocida type D, B. bronchiseptica, H. parasuis, A. pleuropneumoniae, S. suis, E. coli. Sixty-seven samples (44.7%) presented one bacterial agent only, while 41 (27.3%) had more than one. The bacterial frequencies among the 67 samples were: 18/67 (26.9%) of S. suis, 7/67 (10.4%) of A. pleuropneumoniae, 22/67 (32.8%) of P. multocida type A, 6/67 (9.0%) of P. multocida type D, 3/67 (4.5%) of B. bronchiseptica, 7/67 (10.4%) of H. parasuis and 4/67 (6.0%) of E. coli. In the 41 samples with more than one of these bacteria, 24 different pathogens combinations were observed. The distribution of the bacteria in the Brazilian states studied showed diversity. The most prevalent bacteria associations were A. pleuropneumoniae and P. multocida type A; S. suis and P. multocida type A; S. suis and P. multocida type A and H. parasuis. Minas Gerais state showed the major prevalence of bacterial associations. The pulmonary histopathological lesions observed in samples were grouped as: (i) positive association with bacterial infections (47.89%), (ii) negative for bacterial association (52.11%). In the negative group, interstitial pneumonia with thickening of interalveolar walls and inflammatory cells in the alveoli were observed. It was also observed peribronchial and perivascular lymphohistiocytic infiltrates with syncytial cells. In the positive group, pulmonary lesions similar to those from the negative group were observed in 12 samples, while pulmonary lesions with characteristics of bacterial infection were seen in 22 samples.

Discussion

In the present study we observed a wide dispersion of pulmonary bacteria across different swine-producing farms from nine Brazilian states. Furthermore, the frequency of association between PCV-2 and PRDC bacteria was high, suggesting that the PCV-2 immunosuppression can facilitate these pathogens infection. The results confirm that the respiratory infections are widely spread out among Brazilian herds. Our data are in accordance with previous studies that indicated that pulmonary lesions associated with PRDC had prevalence taxes of the 19.7% to 75.7% in swine from different Brazilian states. The high number of different bacterial associations with PCV-2 found reinforce current literature data that demonstrated that the PRDC is a multifactorial disease. It is also important to observe that Minas Gerais is one of the major swine producer states and that its herds are distributed for different states which could explain the dispersion of PCV-2 infection with bacterial associate.

Introduction
An increase in size of the superficial inguinal lymph node is described as a clinical sign of Post-weaning Multisystemic Wasting Syndrome (PMWS). However, examination of the physical properties of the superficial inguinal lymph node indicates that rather than enlargement, the lymph node becomes more prominent as the “flare fat”, around the lymph node, disappears with the loss of weight associated with PMWS and other Porcine Circovirus Diseases (PCVD). In Porcine Dermatitis and Nephropathy Syndrome (PDNS), there was a true enlargement of the superficial inguinal lymph node both in terms of length, width and depth.
It is essential, when describing pathology, to avoid terms like “enlargement” without providing physical dimensions.

Materials and Methods
Normal population: Superficial inguinal lymph nodes were collected from a slaughterhouse or a feed-trial in Western Australia from a variety of live-weight pigs. All the pigs were passed suitable for human consumption or had no gross pathology. The lymph nodes were measured for their length, width and depth. Western Australia was selected because the area is free of many viral pathogens that cause changes in lymph node sizes – particularly Porcine Reproductive and Respiratory Syndrome virus.

Number of animals in each normal group:
10 to 30 kg live weight: 107 pigs
40 to 60 kg live weight: 312 pigs
90 to 110 kg live weight: 125 pigs

Abnormal population: Superficial inguinal lymph nodes were collected from cases of PMWS, PCVAD and PDNS.
Porcine Circovirus Associated Disease (PCVAD) is defined as pigs from farms where there was a PCVAD score ≥1 but there was no clinical evidence of PMWS on the farm.
Count: PCVAD: 33 pigs; PMWS: 17 pigs; PDNS: 10 pigs

Approximate age of the pigs in each group and normal weight range for the age group
PCVAD: 8 to 10 weeks 22 to 30 kg
PMWS: 8 to 16 weeks 22 to 65 kg
PDNS: 16 to 20 weeks 65 to 95 kg

The relative length of the superficial inguinal lymph node in the normal pig and various abnormal states

Discussion
The normal inguinal lymph node increases in size as the pig grows from a mean length of 38 mm in pigs less than 30 kg to 61 mm in the 110 kg finisher pig.
The superficial inguinal lymph node is quite large and is normally virtually invisible; covered by fat.
In cases of cachexia the ‘flare fat’ disappears around the superficial inguinal lymph node, which then becomes clinically very apparent.
In cases of PCVAD and PMWS the lymph node is not enlarged, when compared to the normal pig. However, it becomes more prominent because the surrounding “flare fat” is lost.
The superficial inguinal lymph node is enlarged – in terms of length, breath and depth in cases of PDNS. P<0.001. As the tissues of the skin around the perineal region are infected in cases of PDNS, an enlargement of the draining lymph node is to be expected.

Acute Pulmonary Edema (APE), a New Porcine Circovirus Associated Disease??

Kara M. Theis1 Steve Henry2 Lisa Tokach2
1. University of Minnesota, Lino Lakes, MN, USA; 2. Abilene Animal Hospital, Abilene, KS, USA

Introduction
We are investigating an on-going case involving porcine circovirus (PCV) and PRRS that has striking clinical differences compared to outbreaks before the advent of circovirus vaccines. Historically clinical circovirus is seen in 8-20 week old pigs with lesions of depleted lymphoid tissue in many organs. Gross pathology is varied and the clinical course is chronic, debilitating and progressive. Implementation of PCV vaccine decreased morbidity and mortality dramatically. In our case the clinical presentation differs with acute death pigs in good body condition. The consistent gross lesion, severe interlobular pulmonary edema, is distinguishing. The affected animals have been vaccinated with a product and protocol that has proven highly effective in the past. This particular animal group is suffering from severe disease while cohort animals, raised on other sites, remain normal.

At 21 days of age weaned pigs from two separate PRRS negative breed-to-Wean farms move to one of 20 separate growing facilities, either stand-alone nurseries or nursery-finisher sites. Pigs in nine of the 20 sites remain PRRS negative through their growth period while PRRS infection and seroconversion frequently occurs at 8-10 weeks of age in the other eleven sites. APE associated losses occur in both PRRS positive and PRRS negative populations. The 20 sites are fed by six separate and non-affiliated feed mills. All grain used has been 2008 grain sources. The four affected sites are fed by three different mills. None of the affected sites are located near one another. All pigs were immunized at four and seven weeks of age with Circumvent PCV vaccine (Intervet Schering-Plough Animal Health) Immunization protocol has remained unchanged since 2007 and has been highly efficacious. Groups affected range from 7-14 weeks of age at onset of clinical signs. In severely affected lots mortality ranged from 13-21%. Predominantly the mortality is acute and associated with APE, however some chronic and debilitated animals developed in certain groups.

Materials and Methods
Fresh and fixed tissues were collected from seven pigs of seven weeks of age and weighing approximately 35 lbs. Three pigs were found dead the morning of necropsy. The four remaining pigs were selected as “clinically normal” controls based on clinical evaluation. None of the other pigs in this four room nursery were coughing. They were clinically normal and were highly active. Pigs were sedated with 1ml of pentobarbital via jugular venapuncture. Seventy mls of blood was collected into 10ml serum separator tubes via an intracardiac stick. Animals were then euthanized with 1.5 mls of pentobarbital and necropsied. Gross pathology, histopathology including IHC for Circovirus, differential and quantitative PCR for PCV and PRRS, IFA antibody titers for PCV, viral genome sequencing and compliance antibody differential sampling with baculovirus antibody testing was conducted.

Results and Discussion
On the basis of the viral genome sequencing the circovirus and PRRS viruses present are very similar to those historically known to this region and production flow. Compliance antibody evaluations exhibited responses to vaccination and several groups that exhibited disease appeared to have been well vaccinated based on compliance testing. Through IHC, histopathology and PCR testing circovirus was also demonstrated as the agent associated with the pulmonary pathology, including necrotizing vasculitis, which is not commonly seen with PCV2. The concentrations of circovirus detected in the tissue and the serum were considered extremely high in most cases with Ct <10 for many tissues and Ct < 20 for serum pools.

While interlobular edema is an occasional manifestation of circovirus the pulmonary edema is not. Noncardiogenic pulmonary edema is characterized by diffuse alveolar damage, increased capillary permeability and accumulation of protein rich fluid in the alveoli. The fluid accumulation ultimately results in decreasing oxygenation. This can be caused by either direct alveolar damage i.e. diffuse pulmonary infection or indirectly i.e. severe sepsis resulting from the over expression of the normal inflammatory response. Commonly all of this occurs within 24 hrs manifesting as respiratory failure and acute death a,b.

The consistent lesions of acute death, interlobular edema, necrotizing vasculitis pleural transudate accompanied by very high concentrations of virus in tissues appears clinically to be a new manifestation of PCV2b viremia. Several laboratory tests are still pending.

Introduction and Objectives
Porcine Circovirus type 2 (PCV2) is a worldwide endemic viral pathogen of swine, associated with Postweaning Multisystemic Wasting Syndrome (PMWS). PCV2 infection is essential to the development of PMWS, but other co-factors can influence the evolution of PCV2 infection (1). Between these co-factors there are co-pathogens. An enhancement of PCV2 viral load, severity of the lesions and incidence of PMWS have been highlighted when PCV2 co-exists with other swine pathogens like PRRSV or Mycoplasma hyopneumoniae (2,3). Through the diagnostic outcome of investigations, carried out between January 2007 and August 2009 at IZSLER-Brescia, the aim was to determine the prevalence of several viral and bacterial swine pathogens, frequently associated with PCV2 in PMWS cases.

Material and Methods
193 PMWS affected pigs, from 92 farms, were investigated for other swine pathogens. For diagnosis of PMWS was applied a protocol according to Opriessnig et al. 2007(1). For PRRSV was applied a reaction One-Step RT-PCR multiplex with specific primers, described by Persia et al., 2001(4). For SIV a RT-PCR according to the protocol described by Spackman et al., 2002(5). For Mycoplasma hyopneumoniae a PCR according to the protocol described by Stakenborg et al., 2006(6). For Lawsonia intracellularis a PCR as described by Jone et al., 1993(7). For Haemophilus parasuis was applied a PCR described by Angen et al., 2007(8). Isolation of bacterial agents was performed by routine culture procedures.

Results and Discussion
The viral and bacterial pathogens identified in PMWS affected pigs are reported in the table below.

The co-pathogens association are shown in Graphic 1.
A preliminary study of the effects of treating diarrhoeic pigs with oxytetracycline on shedding of Porcine Circovirus Type 2 and Lawsonia intracellularis

Introduction
There is pressure to minimize antibiotic use in food-producing animals due to the risks of selecting resistant strains of bacteria. In Denmark, pressure to reduce macrolide antibiotics has resulted in a tendency to increase the use of tetracyclines.1 Most antibiotics are used to treat intestinal infections of grower (>10 weeks) pigs, thought to be caused by Lawsonia intracellularis (L. intracellularis) and/or Porcine Circovirus Type 2 (PCV2). Our hypothesis was that individual treatment of diarrhoeic pigs for three days with an oxytetracycline antibiotic would reduce diarrhoea and the faecal shedding of L. intracellularis and/or PCV2.

Materials and Methods
Forty grower pigs were selected on each of six farms (total of 240 pigs) in Denmark for a case-control study. Each pig was ear-tagged and assessed for faecal consistency (normal, loose, fluid). Approximately half of the pigs had loose or fluid faeces and were classed as ‘diarrhoeic’. Faecal samples were collected from each pig and tested using real-time PCR specific for PCV2 and L. intracellularis.2,3 Half of the pigs in each group were randomly selected on Day 1 and injected for three consecutive days with oxytetracycline (Engemycin, Intervet). Pigs were re-assessed on Day 4, when repeat faecal samples were collected. The effect of oxytetracycline treatment on faecal PCV2 quantity (negative/low versus moderate/massive), and L. intracellularis bacterial quantity (negative/low versus moderate/massive) on Day 4 were analysed, with diarrhoea status (+/-), PCV2 quantity and L. intracellularis quantity on Day 1 included as fixed effects. All analyses were conducted using generalized linear mixed models, with pen and farm as random effects (Genstat 11th edition).

Results
Two farms had no pigs with moderate/massive PCV2 results in faeces. One farm had no pigs with a negative/low faecal PCV2 result. Two farms had pigs with no moderate/massive L. intracellularis results. There appeared to be within-pen clustering of PCV2 infection on Day 1, with all or no pigs in some pens being infected. This was also true for L. intracellularis on Day 4. Hence, pen was removed from subsequent analyses involving these variables. Pigs that had diarrhoea on Day 1 and had not been treated with oxytetracycline had 2.6 (95% CI 2.3, 3.2) times the odds of having diarrhoea on Day 4 than pigs that were treated (p<0.05). The farms where no pigs had moderate/massive quantities of PCV2 and/or L. intracellularis were excluded from analyses of associations between the two pathogens. Oxytetracycline treatment and PCV2 quantity on Day 1 did not affect PCV2 quantity on Day 4 (p>0.05). There were no significant associations between the quantities of L. intracellularis bacteria on Days 1 and 4 (p>0.05). However, treated pigs had 0.076 (95% CI 0.03, 0.19) times the odds of having moderate/massive quantities of L. intracellularis on Day 4 than non-treated pigs.

Discussion
These preliminary results suggest that oxytetracycline treatment of growing pigs did not affect the quantity of PCV2 shed in faeces. Treating pigs for three consecutive days with injectable oxytetracycline reduced the incidence of diarrhoea and the quantity of L. intracellularis shed in faeces, suggesting that this pathogen played a role in causing diarrhoea, and that the treatment was effective.

Presence of porcine circovirus type 2, Lawsonia intracellularis and Brachyspira hyodysenteriae in pigs with diarrhoea

Anna Szczotka; Jacek Zmudzki; Zygmunt Pejsak; Tomasz Stadejek
National Veterinary Research Institute, Pulawy, Poland

Introduction
The aim of the study was to analyze the presence of porcine circovirus type 2 (PCV2) in cases of antibiotic non-responsive diarrhoea and to evaluate the possible role of the virus in development of enteritis in pigs. For differential diagnosis identification of Lawsonia intracellularis (L. intracellularis) and Brachyspira hyodysenteriae (B. hyodysenteriae) was performed.

Materials and Methods
Internal organs and feces were collected from 76 pigs, 5 – 19 weeks old, from 50 farrow-to-finish farms, PMWS-positive or PMWS-suspected. Sections of lymph nodes and intestines (ileum, caecum and colon) were analyzed for presence of PCV2 DNA by in situ hybridization test (ISH) (2). They were also hematoxilin-eosin (HE) stained for standard histopathological examination. Additionally, fecal samples were tested for presence of B. hyodysenteriae and L. intracellularis by PCR (3).

Results
In samples from 37 pigs, 10 – 17 weeks old, large amounts of PCV2 DNA, typical for PMWS, were detected in lymph nodes by ISH. In this group, in samples from 19 pigs, PCV2 was also found in abundant amount in samples of ileum. The remaining 18 pigs, PCV2-positive in lymph nodes, were negative in ileum. In samples from only 1 animal lymph nodes were negative for PCV2 in ISH, but virus was detected in considerable amount in ileum. In HE stained sections of lymph nodes histopathological lesions characteristic for PMWS were identified. Similar lesions were observed in PCV2-positive samples of ileum. Seventy samples of feces were negative in PCR for B. hyodysenteriae and L. intracellularis. DNA of L. intracellularis was found in feces from 3 pigs and mixed infection caused by both bacteria was detected in 3 animals.

Discussion
According to the obtained results in PMWS-affected pigs similar lesions could be observed both in lymph nodes and in ileum and they correlate with clinical outcome of disease. Also, it was found that presence of PCV2 in ileum could be correlated with diarrhoea in PMWS-free animal, which confirms that the emergence of this virus as an intestinal pathogen may represent a new phenomenon (1). In the animals negative for B. hyodysenteriae and L. intracellularis and PCV2 other causative agents of diarrhoea should be considered. Further investigation on larger number of samples needs to be performed to confirm the role of PCV2 as an etiological agent of diarrhoea in pigs.

Co-infection between porcine circovirus type 1 (PCV1) and genogroups 1 and 2 of porcine torque teno virus (TTV) in fetuses naturally infected by porcine circovirus type 2 (PCV2)

1. Virus and Prion Diseases Research Unit, NADC, ARS, USDA, Ames, IA, USA; 2. Embrapa Swine and Poultry Research Center, Animal Healthy Laboratory, Concordia, SC, Brazil; 3. Agroveterinarian Science Center - CAV – University of Santa Catarina State – UDESC, Lages, SC, Brazil; 4. College of Agronomy and Veterinary Medicine, University of Passo Fundo, Passo Fundo, RS, Brazil; 5. Oswaldo Cruz Institute, Rio de Janeiro, Brazil

Introduction
Porcine circovirus 2 (PCV2) associated diseases (PCVAD) includes reproductive failures (1). PCV2 DNA has been detected by nested-PCR in organs of fetuses naturally infected (8,5). In contrast PCV1 has not been associated with pathologies in pigs. Another DNA circular virus, porcine torque teno virus has also been detected in swine, with at least two genogroups, TTV1 and TTV2 (7). Recent studies have shown a possible role of TTV in increasing clinical signs and severity of lesions caused by PCV2 on piglets (3). The objective of this work is to study the co-infection of both porcine circular DNA viruses, TTV1, TTV2 and PCV1 in organs from fetuses naturally infected by PCV2, aiming to verify the importance of them.

Material and Methods
Organs from 29 fetuses, previously tested for PCV2, from 11 swine farms, were processed to detect PCV1, TTV1 and TTV2 nucleic acids. Samples of heart, lung, liver, kidney, lymphoid organs and nervous tissues were tested by nested-PCR. Nested-PCR reactions were performed using specific primers to detect sequences of PCV1, TTV1 and TTV2 as previously described (3, 4).

Results
Organs samples of 29 fetuses were tested by nested-PCR and PCV1 DNA was detected in 8 (27.6%) of them. In addition, TTV1 and TTV2 was detected in 7 (24.1%) and 24 (82.8%) fetuses respectively (Figure 1), and viral sequences were found in several tested organs.

Discussion
These results show the occurrence of TTV1 and TTV2 in analyzed samples, indicating its importance of TTV co-infections with PCV2. In swine, TTV alone has not showed to be pathogenic, but, its role in co-infections with other pathogens has been investigated.

Recent studies showed the first indications of TTV in utero transmission to piglets (6). Other studies claim that TTV is widely spread in Spain and could be associated with PCV2 infections (5). Porcine TTV infections are also widespread in herds of the USA, Canada, China, Korea and Thailand (9). Multiple infections of novel four U.S prototypes of porcine TTV in a single pig also have reported (10), suggesting that these co-infections are important for disease severity. The co-infection of TTV and PCV2 in piglets from Brazilian herds has also been reported (2). These findings raise the question of the importance of PCV and TTV co-infection in the pathology of PCVAD associated reproductive failures and vertical transmission in swine farms.

**Introduction**

Porcine Circovirus type 2-associated reproductive failure (PCV2-RF) is characterized by increased abortions, stillbirths and neonatal mortality. Transplacental transmission is acknowledged and the most consistent lesion in the fetus of PCV2-RF is a non-suppurative myocarditis with intralesional PCV2. PCV2-RF has been described without co-infection with porcine parvovirus (PPV), encephalomyocarditis virus (EMCV) and porcine respiratory and reproductive syndrome virus (PRRSV). The aim of the present work was to determine PCV2 role in RF development.

**Materials and Methods**

In order to assess the role of PCV2 in reproductive failure in Mexico, 107 hearts (predominantly fetal samples) with presumptive diagnosis of PCV-RF were evaluated by standard procedures of histopathology and in-situ hybridization (ISH) using a digoxigenin-labelled PCR-derived probe specific for PCV2. Cases were grouped as follows: Fetuses with myocarditis (Group 1), fetuses without myocarditis (Group 2), stillborns/neonates with myocarditis (Group 3), and stillborns/neonates without myocarditis (Group 4). Among these 107 cases, 50 were selected to perform nested PCR from paraffin-embedded samples. The data were analyzed by Chi-square test, Cramer coefficient and analysis of variance for categorical data. The later was used to evaluate cardiac lesion degree and PCV2 distribution.

**Results**

Microscopically, 48 cases (45%) exhibited non-suppurative myocarditis, of which 35/48 were PCV2 positive (73% of cases with myocarditis, 32.7% overall) and 13 were PCV2 negative (27% of cases with myocarditis, 12.4% overall). There were 5 (4.67%) fetal cases PCV2 positive by ISH with no myocarditis. A diagnosis of myocarditis and a positive ISH showed a high relationship (J2<0.005 y Cramer coefficient= 0.64) revealing that both tests are comparable for disease diagnosis. Twenty out of 107 additional cases, regardless of myocarditis, were detected by PCR, increasing to 55 (51.4%) the cases positive to PCV2, 42/107 (38.75%) with myocarditis and 13 cases (9 fetal) without myocarditis. In total, 50 fetal cases were PCV2 positive. The myocarditis severity was mild to moderate in groups 3 y 4, and moderate to severe in fetal tissues. The lesion severity was statistically significant, showing values of P=0.04 y P=0.0001 for 1-3 and 2-4 groups, respectively. The ISH signals were mild, variable sized and randomly distributed (Figures 4-5), precluding a statistical analysis.

**Discussion**

The use of histopathology as screening test is highly recommended but association to PCV2-RF must be confirmed by ISH and/or PCR. Few viral agents produce both non-suppurative myocarditis and RF. Therefore, 33-39% cases are compatible to PCV2-RF, based on criteria diagnosis, and the vertical transmission was of 46.72% (50/107 fetal samples) which is higher than previous reports. Cases with myocarditis but PCV2-negative suggest a separate, unknown etiology. Furthermore, no other viruses could be examined since only cardiac tissues were submitted, Therefore, co-infection cannot be entirely excluded.

PCV2 relies on cell mitotic activity and DNA polymerase availability. Our findings are in agreement, because the lesion severity was age-dependent. The ISH signals suggest low viral load. Thus, real-time PCR is being performed to assess the relationship between lesion severity and viral load.

Natural infection of porcine circovirus type 2 (PCV2) in fetuses from sows with reproductive failures

Giseli A. Ritterbusch1 Camila Sa Rocha2 Nelson Mores2 Neide L. Simon2 Janice R. Ciacci-Zanella1
1. Virus and Prion Diseases Research Unit, NADC, ARS, USDA, Ames, IA, USA; 2. Embrapa Swine and Poultry Research Center, Animal Healthy Laboratory, Concordia, SC, Brazil; 3. Agroveterinarian Science Center - CAV – University of Santa Catarina State – UDESC, Lages, SC, Brazil

Introduction
Porcine Circovirus Type 2 (PCV2), etiologic agent of PCVAD or PCV2 associated diseases, can cause reproductive failure in swine (1, 4, 5). PCV2 has been detected in farms with high occurrence of aborted, mummified and stillborn fetuses, and viral DNA and antigen has been detected by nested-PCR and immunohistochemistry (IHC), respectively, in organs from fetuses naturally infected (4,6). In order to study the pathogenesis of the disease in Brazilian swine herds, the objective of this work is to study the natural infection of PCV2 in organs of fetuses from sows with reproductive failures.

Material and Methods
Samples from field cases, as aborted fetuses, mummified, still-born and fragile piglets were collected and processed in order to detect PCV2 DNA and antigens. Samples were collected from 21 farms previously identified with occurrence of reproductive losses, and a total of 169 fetuses were necropsied. Fragments of organs, including heart, lungs, liver, kidney, lymphoid organs and nervous tissues were processed for viral and histopathological diagnostic. For viral isolation, DNA was extracted and nested-PCR reactions were performed using specific primers to detect sequences of PCV2 as previously described (3). For histopathological examination, organs were fixed in 10% buffered formalin and embedded in paraffin, sectioned at 5μm thick and stained with hematoxylin and eosin for light microscopical examination. Moreover, viral presence was confirmed by IHC, carried out as previously described (2) and performed in tissues that resulted positive by PCR.

Results
Organs samples of 169 fetuses were tested by nested-PCR and PCV2 DNA was detected in 29 (17.1%) of them. Viral sequences were found in several tested organs. Microscopic lesions were found in 15.4% of the samples, mainly on heart and lymphoid organs, with the presence of infiltration of inflammatory cells, syncytial cells and varying degrees of lymphocellular depletion. In addition, IHC was performed and viral antigen was detected in 17 out of 29 positive fetuses (58.6%).

Discussion
These results show the occurrence of natural infection of PCV2 in analyzed samples, confirming the importance of PCV2 infection in reproductive failures. Among the analyzed samples, heart was the organ where PCV2 DNA was most frequently detected, following by lymphoid organs and nervous tissues, which agree with results reported by others studies (5,6). Genomic sequencing analyses are underway to classify the different PCV2 isolates. By IHC staining it was observed a variable amount and distribution of viral antigen in tissues, and positive cells were found most commonly on macrophages (Figure 1). These findings raise the question of the importance of PCVAD associated reproductive failures and vertical transmission in swine farms.

Distribution of porcine parovirus type 2 (PPV2, Myanmar erythroivirus) and porcine hokovirus (PHoV) in pigs from post-weaning multisystemic wasting syndrome (PMWS)-affected and non-affected farms in archival samples from UK and Republic of Ireland

John McKillen1  John P. McKillen1  Michael McMenamy2 Irene McNair1 Gordon Allan1
1. Agri-Food & Biosciences Institute, Belfast, UK; 2. Department of Veterinary Science, The Queen’s University of Belfast, Belfast, UK

Introduction

In 2001 PPV21, a novel parvovirus related to the genus erythroivirus, family Paroviridae was detected in swine from Myanmar. PHoV2 is also a member of the family Paroviridae and along with bovine hokovirus (BHoV) and PARV4 form a distinct cluster within the family Paroviridae. This has been proposed as a separate genus, Hokovirus. Porcine circovirus type 2 (PCV2) is the causative agent of PMWS3. PMWS does not however, always occur in PCV2 infected pigs. It is likely that other agents may contribute to the development of PMWS. Here we investigate the distribution of PPV2 and PHoV in archival PMWS-affected and non-affected tissue and serum samples recovered from pigs in the UK and Republic of Ireland from 2000 to 2006.

Materials & Methods

44 sera samples were collected from pigs on PMWS-affected UK farms. Also tissues were taken from 64 PMWS-affected pigs and 55 non PMWS-affected pigs, from the UK and Republic of Ireland. Tissues included lung, liver, kidney, spleen and lymph nodes. Viral nucleic acids were extracted from sera and 10% homogenised tissue samples using Roche MagNA Pure LC. All tissue and sera samples were analysed by real-time QuantiTect SYBR Green I PCR for the presence of PPV2 and PHoV using in-house specific primers designed against deposited GenBank sequences. Between 1 and 4 tissues were tested for each animal. A selection of positive amplicons was cloned into TOPO TA vectors and sequenced using standard protocols. Sequences were compared to GenBank using nucleotide BLAST.

Results

With one exception all tissues tested positive in any positive animal. Generally PPV2 was present in significantly higher amounts than PHoV as judged by Ct values, as well as being more prevalent. Both PPV2 and PHoV were more prevalent in tissues of non-PMWS-affected pigs. Sequencing of the amplicons confirmed the specificity of the PCR. No data was available for sera from PMWS -ve farms. Tables 1 and 2 show the % of animals testing +ve for the two viruses in relation to their PMWS status.

Discussion

PHoV was detected in only 6.7% of tissue samples and 15.9% of sera samples tested in this study. In Hong Kong2 44.4% of porcine samples tested +ve for PHoV. PPV2 was detected in 39.5% of the tissues tested and 18.2% of the sera, as opposed to 10.5% of tested sera from Myanmar1. These preliminary studies suggest that the distribution of these viruses could be widespread and that the extent and geographical range should be further investigated. The significance of these viruses in terms of swine health is not known. Their role as potential pathogens or as co-factors in other disease complexes such as PMWS merits further investigation although higher prevalence in PMWS-affected animals and farms has not been shown in this study.

Reproductive failure associated to PCV2 and its distribution in the Mexican Republic

Victor Quintero; Yolanda Romero; Karina Enriquez; Lucia A. Garcia-Camacho
FESC-UNAM, Cuautitlán, MEX, Mexico

Introduction
Porcine circovirus type 2 (PCV2) has been associated to reproductive failure (RF) promoting increases of infertility abortions, stillborn, mummifications as well as a marked increase on pre-weaning mortality. The most consistent microscopic lesions are non suppurative miocarditis with perivascular and interstitial mononuclear infiltrates, degeneration and necrosis of myocytes and myocardium fibrosis. The association to PCV2-RF is confirmed by reproductive failure to PCV2 is by immunohistochemistry, in situ hybridization (ISH), and PCR in cardiac samples.

Material and methods
The aim of this work was to determine the non-suppurative myocarditis positivity and PCV2 status as well as the locality of origin of cases presented for histopathology diagnosis in the Pathology Department of FES-Cuautitlan, UNAM during the period of 2006-2008. The heart samples were formalin-fixed and paraffin-embedded for routine microscopic evaluation. The PCV2 detection from non-suppurative myocarditis positive cases was done by ISH using a specific digoxigenin-labelled PCR-derived probe.

Results
A total of 269 heart samples from fetuses and stillborn from 39 cases from different Mexican states were microscopically evaluated. The case distribution regarding origin, myocarditis positivity and PCV2 status is shown in Table 1. Microscopically, 120 cases (44.6%) exhibited varying degree of non-suppurative myocarditis, of which 100/120 were PCV2 positive (83.3%) by ISH. The lesions consisted of perivascular and/or interstitial accumulation of lymphocytes and macrophages, myocardial degeneration, necrosis, and/or fibrosis. Additionally, subepicardial and subendocardial congestion, edema and hemorrhage were observed. Concerning the sample origin, the states with higher case frequency, such as Veracruz and Jalisco, exhibited lower proportion of myocarditis.

Discussion
Our findings strongly support the role of PCV2 as a cause of RF in Mexican farms since PCV2 was detected throughout the country. In fact, PCV2 was present in the Mexican central states, such Guanajuato, Michoacan and Jalisco where are located the main pig production areas. Furthermore, the proportion of PCV2 in fetal and neonatal tissues is in agreement of reports elsewhere. In this study, no other viruses could be examined since the submitted samples were exclusively hearts. Therefore, co-infection cannot be entirely excluded. In fact, the low ratio of myocarditis and/or PCV2 positive cases in states with high case frequency suggests that the cause of abortion must have been different from PCV2. Thus, co-infection with other agents such as PRRSV, porcine parovirus, Aujeszky virus and porcine rubulavirus must be considered.

Detection of porcine single-stranded DNA viruses in reproductive organs of culled sows

Camila Sa Rocha², ³ Giseli A. Ritterbusch², ³ Nelson Mores³ Neide L. Simon³ Leonardo Diniz-Mendes⁴ Christian Niel⁴ Janice R. Ciacci-Zanella¹

1. Virus and Prion Diseases Research Unit, NADC, ARS, USDA, Ames, IA, USA; 2. Agroveterinarian Science Center - CAV – University of Santa Catarina State – UDESC, Lages, SC, Brazil; 3. Embrapa Swine and Poultry Research Center, Animal Healthy Laboratory, Concordia, SC, Brazil; 4. Oswaldo Cruz Institute, Rio de Janeiro, Brazil

Introduction

Several reasons determine the removal of sows from a swine herd. Sows are culled when they are considered unsuitable for further production and reproductive failure is the predominant cause, ranging between 13 – 49% of removals (1). Infectious causes of reproductive failures vary, however many can be due to viral agents (1). Among them the single stranded DNA (ss-DNA) viruses play an important role in the co-infections of these diseases. Porcine circovirus 2 or PCV2 (2), porcine parvovirus or PPV (7) and porcine torque teno virus (TTV) with at least two genogroups, TTV1 and TTV2 (3) have been identified in swine fetuses and sows tissues as the cause of infectious reproductive failures. Although a member of the Circoviridae family, PCV1 has not been associated with pathologies in pigs, but it is also an agent to be included in co-infections. Other viral agents, such as porcine reproductive and respiratory virus (PRRSV) can cause significant losses, but are not present in Brazilian swine herds (4). Thus, the objectives of this work is to detect the infection by porcine ssDNA viruses, PCV2, PCV1, PPV, TTV1 and TTV2 in reproductive organs of culled sows, aiming to verify the importance of them in those sites.

Material and Methods

Reproductive organs from 83 culled sows, from four slaughterhouses of Santa Catarina State, were collected. The reason of their removal was not particularly due to reproductive failures. A total of 71 samples of ovarian follicular fluid (OF) and 83 fragments of ovaries and 83 fragments of uterus were processed for DNA extraction followed by amplification of PCV2, PCV1, PPV, TTV1 and TTV2 nucleic acids. Nested-PCR reactions were performed using specific primers as previously described (5, 6, 7).

Results

Organs samples such as ovaries, uterus and ovarian follicular fluids (OF) of 83 culled sows were tested individually by nested-PCR for ssDNA viral amplification of PCV2, PCV1, PPV and TTVs. PCV1 DNA was detected in 14 (16.9%) of sows organs. Nucleic acids of PCV2 were amplified from 5 (6.0%) sows. TTV1 and TTV2 were detected in 25 (30.1%) and 41 (49.3%) sows respectively. For TTV2 particularly, 27 samples (38%) tested positive in OF; 19 (23%) in ovaries and 14 (17%) in uterus. Viral sequences of PPV were amplified in 6 (7.2%) sows. In some cases, the occurrence of co-infections between viral agents in sampled sows was observed.

Discussion

The present study demonstrates the occurrence of infection of porcine ssDNA viruses in reproductive organs of culled sows. These results show higher prevalence of TTV1 and TTV2 in analyzed samples, indicating its importance, mainly in co-infections with PCV2. TTV2 is more frequently related to PCV2 associated diseases (PCVAD) compared to TTV1 in Spain (77% prevalence) (5). Other reports indicate that TTV1 viral infection facilitates PCVAD (8). In swine, TTV alone has not showed to be pathogenic, but, its role in co-infections with other pathogens has been investigated. Recent studies showed the first indications of TTV in utero transmission to piglets (3). PPV has been associated with PCV2 and other swine virus such as PRRSV in samples of piglets born from sows with reproductive failure from China and Korea (9, 10). These findings raise the question of the importance of these viral infections in the pathology of reproductive failures and vertical transmission in swine.

Diagnostic of postweaning multisystemic wasting syndrome in pigs in Cuba

Patricia Dominguez Perez2 Humberto Ramirez-Mendoza1 Carlos Bulnes Goicochea2 Lester Josue Perez 2 Maria Iriam Percedo 2 Daine Chong2 Jose Francisco Rivera-Benitez1
1. Departamento de Microbiologia E Immunologia, FMVZ-UNAM, Distrito Federal, DF, Mexico;
2. Centro Nacional de Sanidad Agropecuaria, La Habana, Cuba

Introduction
Porcine circovirus diseases (PCVDs) are nowadays considered as a significant international problem due to increased mortality rates and reduced feed conversion efficiency in weanling and fattening pigs at the worldwide (Segalés et al., 2005). The Post-weaning multisystemic wasting syndrome PMWS is economically the most important disease included within this group. This new disease syndrome was firstly identified in Canada in 1991 (Clark, 1997; Harding, 1997) since then, the PWMS has been reported in many part of the word (LeCann et al., 1997; Segalés et al., 1997; Kennedy et al., 1998).

Materials and Methods
Thirty three pigs from five farms were investigated. Clinical signs evaluated included body condition, presence of respiratory and digestive clinical signs (coughing, dyspnea and diarrhoea), behaviour (depression), skin pallor, and enlargement of superficial inguinal lymph nodes. The farms were located in three different provinces of Cuba. Affected pigs were aged 7–15 weeks. Morbidity on the five farms ranged from 10–25%; mortality was at least 50% of affected animals on all farms. Samples of tonsil, lung, kidney, spleen, jejunum, ileum, colon, liver and lymph nodes (including superficial inguinal and mesenteric) were collected and fixed by immersion in 10% neutral buffered formalin. One section was processed for routine histopathology and stained with hematoxylin and eosin. The second tissue section was processed for PCV2 nucleic acid detection by in situ hybridization (ISH). On the other hand the other section was processed for immunohistochemistry. Tissues were evaluated for presence or absence of the PMWS (Segalés et al., 2005) specific lesions.

Results
The discoveries anatomicopathology included the widespread increase of the lymph nodes, especially superficial inguinal and mesenteric, witnesses of whitish diffuse stains in the liver and kidneys and, consolidation of the lobes lung. Histopathological changes were characterised by depletion of lymphocytes in the interfollicular areas and follicular centres. Infiltration by macrophage and multinucleate giant cells were also observed in the lymph nodes.

Porcine circovirus (PCV-2) antigen and nucleic acid were regularly found in lymphoid organs. In lymph nodes, depletion was observed within lymphoid follicles or in the paracortical zones. PCV-2 antigen was detected in 23 pigs. In all tissues examined was most frequently seen in the cytoplasm of cells. Nuclear labelling was less commonly seen but occasionally appeared to be almost as abundant as cytoplasmic labelling. The smooth muscle trabeculae of the spleen were occasionally labelled. PCV-2 nucleic acid was detected in most of the pigs was found mostly in the cytoplasm of infected cells, and to a lesser extent in the nucleus.

Discussion
This is the first diagnostic of the PMWS in Cuba, based on all three accepted diagnostic criteria (Segalés et al., 2005) for the case definition of this disease syndrome. The pigs evaluated showed the clinical signs compatible with this illness. Besides, lesions on lymphoid tissues were found. Moreover, the presence of the PCV2 within these lesions in moderate or high amounts of the virus was observed. This study describes the pathological findings in 23 natural cases of PMWS, together with the tissue distribution of PCV antigen and nucleic acid. Pigs were classified as cases of PMWS on the basis of macroscopic and microscopic lesions, and the detection of PCV antigen or nucleic acid (Segalés et al., 1997).

In Cuba, PCV2 infections of the swine herds have been described recently (Pérez et al., 2009). In addition, co-infection PCV2/PPV in several farms of the different geographic region of the country was found (Pérez et al., 2009). On the other hand, classical swine fever is an endemic disease in Cuba. The use of vaccination is an important tool for combat against outbreaks of this disease. Nevertheless, if the vaccinations against classical swine fever virus can act as trigger fact of PMWS will be needed to be explained.

Setor de Virologia, Instituto de Pesquisas Veterinarias Desidério Finamor, RS, Porto Alegre, RS, Brazil

Introduction

Porcine circovirus type 2 (PCV2) is ubiquitous in swine herds over the world. It is associated with different disease and syndromes in pigs mainly to postweaning multisystemic wasting syndrome (PMWS). In Brazil, PCV2 was first identified in South region, in 2000 and in other regions later on. All Brazilian studies were conducted in commercial and intensive raising systems animals (Ciacci-Zanella et al., 2003; Ruiz et al., 2004). In peripheral areas of large cities in Brazil, it is common to create a few pig herds (backyard pigs), for own consumption, under poor hygienic and sanitary conditions and in close contact with others animals species and humans. This swine population is a unique type of extensive raising swine system (ERSS). At our knowledge, no other study was done to verify PCV2 infection in these swine population. The present study was performed to identify PCV2 DNA in clinical specimens of pigs in Goiás State, Brazil ERSS’s.

Material and Methods

A total of 200 serum samples from swine of different age groups were collected from 25 ERSS in Goiás state. Tissue samples (lymph nodes, lungs, liver, brain, kidney and spleen) from 5 pigs with growth impairment and 6 pigs with signs of neurological disease were also included. Viral DNA was extracted with standard phenol-chloroform-isomyl alcohol extraction procedure. Previous described specific primers to ORF2 region of PCV2 [F5’-CGGATATTGTAGTCCTGGTCG-3’] and [R5’-ACTGTCAAGGTCATCACCACAGTC-3’] and PCR conditions were used for DNA PCV2 identification (Kim et al., 2001). A fragment of 480pb length was expected.

Results and Discussion

Out of the serum samples, 57 (28.5%) were positive. This frequency is lower than that observed in other studies (Casalmiglia et al., 2002; Grau-Roma et al., 2008) although it may represent the occurrence of PCV2 infection in this particular type of swine herd. Seven (63.6%) of the eleven animals tested showed positivity in at least one tissue sample. Viral DNA was found in inguinal nodes (6/7), lung (1/7) and kidney (1/7). Other authors also found high frequency of identification of PCV2 DNA in inguinal lymph nodes and assert that they are one the main targets for PCV2 replication (Yu et al., 2007). Despite viral DNA had been found in two fragments of pigs with growth impairment it is not enough to ensure the occurrence the syndrome. This also should be associated with clinical signs and pathological findings (Segalés et al., 2003). The results here presented may point out that PCV2 occur in pigs under extensive raising system in Goiás, Brazil.

Introduction
Torque Teno virus (TTV) is a non-enveloped, circular, single stranded DNA virus that may infect human, non-primate and domestic species including swine. Two TTV genogroups (TTV1 and TTV2) have been described in pigs. TTV is considered non-pathogenic, but a recent study has shown an increased prevalence of TTV2 in PCV2-associated diseases compared to non-affected ones (2,3). In Brazil PCV2-associated disease is expected to diminish with the introduction of PCV2 vaccination. However, PCV2-associated disease is still a problem in swine herds. Since the main virus, PRRS, involved in the co-infection of PCV2 to the development of the disease, is absent in Brazil, others agents became important. Nowadays, there are few information about TTV in Brazilian swine herd. Therefore, the aim of this work is to describe, for first time, the detection of co-infections of TTV2 and PCV2 in a high health swine herd.

Materials and Methods
Twenty and six serum samples were collected from sows from a high health herd located in São Paulo state, Brazil. DNA was extracted from serum using the phenol:chloroform Proteinase K protocols. TTV DNA was amplified a fragment of 250 bp using a PCR with primers targeting two conserved domains within an untranslated region of the viral genome (4). The detection of PCV-2 was performed by PCR using primers Fa/Ra that amplify a 476 bp fragment (1). One sample was randomly selected and sequenced. Nucleotide sequences were aligned with sequences contained at the GenBank database of the swine TTV and phylogenetic tree constructed.

Results
TTV2 was detected in 14 (58.3 %) out of the 24 serum samples examined. Among the 14 TTV2 positive samples, five (5/9) was co-infected with PCV2. PCV2 alone was detected in five sow serum samples (Fig. 1). The alignment of the TTV2 sequence obtained in this study showed nucleotide and amino acid identities values of 91.6 % to 82.4 % and 61.0 to 64.6 % with available GenBank sequences of TTV2 and TTV1, respectively. A Neighbour-Joining tree was assembled and showed that this sequence had been classified TTV2 group (Fig. 2).

Discussion
This is the first report of TTV-2 and PCV2 co-infections in Brazilians pigs. The alignment of one sample confirms that the TTV detected belongs to group 2. These results, also, demonstrated that TTV2 is circulating in high health swine herd in Brazil. Previous research showed higher prevalence of TTV2 in PMWS-affected pigs than in healthy ones (2). The involvement of TTV2 in the development of diseases associated with PCV2 is not clear, but the absence of PRRS in Brazil and the low detection of PPV in PCV2-associated disease, make TTV a possible candidate to be involved in disease cases.

Evaluation of the Ct values of non-quantitative real time RT-PCR as a proxy for determining PRRS viral load and its potential for monitoring swine populations, areas and regions

Dale Polson; Enrique Mondaca; Kent Doolittle; Greg Hartsook; Eric Vaughn
Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA

Introduction
The temporal frequency and dynamic rate with which PRRS virus (PRRSv) transmits within and among swine populations is related to: [1] the inherent infectiousness of a particular PRRS viral isolate, [2] a plethora of environmental factors that influence contact events and rates between infected and susceptible animals, and [3] host animal factors which enable or impede the occurrence of infection events and the resultant magnitude and duration of further transmission risk. Thus, one key component of PRRSv transmission risk within a population would be the magnitude and duration of viral presence occurring within and emanating from infected pigs within a population. In turn, transmission risk among populations would be influenced by the magnitude and duration of viral presence occurring within and emanating from infected populations within areas, regions, flows and networks. The pig and population viral magnitudes and durations will be termed as “viral load”. To monitor transmission risk of PRRSv within and among areas, regions, flows and networks – as well as assess the impact of pig, population and area/regional-scale interventions – requires a means with which to reasonably estimate “viral load”.

Estimation and monitoring of “viral load” in human medicine has moved beyond the confines of experimental research application into routine operational use, having become a standard method with which to monitor the care of HIV patients and effectiveness of antiretroviral therapies. As in human medicine, monitoring of PRRS viral load holds potential for routine operational use to monitor the PRRS-related ‘care’ of populations, areas/regions and networks; and to assess the effectiveness of PRRS control and elimination interventions.

For PRRSv, quantitative RT-PCR (qRT-PCR) is currently used in a relatively limited manner to quantify viral load of experimentally challenged pigs. One factor that has limited broadening the use of qRT-PCR to a more routine operational use is the assay’s cost and difficulty with its interpretation. In contrast, the result of a non-quantitative real time RT-PCR assay (rtRT-PCR) is simply reported as a Ct (cycle threshold) value. Although not technically a quantitative measure, Ct values have been used as a means with which to quantify a sample’s genetic material.

Materials and Methods
Serum samples from three experimental PRRSv inoculation studies were obtained. Both PRRS qRT-PCR (Lab A) and rtRT-PCR Ct (Lab B) testing were done on all samples and the results compared.

Results

Figure 1: Scatterplot of 599 paired PRRS rtRT-PCR Ct and qRT-PCR Log10 testing results (R = -0.961, P<0.001).

Discussion
Although not technically a quantitative measure Ct values generated by rtRT-PCR assays for PRRSv detection hold potential for use as a key component for monitoring viral load and tracking progress where PRRS control and elimination are being pursued. Clearly, further evaluation and refinement is needed before rtRT-PCR Ct values are ready for broad application to monitor PRRS viral load within and among pig populations, across areas and networks, and over time. Standardization of methods for quantitative viral load estimation using Ct values will be needed within testing laboratories over time and among testing laboratories and the various rtRT-PCR assays – including accounting for the influence of PRRS genetic variation and assay component (e.g., primers) detection variation. Further, standardized (as well as inexpensive and convenient) sample procurement methods as well as methods for calculating valid aggregate viral load metrics progressing from animals within sampling, samplings within population, and populations within areas will be required.

**Comparison of four ELISAs for the detection of antibodies against PRRSV with special respect to false positive outliers**

Christiane Lang¹ Andrea Ladinig¹ Alphonse Minani² Wolfgang Sipos¹ Friedrich Schmoll³ Louis Fischer⁴ Mathias Ritzmann¹

1. Clinic for Swine, Vienna, Austria; 2. Noack & Co, Vienna, Austria; 3. Institute of Veterinary Public Health, University of Veterinary Medicine, Vienna, Austria; 4. Labovet GmbH, Vienna, Austria

**Introduction**

The points of interest of PRRS control programs are an early detection of disease, a rapid laboratory confirmation and a reliable confirmation of a negative herd status. The most used serological diagnostic tool for PRRS monitoring is the ELISA. A new product, the Ingezim PRRS DR (Ingenasa, Madrid, Spain) was developed, which is able to detect not only IgG but also IgM antibodies, which occur earlier in the course of infection. Furthermore, the high specificity of this test should minimize the risk of false positive results in negative herds. The purpose of this study was to evaluate the performance of four European commercial tests.

**Materials and Methods**

In total, 478 pig sera were analysed via four different ELISA test systems (Ingezim PRRS DR (ING-DR) and Ingezim PRRS Universal® (ING-U), Ingenasa, Madrid, Spain, IDEXX HerdCheck® Porcine Reproductive and Respiratory Syndrome Virus Antibody Test Kit (ID), IDEXX Laboratories, Wörrstadt, Germany, Civtest suis PRRS E/S (CIV), Laboratorios HIPRA, S.A., Amer, Spain) according to the manufacturers’ specifications. 353 of these serum samples had been collected during routine diagnostic of 148 farms, 16.4 % could be defined as “outliers”. An “outlier” was defined as possible false positive sample, which means single samples of randomly tested herds that were positive, while all other analysed samples were negative and showed a S/P (sample/positive control) ratio < 0.4 in the IDEXX ELISA. 125 sera were collected during a PRRSV challenge.

**Results**

The analysis via ING-DR showed a seroprevalence of 67.6 %, via ING-U of 56.3 %, via ID of 59.2 % and via CIV of 29.9 %. The correlations of the different test systems and sample sets were expressed as Spearman’s coefficient of correlation ρ (Table 1). When results from the four different tests were compared, it was found that 24.1 % were positive in all four tests and 21.6 % were negative in all tests. 45.1 % showed no corresponding result. 16.1 % of these non-corresponding results were outliers.

**Discussion**

This study underlines the complexity of PRRSV serology. The analysis of the coefficient of correlation of the complete sample set showed differences between the ELISAs, which were even more distinctive comparing only the outliers. In contrast, the results improved essentially, when outliers were excluded of the calculation. The best correlation could be found evaluating the samples of the challenge, which were defined positive or negative. The ING-DR resulted in the highest seroprevalence because of its ability to detect IgM and IgG, but nevertheless its specificity of 97.3 % should be sufficient to minimize the risk of false positive results. The different answers to different ELISAs could also be related to significant field strain differences, to the phase of the infection or other factors (1).

Introduction

Routine diagnosis of PRRS is generally done by means of antibodies detection against the virus, most often using indirect or blocking ELISA. With those tests seroconversions are usually detected at +14 post-inoculation (1, 2). In other instances, RT-PCR is chosen as diagnostic test for PRRS. RT-PCR usually allows and earlier detection of infected animals compared to serology. Early diagnosis of PRRS is particularly crucial in two circumstances: entry of gilts in PRRS-free farms and testing of boars. INGENASA has recently developed a new ELISA based on the concept of double recognition (DR) of the antigen (3). In the Ingezim PRRS DR (11.PRS.K0) (Ingenasa) for PRRS, plates are coated with the viral protein N. Serum and protein N conjugated to horseradish peroxidase are added to the coated plates in one-step incubation. If PRRS virus (PRRSV)-specific antibodies were bound to the plate, the free binding sites of those antibodies will be able to bind the conjugated N-protein and thus, an increased sensitivity will be obtained after revealing the reaction with a colorimetric substrate. The aim of the present study was to evaluate the performance of the DR for early detection of anti-PRRSV antibodies raised against different genotype-1 strains in experimental or field conditions. Comparison with HerdChek 2XR® (Idexx Laboratories) was also performed.

Material and Methods

ELISAs. Two different ELISAs were used in the present study. In all cases, sera were examined by Ingezim PRRS DR (11.PRS.K0) (INGENASA) and for particular comparisons HerdChek 2XR® (Idexx Laboratories) was used. All tests were used as recommended by the manufacturer. Results were expressed as a ratio of the optical density (OD) of a given sample over the OD of the positive control provided by the test (S/P ratio).

Sera from experimental infections. Sera (n=38) obtained from five experimental infections (days 0 to 28 post-inoculation) of piglets (4 week old) with different PRRSV genotype I strains (S1-S5) were used. Selected strains shared from 90.6% to 96.0% of similarity in protein N. In all cases, animals were intranasally inoculated with ≥1x10⁵.⁵ TCID₅₀/ml. All sera were analyzed using DR. Samples for strains S4 and S5 were also examined by the HerdChek ELISA®.

Cross-sectional profiling of an endemic farm. A cross-sectional serological profiling was comparatively performed in an endemic farm (pigs of 3, 6, 9, 12, 15 18 and 21 weeks of age) using both ELISAs.

Results

Sera from experimental infections. At day +7 PI, DR detected 29/38 sera as positive. Interestingly, for strains S4 and S5 HerdChek® did not detect any positive pig by day +7 PI while DR recognized all animals infected with S4 (8/8) and one pig in the group infected with S5 (1/8). By day +14 PI, all sera were positive in both HerdChek® and DR tests.

Cross-sectional profiling. Both DR and HerdChek® showed that PRRSV did spread explosively around 9-12 weeks of age as indicated by the seroprevalence but DR had an increased sensitivity for detecting low levels of maternal antibodies or early infections as seen in 3-week-old piglets and in the higher proportion of seropositive pigs from week 15 afterwards (Figure 1).

Discussion

DR-ELISA allowed an earlier detection of experimentally infected pigs (76% at 7 PI). On the basis of the results in field conditions, DR also showed some enhanced sensitivity related to HerdChek®. Present results indicate the suitability of the DR-ELISA for early detection of PRRSV infection.

Development and characterization of indirect ELISA using heparin-coated PRRSV as an antigen

Hye-Kwon Kim¹ Hyoung-Joon Moon² Seong-Jun Park¹ Hyun-Ok Keum¹ Se-Mi Rho¹ Jae-Yeon Han¹ Van-Giap Nguyen¹ Bong-Kyun Park¹

Introduction
Heparan sulfate is known as a receptor for PRRSV attachment (1). The heparin is a soluble form of heparan sulfate. A recent study showed that the use of heparin with virus-like particles as an antigen was effective to reduce non-specific ELISA reaction especially originated from antigenic linearization during coating process in order to detect human papillomavirus-specific antibodies (2). Therefore, this study was performed to estimate the property of the use of heparin with whole viral antigen in PRRSV-specific ELISA.

Materials and Methods
At first, heparin-binding assay of PRRSV was performed using slightly modified method (two times dilution of whole viral antigen & 20 times dilution of sera) of previous report about heparin-based ELISA (2). MARC-145 cell-derived whole viral antigen was mixed with 1mg/ml of heparin in PBS in 1:8 ratio and coated on 96well plates (polysorb, Nunc). After fixing with cold ethanol, the plate was blocked with 10% Horse serum and used as an ELISA reaction. For serum dilution, swine sera was 40 times diluted with a 1:1 mixture of 10% Horse serum in PBS-T and culture supernatant. After final colorimetric reaction, the O.D values at 450 nm of viral antigen and cell control coating wells were estimated.

After experimental infection of type I PRRSV, LCS-EU (105 TCID50/ml) and type II PRRSV, CP07-401-9 (105 TCID50/ml), the collected sera until 21 days post challenge (dpc) were tested with commercial ELISA kit (Herdcheck PRRS 2XR, IDEXX) and heparin-ELISA system. The sera were also tested by modified serum neutralizing test (SN test). The heparin-ELISA was tested with not only experimental sera, but also field sera.

The sensitivity and specificity of heparin ELISA were calculated using 310 field swine sera, when IDEXX kit was used as the gold standard. IFA test was also included to confirm true positive or negative in 28 mismatched sera between IDEXX and heparin-ELISA.

Results
Heparin-specific PRRSV binding was observed in the heparin-PRRSV binding assay with the different concentrations of heparin (fig. 1). In heparin-ELISA system, some unexpected non-specific reactions found in cell control wells were also reduced in heparin-coating system of this ELISA. (data not shown)

In the experimental infection study, PRRSV-specific IgG began to be detected from 18 to 21 dpc by heparin-ELISA, and from 9 to 10 dpc by IDEXX ELISA. During the study, serum neutralizing ability was not proven by conventional SN test. However, when modified SN test (3) was applied, serum neutralizing ability was detected around 8-9 dpc and 18-21 dpc. In the field sera, IgG detected by heparin ELISA was increased after the viremia of wild type PRRSV.

When IDEXX (2XR) ELISA was regarded as gold standard, the sensitivity and specificity of heparin-ELISA were 89.6 % and 92.5 %, respectively (0.81 of kappa value). Although 91% (10/11) of false positive in heparin-ELISA was confirmed by IFA test, 60% (9/15) of false negative in heparin ELISA was true negative by IFA test.

Discussion
Heparin treatment could be useful for specific detection of IgG specific for PRRSV and theoretically protect viral proteins from linearization during the coating process (2). The detection time of IgG for PRRSV by heparin-ELISA was delayed compared to IDEXX ELISA, but correlated with the appearance of neutralizing antibodies that was detected by modified SN test (3). With the fair sensitivity and specificity, the heparin-ELISA was easy to prepare and may provide another approach for PRRSV serology.

In order to establish a reverse transcript loop-mediated isothermal amplification method for the rapid detection of porcine reproductive and respiratory syndrome virus, 4 primers specific to 6 regions of N gene were designed. After amplifying in an isothermal water bath for 1 h, the ladder-like products would be generated with those porcine reproductive and respiratory syndrome virus positive samples while no product was generated with porcine parvovirus, porcine circovirus, classic swine fever virus, pseudorabies virus and swine testis cells. The sensitivity and specificity of this assay were evaluated by comparison with reverse transcript polymerase chain reaction. The detection limit of the assay was shown to be equivalent to 1x100~1x101 PRRSV copies/reaction, was about 100 times more sensitive than RT-PCT reaction. The coincidence ratio was showed to be 96.2%. Due to its specificity and simplicity, the assay could be a useful diagnostic tool for the diagnose of PRRSV infection.
**Multiplex PCR for PRRSV detection and typing**

Van-Giap Nguyen¹ Hyoung-Joon Moon² Seong-Jun Park¹ Hye-Kwon Kim¹ Hyun-Ok Keum¹ Se-Mi Rho¹ Jae-Yeon Han¹ Bong-Kyun Park¹

**Introduction**

Since it was first discovered in United States in 1987, PRRS has spread worldwide and become one of the most devastating diseases of swine. The causative agent, PRRSV is divided into two distinct groups: the European (Type 1) and the North American (Type 2). It is well defined about the marked genetic differences between the two genotypes as well as among viruses within each genotype. To identify PRRSV, RT-PCR is one of methods that has been widely applied. However, because of the high degree of sequence variation, the accuracy of RT-PCR might be influenced, especially if mutations are located in the primer or probe binding regions of PCR (3). To overcome those difficulties, previous studies prefered designing primer to amplify part of conserved region of PRRSV genome: ORF1b and ORF7 (1,5).

In this study, a PRRSV detection and typing Multiplex PCR was developed. In our system, the primers were designed to co-amplify conserved regions ORF1b and ORF7. In addition, primer set for ORF7 amplicon was type specific that make it possible for differentiation between PRRSV Type 1 and Type 2.

**Materials and Methods**

**PRRSV reference strains:** Type 1 (105.0 TCID50/ml), Type 2 (104.5TCID50/ml, passage 7 on MARC-145 cell).

**Primer design:** primers were designed based on PRRSV complete sequence of Type 1 and Type 2 (Genbank: M96262.2, AF046869.1). In details, the following amplicons were amplified: 615bp of ORF1b by CF: IAGGACCATCCTGGGCACCAACA, CR: IIGACGGTTTT CTTTGGGTCCGT; 425bp of Type 1 ORF7 by N26: GCCCTAATTGAATAGGTGAC, FT1: AGAAAAAGAAA AGTACAGCTCCGAT; 265bp of Type 2 ORF7 by N26/FT2.1: GTGAGCGGCAATTGTGTCTGTCG.

**RNA extraction and cDNA synthesis:** RNA was extracted using Trizol-Chloroform method. cDNA was synthesized by M-MLV reverse transcriptase kit (Invitrogen, USA) using random hexamers method.

**Multiplex PCR reaction:** Multiplex was set up according the guidance of previous paper (2) using i-StarMaster mix PCR kit (iNtRON Biotechnology, Korea).

**Results**

Specificity and sensitivity of primer set: PCR product was not generated with test RNA virus (TGEV, PEDV) and DW as negative control. In addition, there was no cross reaction of type specific primers. Taken into account with sequencing target bands (data not show), the specificity of primer set was confirmed. By serial 10 fold dilution known titration of PRRSV, the sensitivity of primer set was 102.5TCID50/ml (Type 2), 103.0TCID50/ml (Type 1) and 103.5TCID50/ml (mixing of Type 1 & 2).

Sensitivity (Sn) and specificity (Sp) of Multiplex PCR: total 214 field samples (tissue and pool sera originated from different farms) were screening. Comparing to Nested PCR for PRRSV typing (4) (routine in our lab), 150/214 samples was judged PRRSV true positive. Also, there was no conflict in typing result between Multiplex and Nested PCR. Interestingly, there were 5 tissue samples showed both Type 1 and Type 2 positive. The Sn and Sp of Multiplex PCR was 94.34% and 90.91% respectively.

**Discussion**

Previous study evaluating RT-PCR method for PRRSV detection (6) concluded that ‘the majority of incorrect diagnoses were false-negative results’. One main reason might be the occurrence of mutation that drives a genetic heterogeneity within annealing region of primers. To our knowledge, the probability of false negative will be minimized when more than one conserved regions were co-amplified in PCR. This is partly reflected by the high degree of agreement between new Multiplex PCR and Nested PCR (Kappa value: 0.83). Also, this is the first time Multiplex PCR was set up to co-amplify both conserved regions of PRRSV genome. Slightly high of Sn and Sp might cause by the appropriate primer to the sequence of circulation PRRSV strains. Therefore, more labor is needed in order to get more suitable primer set with recent prevalence PRRSV, Korean strains.

Introduction

Porcine reproductive and respiratory syndrome (PRRS) is one of the most important diseases in pig farms almost worldwide (1). The PRRS virus (PRRSV) causes severe economic losses due to reproductive failures in sows and gilts and respiratory distress in piglets and fattening pigs (1). We analyzed results of diagnostic testing for PRRS in order to obtain current information about PRRS in German pig herds and to determine any associations between different test results, motivation for examination, pig farm type, and the animals’ vaccination status.

Material and Methods

A total of 27,077 serum samples from pigs in Germany were analyzed from October 1, 2007, to September 30, 2009. Antibodies against PRRSV were detected by IDEXX HerdChek® PRRS 2XR Antibody ELISA as described by the manufacturer. Three to five individual serum samples from a single farm were pooled, and these pooled samples (6,246) were also analyzed by PCR based on the ORF7 gene (2). In order to compare the two methods, the individual ELISA results from each pool were averaged to give a pooled ELISA result. From January 1, 2009, data were also collected on herd (type and size, motive for examination, PRRS vaccination status).

Results

ELISA tests for PRRSV were positive in 52.5% (n = 14,213) of all individual pig serum samples (n = 27,077), whereas PCR tests were positive in 29.0% (n = 1,816) of all pooled samples (n = 6,346). Of the pooled samples from vaccinated pigs (n = 477), 42.1% tested positive by both ELISA and PCR, and 9.9% tested negative by both methods. Only 2.5% of the serum sample pools from vaccinated pigs tested positive by PCR, but negative by ELISA. Of the serum pools from vaccinated animals, 45.5% tested positive by ELISA only (and negative by PCR). On the other hand, 31.0% (n = 52) of the pools from unvaccinated pigs (n = 522) tested positive by both ELISA and PCR, and 42.7% tested negative by both methods. Of the pooled samples from unvaccinated pigs, 5.4% tested positive by PCR but negative by ELISA, while 20.9% of these samples tested positive by ELISA only (and negative by PCR). (Tab. 1)

Most testing of pig serum samples (55.0%) was conducted as part of herd monitoring (n = 4,595).

Discussion

As expected, we found that vaccination had a very strong effect on the number of positive ELISA tests in pigs. PCR was also affected by the vaccination status of animals, but to a lesser degree. Nevertheless, 57.3% of the unvaccinated pigs tested positive by ELISA and/or PCR, and thus were shown to be infected with PRRSV.

The vaccination status of the animals depended on the type of pig farm. Most animals (75.2%) from fattening units (n = 427) or multipliers (n = 161), respectively, were unvaccinated, while half (50%) of the animals from breeding herds (n = 2,575) or nursery units (n = 423) were unvaccinated.

Individual ELISA tests were positive in 59.8% of unvaccinated pigs from fattening units (n = 321), whereas these were positive in only about 40% of unvaccinated pigs from breeding herds (n = 1,277), nursery units (n = 217) and multipliers (n = 107). PCR tests were positive in 36% of the pools from unvaccinated pigs from breeding herds (n = 275) and nursery units (n = 47). The most positive PCR results were found in unvaccinated pigs from fattening units: 46.7% (n = 35; total n = 75).

Analysis of amplification of North America PRRS virus RNA from serial diluted oral fluid samples

Ricardo A. Munoz¹ R Shah¹ R.R. Rowland² J. El-Attrache¹ J. Zimmerman³
¹. Applied Biosystems, Austin, TX, USA; ². Kansas State University, Manhattan, KS, USA; ³. Iowa State University, Ames, IA, USA

Introduction
Porcine Reproductive and Respiratory Syndrome Virus (PRRSv) surveillance for the purpose of monitoring herd status requires frequent sampling and testing. Less invasive techniques are continuously being explored such as passive blood collection, as well as the use of swabs to collect matrices that contain swine pathogens. Recently, more innovative monitoring techniques and protocols, such as oral fluid collection, have been developed for the swine industry that notably mirror the techniques of pathogen detection employed for human medicine.

The oral fluid is a combination of saliva and “oral mucosa transudations”. Saliva is produced by the salivary glands; oral mucosal transudations enter the mouth via the buccal mucosa from the blood capillaries¹. The purpose of this study was to find a reference performance of sampling protocols in terms of PRRSv North America (NA) strain potential amplification from oral fluid samples after artificial dilution of the original oral fluid samples, using PRRSv negative oral fluid samples. The intention was to mimic what could happen in the field, when just one pig could get infected at the beginning, and other factors, such as the number of negative pigs chewing the rope.

Collection of oral fluids¹:
• Use cotton rope, it is more absorbent than synthetic fiber.
• Use 1/2" rope for nursery and 5/8" for growth and finishers.
• Place the ropes in a clean area, away from water and feed sources.
• Hang the rope at pig shoulder height (do not allow to contact dirt or feces).
• Squeeze the rope inside a plastic bag, avoiding contacting the rope with your exposed hands (to reduce the risk of cross-contaminations).
• Cut one of plastic bag corners and pour into a tube, if there are visible particles, then centrifuge for approximately 10 minutes.
• Maintain cold chain (4 to 7 °C) prior to sample submission

Oral fluids are managed the same as serum samples.

Materials and Methods
Samples were obtained from a virus challenge study conducted at Kansas State University. In a single experiment, 190 pigs were divided among 12 pens and experimentally infected with 105 TCID50 of a PRRSv 97-7985 strain (NA like virus). Oral fluid samples were collected from each pen and individual animals were bled in intervals over 42 days.

Serial Dilution Experiment:
Take high titer sample (~15 cts) and make a 12 point serial dilution of the sample using negative oral fluid. Dilution series will include 10 fold, 4 fold and 2 fold dilution points. Isolate diluted samples using AM1836 and obtain results using RT-PCR.

This experiment will give us the linear amplification range of and also tell us important dilution information such as, the sample that is a 20 fold dilution of the stock will equate to a sample from one positive pig that has been pooled with 19 negative pigs, assuming they all contribute the same amount of oral fluid to the mix.

Pooling Experiment:
Take a high titer sample and dilute it in 5, 10 or 20 different negative samples to simulate a high positive pig in a pen with 4, 9 or 19 negative pigs. Isolate and run Real-Time PCR to get results. Do the same for a low titer sample to simulate a low positive pig with 4, 9 or 19 negative pigs in a pen. This will give us information about detection limits within pens and how many samples can be tolerated before loss of amplification.

Some pigs may contribute a higher amount of oral fluid compared to others. These experiments assume that the same amount of oral fluid is contributed by each pig.

Summary
The presence of PRRS virus RNA was identified in an early infectious stage utilizing oral fluids as a sample matrix. Real-time PCR can be effectively utilized to amplify PRRS virus RNA obtained from oral fluids samples. Predictably, this type of analysis could provide an enhancement to the routine monitoring and surveillance of populations.

Detection of PRRSV in oral fluid samples: longitudinal study under field conditions

Loris G. Alborali; Matteo Gradassi; Pavesi Roberta; Beatrice Boniotti; Claudia Nassuato; Stefano Giovannini; Enrico Giacomini; Silvia Bellini; Maria Pacciarini

IZSLER, Brescia, Italy

Introduction and Objectives
PRRS (Porcine Reproductive and Respiratory Syndrome) control in swine farms is an ambitious challenge that has to be based on different measures and intervention strategies and that, because of the high amount of diagnostic samples required, is often cost prohibitive (1). The selection of oral fluid as diagnostic specimen is likely to be a promising alternative to serum. At present, there are experimental evidences that porcine saliva is a valuable alternative to serum for detection of PRRSV genome (2,3). The main purposes of the present experimental study was to monitor PRRSV infection towards a longitudinal sampling of sera, according to the traditional diagnostic protocols, and match individual serum with collective pen-based oral fluid results.

Material and Methods
Four site-2 swine commercial farms site in North Italy participated in the study. On each of them, 4 pens of 30 piglets were selected and, at 3, 5, 7 and 9 weeks of age, the following specimen were collected: individual serum samples of 10 ear-tagged pigs/pen and collective oral fluid samples (1 cotton rope/pen). The serum were analysed individually. The presence of PRRSV RNA was shown using a real-time qRT-PCR (Applied Biosystem TaqMan NA/EU PRRSV Kit).

Results
Comparison showed a good agreement (87.5%) between PRRSV detection in porcine pen-based oral fluid and individual serum samples, as visualised in Figure 1 and 2.

Discussion
Our data corroborates that oral fluid samples can be considered a valuable and promising alternative to serum to track PRRSV field infection. Moreover, compared to drawing blood specimen from individual pigs, pen-based saliva offered significant advantages, such as reduced costs, less labour and simplicity. Preliminary data on the diagnostic sensitivity of the quantitative RT-PCR on oral fluids, compared to the gold standard (RT-PCR on individual serum samples), can be accounted as satisfactory. Further analyses are in progress in order to validate saliva qRT-PCR at pen level.

Optimization of PRRS PCR for oral fluid testing

Apisit Kittawornrat; Wayne Chittick; Wendy Stensland; John R. Prickett; Chong Wang; Erin Strait; K-J Yoon; Jeffrey J. Zimmerman
Iowa State University, Ames, IA, USA

Introduction
Oral fluids have been reported to be useful specimens for the detection or diagnosis of infection,1,2,4 including PRRSV.5,6 Our initial work revealed a low sensitivity for PRRSV PCR on swine oral fluid samples using extraction methods established for serum samples. This sample matrix-related difference has been reported by others, as well.1-3 Thus, oral fluid samples are known to inhibit PCR efficiency.1,3

Preliminary work at the ISU-VDL found that an extended lysis/processing adaptation to an existing extraction method improved test sensitivity (Stensland, unpublished data). In this study, we sought to continue to improve PRRSV PCR for oral fluids. Specifically, we evaluated 5 nucleic acid extraction protocols and assessed the presence of PCR inhibition in swine oral fluids through the use of an internal PCR control.

Materials and Methods
Oral fluid samples (n = 106) were randomly selected from an earlier study in which pigs were inoculated with PRRSV.5 The sample set included 63 pen-based oral fluid samples collected between 7 DPI and 29 DPI and 43 samples from negative control pens. These samples were used to compare 5 extraction protocols based on commercially-available kits using magnetic bead-based extraction (protocols 1 through 4) and spin-column based extraction (protocol 5).

1. Applied Biosystems MagMax™ Viral RNA Kit – ISU-VDL modified protocol;
2. Applied Biosystems MagMax™ Viral RNA Kit – High-volume, ISU-VDL modified protocol;
3. Qiagen BioSprint® Vet One-For-All Kit;
4. Applied Biosystems MagMax™ Total Nucleic Acid Isolation Kit;
5. Qiagen QIAamp® Viral RNA Mini-Kit.

PRRSV RNA was detected using Applied Biosystems Ag-Path PRRSV real-time PCR reagents, which contains an internal control for detecting failed reactions. Initially, a standard master mix was prepared according to the instructions from the manufacturer. Later, PCR was re-run using modified master mix with double the amount of enzyme mix (containing both reverse-transcriptase and Taq polymerase enzymes).

Results
Results indicated significant differences among extraction protocols in the level of detection in PRRS-exposed pen samples, ranging from 17% to 43%. In general, doubling the PCR enzyme resulted in improvements in detection among all extraction protocols, ranging from 32% to 56%. The internal control data suggested a differing level of failed reactions among the extraction protocols tested, suggestive of PCR inhibition, although the results were not statistically significant. All protocols had reduced number of failed internal controls when enzymes were doubled.

Discussion
The oral fluid sample matrix is known to inhibit PCR test process1-3. Cumulatively, our work confirmed this observation and demonstrated that not all extraction methods work equally with the oral fluid matrix.

Introduction
Porcine reproductive and respiratory syndrome virus (PRRSV) is a widespread viral disease in the pork industry (Greiner et al., 2000) and causes a potentially devastating disease in swine herds (Wills et al., 2000). Because its potential for rapid spread, significant production and economic losses is considered the most economically important viral disease at swine production. PRRSV has been recorded in most major pig-producing areas throughout the world. However, the disease is considered as an exotic disease in Brazil.

Nowadays, in order to improve the genetics of Brazilian breeding herds, producers imported genetic material (semen and live animals) origin from countries which are recognized by their genetic technology. This trade can lead serious problems for the health status of the piggery because it is well known that PRRSV can be shed and transmitted through boar semen (Christopher-Hennings et al., 1996).

The aim of this study was to perform a swine bioassay (in vivo) to test the safety for PRRSV on imported semen from Germany to be used in swine genetics too Topgen Ensure the safety

Materials and Methods
Six pigs were randomly assigned and kept in fly-proofed isolation pens. Four piglets were inoculated intraperitoneally which a pool of 2 ml of porcine German imported semen provide from TOPGEN swine Genetics. The other two animals were designed as negative control. Rectal body temperature and PRRS clinical sings (fever, anorexia, lethargy, diarrhea, respiratory symptoms, chemosis, tremors) were done daily from those pigs. Blood samples with EDTA were collected from the sow and each pig at weaning, immediately before PRRSV inoculation an on days 7, 14, 21 post inoculums (PI). Blood samples were analyzed for hematological parameters. At the same day serum samples were collected too in order to test serum-conversion by the PRRS using a commercial Kit - Idexx - Herdcheck PRRS 2XR ELISA. Two piglets were euthanized on day 7PI and 21 AI at the necropsy room at Laboratório de Sanidade de Suínos at São Paulo State University by electrocution and the necropsy were performed immediately as performed by Ciacci-Zanella et al 2004. At the necropsy, all of the sow were thoroughly examined, blood, serum and organs were collected for histopathology and viral tests.

Results
For the period of 21 days, none of the inoculated piglet presented characteristic PRRS symptoms. The blood parameters were normal. At the necropsy, no pathological lesions (macro or microscopic) were found by histopathology. Also the tested pigs were negative to the ELISA test methods.

Discussion
The goals of this work were achieved. The safety of the semen demonstrates the efficiency of government agencies that oversee the transit of animals and their products through constant monitoring. Swine bioassay is an excellent tool for detecting PRRSV although it is laborious (Christopher-Hennings et al., 1996). The trial period had time for a possible seroconversion that occurs between 14 and 28 days (Wills et al., 2000).

Introduction
Porcine Reproductive Respiratory Syndrome (PRRS) was a problem, is a problem and will be a problem in pig farming. The aim of the vet who is facing this disease is to get a PRRS stabilize population of animals. PRRSV serologic screening results are essential to understand the PRRSV epidemiology in the farm, which is necessary to take the proper decisions in each PRRSV infection scenario. So, in the pig veterinary practice, transversal serum profiles are usually implemented to take most proper decisions in order to control PRRSV.

Materials and Methods
200 transversal serum profiles from 200 different farms located in Spain, Hungary, Poland, Czech Republic, Slovakia, Italy and Denmark were analysed. Each serum profile was made from serum samples collected from different pig groups (gilts, sows, piglets and fattening pigs). The sows were grouped together by age (by parities), they were sampled from day of gestation 70 to 100. Piglets and fattening pigs were sampled by weeks of age (4, 7, 10, 13, 16, 19, 21 and 24). The sample was blood sera and the amount of samples per group depended on the size of the farm and the estimated infection prevalence. The average number of serum samples per group was 7. Serology analysis was made with ELISA (CIVTESTsuis PRRS/ES Laboratorios Hipra, Amer, España) following the manufacturer instructions. From each monitored farm was noted the productive data, the vaccination program and the clinic situation.

Results
After testing and analyzing 200 farms, we could determine 3 clear PRRSV infection patterns which let us to define 3 different PRRSV epidemiologic status: 1. Clinically not stable and serologically not stable, (42 farms out of 200) (Graphic 1); 2. Clinically stable and serologically not stable, (112 out of 200) (Graphic 2); 3. Clinically stable and serologically stable, (36 farms out of 200) (Graphic 3). 10 farms could not be classified in any of these 3 patterns.

Discussion
Samples results from pigs at 7 weeks of age became essential information. Passive immunity does not reach with high IRPC levels to 7 weeks of age. If we observe high antibody titers at this age we can suspect that the piglets were already vireamic at weaning and for this reason, we can suspect that. So sows were probably farrowing infected PRRSV piglets. In farms where the piglets were vaccinated, we could not determine any pattern, because vaccination serology response could be confused with a serology positive result due to a wild PRRSV infection. However PRRSV sow vaccination does not interfere with this classification, since we observe that the serology response induced by vaccination does not result in IRPC values higher than 100. Recent wild virus infection induces IRPC values higher than 100. We observed that the evolution of PRRSV infection in farms followed these 3 statuses, evolving from one status to the other within 6 to 12 months period. We do not observe differences among the farm status from different countries. We observed that most of the farms that implemented at least vaccination in sows belonged to the second PRRSV infection pattern (Graphic 2). To sum up, according to this classification, swine vet specialists can monitor and take their proper decisions to control PRRSV.

Porcine reproductive and respiratory syndrome (PRRS) on a large pig farm in Slovenia

Zdravko Valencak1 Alojz Pertoci2
1. Veterinary Faculty, Ljubljana, Slovenia; 2. Panvita, Veterina, Beltinci, Slovenia

Introduction

PRRS is an economically significant viral disease of swine (1). Slovenia was PRRS free country and later on country with low seroprevalence to PRRS in small pig farms (2). In last years seroprevalence to PRRS increased on small farms and also large pig farms became positive. Vaccination after PRRS outbreak is used control measure (3). In 2008 in one of the large one site pig farm production results and increased mortality leaded to suspision of PRRS. PRRS was confirmed in May 2008 with testing of 152 pig with ELISA, from which 112 were positive to PRRS. Farm started with control measures.

Materials and Methods

Vaccination programme

• June 2008 all sows on the farm were vaccinated with inactiveted vaccine in three weeks.
• August 2008 vaccination with live vaccine. Sows were vaccinated 6 th day after farrowing and 60 th day of pregnancy.
• From July to November piglets were vaccinated with live vaccine at beginig all and after at age of 14 days.
• December 2008 piglets were vaccinated at age of 24 days.
• From may 2009 till October piglets were not vaccinated.
• From August 2009 in sows at 60 th day of gestiation the inactiveted vaccine was used.
• October 2009 all sows were vaccinated with live vaccine in 2 days and all piglets were vaccinated at weaning.
• In January 2010 all sows were vaccinated with live vaccine.

Serological control

In year 2008 were tested 101 samples from June to December, and in 2009 562 samples with IDEXX PRRS ELISA.

Selected production Results

Results of 2007, 2008 and 2009 were compared (abortions, farrowing rate, mating rate, weaned piglets per litter, preweaning mortality, postweaning mortality).

Results

In 2008 only 48 samples (47,5%) were seropositive. In 2009 537 (95,5%) sera reacted positive.

<td>7,20</td>
</tr>
</tbody>
</table>

Average number of abortions per month in year 2008 from January to October was 14,8 but increased in November to 153 and in December to 212. In 2009 average number of abortions from January to October was 59,7 monthly, but in November 102 and in December 23.

Discussion

PRRS reached culmination in November in December 2008 in spite of used programme of vaccination. Success of vaccinaion in 2009 was not satifactory. In October 2009 the vaccinaion scheme was changed fundamentaly. With vaccination of all breeding sows in short interval stabilization of herd was expected. Preliminary results shows that number of abortions decreased significantly and number of seropositive animals is improving. Results in January 2010 indicates that vaccine did not achieve long lasting immunity and PRRS virus still circulates in breeding herd and that repeat vaccination of all sows is appropriate measure to improve production results.

Impact of the Porcine Reproductive and Respiratory Syndrome (PRRS) on reproductive performance in Austrian sow herds

Eva-Maria Peinhart1 Bettina Exel2 Franz Dieber3 Wolfgang Sipos1

1. University of Veterinary Medicine Vienna, Vienna, Austria; 2. Artificial Insemination Stud Gleisdorf, Gleisdorf, Austria; 3. Styrian Animal Health Service, Graz, Austria

Introduction
Since the first appearance of porcine reproductive and respiratory syndrome (PRRS) in 1987 in the USA and in the early 1990’s in Europe PRRSV has become endemic in most pig producing countries and causes high economic losses (1). PRRSV causes a persistent infection and virus excretion can be detected over several months post infection (2). However, data to substantiate the role of PRRSV on reproductive performance of sows in Austrian pig herds were not available. Due to the different structure of the farms, the data obtained from other countries with much higher concentrated pig herds and higher numbers of animals per herd are not directly comparable to the situation in Austria. So the aim of the study was to evaluate the effect of PRRSV on the reproductive performance of Austrian sow herds.

Materials and Methods
140 Styrian (South-East Austria) production herds were randomly selected. The mean number of sows per herd was 74 animals. The main inclusion criteria were that the farmers had to use the SPon Web soft-ware for reproductive management and to be a member of the Styrian animal health service. On each farm 14 random blood samples were collected. These samples comprised 4 sows, 4 gilts, 4 growers, and 2 boars, if available. All samples were analysed by the IDEXX Herdcheck® PRRS Antibody (Ab) test kit.

Then, the farms were divided into three groups: PRRSV-Ab-positive (at least one animal seropositive, no history of vaccination, n=66), PRRSV-Ab-negative (n=60) or vaccinated (EU-strain MLV vaccine, n=14). Following, reproductive performance data were compared between these three groups.

Results
No significant difference in the number of live born piglets per sow and year could be found between the PRRSV-Ab-negative (median=27.4) and the PRRSV-Ab-positive (median=27.0) group. In contrast the vaccinated herds exhibited a significantly (p<0.05) worse productivity with a median of 25.2 live born piglets. However, the PRRSV-Ab-positive herds showed a trend towards greater losses in the suckling period (median=14.6) than PRRSV-Ab-negative (median=13.2) and vaccinated herds (median=11.4).

Discussion
This study shows that the results from the USA are not directly comparable to the situation in Europe, especially to the one in Austria with its different structure of swine herds. Our data show, that PRRSV-Ab-positive and PRRSV-Ab-negative herds can obtain nearly the same reproductive performance, given PRRSV infection is stable. Interestingly, the number of live born piglets was significantly lower in vaccinated herds. There are several possible explanations for this finding, for example the vaccine does not cover all relevant strains or vaccination regimens were not optimal. However, vaccinated herds achieved better results during the suckling period, which could be a consequence of the initially smaller litter sizes in vaccinated sow herds.

References
**Introduction**

As a method of gilt acclimatization to porcine reproductive and respiratory syndrome virus (PRRSv), many swine producers commingle naive “5 kg” replacement gilts (NG) with their PRRS positive resident nursery pigs. Surprisingly, the NG often perform better than the resident piglets (RP). The objective of this study was to describe and compare temporal variation of hematologic, serologic and viremic characteristics between NG and RP.

**Materials and Methods**

RP and NG were introduced in an all-in-all-out nursery (d0) at approximately 20 and 40 days of age, respectively. They were transferred to a growing-finishing (GF) unit at d45 of the study. A total of 24 piglets were selected, 12 NG and 12 RP. Blood was collected at d0, d6, d13, d20, d27, d42, d48, d55 and d95. Selected piglets were housed in 6 pens (3 for NG and 3 for RP) of 4 piglets in three different rooms of a capacity of 72 piglets each. NG were in separate pens but they had nose-to-nose contact with RP through the fence. All 24 piglets were weighed and scored for clinical signs (1: normal; 2: unthrifty; 3: sick) at each sampling day of nursery. Presence in serum of PRRSv and antibodies against PRRSv were tested by a quantitative RT-PCR (qPCR) and IDEXX-2XR ELISA on all samples. Serum protein electrophoresis and complete hematologic profile were done on most sampling days. Finally some sera (d6, d13, d27 and d42) were screened for influenza H1N1 and H3N2 antibodies (IHA). Differences between groups of pigs, sampling days and interaction were tested with mixed models.

**Results**

Viremia for PRRSv (qPCR positive) was observed in only 2 RP at d0 and in 3 RP at d20. From d42 to d48, most piglets became viremic (PRRSv peak), but no clinical signs were observed on neither group of pigs during this period. All piglets had seroconverted (ELISA) by d95. Clinical signs (mainly dyspnea and unthriftiness) were observed between d13 and d20 on most piglets and were found to be related to the circulation of H3N2 influenza virus (paired sera). Clinical signs were less severe in NG. However, piglets in both groups had similar nursery growth rates (ADG=0.487 kg).

**Discussion**

Almost no viral circulation of PRRSv was observed among selected piglets until the end of the nursery period (d42); infection of NG occurred later than expected even though there was nose-to-nose contact with infected piglets. In this study, NG were less affected by the influenza virus than RP and showed different immune responses (cellular and humoral). It could be that NG had a more mature immune system than RP because they were older when introduced in the nursery. Also NG had a higher health status than RP; their immune resources were possibly more readily available to fight pathogens.

**Time-course of the immune response to Porcine Reproductive and Respiratory Syndrome Virus (PRRSV) in gilts**

**Silvia Dotti**¹ Giampietro Sandri² Riccardo Villa¹ Elisabetta Razzuoli¹ Enrico Sossi¹ Massimo Amadori¹  
1. Istituto Zooprofilattico Sperimentale Lombardia Emilia Romagna, Brescia, Italy; 2. Soc. Agricola Tre Valli, Gruppo Veronesi, Parma, Italy

**Introduction**

The aim of this study was to evaluate the time-course of the immune response to PRRS virus in two PRRSV-positive farms. Gilts came from a PRRS-free herd and the purpose was to house them without causing PRRS outbreaks in the two farms under study. For this reason, two different strategies were adopted: vaccination in farm 1 and direct contact with viremic animals in farm 2. The cell-mediated immune response was evaluated by a PRRSV-specific interferon-γ release assay; also, an ELISA assay was performed to detect PRRSV-specific IgA Abs in saliva, the assessment of which could be useful in association with other routine diagnostic tests.

**Materials and Methods**

Animals. Two PRRS-positive farms, hereunder named 1 and 2 were chosen for the study. Gilts came from a PRRS-free herd, 10 animals from farm 1 and 15 animals from farm 2, respectively. Pigs from herd 1 were primo-vaccinated i.m. with MLV Porsilis® PRRS Intervet at 5 weeks of age, and a second vaccination with KV Progressis® Merial was carried out by the same route on 5-months old animals. In herd 2, animals were housed with viremic pigs until they were 5 months old. In farm 1, blood samples were collected twice: T0, 60 days after MLV vaccination and T1, 60 days after KV vaccination. In farm 2, blood samples were collected three times: T0 (3-month old animals), T1 (5-months old animals during contact with viremic pigs), T2 (9-months old animals). Moreover, these animals were checked for PRRSV-specific IgA Abs in saliva samples at T1 and T2. Laboratory analyses. Blood samples were collected in tubes with and without lithium-heparin, in order to obtain both serum (for anti-PRRSV IgG, RT-Real Time PCR, anti-SIV Ab) and plasma samples (for IFN-γ assay). The IgG Abs ELISA was performed as recommended by the producer (Herdcheck® IDEXX Porcine Reproductive and Respiratory Syndrome Antibody Test Kits); moreover, sera were used in RT-Real Time PCR to detect PRRSV RNA (3) and inhibition of haemoagglutination (IH) for influenza virus type A/SW/H1N1, A/SW/H1N2 and A/SW/H3N2 (4). After incubation of whole blood with PRRSV and mock antigens, IFN-γ was measured by sandwich ELISA using anti-swine IFN-γ capture mAb P2F6 and biotinylated, anti-swine IFN-γ mAb MP701B (Thermo Scientific, Rockford, IL). Swine IFN-γ was revealed by HRP-conjugated streptavidin, and ortho-phenilenediamine as substrate of the color reaction. Samples were scored positive if the OD corresponding to PRRSV-stimulated whole blood was higher than that of mock-stimulated and unstimulated blood by 20 mOD at least. PRRSV-specific IgA in saliva samples was investigated by an ELISA assay; samples were reacted with sucrose-purified type I PRRSV and mock antigen, respectively. Mucosal Abs were revealed by an anti-swine IgA, HRP-conjugated antiserum and ortho-phenilenediamine. Samples were scored positive if the OD corresponding to PRRSV antigen was higher by 20 mOD at least (background level shown in SPF pigs).

**Results**

Animals remained healthy until the end of the study. In farm 1 all pigs, but one, were PRRSV-negative in RT-Real Time PCR at T0 and T1, while they were IgG-positive at both T0 (except 1 animal) and T1; a PRRSV-specific IFN-γ response was absent at T0. Instead, there were 4 specific and 2 non-specific responses at T1. These animals also showed a seroconversion to H2N1 SIV. In farm 2, RT-Real Time did not reveal any PRRSV-positive sera; IgG ELISA indicated instead a seroconversion at T1 (except 1 animal), and low Ab titres at T2, too. The IFN-γ response was absent at T0; then, 3 PRRSV-specific and 3 non-specific reactions were scored at T1 and T2, respectively. The IgA ELISA assay revealed 10 and 3 positive reactors at T1 and T2, respectively, with an inverse frequency ratio to IgG reactors in serum.

**Discussion**

In both farms, the cell-mediated immune response occurred at low intensity as opposed to the Ab response. This finding confirms the results by other authors (1, 2), i.e. the discrepancy between humoral and CMI response to PRRSV following both vaccination and direct contact with viremic animals. Also, these preliminary data indicate a different time-course between IgA and IgG Ab responses, as a possible strategy of PRRSV to escape immune pressure.

Serological screening in PRRSV infection

Viorel Herman; Corina Pascu; Luminita Costinar; Bogdan Faur; Ioana Vaduva; Nicolae Catana
Faculty of Veterinary Medicine, Timisoara, Romania

Introduction
Porcine Reproductive and Respiratory Syndrome was first described in 1980 in North America, following (from 1990) in Europe. From here PRRS occurs worldwide in most major swine-raising countries.

Both domestic and wild boars were the known susceptible species at PRRSV in natural condition.

There are kits to detect specific antibodies against PRRSV in serum samples. The most used kits are: indirect immunofluorescent antibody (IFA), ELISA and serum neutralization.

The formation and decline antibodies kinetic in IFA and ELISA are similar. The ELISA advantages are: rapid execution, low results variation comparing with results interprets by a technician.

Materials and Methods
For antibodies detection was samplings sows from breeding farm and from pigs from fattening unit that belongs to the anterior mentioned farm. From sows are sampling in the first period of gestation and from fattening pigs at 2, 3 and 5 months of age.

The trials were performed using PRRS IDEXX ELISA (HerdCheck IDEXX Laboratories Switzerland AG.), and xChek (Laboratories IDEXX) software.

Results and discussions
In the breeding farm were observed more reproductive disorders, and there were serological tested against PRRS.

Figure 1

The obtained results are presents in table 1. As it could be observed, in breeding farm and in fattening farm both are present the PRRS infection.

Table 1

</tbody>
</table>

In breeding farm, 80% from samples were positive. In fattening farm, at first sampling 75% samples were positive, at second sampling, 70% samples were positive and at third sampling, just after slaughtered, 91% samples were positive. This proved the seroprevalence rising.

Graphic 1. Dynamic of positive samples in fattening pigs

Conclusions
The breeding farm was positive in a significant proportion (80%). Also, all three samplings from fattening farm revealed positive reactions, as it follows: 75% at 2 months old, 70% at 3 months old and 91% at 5 months old.

Early identification of PRRS infected herds is essential for epidemiological surveillance and disease control. The herds moving is necessary to be done only between herds with the same immune status, through this disease spreading is limited.

Risk factors for the porcine high fever disease in a region of Vietnam

Hien T. Le1, 2 Zvonimir Poljak1 Rob Deardon3 Cate Dewey1
1. Population Medicine, Guelph, ON, Canada; 2. Nong Lam University, Ho Chi Minh, Vietnam; 3. Department of Mathematics and Statistics, University of Guelph, Guelph, ON, Canada

Introduction

Porcine high fever disease (PHFD) emerged in 2007 as a large and rapidly evolving outbreak affecting most of China, and subsequently, Vietnam (1). The disease was characterized by fever, depression, anorexia, and respiratory distress; with high morbidity. One genotype of the porcine reproductive respiratory syndrome virus (PRRSV) was considered to be the etiological agent, possibly with involvement of other pathogens, because of the disease's unusual characteristics (1). However an interaction between PRRSV and other pathogens was not confirmed. It is important to understand the epidemiological characteristics of PHFD. This study's objective was to evaluate the distribution of, and risk factors for, the occurrence of PHFD in a region of Vietnam which underwent a recent outbreak.

Materials and Methods

Study area: The area of interest was a district of a province of southern Vietnam that had reported the outbreak of PHFD during 2008. A study area, approximately 10x10 kms in dimension, which contained 5 communes and a total of 37 hamlets, was selected.

Data collection: A survey was conducted in the study area to collect information about the swine health problems during 2008. A group of trained interviewers went to almost all households having pigs with local veterinarians to fill questionnaires, which included 3 sections: general information, clinical signs of disease in pigs, and production factors hypothesized to be risk factors.

Definition of case at household level: Based on clinical signs from the literature (1,2), and opinions of experts and experienced veterinarians in the area, cases were defined as households that experience a pig that died or aborted accompanied by one of the suspected signs, including: high fever (41.5oC), blue ear, respiratory problems in sows, stillbirths, pre- and post weaning death up to 20%, or with mortality over 10% accompanied by fever and respiratory symptoms in other pigs

Data analyses: Questionnaire data were entered into EpiData 3.1 (EpiData Association, Odense, Denmark). Logistic regression with a random intercept at the hamlet level was used to assess risk factors for PHFD at the household level using Stata 10 (Stata Corporation, Texas, USA).

Results

Of 955 households with questionnaire data, 33.4% were classified as cases. Cases occurred over the entire year (2008) with peak frequency in June. In addition to clinical signs defined for cases, agalactia and lameness were observed in sows while trembling and excessive wasting were observed in suckling and nursery pigs. Diarrhea and redness of skin were observed in finishing pigs. The risk factors associated with the occurrence of cases were: higher number of sows and finishing pigs (log 2 transformed), receiving pigs from an external source, and the interaction between using “water green plants” (WGP) as pig feed and owning ducks with/without contact with pigs (duck ct/duck nct) in the household (Table 1).

Discussion

Number of sows and finishing pigs were used in the model to control for confounders. The final model fitted suggested that the movement of pigs (i.e. receiving nursery pigs from another farm) might be a risk factor with OR=1.70 (1.16-2.48). This factor might have contributed to the observed pattern of disease transmission over the area. The interaction between duck and feeding WGP suggested that potential pathogens originating from a water source, and which further multiplies in ducks, could contribute to occurrence of PHFD.

Risk assessment of PRRS outbreak in endemic farms according to productivity and health management variables

Antonio Callen² I. De Blas³ J. Q. Cabanes⁴ J. A. Munoz⁴ François Joisel¹

1. Merial S.A.S., Lyon, France; 2. Merial Laboratorios S.A., Barcelona, Spain; 3. Veterinary Faculty, Universidad de Zaragoza, Zaragoza, Spain; 4. Agrocesa, Valladolid, Spain

Introduction
Porcine reproductive and respiratory syndrome (PRRS) is a devastating disease in intensive pig production and is an endemic disease in most farms in the world, but triggering factors for outbreaks should be studied for each scenario.

The objective of this study was to assess the factors linked with PRRS outbreak presentation in field conditions.

Material and Methods
Forty-three Spanish farms, belonging to the same company and with a census between 100 and 5,250 sows and gilts (mean±SD: 643±1,012) were surveyed during a minimum period of 3 years (and a maximum of 10 years) (total of 397 farm-years) in a prospective observational study.

Twelve variables related to farm facilities, stocking management, health status and strategies were studied.

Four different strategies for PRRS control were used in these farms: S1: PRRS-Positive Gilts, Live Vaccine and No Infection with Piglets; S2: PRRS-Positive Gilts, Live Vaccine and Infection with Piglets; S3: PRRS-Positive Gilts, Killed Vaccine and Infection with Piglets; and S4: PRRS-Negative Gilts, Killed Vaccine and Infection with Piglets. Live vaccine was AMERVAC®-PRRS (HIPRA) and killed vaccine was PROGRESSIS® (MERIAL). They were applied according to producer specifications. A commercial indirect-ELISA test was used to confirm PRRS diagnosis (Ingezim PRRS K1, Ingenasa).

In this study, a PRRS outbreak was defined as the sudden occurrence of reproductive problems associated to an abrupt increase of seroprevalence to this disease. Comparison of outbreak frequencies was performed with Likelihood Ratio test (for more than 2 frequencies) or Fisher’s exact test (for 2 frequencies). Relative Risk and 95% confidence interval were calculated for significant associated variables. Error α was established at 0.05. All statistical analyses were carried out with SPSS® 15.0 for WINDOWS®.

Results and Discussion
During the study period only 7 PRRS acute outbreak were recorded. The only variable significantly associated with outbreak risk was the stock variation (see Table 1), so an increase of census led to a higher probability of PRRS outbreak occurrence (40%) versus a probability of 1.3% when no changes in census; that corresponded to a significant Relative Risk of 31.2 (95%CI: 7.8 – 124.3). It means, that there is 31 2 times more risk for PRRS outbreak to occur in farms that undergo a relevant increase of population size, than in farms with constant census.

Other variables had not been associated with PRRS outbreak (Table 1). In this study, we didn’t find any significant impact of the type of vaccine used (live or killed) on the outbreak risk.

However several variables could be related to outbreak risk, but the very low number of outbreaks did not allow us to get significant results (i.e. existence of infected piglets in post-weaning, use of outsource gilts and presence of in-farm AI station).

¹ Likelihood Ratio test p-value; ² Fisher’s exact test p-value

Conclusion
Increase of the population size is a critical risk factor for acute outbreak in farms with endemic PRRS independently of implemented health strategies.

Correlation between genetic, temporal and geographic distances of porcine reproductive and respiratory syndrome virus (PRRSv) strains isolated in swine herds from a high density area in Quebec, Canada

Marie-Ève Lambert1 Zvonimir Poljak2 Julie Arsenault1 Sylvie D’Allaire2
1. University of Montreal, Faculty of Veterinary Medicine, St. Hyacinthe, QC, Canada; 2. University of Guelph, Ontario Veterinary College, Guelph, ON, Canada

Introduction
The transmission of PRRSv between herds can occur over long distance by the introduction of infected animal or semen (1), but also over short distances by mechanisms such as aerosols or various mechanical/biological vectors (2). Short distance processes of transmission could be largely enhanced in high density production area, complicating PRRS control at a herd level. PRRSv strains sharing a high level of homology are suggestive of a common source of infection, and thus can be used to explore the temporal and geographical spread of the virus. The objective of our study was to determine the correlation between genetic, temporal and geographical distances of PRRSv strains in a high density area of swine production.

Materials and Method
As a part of a larger study on the transmission and control of PRRS, a census of production sites was conducted in 10 municipalities located in a high density area (Monteregie) between February 2005 and June 2007. PRRS herd status was determined by ELISA and qRT-PCR and when PCR positive, sequencing of ORF5 was performed. For each production site, geographical coordinates were obtained using GPS at the closest building from public road. A pairwise alignment of all ORF5 sequences obtained was generated in Bionumerics software and genetic distances were calculated from nucleotides. Euclidian and temporal distances were calculated in SAS (SAS Institute 1989). Mantel test procedure was computed in R software to examine the correlation among genetic, geographical and temporal distances. P-values were computed based on 999 permutations.

Results
PRRS herd status was determined on 191 of the 200 participating sites, of which 176 were positive for PRRSv. One sequence was identified for 132 production sites, which were attended by 25 different veterinarians. Independent and integrated producers (7 production systems) accounted for 61% and 39% of the total. Sequences were identified on farrowing/farrow-to-finish and on weaner/finisher sites in a proportion of 58% and 42%, respectively. Table 1 shows descriptive results of pairwise distances included in the distance matrices used to compute the Mantel test. The bivariate Mantel test revealed a significant association between genetic and temporal distances ($r_M=0.06$ $p=0.04$). No significant relationship was found between geographical distance and either genetic ($p=0.68$) or temporal ($p=0.60$) distances.

Discussion
The correlation observed between genetic and temporal distances revealed that sequences isolated far away in time showed more genetic diversity, suggesting possible genetic evolution of the virus during the study period. The absence of correlation between genetic and geographic distances as previously reported (3) suggests that many processes could be involved in the between-herd transmission of the virus at both short and long distances. Further analyses will be performed to take into account other factors such as corporate organization membership.

Risk factors for introduction and spread of PRRSV and PCV2 in pig farms in Korea

Oun Kyong Moon
National Veterinary Research & Quarantine Service, Anyang, Korea

Introduction
Although Porcine Reproductive and Respiratory Syndrome (PRRS) and Porcine Circovirus Disease (PCVAD) induce severe economical losses in domestic pig farms, most research are concentrated on the diagnosis of the causative agent and there is a need for more studies on epidemiological analysis of risk factors related to the transmission of these diseases. In this study, we conducted a survey to identify risks factors for PRRS and PCV2 infection in pig farms in Korea.

Materials and Methods
Survey was conducted from July 2008 to December 2009 through on-farm visits and use of questionnaires which were designed based on risk factors identified during previous epidemiological investigations conducted for Foot-and-Mouth Disease and Classical Swine Fever. Also, swab samples were collected from various key areas and equipments in the participating farms and tested to identify the degree of PRRS and PCV2 contamination during each season in 2009. Samples were tested using RT-PCR and nested PCR.

Results
A total of 58 pig farms in 9 provinces were surveyed. In our survey, the percentage of farms that disinfected the farm entrance, pig house entrance, inside of the pig house and farm surroundings were 36%, 26%, 22% and 16%, respectively. For tools, equipment and feces removal vehicles, disinfection was conducted in 93%, 93% and 69% of the farms, respectively when entering the farms. In contrast, disinfection was conducted in only 42%, 38% and 42% of the farms, respectively when leaving the farms. For refrigerators used to store veterinary drugs, 29% of the farms responded that they conducted disinfection.

Samples were collected from pig farms during spring, summer, autumn and winter, which were totals of 6, 14, 24 and 21 farms, respectively. The percentage of farms where PRRSV and PCV2 were detected were 83.33% and 10.00%, respectively during spring, 3.35% and 16.32%, respectively during summer, 19.62% and 38.06%, respectively during autumn, and 39.94% and 54.45%, respectively during winter. In particular, investigation of refrigerators in 6 pig farms during each season showed PRRSV and PCV2 contamination in 100% and 33.3% of the farms, respectively during spring, 0% and 16.7%, respectively during summer, 0% and 66.7%, respectively during autumn, and 0% and 80.0%, respectively during winter. Viruses were consistently detected from shoes, vehicles or various tools and equipment such as wheel barrows and shovels used in the farms, although there were slight variations depending on the season. Also, there was persistent detection of viruses from the floor of pig houses.

Discussion
This study demonstrated that pathogens can be transmitted during the movement of people or equipment associated or used in pig farms, and the rates of detection of these two viruses were different according to the season. Refrigerators could become an important source of diseases as viruses in refrigerators would be less influenced by the difference in the season. On a positive note, the rates of detection of viruses were lower on the secondary tests after the farm had been educated, than on the primary investigation. The method used in this study including sample collection and epidemiological investigation can be applied to the standard surveillance for porcine diseases conducted in Korea. Widespread use of this method in the porcine industry would result in a more scientifically sound surveillance allowing for more effective disease control measures to be implemented.

**Spatiotemporal distribution of the dominant PRRSV genotype in Ontario**

**Thomas Rosendal; Cate E. Dewey; Robert M. Friendship; Sarah K. Wootton; Young Beth; Zvonimir Poljak**

*University of Guelph, Guelph, ON, Canada*

**Introduction**

Modeling the spatiotemporal distribution of porcine reproductive and respiratory syndrome virus (PRRSV) is important in the pursuit to understand how PRRS spreads in a population of pig herds. The distribution in space and time of PRRSV describes part of a set of connections between herds. The objectives of this study are to search for trends and clusters in space and time of a common genotype of PRRSV in Ontario and to assess the importance of ownership structure in of PRRSV genotypes in Ontario.

**Methods**

Herd managers who were willing to participate were interviewed to determine herd ownership. The ORF5 gene of the PRRSV positive sample was sequenced and the RFLP type according the University of Minnesota method was determined. Spatial and temporal autocorrelation and clustering of the most common type, Minnesota RFLP type 1-18-4, were investigated using the space-time k-function and the SaTScan Bernoulli model. The distribution in space and time was modeled using the generalized additive model (GAM). The effect of ownership on the space-time distribution was tested using fixed effects in the GAM for the owners with the largest number of members.

**Results**

The k-function showed that autocorrelation was present in PRRSV type 1-18-4 up to a distance of 6 km and 45 days as well as a distance of 12 km and 15 days. A cluster of cases was found in the eastern part of the study period lasting 4 months from Nov/2005 - Feb/2006 (P=0.046). A trend in the spatial distribution of type 1-18-4 was found using the GAM (P=0.001) and no significant temporal trend was found (P=0.09). An association was found between ownership of herds and the presence of type 1-18-4 (P=0.005). When ownership was added to the space-time model the shape of the spatial trend did not change. Two owners had OR= 7.3 (P=0.004) and OR=6.7 (P=0.02) of having type 1-18-4, where small owners, those with less than 6 herds in the study, were at reduced odds, compared to large ownerships, of having type 1_18_4 (OR=0.12, P<0.001).

**Discussion**

The autocorrelation in cases of 1-18-4 indicates that herds up to 6 km from a case herd are more likely to be cases if tested within 45 days of each other but also out to as far as 12km if they are tested within 15 days of each other. Type 1-18-4 was also not uniformly distributed in Ontario during the study period (Fig 1a). Although, some of the variation can be explained by the ownership structure, a spatial trend remains after accounting for ownership (Fig 1b). The shape of the spatial trend did not change after accounting for ownership; this is an indication that the spatial effect and the effect of ownership are not confounded, meaning that the spatial effect is not explained by ownership. Further investigation is needed to shed light on the origin of this trend. The spatial pattern could be a result of similarities of breeding stock, animal or semen suppliers between herds or be an indication of transmission between herds. The variables describing herd suppliers could not be adequately accounted for using these methods and future work will address these connections.
Association between genetic similarity of the PRRSV ORF5 sequence and the similarity in clinical signs of PRRS in Ontario swine herds

Thomas Rosendal; Cate E. Dewey; Robert M. Friendship; Sarah K. Wootton; Young Beth; Zvonimir Poljak
University of Guelph, Guelph, ON, Canada

Introduction
Porcine reproductive and respiratory syndrome (PRRS) is a clinically variable disease. Clinical signs that are recognized by the producer include abortion and anorexia in sows, stillborn and mumified piglets, dyspnea, respiratory disease and increased mortality in all ages of pigs (1). Isolates of PRRSV are genetically variable in the ORF5 gene. The association between clinical disease and the ORF5 gene have been infrequently investigated under field conditions (2). The objectives of the present study were to measure the association between RFLP type and clinical signs of PRRS in the herd and to assess the association between clinical similarity between herds and the similarity of PRRSV isolates from the herds.

Materials and Methods
Herds were eligible for the study if a PRRSV PCR test result from the Animal Health Laboratory at the University of Guelph was found between Sept 2004 and Aug 2007. Herd managers were surveyed about clinical signs of PRRS in the herd and ORF5 of the PRRSV isolate was sequenced. The RFLP type of the virus was determined and the genetic similarly of all virus pairs was calculated. The similarity of each clinical sign was determined to be either similar or dissimilar for all pairs of herds.

The association between RFLP type and clinical disease was tested by regressing each clinical sign on the RFLP types using logistic regression (P<0.05 was significant). The association between sequence similarity and clinical similarity was tested by the Mantel test and the generalized additive model where the outcome was similarity of a given clinical sign and the independent variable was the similarity of the ORF5 gene.
